USENIX ATC '19: 2019 USENIX Annual Technical Conference

July 10–12, 2019 Renton, WA, USA

Refreshing ATC – USENIX ATC '19 Program Co-Chairs Message xi

Real-World, Deployed Systems

The Design and Operation of CloudLab 1
Dmitry Duplyakin, Robert Ricci, Aleksander Maricq, Gary Wong, Jonathon Duerig, Eric Eide, Leigh Stoller, Mike Hibler, David Johnson, and Kirk Webb, *University of Utah;* Aditya Akella, *University of Wisconsin–Madison;* Kuangching Wang, *Clemson University;* Glenn Ricart, *US Ignite;* Larry Landweber, *University of Wisconsin–Madison;* Chip Elliott, *Raytheon;* Michael Zink and Emmanuel Cecchet, *University of Massachusetts Amherst;* Snigdhaswin Kar and Prabodh Mishra, *Clemson University*

Everyone Loves File: File Storage Service (FSS) in Oracle Cloud Infrastructure 15
Bradley C. Kuszmaul, Matteo Frigo, Justin Mazzola Paluska, and Alexander (Sasha) Sandler, *Oracle Corporation*

Zanzibar: Google's Consistent, Global Authorization System 33
Ruoming Pang, Ramon Caceres, Mike Burrows, Zhifeng Chen, Pratik Dave, Nathan Germer, Alexander Golynski, Kevin Graney, and Nina Kang, *Google;* Lea Kissner, *Humu, Inc.;* Jeffrey L. Korn, *Google;* Abhishek Parmar, *Carbon, Inc.;* Christina D. Richards and Mengzhi Wang, *Google*

IASO: A Fail-Slow Detection and Mitigation Framework for Distributed Storage Services 47
Biswaranjan Panda and Deepthi Srinivasan, *Nutanix Inc.;* Huan Ke, *University of Chicago;* Karan Gupta and Vinayak Khot, *Nutanix Inc.;* Haryadi S. Gunawi, *University of Chicago*

Runtimes

PARTISAN: Scaling the Distributed Actor Runtime 63
Christopher S. Meiklejohn and Heather Miller, *Carnegie Mellon University;* Peter Alvaro, *UC Santa Cruz*

Unleashing the Power of Learning: An Enhanced Learning-Based Approach for Dynamic Binary Translation 77
Changheng Song, *Fudan University;* Wenwen Wang, Pen-Chung Yew, and Antonia Zhai, *University of Minnesota;* Weihua Zhang, *Fudan University*

Transactuations: Where Transactions Meet the Physical World 91
Aritra Sengupta, Tanakorn Leesatapornwongsa, and Masoud Saeida Ardekani, *Samsung Research;* Cesar A. Stuardo, *University of Chicago*

Not So Fast: Analyzing the Performance of WebAssembly vs. Native Code 107
Abhinav Jangda, Bobby Powers, Emery D. Berger, and Arjun Guha, *University of Massachusetts Amherst*

Filesystems

Extension Framework for File Systems in User space 121
Ashish Bijlani and Umakishore Ramachandran, *Georgia Institute of Technology*

FlexGroup Volumes: A Distributed WAFL File System 135
Ram Kesavan, *Google;* Jason Hennessey, Richard Jernigan, Peter Macko, Keith A. Smith, Daniel Tennant, and Bharadwaj V. R., *NetApp*

EROFS: A Compression-friendly Readonly File System for Resource-scarce Devices 149
Xiang Gao, *Huawei Technologies Co., Ltd.;* Mingkai Dong, *Shanghai Jiao Tong University;* Xie Miao, Wei Du, and Chao Yu, *Huawei Technologies Co., Ltd.;* Haibo Chen, *Shanghai Jiao Tong University / Huawei Technologies Co., Ltd.*

QZFS: QAT Accelerated Compression in File System for Application Agnostic and Cost Efficient Data Storage . . . 163
Xiaokang Hu and Fuzong Wang, *Shanghai Jiao Tong University, Intel Asia-Pacific R&D Ltd.;* Weigang Li, *Intel Asia-Pacific R&D Ltd.;* Jian Li and Haibing Guan, *Shanghai Jiao Tong University*

Big-Data Programming Models & Frameworks

Apache Nemo: A Framework for Building Distributed Dataflow Optimization Policies 177
Youngseok Yang and Jeongyoon Eo, *Seoul National University;* Geon-Woo Kim, *Viva Republica;* Joo Yeon Kim, *Samsung Electronics;* Sanha Lee, *Naver Corp.;* Jangho Seo, Won Wook Song, and Byung-Gon Chun, *Seoul National University*

Tangram: Bridging Immutable and Mutable Abstractions for Distributed Data Analytics 191
Yuzhen Huang, Xiao Yan, Guanxian Jiang, Tatiana Jin, James Cheng, An Xu, Zhanhao Liu, and Shuo Tu, *The Chinese University of Hong Kong*

STRADS-AP: Simplifying Distributed Machine Learning Programming without Introducing a New Programming Model 207
Jin Kyu Kim and Abutalib Aghayev, *Carnegie Mellon University;* Garth A. Gibson, *Carnegie Mellon University, Vector Institute, University of Toronto;* Eric P. Xing, *Petuum Inc, Carnegie Mellon University*

SOPHIA: Online Reconfiguration of Clustered NoSQL Databases for Time-Varying Workloads 223
Ashraf Mahgoub, *Purdue University;* Paul Wood, *Johns Hopkins University;* Alexander Medoff, *Purdue University;* Subrata Mitra, *Adobe Research;* Folker Meyer, *Argonne National Lab;* Somali Chaterji and Saurabh Bagchi, *Purdue University*

Security #1: Kernel

libmpk: Software Abstraction for Intel Memory Protection Keys (Intel MPK) 241
Soyeon Park, *Georgia Institute of Technology;* Sangho Lee, *Microsoft Research;* Wen Xu, *Georgia Institute of Technology;* Hyungon Moon, *Ulsan National Institute of Science and Technology;* Taesoo Kim, *Georgia Institute of Technology*

Effective Static Analysis of Concurrency Use-After-Free Bugs in Linux Device Drivers 255
Jia-Ju Bai, *Tsinghua University;* Julia Lawall, *Sorbonne Université/Inria/LIP6;* Qiu-Liang Chen and Shi-Min Hu, *Tsinghua University*

LXDs: Towards Isolation of Kernel Subsystems 269
Vikram Narayanan, *University of California, Irvine;* Abhiram Balasubramanian, Charlie Jacobsen, Sarah Spall, Scott Bauer, and Michael Quigley, *University of Utah;* Aftab Hussain, Abdullah Younis, Junjie Shen, Moinak Bhattacharyya, and Anton Burtsev, *University of California, Irvine*

JumpSwitches: Restoring the Performance of Indirect Branches In the Era of Spectre 285
Nadav Amit, *VMware Research;* Fred Jacobs, *VMware;* Michael Wei, *VMware Research*

Parallelism & Synchronization

Multi-Queue Fair Queuing 301
Mohammad Hedayati, *University of Rochester;* Kai Shen, *Google;* Michael L. Scott, *University of Rochester;* Mike Marty, *Google*

BRAVO—Biased Locking for Reader-Writer Locks 315
Dave Dice and Alex Kogan, *Oracle Labs*

Mitigating Asymmetric Read and Write Costs in Cuckoo Hashing for Storage Systems 329
Yuanyuan Sun, Yu Hua, Zhangyu Chen, and Yuncheng Guo, *Huazhong University of Science and Technology*

Programmable I/O Devices

NICA: An Infrastructure for Inline Acceleration of Network Applications 345
Haggai Eran, *Technion–Israel Institute of Technology & Mellanox Technologies;* Lior Zeno, Maroun Tork, Gabi Malka, and Mark Silberstein, *Technion–Israel Institute of Technology*

E3: Energy-Efficient Microservices on SmartNIC-Accelerated Servers 363
Ming Liu, *University of Washington;* Simon Peter, *The University of Texas at Austin;* Arvind Krishnamurthy, *University of Washington;* Phitchaya Mangpo Phothilimthana, *University of California, Berkeley*

INSIDER: Designing In-Storage Computing System for Emerging High-Performance Drive 379
Zhenyuan Ruan, Tong He, and Jason Cong, *UCLA*

Cognitive SSD: A Deep Learning Engine for In-Storage Data Retrieval 395
Shengwen Liang and Ying Wang, *State Key Laboratory of Computer Architecture, Institute of Computing Technology, Chinese Academy of Sciences, Beijing; University of Chinese Academy of Sciences;* Youyou Lu and Zhe Yang, *Tsinghua University;* Huawei Li and Xiaowei Li, *State Key Laboratory of Computer Architecture, Institute of Computing Technology, Chinese Academy of Sciences, Beijing; University of Chinese Academy of Sciences*

Graph Processing Frameworks

SIMD-X: Programming and Processing of Graph Algorithms on GPUs 411
Hang Liu, *University of Massachusetts Lowell;* H. Howie Huang, *George Washington University*

LUMOS: Dependency-Driven Disk-based Graph Processing 429
Keval Vora, *Simon Fraser University*

NeuGraph: Parallel Deep Neural Network Computation on Large Graphs 443
Lingxiao Ma and Zhi Yang, *Peking University;* Youshan Miao, Jilong Xue, Ming Wu, and Lidong Zhou, *Microsoft Research;* Yafei Dai, *Peking University*

Pre-Select Static Caching and Neighborhood Ordering for BFS-like Algorithms on Disk-based Graph Engines 459
Eunjae Lee, *UNIST;* Junghyun Kim, *TmaxOS;* Keunhak Lim, *Nexon;* Sam H. Noh, *UNIST;* Jiwon Seo, *Hanyang University*

Virtualization Flavors

From Laptop to Lambda: Outsourcing Everyday Jobs to Thousands of Transient Functional Containers 475
Sadjad Fouladi, Francisco Romero, Dan Iter, and Qian Li, *Stanford University;* Shuvo Chatterjee, *unaffiliated;* Christos Kozyrakis, Matei Zaharia, and Keith Winstein, *Stanford University*

Hodor: Intra-Process Isolation for High-Throughput Data Plane Libraries 489
Mohammad Hedayati, Spyridoula Gravani, Ethan Johnson, John Criswell, and Michael L. Scott, *University of Rochester;* Kai Shen and Mike Marty, *Google*

A Retargetable System-Level DBT Hypervisor 505
Tom Spink, Harry Wagstaff, and Björn Franke, *University of Edinburgh*

***MTS*: Bringing Multi-Tenancy to Virtual Networking** 521
Kashyap Thimmaraju and Saad Hermak, *Technische Universität Berlin;* Gabor Retvari, *BME HSNLab;* Stefan Schmid, *Faculty of Computer Science, University of Vienna*

Security #2: Isolation

StreamBox-TZ: Secure Stream Analytics at the Edge with TrustZone 537
Heejin Park and Shuang Zhai, *Purdue ECE;* Long Lu, *Northeastern University;* Felix Xiaozhu Lin, *Purdue ECE*

CoSMIX: A Compiler-based System for Secure Memory Instrumentation and Execution in Enclaves 555
Meni Orenbach, *Technion;* Yan Michalevsky, *Anjuna Security;* Christof Fetzer, *TU Dresden;* Mark Silberstein, *Technion*

Secured Routines: Language-based Construction of Trusted Execution Environments 571
Adrien Ghosn, James R. Larus, and Edouard Bugnion, *EPFL*

Supporting Security Sensitive Tenants in a Bare-Metal Cloud 587
Amin Mosayyebzadeh, *Boston University;* Apoorve Mohan, *Northeastern University;* Sahil Tikale, *Boston University;* Mania Abdi, *Northeastern University;* Nabil Schear, *MIT Lincoln Laboratory;* Trammell Hudson, *Two Sigma;* Charles Munson, *MIT Lincoln Laboratory;* Larry Rudolph, *Two Sigma;* Gene Cooperman and Peter Desnoyers, *Northeastern University;* Orran Krieger, *Boston University*

Exotic Kernel Features

Asynchronous I/O Stack: A Low-latency Kernel I/O Stack for Ultra-Low Latency SSDs 603
Gyusun Lee, Seokha Shin, and Wonsuk Song, *Sungkyunkwan University;* Tae Jun Ham and Jae W. Lee, *Seoul National University;* Jinkyu Jeong, *Sungkyunkwan University*

M³x: Autonomous Accelerators via Context-Enabled Fast-Path Communication 617
Nils Asmussen, Michael Roitzsch, and Hermann Härtig, *Technische Universität Dresden, Germany; Barkhausen Institut, Dresden, Germany*

(continued on next page)

Deduplication

SmartDedup: Optimizing Deduplication for Resource-constrained Devices **633**
Qirui Yang, Runyu Jin, and Ming Zhao, *Arizona State University*

Data Domain Cloud Tier: Backup here, backup there, deduplicated everywhere! **647**
Abhinav Duggal, Fani Jenkins, Philip Shilane, Ramprasad Chinthekindi, Ritesh Shah, and Mahesh Kamat, *Dell EMC*

Exotic Kernel Features #2

GAIA: An OS Page Cache for Heterogeneous Systems **661**
Tanya Brokhman, Pavel Lifshits, and Mark Silberstein, *Technion—Israel Institute of Technology*

Transkernel: Bridging Monolithic Kernels to Peripheral Cores **675**
Liwei Guo, Shuang Zhai, Yi Qiao, and Felix Xiaozhu Lin, *Purdue ECE*

Detecting Asymmetric Application-layer Denial-of-Service Attacks In-Flight with FineLame **693**
Henri Maxime Demoulin, Isaac Pedisich, Nikos Vasilakis, Vincent Liu, Boon Thau Loo, and Linh Thi Xuan Phan, *University of Pennsylvania*

SemperOS: A Distributed Capability System **709**
Matthias Hille, *Technische Universität Dresden;* Nils Asmussen, *Technische Universität Dresden; Barkhausen Institut;* Pramod Bhatotia, *University of Edinburgh;* Hermann Härtig, *Technische Universität Dresden; Barkhausen Institut*

Key-Value Stores

Pragh: Locality-preserving Graph Traversal with Split Live Migration **723**
Xiating Xie, Xingda Wei, Rong Chen, and Haibo Chen, *Shanghai Jiao Tong University*

ElasticBF: Elastic Bloom Filter with Hotness Awareness for Boosting Read Performance in Large Key-Value Stores **739**
Yongkun Li, Chengjin Tian, Fan Guo, Cheng Li, and Yinlong Xu, *University of Science and Technology of China*

SILK: Preventing Latency Spikes in Log-Structured Merge Key-Value Stores **753**
Oana Balmau, Florin Dinu, and Willy Zwaenepoel, *University of Sydney;* Karan Gupta and Ravishankar Chandhiramoorthi, *Nutanix Inc.;* Diego Didona, *IBM Research–Zurich*

Unification of Temporary Storage in the NodeKernel Architecture **767**
Patrick Stuedi, *IBM Research;* Animesh Trivedi, *Vrije Universiteit;* Jonas Pfefferle, *IBM Research;* Ana Klimovic, *Stanford University;* Adrian Schuepbach and Bernard Metzler, *IBM Research*

Solid-State & Hard Disk Drives

Evaluating File System Reliability on Solid State Drives **783**
Shehbaz Jaffer, Stathis Maneas, Andy Hwang, and Bianca Schroeder, *University of Toronto*

Alleviating Garbage Collection Interference Through Spatial Separation in All Flash Arrays. **799**
Jaeho Kim, *Virginia Tech;* Kwanghyun Lim, *Cornell University;* Youngdon Jung and Sungjin Lee, *DGIST;* Changwoo Min, *Virginia Tech;* Sam H. Noh, *UNIST*

Practical Erase Suspension for Modern Low-latency SSDs **813**
Shine Kim, *Seoul National University and Samsung Electronics;* Jonghyun Bae, *Seoul National University;* Hakbeom Jang, *Sungkyunkwan University;* Wenjing Jin and Jeonghun Gong, *Seoul National University;* Seungyeon Lee, *Samsung Electronics;* Tae Jun Ham and Jae W. Lee, *Seoul National University*

Track-based Translation Layers for Interlaced Magnetic Recording **821**
Mohammad Hossein Hajkazemi, *Northeastern University;* Ajay Narayan Kulkarni, *Seagate Technology;* Peter Desnoyers, *Northeastern University;* Timothy R Feldman, *Seagate Technology*

Networking

Your Coflow has Many Flows: Sampling them for Fun and Speed 833
Akshay Jajoo, Y. Charlie Hu, and Xiaojun Lin, *Purdue University*

PostMan: Rapidly Mitigating Bursty Traffic by Offloading Packet Processing 849
Panpan Jin, Jian Guo, and Yikai Xiao, *National Engineering Research Center for Big Data Technology and System, Key Laboratory of Services Computing Technology and System, Ministry of Education, School of Computer Science and Technology, Huazhong University of Science and Technology, China;* Rong Shi, *The Ohio State University, USA;* Yipei Niu and Fangming Liu, *National Engineering Research Center for Big Data Technology and System, Key Laboratory of Services Computing Technology and System, Ministry of Education, School of Computer Science and Technology, Huazhong University of Science and Technology, China;* Chen Qian, *University of California Santa Cruz, USA;* Yang Wang, *The Ohio State University, USA*

R2P2: Making RPCs first-class datacenter citizens 863
Marios Kogias, George Prekas, Adrien Ghosn, Jonas Fietz, and Edouard Bugnion, *EPFL*

Lancet: A self-correcting Latency Measuring Tool 881
Marios Kogias, *EPFL;* Stephen Mallon, *University of Sydney;* Edouard Bugnion, *EPFL*

Non-Volatile Memory

Pangolin: A Fault-Tolerant Persistent Memory Programming Library 897
Lu Zhang and Steven Swanson, *UC San Diego*

Pisces: A Scalable and Efficient Persistent Transactional Memory 913
Jinyu Gu, Qianqian Yu, Xiayang Wang, Zhaoguo Wang, Binyu Zang, Haibing Guan, and Haibo Chen, *Shanghai Jiao Tong University*

Scheduling Things

EdgeWise: A Better Stream Processing Engine for the Edge 929
Xinwei Fu, Talha Ghaffar, James C. Davis, and Dongyoon Lee, *Virginia Tech*

Analysis of Large-Scale Multi-Tenant GPU Clusters for DNN Training Workloads 947
Myeongjae Jeon, *UNIST and Microsoft Research;* Shivaram Venkataraman, *University of Wisconsin and Microsoft Research;* Amar Phanishayee and Junjie Qian, *Microsoft Research;* Wencong Xiao, *Beihang University and Microsoft Research;* Fan Yang, *Microsoft Research*

Storage Failure & Recovery

Lessons and Actions: What We Learned from 10K SSD-Related Storage System Failures 961
Erci Xu, *Ohio State University;* Mai Zheng, *Iowa State University;* Feng Qin, *Ohio State University;* Yikang Xu and Jiesheng Wu, *Alibaba Group*

Who's Afraid of Uncorrectable Bit Errors? Online Recovery of Flash Errors with Distributed Redundancy 977
Amy Tai, *Princeton University and VMware Research;* Andrew Kryczka and Shobhit O. Kanaujia, *Facebook;* Kyle Jamieson and Michael J. Freedman, *Princeton University;* Asaf Cidon, *Columbia University*

Dayu: Fast and Low-interference Data Recovery in Very-large Storage Systems 993
Zhufan Wang and Guangyan Zhang, *Tsinghua University;* Yang Wang, *The Ohio State University;* Qinglin Yang, *Tsinghua University;* Jiaji Zhu, *Alibaba Cloud*

OPTR: Order-Preserving Translation and Recovery Design for SSDs with a Standard Block Device Interface 1009
Yun-Sheng Chang and Ren-Shuo Liu, *National Tsing Hua University*

Machine Learning Applications & System Aspects

Optimizing CNN Model Inference on CPUs 1025
Yizhi Liu, Yao Wang, Ruofei Yu, Mu Li, Vin Sharma, and Yida Wang, *Amazon*

Accelerating Rule-matching Systems with Learned Rankers 1041
Zhao Lucis Li, *University of Science and Technology China;* Chieh-Jan Mike Liang and Wei Bai, *Microsoft Research;* Qiming Zheng, *Shanghai Jiao Tong University;* Yongqiang Xiong, *Microsoft Research;* Guangzhong Sun, *University of Science and Technology China*

(continued on next page)

MArk: Exploiting Cloud Services for Cost-Effective, SLO-Aware Machine Learning Inference Serving 1049
Chengliang Zhang, Minchen Yu, and Wei Wang, *Hong Kong University of Science and Technology;* Feng Yan, *University of Nevada, Reno*

Cross-dataset Time Series Anomaly Detection for Cloud Systems 1063
Xu Zhang, *Microsoft Research, Nanjing University;* Qingwei Lin, Yong Xu, and Si Qin, *Microsoft Research;* Hongyu Zhang, *The University of Newcastle;* Bo Qiao, *Microsoft Research;* Yingnong Dang, Xinsheng Yang, Qian Cheng, Murali Chintalapati, Youjiang Wu, and Ken Hsieh, *Microsoft;* Kaixin Sui, Xin Meng, Yaohai Xu, and Wenchi Zhang, *Microsoft Research;* Furao Shen, *Nanjing University;* Dongmei Zhang, *Microsoft Research*

Refreshing ATC – USENIX ATC '19 Program Co-Chairs Message

Dan Tsafrir
Technion – Israel Institute of Technology and VMware Research

Dahlia Malkhi
VMware Research and Calibra

1 Introduction

Welcome to ATC '19: the 2019 USENIX Annual Technical Conference. The scope of ATC covers all practical aspects related to systems software, and its goal is to improve and further the knowledge of computing systems of all scales, from small embedded mobile devices to large data centers, while emphasizing implementations and experimental results.

The ATC '19 program is the result of tremendous efforts by many in our community. We are most thankful to the authors who submitted their high-quality work and to the reviewers who undertook the challenging task of evaluating hundreds of submissions and providing constructive feedback to the authors. While working on creating the program, we have been repeatedly inspired by our reviewers' competence, experience, patience, and dedication. Thanks to their efforts, we are happy to report that the excellent program of ATC '19 achieves its aforementioned goal.

Briefly, we received 356 submissions and accepted 71 (19.9% acceptance rate) through a double-blind, two-rounds review process. The statistics that describe the submitted and accepted papers, along with the details of the review process, are summarized in Table 1 and are further discussed below.

This document is somewhat longer than is typical for a "message from the ATC program co-chairs". What motivated us to write this detailed report is the many changes that have been introduced to ATC this year, the reasoning underlying them, and the new things we have learned while working on creating the program. The potential target audience for this document is future chairs, or readers who wish to learn more about the process.

count	*description*
i. all submissions (short & full):	
356	submitted (458 registered)
29	violated format, given 24 hour to fix
2	rejected+withdrawn due to said format violations
2	withdrawn before review process ended
352	underwent the full review process
184	promoted to review round #2 (R2)
80	R2 submissions pre-rejected during online discussions
37	R2 submissions pre-accepted during online discussions
67	R2 submissions discussed at PC meeting (accepted 34)
71	accepted (19.9% acceptance ratio)
ii. short submissions:	
32	submitted
1	rejected+withdrawn due to format violations
8	promoted to R2
7	R2 submissions pre-rejected during online discussions
1	discussed at the meeting and accepted
1	full submission accepted as short
iii. committee & reviewing load:	
66	heavy weight PC members; 18–19 reviews per member
28	light weight PC members; 13 reviews per member
22	external review committee (ERC) members; 5 reviews
116	committee members
51	external reviewers; 1 review
iv. reviews:	
3–4	per submission in R1 (at least 2 by heavy members)
5–6	per submission in R2 (at least 4 by heavy members)
1,347	reviews in R1
405	reviews in R2
1,752	total, consisting of 1,097,815 words (6.7MB)
v. authors:	
1,695	all submissions (1,442 unique, with 409 affiliations)
384	accepted (361 unique, with 118 affiliations)

Table 1: *ATC '19 submissions and reviewing statistics.*

2 Changes

We have introduced some notable changes to ATC this year, primarily to meet higher reviewing standards used by other major systems conferences. We discuss these changes next.

2.1 Increased Number of Reviews

Top-tier system conferences typically employ a two-rounds reviewing process in which each submission receives at least three reviews in the first review round (R1), and then, if the submission is promoted to the second round (R2) based on its R1 reviews, it gets at least two additional reviews, amounting to at least five reviews per R2 submission.

In contrast, until this year, ATC R1 and R2 submissions received only two and four reviews, respectively. Upon investigation, we have learned that the decision to employ fewer reviews than other systems conferences has been made more

than a decade ago, by the program co-chairs of ATC 2008.

We and many others believe that making review-round promotion decisions based on only two R1 reviews is less informed, and hence leads to higher variability in the result. We further feel that the minimal number of R2 reviews should be similar to that of the other main system conferences, to allow for a better, more rigorous paper selection process. Consequently, this year, all submissions have indeed received at least three R1 reviews and at least five R2 reviews.

2.2 Double Blindness

Ever since ATC has been established, and until this year, the conference has employed a single-blind reviewing process, whereby reviewers see the names of the authors of the submissions that they review. While simplifying the review process, studies show that single-blindness might lead to bias against minorities and in favor of well-known authors and organizations. For example, Tomkins et al. show that

> *"Reviewers in the single-blind condition typically bid for 22% fewer papers and preferentially bid for papers from top universities and companies. Once papers are allocated to reviewers, single-blind reviewers are significantly more likely than their double-blind counterparts to recommend for acceptance papers from famous authors, top universities, and top companies. The estimated odds multipliers are tangible, at 1.63, 1.58, and 2.10, respectively."* [14]

Similarly, Goues et al. show that

> *"Reviewers with author information were 1.76x more likely to recommend acceptance of papers from famous authors, and 1.67x more likely to recommend acceptance of papers from top institutions. [...] When reviewers knew author identities, review scores for papers with male-first authors were 19% higher, and for papers with female-first authors 4% lower."* [4]

The latter study also shows that reviewers are usually unable to deanonymize authors of submissions by guessing, even if they believe themselves to be experts on a submission's topic.

Accordingly, major systems conferences (including SOSP, OSDI, ASPLOS, Eurosys, FAST, NSDI, and USENIX Security) employ a double-blind reviewing process by keeping author identities concealed from reviewers.

For ATC '19, we employed this policy as well, and we hope future chairs will continue to do so. The ATC '19 call for papers (CFP) requires authors to make a good faith attempt to anonymize their submissions by avoiding identifying themselves or their institution, either explicitly or by implication, e.g., through references, acknowledgments, online repositories that are part of the submission, or direct interaction with committee members. When authors cite their own studies, the CFP specifies two possibilities: either cite them as written by a third party (preferable), or as anonymized supplemental material uploaded to the HotCRP submission management system (most useful when the cited work is currently under review or awaiting publication). Prior publication as a technical report or in an online repository does not constitute a violation of anonymity.

2.3 Author Responses

Most premier systems conferences – e.g., OSDI, SOSP, ASPLOS, USENIX Security – give authors a few days to write a response to the reviews. The authors' response is known as "rebuttal", and it is optional. It allows authors to provide answers to specific questions raised by reviewers and, importantly, to correct factual errors or misunderstanding in the reviews. (It may *not* provide new results or reformulate the presentation.) Some researchers perceive rebuttals as essential for the reviewing process, to keep it fair and transparent [6], and some ACM SIGs encourage program chairs and steering committees of SIG-sponsored events to employ rebuttals, based on feedback from their members [13].

Therefore, for ATC '19, we chose to allow authors to rebut. Similarly to our past experiences in forming programs while serving in committees of conferences that employ rebuttals, our sense is that the author responses have contributed to the ATC '19 process. Primarily because they allowed the reviewers to make better informed decisions in certain cases. But also because they implicitly encouraged reviewers to write more accountable reviews and, importantly, to submit them on time so as to be visible during the authors response period; the latter allowed the online discussion period to start on time with all the required material available.

We used a 500-words soft limit on the size of the rebuttal; reviewers were not required to read more. The reviews were made visible to authors in the rebuttal period, during which reviewers were asked to avoid modifying them. After the rebuttal period ended, reviews became invisible to authors again, allowing reviewers to update them based on the rebuttal, the online discussions, and the program committee (PC) meeting.

2.4 Submission Chairs

The ever-increasing number of submissions to systems conferences (approaching 400 in the last two ATCs) makes it increasingly challenging for everyone involved to create a program. For example, it is challenging for reviewers to bid on hundreds of submissions so as to express review preferences. It is likewise challenging to arrange things such that the submission system accurately reflects conflicts associated with more than a hundred reviewers and an order of magnitude more authors (experience repeatedly shows that many conflicts are missing because reviewers and authors neglect

to declare all their conflicts). It is also challenging to manage a "dual track" PC meeting (where the PC is split between two rooms part of the time) in a manner that ensures that all committee members are found in the right room at the right time in order to discuss the submissions they have reviewed. Many other examples exist.

For this reason, we decided to formalize the role of a "submission chair" as part of the official organizers of ATC. The job of the submission chair is to help the program chair in accomplishing tasks such as those listed above by, for example: adding missing conflicts to HotCRP based on DBLP; helping reviewers' bidding by identifying the submissions that cite their papers and communicating this information to the reviewers; checking format violation in uploaded PDFs and communicating with authors to quickly fix those through reformatting and content deletion; helping to ensure that the quality of the reviews assignment is high (HotCRP assignments might be far from optimal); helping to make sure that per-submission administrative tasks are being carried out and progress is achieved, e.g., by following up on submissions that were not yet tagged as passing the "review sufficiency check"; helping in scheduling of the dual track meeting; and serving as scribes during the meeting while making sure the scheduling of PC members in rooms works as expected.

Submission chairs get admin privileges in the HotCRP system in order to carry out their duties. Their role, however, never requires them to make decisions that affect the outcome of the review process. For example, they do not steer online discussions. It is productive for the program chair and submission chair to be geographically located near each other, allowing them to physically meet when the need arises.

2.5 Extended Review Committee (ERC)

Most of the premier systems conferences, which must review a few hundreds of submissions, typically employ a light-heavy program committee model, where "light" PC members review fewer submissions but do not attend the PC meeting, whereas "heavy" members review more submissions and attend the meeting. This model is needed in order to decrease the high reviewing load of PC members, while keeping in mind that the number of people who can sit in one room and conduct a productive discussion is bounded.

Last year, unpredictably, ATC '18 received nearly a hundred additional submissions as compared to ATC '17 (377 submissions as compared to 283 submissions, respectively). To our knowledge, the PC of 2018 was the the first ATC PC to employ the light-heavy model. In previous years, all ATC PC members were "heavy", which was viable because the number of submissions was much lower, albeit, even so, past ATC-s reviewing load was sometimes in the range of 25–30 submissions per member. (Some of us were members of those PCs and still remember the pain.)

Our goal for this year was to ensure that the reviewing load of heavy members will not exceed 20 submissions. In parallel, USENIX instructed us to be prepared for an additional sizable increase in the number of submissions. Therefore, to be safe and have some flexibility, we decided to supplement the light-heavy model with an Extended Review Committee (ERC), consisting of members whose review load will be light: about 5 submissions per member.

Notably, due to the light reviewing load, ERC members were easy to draft regardless of their seniority: they typically accepted our invitation (which specified that the expected reviewing load will be 3–7). Additionally, more than a quarter of the ERC members were initially invited to serve as heavy or light members and opted for the lighter alternative instead of declining altogether.

Ultimately, having an ERC was a contributing factor that allowed us to assign four reviewers in R1 to most submissions (without increasing the load on light and heavy members beyond our planned upper bound). Having an initial assignment of four reviews proved to be invaluable when making R2 promotion decisions in the face of multiple late reviews, as three reviews were typically enough to confidently make the call. The ERC members additionally contributed by augmenting the expertise of our pool of reviewers.

2.6 No Abstract Submission Deadline

Last year, in their welcome message, the program co-chairs of ATC '18 stated that

> *"We required authors to submit abstracts a week before the paper submission in the hope of ensuring proper subject area coverage by the program committee and to get an idea of the reviewing load. This did not work. We had over 550 submitted abstracts, meaning almost 40% of the submissions were abandoned. In the end, requiring abstracts to be submitted early did not help with planning due to such a large number of abstracts that did not result in a submission"* [5].

To that we add that requiring committee members to indicate reviewing preferences before the submission deadline would be a waste of their valuable time, as they will inevitably bid on submissions that will not materialize. Stating review preferences given hundreds of finalized submissions is already time-consuming and challenging enough, and needlessly making this task even harder is counterproductive.

Bidding on registered abstracts that will not materialize into submissions would additionally negatively affect the quality of the review assignment, because committee members frequently stop bidding when they feel they have already placed "enough" bids on submissions.

Consequently, this year, we have to cancel the requirement to register abstracts in advance, and we eliminated the corresponding deadline.

2.7 Submission Deadline Closer to New Year

The date at which accept/reject notifications for ATC submissions are sent to authors is typically set by USENIX to around mid April.[1] Accordingly, since 2013, the submission deadline of ATC has been scheduled at the end of January or in early February, which thus far allowed the committee to complete the reviewing process in time to comply with a mid-April author notification date. This year, however, we set an earlier submission deadline: January 10, 2019.

Three issues necessitated this change. First, we needed additional time for the authors response period (Section 2.3) and for the "review sufficiency check" period that preceded it (described in Section 8). Second, as noted in Section 2.6, we had to allocate a few days following the deadline to allow reviewers to place bids on submissions indicating their review preferences; traditionally, such bidding took place before the submission deadline, as authors were required to register an abstract a week in advance.

The third issue that motivated an earlier deadline is the increased number of submissions. To cope with this increase, we allocated two weeks for online committee discussions scheduled before the PC meeting, in order to allow the committee to converge to a decision regarding as many submissions as possible—failing to do so would mean ending up with too many submissions to discuss at the meeting. The increased submission number also required allocating the week following the bidding period in order to assign reviews to members in a manner that would later allow us to reasonably conduct a dual track PC meeting (see details in Section 6).

Scheduling the submission deadline to occur soon after New Year may partially explain this year's somewhat smaller number of submissions as compared to last year: 377 vs. 356 in ATC '18 and ATC '19, respectively.

2.8 Uniform Shepherding

In the past, shepherding in ATC was not used by default. This approach reduces the load from both committee members and authors. A main drawback, however, is the increased likelihood that some of the issues that the reviewers expect authors to address in the camera-ready version remain unresolved.

The alternative approach, used by most of the premier systems conferences, is to assign shepherds to all accepted papers and thereby generally improve quality assurance. As part of our efforts to update the ATC reviewing process in order to make it aligned with that of its sibling conferences, this year, we decided that all accept decisions are conditional and depend on the approval of shepherds.

After the (conditional) accept notification, authors were given a few days to consider how to address the reviewers' comments and email a revision plan to their shepherd. Authors and shepherds then agreed on a timeline that allows the authors to complete the revision, providing enough time for the shepherd to read, consider, and discuss the revision with the authors, while permitting a final round of text polishing if necessary before the camera-ready deadline. At the end of this process, shepherds explicitly "signed off" the inclusion of papers in the program using HotCRP tags, allowing the program chairs to track the progress of turning all conditional accepts to accepts.

2.9 Accept as Short

As members of former ATC PCs, we are aware of full submissions that were accepted to past ATC-s on the condition that their authors will reduce their size to meet the short paper page-limit requirement. ATC program committees made such decisions rarely, limiting them to situations where the alternative is to otherwise reject the paper.

Surprisingly, past ATC call-for-papers were not clear about the possibility to accept as short; the practice was only anecdotally documented in the messages from chairs [2]. Seeing that this practice has been used in the past and may be used in the future, in the interest of transparency, we decided to explicitly declare it in the CFP, which now states that "the program committee may rarely decide to accept a full submission on the condition that it is cut down to fit in the short paper page limit" [19].

This CFP update initiated a discussion with USENIX board members who were concerned that the effort required to transform a full submission to a short paper might be too significant to accomplish between the authors notification date and the camera-ready date. They cited the FAST policy—which states that "the program committee will not accept a full paper on the condition that it is cut down to fit in the short paper page limit" [20]—as potentially preferable.

After consideration, we decided to keep the ATC accept-as-short policy because we believe it produces a significantly better outcome for both the authors and for the community, provided the alternative is to reject. In such rare cases, disallowing the PC to accept as short would result in a lose-lose situation: the authors lose because they are rejected instead of being given a chance to shorten and thereby get accepted; the ATC program loses a short paper; and the systems community loses because the paper would be subsequently resubmitted and hence re-reviewed, requiring the community to spend additional reviewing cycles, whereas reviewing load is already too high.

[1] In odd years, if the appropriate coordination takes place (as is the case this year), ATC notifications occur shortly before the SOSP submission deadline, to allow rejected authors of the former conference to submit an improved version of their study to the latter conference, assuming they have kept working on it while it was under submission at ATC.

2.10 Shorter Presentations

Last year's aforementioned 33% increase in the number of ATC submissions (377 in ATC '18 vs. 283 in ATC '17) and the consequent 27% increase in accepted papers (76 in ATC '18 vs. 60 in ATC '17) motivated the program co-chairs of ATC '18 to avoid hosting "best of the rest" sessions in their program, as well as to generate a longer-than-usual program that ends in the evening of the third day of the conference rather than around lunch time.

Despite having a similarly-sized program this year (71 papers), we wanted to have our cake and eat it too, namely: bring back the "best of the rest" sessions; further add lightning sessions to the program (see Section 2.12); while still end the program around lunch time at the third day, as was done in previous years prior to ATC '18.

To this end, this year, we decided to shorten the presentation time from 25 minutes per paper to 20 minutes. We believe that this change constitutes a reasonable compromise, allowing the conference to accommodate the additional sessions within the traditional time frame, while still providing enough time for presenters to convey the gist of their ideas.

2.11 Poster Requirement

To partially compensate for the shorter presentation time slots, this year, we dedicated the two poster sessions exclusively to accepted papers, and we required all paper-presenting authors to additionally present a poster in one of these sessions. Hopefully, this format will promote and facilitate interaction between authors and attendees who are interested in their work.

2.12 Lightning Sessions

In recent years "lightning sessions" have become standard in top-tier computer architecture conferences (ISCA, ASPLOS, etc.), and this year we decided to adopt them in ATC. Lightning sessions are typically interesting and fun, and, importantly, they are particularly suitable for conferences that have parallel sessions, which inevitably means attendees miss some of the presentations they are interested in. Lightning sessions give attendees a chance to make more informed decisions regarding what interests them the most and which talks are more worthy of their time. Speakers indeed often treat their lightning session presentations as previews aimed at soliciting listeners to attend the associated talks.

A lightning session is a joint session at the beginning of the day, which includes all the talks that will be given on that particular day. After the daily lightning session, the conference splits into its parallel tracks. Shortly before the daily lightning session, the speakers of that day queue in order—they do not sit until they present. Then, each lightning talk is allocated 120 seconds.

Each daily lightning session has a session chair. The chair is responsible for: interacting with speakers to get their slides beforehand; ordering slides on her laptop based on their order in the program, and making sure they display nicely; informing the speakers regarding the order; and regulating time during the session if necessary (we have never witnessed a lightning session chair having to actually exercise this authority).

Lightning speakers are additionally requested to submit lightning videos beforehand, which are made available in the conference web page before the conference. Both lightning presentations and videos are currently available in the ATC '19 technical sessions webpage.

In the past, USENIX conference talks were videoed, a very useful service that largely stopped due to financial reasons. Our hope is that lighting videos, which do not incur video recording costs, can partially provide some of this service: optimally, lightning videos would allow people who wish to only understand the gist of the idea to do so in 120 seconds.

3 Changes to Consider

3.1 Steering Committee

The one remaining notable difference between ATC and its sibling academic systems conferences (USENIX-sponsored: FAST, NSDI, OSDI, USENIX Security; SIGOPS-sponsored: ASPLOS, Eurosys, SOSP) is that ATC does not have a formal, broad, long-term steering committee. To make ATC more valuable to the community, we—nearly all ATC program chairs since 2015—believe that ATC should have such a committee, and we propose to form it, thus completing the transition of ATC into a conference that is governed by policies generally acceptable in the academic systems community.

We propose that the newly formed ATC steering committee will assume all responsibilities typically assigned to such committees, including providing advice and guidance to the current program co-chairs, selecting future program co-chairs, sustaining organizational memory, suggesting and considering new ideas when the need arises; and ultimately shaping the role of ATC. The identity of the steering committee members should be publicized along with call-for-papers to allow interested parties to address the committee with respect to matters that concern the conference long-term.

The members of the committee could, for example, be the USENIX executive director, relevant members of the USENIX board, and the program chairs from the last n ATC instances, such that members who chaired ATC in year $Y - n$ will be replaced by the ATC chairs of year Y shortly after the latter conference takes place. Joining the steering committee will of course be voluntary.

In October 9, 2018, a letter consisting of the content of this subsection has been submitted to the USENIX board. The letter was signed by all the ATC program chairs since 2015 except two (one responded too late and the other serves on

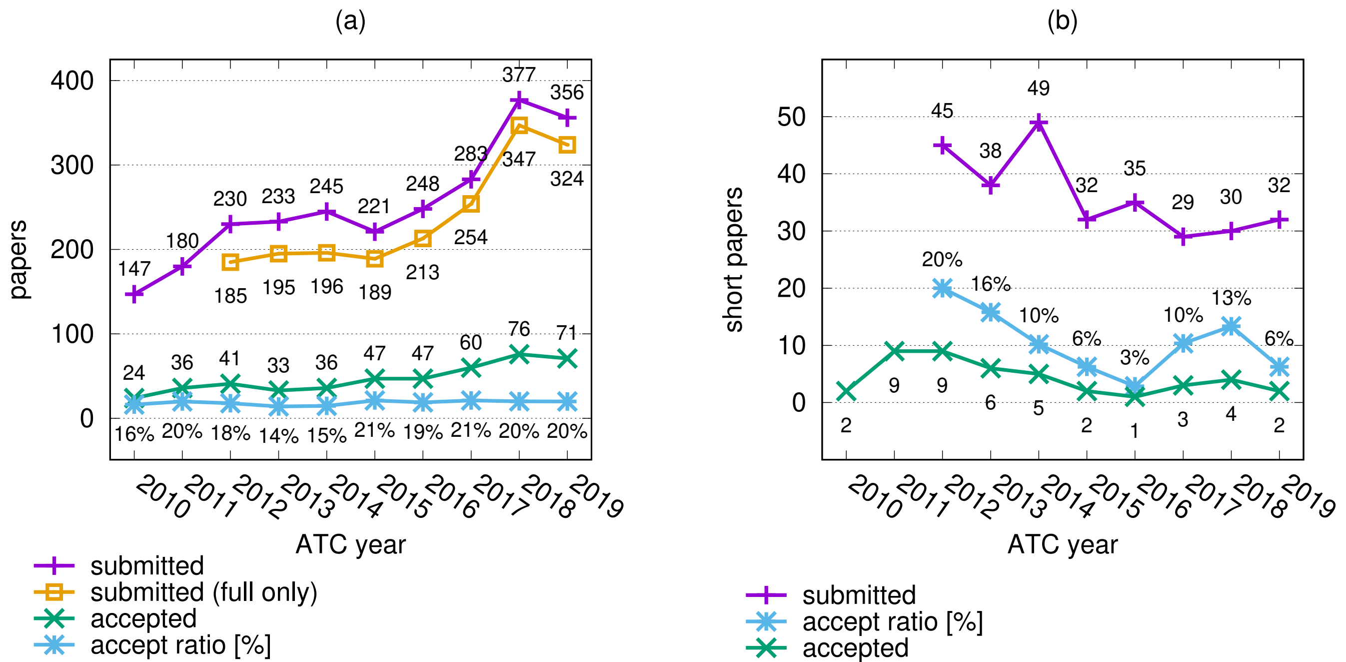

Figure 1: *(**a**) Submission and acceptance statistics of ATC papers (including both full and short) in the last decade, based on the corresponding proceedings' message from the ATC program chairs. (**b**) The same, but only for short papers. In 2010–2011, short submission numbers were not reported. In 2019 and 2013, one and three of the accepted short papers were submitted as full, respectively; we do not have this information for the other years.*

the Usenix board and is one of the decision makers regarding the steering committee issue). All who signed volunteered to serve on the steering committee when it is formed. The response of the relevant people in USENIX seems positive, but a steering committee has not yet been established.

3.2 Test of Time Award

All the premier systems conferences—except ATC—annually recognize historical, influential papers that have stood the test of time. This includes: USENIX Test of Time Award for FAST, NSDI, and USENIX Security [18]; SIGOPS Hall of Fame Award, which is typically handed to SOSP and OSDI papers [17]; Eurosys Test of Time Award [16]; and SIGARCH/SIGPLAN/SIGOPS ASPLOS Influential Paper Award [15].

The procedure to select the awarded papers varies. A common way employed is for the program committee of the conference to nominate influential papers published in that conference around ten years ago, with the final selection being made by the conference's steering committee (which, as noted, ATC still does not have). ATC is much older than ten years and, arguably, has changed its nature and goals over the years. So when/if an ATC test of time award is established, the steering committee will need to decide how to address older papers and handle the backlog. Jeff Mogul documented some of SIGOPS's considerations when establishing its Hall of Fame Award in 2005 and addressing similar questions [12].

3.3 Short Submissions

Figure 1a shows the submission and acceptance numbers of ATC papers in the last decade. Figure 1b shows the same statistics for short papers only. Getting a short submission accepted to ATC is clearly harder. We do not know why and can only speculate about the reason. Perhaps there is a mismatch between PC members' expectations and what can actually be accomplished in the scope of a short paper. Perhaps authors wrongfully believe that the bar for short submissions is lower. And perhaps there is a loose negative correlation between the increasing number of full submissions and the decreasing number of accepted short papers because PC members feel they have stronger papers to accept, relatively speaking.

Regardless of the reason, the fact that ATC PCs have reviewed 29–35 short submissions per year in the last five years only to accept 1–4 of them raises the question of whether the effort is worth it, since the reviewing effort to accept short papers is significantly greater than the effort to accept full papers (3%–13% vs. about 20% acceptance rate for short and short+full submissions in the last five years, respectively).

This year provides an extreme demonstration of how much harder the PC has to work in order to accept short papers. Table 2 specifies the number of reviews that the ATC '19 PC wrote for full and short submissions, as well as the resulting

scenario	*submission type*	*written reviews*	*accepted papers*	*work ratio*
real (worst case)	full	1620	70	23:1
	short	132	1	132:1
extrapolated (best case)	short	132	4	33:1

Table 2: *The number of reviews that the ATC '19 PC wrote for full and short submissions demonstrates that the PC had to work much harder in order to accept a single short paper ("real"). Even if we hypothetically assume that the PC had accepted four short paper instead of one as in last year (best case scenario in the last five years), the reviews-to-accepts work ratio would still be nearly 1.5x higher ("extrapolated").*

number of accepts. It turns out that the PC wrote 132 reviews in order to accept a single short paper, as opposed to writing "only" 23 reviews in order to accept a full submission. Namely, the PC had to work nearly 6x times as hard.

That said, as can be seen in Figure 1b, this year has been especially bad for short submissions. But even if we hypothetically assume the best case scenario across the last five years of accepting four short papers, the corresponding reviews-to-accepts ratio would have been 35:1, which is still nearly 1.5x harder than accepting a full paper.

ATC enjoys a steadily increasing number of full submissions. As a consequence, the reviewing load becomes heavier, requiring bigger PCs that already hardly fit into one room. Considering the relatively low return on investment (a significantly higher reviews-to-accepts ratio), it may make sense for future ATCs to consider to stop soliciting short papers.

We note in passing that, this year, we revised the CFP definition of short submissions to exclude workshop-style papers ("a short paper is not like a workshop paper—it presents a complete idea, which does not require full length to be appreciated" [19]). We introduced this change hoping to increase the short submission success rate by discouraging authors from submitting work that (our experience suggests) ATC reviewers tend to reject. The data shown in Figure 1b suggests this change was ineffective .

3.4 Early Rejects or R1 Rebuttals

The program co-chairs of this year debated about the issue of whether or not to send early reject notifications to authors of submissions who did not make it to R2. The reasoning to oppose sending early rejects was that such notifications might provide an unfair advantage to R1 rejects over R2 submissions that will be rejected later on, because the authors of the former will be free to resubmit their work elsewhere much sooner. Additionally, early rejects might translate to even higher reviewing loads that the community must handle due to said earlier resubmissions. Lastly, and importantly, postponing the R1 reject notification would allow PC members to re-calibrate during the second round and the deliberations and potentially change their opinion.

The reasoning to supported early rejects was that delaying reject notifications would be counterproductive for authors who do not abuse the system but rather leverage the reviewers' feedback to improve their work before they resubmit. Arguably, the ATC reviewing process should not replace one evil ("helping" authors who might abuse the system by ignoring the reviewers' feedback and resubmitting prematurely) with another (allowing authors to believe that they have a chance to get accepted for a good few weeks whereas in fact they do not).

Eventually, since we already introduced many changes to ATC this year (Section 2), we decided to leave things as they are in this particular case and avoid sending early reject notifications. But we encourage future ATC program chairs (and/or the ATC steering committee if it is established) to reconsider.

Because decisions were collectively sent to authors shortly after the PC meeting, R1 rejects were given a chance to write a rebuttal (Section 2.3), which the committee members read and considered. Two R1 rejected submissions were resurrected as a result. These submissions were promoted to R2 and urgently assigned two additional reviewers. In the end, however, both were rejected. We speculate that allowing authors to rebut (also) after R1 (as is done by some conferences) would have had a bigger effect. But doing so would require more labor and an even earlier deadline, which would be closer to New Year, which might result in fewer submissions (see Section 2.7).

3.5 Physical PC Meeting

The number of submissions the PC can discuss in one day (let us denote it as c) is bounded. For example, it takes more than eight hours to discuss $c = 70$ submissions if allocating 7 minutes per submission, as is typical. PCs also usually dedicate 2–3 minutes to present each submission that was pre-accepted in the online discussion phase (ATC '19 had 37 such submissions), and they take about 30 minutes for lunch. It is challenging to squeeze all these activities into one day.

Let m denote a member of the PC, and let r denote the number of submissions reviewed by m. Similarly to c, the value of r is bounded. At the risk of overgeneralizing, we roughly approximate that $r = 15$, $r = 20$, and $r = 25$ reviews per member are nowadays considered light, average, and heavy reviewing loads in academic systems conferences, respectively. The value of r cannot be raised arbitrarily.

In contrast to c and r, the total number of submissions that the PC must review (let us denote it as n) is unbounded and keeps increasing. The practical meaning of this increase is that, on average, fewer and fewer of the r submissions that m reviewed are getting discussed at the meeting. Figure 2 demonstrates this trend, assuming $c = 70$ submissions are discussed at the meeting, and that 2/3 and 1/3 of the r submissions assigned to m are reviewed in R1 and R2, respectively. The x axis shows n, and the y axis shows the corresponding

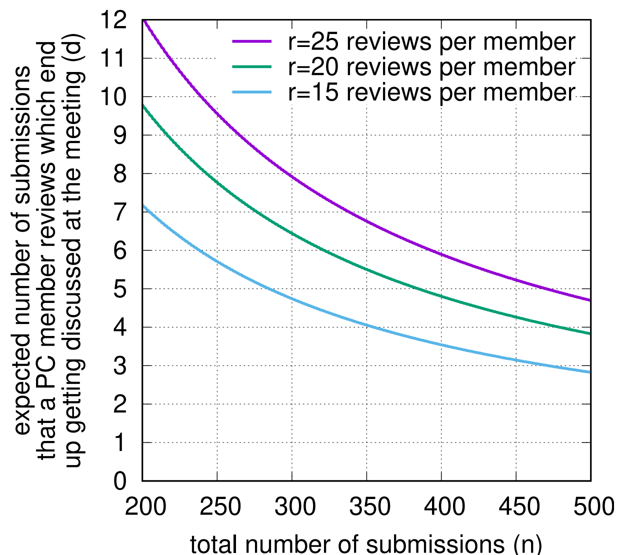

Figure 2: *Increased number of submissions translates to fewer submissions that each PC member gets to discuss at the PC meeting; see Appendix A for details.*

expected number of submissions that have been reviewed by m and ended up being discussed at the meeting (let us denote it as d), which is monotonically decreasing.

In Appendix A, we show that under our assumptions, $d \approx 4rc/3n$ is a reasonable approximation of the expected number of submissions that m reviewed and discussed at the meeting. As noted, because r and c (numerator) are bounded, d asymptotically behaves like $1/n$ (denominator).

Our PCs received $n = 356$ submissions and used an upper bound of 18–19 reviews per heavy member, which more or less corresponds to the line associated with $r = 20$ in Figure 2. In the relevant range of n, we see that $d = 5.5$ submissions discussed at the meeting per member. Because d is just an average, some members discussed more submissions, but others discussed less: as little as 2–3 submissions in certain cases. Flying to California to discuss such a small number of submissions is, arguably, counterproductive.

In 2018, the PC meeting spanned across two days, allowing the committee to make fewer decisions during the online discussions period and instead discuss $c = 124$ submissions in person at the meeting (with $n = 377$ and $r = 18$). Therefore, by our calculation, each member discussed about 8 submissions on average, alleviating the problem somewhat. On the other hand, 8 submissions during two days means 4 submissions per day (as compared to 5.5 per day in 2019), which is not necessarily preferable.

When discussing this issue with some of the members during the PC dinner, it seemed like most agreed that there is a problem: the time overhead and carbon emission associated with physical PC meetings are possibly becoming excessive considering the smaller number of submissions that each member gets to discuss. Still, there was a sense that the program turned out better due to the physical meeting, which allowed the members to calibrate. Additionally, several members—both junior and senior—pointed out that a notable value they get from PC meetings is the chance to network and interact with their peers.

In light of the above, it may be advisable for future program chairs to consider if in-person, physical PC meetings are worth it, at least in their current format. If they decide in favor of physical meetings, one conceivable way to increase their value is, for example, to couple them with workshop-style events, where committee members briefly present their ideas and get feedback from their peers.

4 Assembling the Committee

After we accepted the position of the ATC '19 program co-chairs, we were asked by USENIX to take into account that the number of submissions in 2019 might exhibit the same growth rate as it did in 2018, which would bring us to about 500 submissions (a.k.a. "the nightmare scenario" :-)), requiring $3 \times 500 + 2 \times 250 = 2000$ reviews assuming 50% of the submissions move to R2 (see Section 2.1). A smaller, more conservative estimate of 400 submissions would require $3 \times 400 + 2 \times 200 = 1600$ reviews. In comparison, a sizable heavy PC of 60 members each contributing 20 reviews—a threshold we were hoping and planning not to exceed—provides $60 \times 20 = 1200$ reviews. Taking into account these numbers, we decided to draft a heavy PC, a light PC, and an ERC (see Section 2.5) with target sizes of 65, 25, and 25, respectively.

Drafting about 115 committee members is a challenging task. In preparation for it, we compiled a list of all those who served on PCs in the last three instances of the main systems conferences, such that we had a pool of candidates to helps us (we used: ASPLOS 2017–2019, ATC 2016–2018, Eurosys 2017–2019, FAST 2017–2019, NSDI 2017–2019, OSDI/SOSP 2016–2018, and USENIX Security 2016–2018).

Analyzing this database brought up an interesting insight, which might indicate that our community has scalability issues in terms carrying out the reviewing load. Table 3 shows the relevant statistics. The aggregated sum of the size of the 21 PCs we have included in our analysis is 1118. These membership positions were manned by 655 unique individuals, a finding that could be interpreted to mean that members serve in $1118/655 \approx 1.7$ PCs in three years, on average. A deeper look at the data, however, reveals that 284 individuals participated in two or more of the PCs in our database, and these individuals are responsible for manning 783 (70%) of the 1118 positions. This finding implies that a relatively small group of people shoulders most of the reviewing load.

Figure 3 depicts the histogram of how many of the members in our database (y) served in how many of the PCs that we included (x), which demonstrates the reviewing effort dis-

memberships (aggregated sum of PC sizes)	1,118
number of unique members	655
number of unique recurring members	284

parity. We can see, for example, that one member served in 8 PCs, and four members served in 7.

The list we compiled was helpful in drafting the committee. When sending heavy member invitations, we allowed the candidates to accept as light or ERC, and when sending light member invitations, we allowed the candidates to accept as ERC. The number, type, and outcome of the invitations are specified in Table 4, and the demographic information of the resulting PC is specified in Table 5. Nearly 2/3 of the invitations sent were accepted, and as can be seen, this relatively high success rate is partially because we allowed candidates to opt for roles that involve a smaller reviewing load.

5 Conflicts and Bidding

5.1 Missing Conflicts

Before assigning submissions to reviewers, it is important for the submission management system, HotCRP, to have accurate conflict of interest information as defined by the ATC '19 call for papers [19]. In addition to the conflict information that authors and reviewers explicitly specify, HotCRP helps by highlighting potential conflicts based on the information available to it, which is productive. This year, we also used the PC Chair Kit [3] that was written for ISCA '18 to find missing conflicts based on authorship information available via DBLP.[2] The script downloads the relevant DBLP information and checks if there are any co-authors of submission authors from the last n years that are not already listed as HotCRP conflicts.

Our submission co-chairs found 150 such undeclared conflicts and verified them manually. They identified a few false positives (e.g., two researchers with identical name, a summer school report authored by many authors that should not be considered as a real conflict), but the rest of the conflicts were valid.

5.2 Helping Committee Members to Bid

Authors associate topics from a predetermined list with their submissions, and committee members declare their per-topic level of (dis)interest for each such topic. This information is important, because it is utilized by HotCRP to compute a per-member score for each submission, and members use these scores to sort through hundreds of submissions and thereby ease the process of bidding—the act of associating integers with submissions to indicate reviewing preference. HotCRP then uses bids (as well as topic scores when, e.g., bids are absent) to assign reviews to reviewers.

Instructions for Committee Members We requested committee members to favor bidding on submissions for which

[2] More accurately, we used a fork of that kit [7].

they can provide expert or knowledgeable reviews, rather than on submissions that they find interesting but do not fall in their area of expertise.

We additionally requested committee members to limit the range of the numeric values they use to express preference to -20 to 20. The HotCRP system does not compare preference values of different users in the automatic review assignment algorithm and so members need not use the same scale. Some review assignments, however, are inevitably done manually by program chairs, and then having a common scale is helpful.

Defining Topics Last year, in ATC 2018, the aforementioned predetermined list consisted of 62 topics, as opposed to years 2017 and 2016, at which ATC used a list consisting of 17 topics. Some speculate that having this many topics is cumbersome, overly verbose, and unhelpful [9], and we seriously considered minimizing the list and consolidating topics when defining it for 2019. But a closer look at the historical data (from ATC '18, as well as from ASPLOS '19, which used a similarly sized list) indicated that authors and reviewers do use most topics in the longer lists.

Considering that (1) the task of bidding is really hard when there are hundreds of submissions, and that (2) PC members do primarily rely on topics when bidding as a way to cope with this submission volume, we eventually decided that it might be counterproductive to shrink the topic list and risk making bidding harder. A concise (or at least coarser grained) list could be preferable, and mining past data more seriously may provide evidence that support this hypothesis. But as we currently do not know, we decided to stick with the more sizable, finer grained list (although we made changes).

Figure 4 shows the 59 topics used in ATC '19, ranked by the number of submissions that used them. It could be argued that even our least popular topic ("cryptography", which was associated with only three submissions) is worthwhile, because it is preferable for the associated submissions to be reviewed by the appropriate committee members who are actually capable of doing it, and it seems reasonable to speculate that the odds of that happening would have been smaller without the topic.

Grouping Topics Given that there are dozens of topics, it makes sense to group related topics when they are presented to authors and committee members within HotCRP, which makes using them easier. In ATC '18, the program co-chairs did so in an ad hoc manner by adding grouping prefixes to topic strings that are separated from the topic names by a colon (for example: "storage:deduplication", "storage:disk (CMR, SMR, etc.)", "storage:erasure coding", and so on). In ATC '19, we used the same notation but also kindly requested the HotCRP maintainer to directly support the concept, which he did [9], making the HotCRP presentation of grouped topics more elegant, usable, and effective. The topic groups we used are: general, devices, networking, OS, PL/SE (abbreviation of programming languages and software engineering), security, storage, systems, and techniques/aspects.

total number of citations of committee papers	1266
average number of citations per member	11.6
median number of citations per member	7
standard deviation	11.5
citations of top-most cited member	67
citations of 2nd-most cited member	61
citations of 3rd-most cited member	43

Table 6: *Statistics of citations of committee member papers found in the ATC '19 submissions and communicated to members to help with their bidding.*

Pinpointing Submissions that Cite Members As noted, having to place bids to decide which submissions to review is becoming more challenging due to the increasing number of submissions. Merely reading the titles of 300–400 submissions is time-consuming, and many reviewers need more information than just the title to decide to bid. Attempting to ease the process of bidding, we generated for, and shared with each committee member a list that specifies all the ATC '19 submissions that cite that member's papers. The list was generated by our submission co-chairs using the aforementioned PC Chair Kit [7].

Table 6 provides some statistics about the citations we have found. Since there are more than a thousand of them, hopefully, they provided a usable signal to some of the committee members.

Dealing with Unpopular Submissions Despite the fact that nearly 90% of the committee members placed positive bids on 20 submissions or more (and 2/3 of the members placed positive bids on 40 submissions or more), some submissions were associated with relatively few positive bidders. Perhaps unsurprisingly, some submissions are much more popular than others. The line associated with "before" in Figure 5 depicts the disparity of popularity. The x axis shows the rank of each submission based on the the number of members that bade positively on it, and y axis shows the corresponding number of bids.

Focusing on the bottom right, we can see that 60 submissions received only 6 positive bids or less, which would have likely hampered the review assignment process. We therefore labeled these 60 as "lowbids" in HotCRP and asked our committee members to consider positively bidding on some of them if they are within their domain of expertise, stating that if everyone does this truthfully, no one will be tasked with arbitrary submission assignments. The line associated with "after" in Figure 5 demonstrates that this request was effective. (Albeit the data is distorted somewhat by the fact that the "after" line additionally accounts for bids we solicited before the beginning of R2.)

Figure 4: *The ATC '19 topics (without their grouping prefix) ranked by the number of submissions that used them.*

Figure 5: *Disparity of popularity among ATC '19 submissions.*

Interestingly, out of those 60 "unpopular" submissions, only three (5%) were accepted to the ATC '19 program, which is 4x lower than the overall acceptance rate. Perhaps this poor success rate suggests that bidding information could be leveraged somehow to make the reviewing process more efficient? A positive answer to this question would be helpful, because the ATC '19 committee wrote 281 reviews for these particular 60 submissions, which is a lot of effort in order to accept only three.

On the other hand, one of these three has been awarded best paper, which is another demonstration of what all of us already know: popularity isn't everything... :)

6 Planning for a Dual-Track PC Meeting

Due to the increasing number of submissions to system conferences, in order to be able to finish the PC meeting on time, several recent program chairs resorted to splitting the meeting into two parallel tracks for part of the time, such that each track is simultaneously headed by a different co-chair. Assuming that the number of submissions is not going down any time soon, it seems like dual-track meetings are here to stay.

However, properly organizing a dual-track meeting is challenging. Notably because it may affect how submissions are assigned to reviewers, as it is nontrivial to arranges things such that *all* PC members are *always* found in the right room at the right time while the meeting takes place.

Currently, there is no standard, generally accepted best-practice for how to arrange a successful dual-tack PC meeting. Program chairs typically need to apply creativity and to spend much effort to come up with an appropriate model they feel would work and would be suitable for their committee. For this reason, before we describe the model we used, we survey the models of dual-track meetings used by program chairs before us, and we briefly discuss their pros and cons. Hopefully, this discussion would be useful for future chairs when deciding upon the model that works best for them, as the state of the art of dual-track PC meetings evolves.

ASPLOS '17 Model The first PC that we are aware of that split into tracks occurred spontaneously at the PC meeting of ASPLOS '17, when attending members and chairs realized it was not realistic for them to finish on time. They therefore split in an ad hoc manner to flexible, parallel discussion groups. The approach was reported to have worked: the program was ready at the end of the day, and the members lived to tell the tale.

ASPLOS '18 Model In the subsequent year, having experienced the difficulties from the previous year, the program co-chairs of ASPLOS '18 carefully planned for the dual-track meeting. They split their PC members into two disjoint equally-sized sets M_0 and M_1, with the stated goal of having equal expertise in both, in all the relevant conference topics. They likewise split the submissions into two equally sized

sets S_0 and S_1, and they exclusively assigned submissions from S_i to M_i, such that no PC member reviewed outside of her sub-committee's pool of submissions. Consequently, by design, running the dual track meeting was easy.

A main concern with this model is that it splits the expertise and thus runs the risk of arbitrarily preventing the most appropriate experts who happen to belong to M_i from reviewing submissions that happen to belong to the "wrong" pool $S_{(i+1) \bmod 2}$.

ASPLOS '19 Model In an effort to alleviate this drawback, the program co-chairs of ASPLOS '19 employed the following approach in deciding how to define M_i and S_i. ASPLOS is an interdisciplinary venue of three communities: SIGARCH (50% sponsorship), SIGOPS (25% sponsorship), and SIGPLAN (25% sponsorship). Accordingly, the chairs initially divided their PC into M_{OS} and M_{PL} containing members from the operating systems community and the programming languages community, respectively. They then searched for an "optimal" division of the PC members from the architecture community into two parts, each added to the initial M_{OS} and M_{PL} to form two equally-sized M_{OS}^{arch} and M_{PL}^{arch} sets that, together, comprise the entire PC.

The said optimality was achieved as follows. The chairs and their helpers used a script that exhaustively enumerated all the possible equally-sized M_{OS}^{arch} and M_{PL}^{arch} group partitions. For each partition, they assigned every submission to the group that maximizes the submission's "affinity" (a combination of reviewer citations, topic score, and normalized bids). Then, they scored that partition by aggregating the affinity across all submissions within their assigned group. The final partition was the one that scored the highest by this metric.

They then calculated the "partitioning penalty" for each submission, which is the total affinity of the submission for the whole PC minus its affinity to the group it was assigned to. They assigned high partitioning penalty papers to the whole PC, thus adding a requirement for a *joint session* at the meeting, in addition to the dual track. To make workload for the two groups even, they took the most highly penalized papers from the larger group and assigned them to the whole PC.

The ASPLOS '19 model is more careful in how it splits S_i and M_i as compared to the ASPLOS '18 model, trying to minimize the penalty associated with splitting. It additionally supports submissions that are discussed jointly. Still, while minimized, the penalties do exist.

We note in passing that the ASPLOS '19 program co-chairs received extensive help in planning for their dual-track meeting from individual whose role was similar to what we formalized as "submission chairs" (Section 2.4).

ATC '18 Model The program co-chairs of ATC '18 decided not to split the PC beforehand and globally assign reviews across all members without any constraints. This approach is simple and entirely eliminates the penalties of splitting. The cost, however, is shifting all the administrative complexity to the PC meeting itself: it raises the question of how to run the dual-track meeting without resorting to the ASPLOS '17 model, which seems to have heavily relied on luck.

The ATC '18 program co-chairs did not rely on luck. They were successful in planning the dual-track PC meeting after (1) all the reviews have been uploaded, (2) the online discussions have been concluded, (3) the list of submissions to be discussed at the meeting have been finalized, and (4) it became known which PC members will call-in rather than attend physically.

The PC meeting timeline was divided into several consecutive sessions T_i $(i = 1, 2, ...)$, such that in each session T_i the PC was split into two groups T_i^i and T_i^{ii} that met in parallel. The group membership changed across sessions, so group T_1^i was different than group T_2^i, for example.

In some sessions, groups T_i^i and T_i^{ii} were disjoint. But in other sessions, some PC members were instructed to physically move to the other group at some point, but such transitions were limited to one move per one member per session. In such non-disjoint sessions, PC members were asked to be aware of the discussion schedule so as to know when to make the transition. But inevitably this did not always work, and so occasionally members were called from the other room. Still, the program co-chairs reported that, overall, the movement between rooms was minimal and not distracting.

One ATC '18 co-chair concluded that "if I would repeat, I would not change what [we] did because it worked fine, and the PC didn't seem to be bothered to move around." But the other co-chair reported that "I would avoid doing what we did in the future even though it worked amazingly well. We lucked out [...], and we barely pulled it off."

Similarly to ASPLOS '19, the ATC '19 program co-chairs received extensive help in scheduling the PC meeting from individuals whose role was similar to what we formalized as submission chairs.

ATC '19 Model Like the program co-chairs of ATC '18, we wanted to refrain from the penalties and complexities involved in splitting the PC beforehand in a manner that affects how reviews are assigned. But we also wanted to completely avoid the aforementioned transitions between rooms, the occasional missing members that must be fetched from elsewhere, and—perhaps most importantly—the sense of uncertainty associated with the "barely pulled it off" sentiment quoted above. We achieved all these goals as described next.

Immediately after the submission deadline passed, the committee members placed their bids, and missing conflicts were identified and uploaded, we repeatedly applied the following simulation procedure.

1. Using standard HotCRP functionality, simulate assigning three R1 reviewers to all submissions as if for real.

2. Randomly select 50% of these submissions (177 in our case) to be the simulated R2 submissions; let us denote this random set as S_2.

3. Using HotCRP functionality yet again, simulate assigning two additional R2 reviews by heavy members to all the submissions in S_2.

4. Randomly select 50% of the S_2 submissions (88 in our case) to be the simulated set of submissions to be discussed at the meeting; denote this random set as S_3.

5. Using a constraint solver, find a split of the heavy PC into two groups that allow for the longest simulated dual-track parallel session of submissions from S_3 (without any transitions of members between the two groups); submissions that cannot be discussed in parallel in this split, will be discussed in a simulated joint session.

6. Compute the time it takes to run these simulated parallel and joint sessions, assuming a 6–7 minutes discussion per submission. If the simulated meeting takes less than eight hours, declare success; otherwise declare failure.

Our submission co-chairs repeated the above procedure multiple times using multiple random selections, and they verified that it *always* declared success. We therefore gained confidence that scheduling our dual-track meeting using a constraint solver is doable, despite using a global review assignment. This was indeed the case in the actual PC meeting.

Before running the above experiment, we did not know whether or not it would be successful, and we were prepared to get a negative result. In this case, we planned to use the framework we developed to attempt to understand the root cause of the failure, and to try to devise constraints for the baseline HotCRP review assignment algorithm that would resolve the underlying issue. Thankfully, we did not have to do that.

HotCRP Multi Live-Meeting Trackers HotCRP has a useful live meeting tracker feature, which helps program chairs run the meeting by keeping attendees in sync, presenting the current and next submissions discussed and the relevant conflicts. The problem was that HotCRP assumed a single track meeting, making the tracker unusable in the case of dual tracks. Thankfully, again, the HotCRP maintainer was willing to accommodate our request to add support for multiple live-meeting trackers [10], which we indeed used in our meeting.

7 Review Assignment Improvements

The review assignment is done by HotCRP using a min-cost max-flow algorithm [8, 11]. This assignment utilizes member bids and topic scores in order to distribute the reviews among reviewers in a manner that attempts to be balanced and fair, both in terms of number of reviews assigned to each member, and in terms of the bidding preferences, such that everyone would hopefully get as many of their top bids as possible.

The review assignment process of the individual conferences frequently involves some constraints that must be taken into account when the assignment takes place. In the case of the first review round of ATC '19, these were: (1) each PC member gets an assignment of 13 reviews; (2) each ERC member gets an assignment of 5 reviews; and (3) each submission gets at least 2, and at most 3, reviews by heavy members.

There is no way we are aware of to express multiple constraints such as these all at once in HotCRP (nor in the underlying min-cost max-flow algorithm, we believe). Instead, a sequence of assignments is conducted that is applied to the various types of members: first heavy, then light, then ERC, and some creativity is involved to get the desired outcome, which is an assignment that adheres to all the constraints.

With the goal of checking the quality of the resulting assignment, we have defined the per-reviewer "goodness" metric as follows. Let n be the number of reviews assigned to the reviewer, namely, in our case, n is 13 and 5 for PC and ERC members, respectively. The goodness metric measures how many of the reviewer's most-preferred n submissions, associated with her highest bid values, were actually assigned to that reviewer. For example, if an ERC member was assigned her five most preferred submissions, then her goodness is $5/5 = 100\%$, but if she was assigned only one of them, then her goodness is $1/5 = 20\%$.

The line that approaches 0% in the bottom right of Figure 6 shows the goodness produced by the default HotCRP assignment algorithm for all PC/ERC members. The committee members are ranked based on their review goodness value, from highest to lowest, and this rank is displayed along the x axis; the y axis shows the goodness value of the corresponding members. The drop towards zero at the right indicates that the default algorithm might produce an unfair assignment when used as described above. Some members get all their top picks and some get none, with 31 members (more than 1/4 of the committee) members getting less than 60% of their top picks. Moreover, the default algorithm made 38 and 6 assignments where the bid placed by the corresponding members was zero or negative, respectively.

For these reasons, we implemented a script that helps improve the assignment as follows. Let r_i be a reviewer, s_i be some submission that r_i was assigned to review, and $b(r_i, s_i)$ be the numeric bid value that r_i placed on s_i. Our script initially attempts to exploit the fact that the default algorithm does not produce a stable marriage [21]. Namely, it is possible to find a subset of n reviewers r_i $(i = 0, 1, ..., n)$, each assigned with a certain submission s_i, such that if r_i hands s_i to $r_{(i+1) \bmod n}$ and reviews $s_{(i-1) \bmod n}$ instead, then: (i) no conflict of interest is violated; (ii) $b(r_i, s_i) \leq b(r_i, s_{(i-1) \bmod n})$, namely, the new assignment is at least as good as the previ-

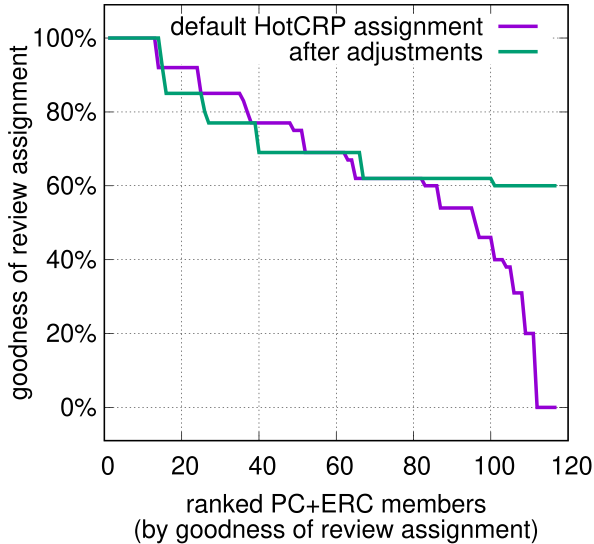

Figure 6: *Per-member goodness of the default HotCRP review assignment, which we improved, obtaining a lower bound of 60% through (i) review swaps that improved the assignments for all reviewers involved, or (ii) at the expense of reviewers who enjoy a much higher goodness value.*

ous for all reviewers involved; (iii) there exist at least one k ($0 \leq k < n$) for which $b(r_i, s_i) < b(r_i, s_{(i-1) \bmod n})$, namely, the new assignment is better than the old for at least one reviewer; and (iv) each submission still gets at least two and at most three heavy reviewers.

The script is repeatedly applied to the member currently associated with the lowest goodness value, who assumes the role of r_k defined in constraint (iii). The script attempts to find a submission switch as defined above, using $n = 2$ and $n = 3$. If no such swap exist, the script relaxes constraint (ii) so as to tolerate goodness reductions due to the swap, provided that the reviewers that suffer the reduction still enjoy a high goodness value after the switch.

Our script initiated 748 HotCRP events to adjust the original default assignment, as specified in Table 7. In the end, as shown in Figure 6, we were able to ensure a minimal goodness value of 60% to all members (namely, PC members got at least 8 of their top-13 preferences assigned to them, and ERC members got at least 3 of their top-5). Additionally, we were able to arrange things such that all committee members were exclusively assigned submissions associated with their positive bids, with two types of rare exceptions: (1) reviewers whose number of positive bids was smaller than 13 for PC or smaller than 5 for ERC; and (2) submissions with only one positive bid by a heavy PC member. In the latter case, the heavy member with the highest topic score was assigned as the second heavy reviewer.

Processing of the review assignment for R2 was similar albeit somewhat more challenging to improve, due to having

HotCRP events	*purpose*
215	eliminate assignments with zero or negative bids
12	at most 3 heavy reviewers per submission
494	increase low goodness to promote fairness
748	sum

Table 7: *Number of individual HotCRP events affecting review assignment that were generated by our script to improve upon the default assignment of R1.*

fewer usable bids, because only heavy members were assigned reviews, and also because of the additional constraint that we could only assign submissions to members who did not yet review them in R1.

Out of the 5–6 additional R2 reviews assigned to heavy members, the initial HotCRP review assignment assigned about 1/4 of the members with 1–5 submissions with which they associated a zero or negative bid. Anecdotally, one such member started off with *all* of his assignments having negative bids. Subsequently, we were able to adjust things such that all committee members were assigned submissions that are exclusively associated with their positive bids, with a few exceptions similar to those found in R1. Overall, half of the heavy PC members were assigned at least three of their (remaining) top picks, and all the them were assigned at least two of their top picks.

8 Reviewing Process

We employed a double-blind reviewing process consisting of two rounds, and we followed standard procedures for handling conflicts of interest. The PC consisted of 66 heavy and 28 light members, assisted by 22 ERC members. Additionally, 51 external reviewers contributed when specific expertise was required. The committee members were allowed to submit papers to the conference; the program co-chairs and submission co-chairs avoided it.

Table 1 summarizes the reviewing process. Out of 458 HotCRP registrations, we received a total of 356 submissions, divided into 324 full submissions (11 pages plus references) and 32 short submissions (5 pages plus references).

Format Violations We visually inspected all the submitted PDFs as well as used the HotCRP style checker to identify 29 submissions that violated the formatting rules. These were given a day to rectify the problem without making any content modifications; if fixing increased the size beyond the page limit, authors were required to remove (never change) content to meet the limit. All violating submissions complied except two, which were then rejected and withdrawn by the co-chairs.

Round 1 In Review Round 1 (R1), the PC members mostly contributed 13 reviews, and the ERC members mostly con-

tributed 5 reviews. Out of all R1 submissions, 277 were assigned four reviewers, and 75 were assigned three reviewers. Regardless, all of the submissions were assigned at least two reviews by heavy members (typical), and at most three. The committee wrote a total of 1,347 R1 reviews.

Round 2 We promoted 184 submissions to Review Round 2 (R2). We assigned each R2 submission with two additional reviewers from the heavy PC. A submission was promoted to R2: (i) if two or more reviewers gave it a positive score ("weak accept" or above); (ii) if a single positive reviewer decided that she supports promotion after considering the other reviews and despite of them, and, if she has so chosen, discussing the matter with the other, negative reviewers; or (iii) if the submission had fewer than three reviews due to late members.

To qualify to be the aforementioned "single positive reviewer", a member must have assigned a score of "accept" or "strong accept". For submissions with three (rather than four) reviews, a "weak accept" also qualified, provided the associated expertise was at least "knowledgeable" or the confidence was "high". Out of the 40 single-supporter submissions (24 with one "accept" or higher), we promoted 17 to R2 (13 with "accept" or higher). The committee wrote 405 R2 reviews and a total of 1,752 reviews in the two review rounds.

Review Sufficiency Check A few days before the rebuttal period, we applied a Review Sufficiency Check (RSC) procedure to all R2 submissions, to ensure that the reviews provide sufficient feedback to authors, as well as sufficient information to the committee to make an informed decision regarding the submission. To this end, for each R2 submission, we appointed one of the reviewers who is a heavy PC member as the "lead" of the submission. Leads were responsible for conducting the RSC by: (1) reading all the associated reviews; (2) asking the relevant reviewers to revise their reviews when the need arises (e.g., by calling out subjective claims that a submission is incremental without adequate citations of prior work, by identifying unclear statements, etc.); and (3) deciding together with the other reviewers if additional reviews are needed when expertise is low.

Online Discussions After the authors uploaded their rebuttals, we discussed the submissions online. Our goal until the meeting was to: (1) revise reviews if needed due to rebuttals; (2) revive R1 submissions if their rebuttals justify it (this happened in only two cases); (3) discuss submissions and attempt to reach consensus, color-tagging them as red to indicate preliminary reject, green to indicate preliminary accept, and yellow to indicate that reviewers are unable to reach consensus, so the submission should be discussed at the meeting; and (4) for red submissions that have a rebuttal, as well as for green submissions, write a post-discussion summary comment, which will be made visible to authors after the PC meeting, briefly explaining the primary reasons for rejections and possibly ways to improve (red), or what is required for the camera-ready (green). Such a summary was eventually written for all submissions that uploaded a rebuttal.

Reviewers who changed their mind about a submission due to the rebuttal or to the other reviews were asked to consider adding a "post-rebuttal feedback" section to their review and explain why. (We requested not to make substantive changes to reviews outside this section, as the reviews have already been seen by the authors and so any changes need to be clearly identified and justified.)

All the submissions, including R1, were assigned discussions leads, whose job was to drive discussion, write the summaries, and ensure progress. We asked leads to make an honest effort to ensure that the opinions of non-heavy reviewers were adequately voiced and represented at the meeting. Non-heavy members were warmly encouraged to champion submissions that they believe should be accepted, and all reviewers were encouraged not to feel pressured to adopt a common denominator point of view, and not to hesitate to go against the majority. Reviewers were encouraged to reflect on each others' opinions, e.g., by considering previous work or confirming an opinion from an expert.

We asked the reviewers to stay positive when possible (particularly when it comes to out-of-the-box ideas) and to keep in mind that we should be looking for reasons to accept a paper rather than reject.

When reviewers were unable to reach consensus (yellow), the online discussion was expected to reconcile as many differences among the reviewers as possible, leaving only a few substantive differences for a focused PC meeting discussion. Namely, tagging yellow was not used as a way to procrastinate or reduce work, because it is impossible to discuss all R2 submissions in one day. The meeting was planned to be dedicated primarily to those submissions that actually require it, focusing on differences that the reviewers had already identified as important.

When making decisions, we requested reviewers to assume shepherding but not for adding new results. (All accepted papers were indeed assigned shepherds, responsible for making sure that revision expectations are met.) Of the R2 submissions, we pre-rejected 80, pre-accepted 37, and tagged 67 as yellow to discuss at the meeting.

During the online discussions, we recognized that about a dozen R2 submissions might not have reviews with enough expertise, so we urgently solicited additional reviews from relevant experts after the rebuttal period. In these cases, we emailed the authors and allowed them to rebut the additional review(s), copy-pasting their response as a comment in the HotCRP relevant page.

Program Committee Meeting The PC meeting took place between 8am–6pm, 12 April 2019, in the VMware campus in

Palo Alto, CA. The program co-chairs, submission co-chairs, and 60 heavy PC members attended the meeting in person, five called in, and one could not participate. The meeting consisted of a morning joint session (8am–12pm), a split session in two rooms (12:30pm–3pm), and an afternoon joint session (3:15pm–6pm), followed by a lively PC dinner.

The split session composition was determined with the help of a constraint solver as described in Section 6. The partition was completely disjoint, and no members transitioned between rooms while it took place. We discussed 12 green (preliminary accept) and 25 yellow (discuss) submissions in the morning joint session, and 7 green and 12 yellow submissions in the afternoon joint session. In the split session, one group discussed 8 green and 16 yellow submissions, and the other group discussed 10 green and 14 yellow submissions. We allocated 3 and 7 minutes discussion time for each green and yellow submissions, respectively.

Out of the 67 yellow submissions discussed, the PC accepted 34, which, together with the 37 preliminary accepts, resulted in a program of 71 papers, of which 2 are short. Accept decisions were reached by consensus, except in two cases that required a PC vote.

9 Best Paper Selection

The best paper award selection process proceeded in two phases. In the first phase, we combined several signals. One was an explicit ranking by reviewers marking papers worthy of consideration for best-paper; any paper marked for such consideration by two or more PC members was passed to the second phase. Additionally, we considered general review ranks and deliberations (both online and during the PC meeting), moving several additional top-ranking papers to the second phase. Last, we collected explicit nominations by PC members for the best paper award.

At the end of the first phase, we generated a short-list of eight papers. At this stage, we appointed a swat team of six PC members consisting of senior and experienced members of the systems research community. During a period of four weeks, the team read papers, and we deliberated each one separately for best-paper worthiness. Conflicted members were excluded from discussions of the relevant papers. We did not place a quota on the number of best-paper awards. Generally, the committee favored papers with original or surprising contribution, and/or ones that would spark interest and establish a new direction for follow on works.

At the end of the second stage, we elected three papers to receive best-paper awards for USENIX ATC '19.

Acknowledgments

The ATC '19 program is the result of the efforts of many. We thank the authors for submitting their work, and the committee members and external reviewers for working so hard to review the submissions. We are deeply indebted to our awesome submission co-chairs, Lalith Suresh and Gerd Zellweger, and also to Igor Smolyar, who helped whenever needed. We also thank the Lightning Talks co-chairs, Deniz Altinbuken and Aasheesh Kolli, and the Best of the Rest co-chairs, Amy Tai and Chia-Che Tsai. We thank Erez Zadok for managing submissions for which both program co-chairs were conflicted.

We thank Eddie Kohler for authoring and maintaining HotCRP, and for supporting us and promptly adding the features we needed. We thank the program co-chairs of ATC '18, Haryadi Gunawi and Benjamin Reed, for being responsive and providing lots of useful information. We are grateful to Emmett Witchel, who co-chaired ASPLOS '19, went through everything a few months before us, and served as a source of much needed knowledge and emotional support. We thank Sarita Adve for accurately documenting her excellent review process in ASPLOS '14 [1], which was quite helpful. We thank Emery Berger for suggesting the idea of test of time award for ATC, and Vijay Chidambaram for so nicely articulating the case for double blindness—much of the text in Section 2.2 originated from him. We also thank Or Hershkovitz for reviewing the math in Appendix A and for finding and elegantly fixing a bug.

We thank the USENIX staff for their outstanding conference management, and notably Casey Henderson, Hakim Weatherspoon, and Angela Demke Brown for their thoughtful advice and guidance; Angela and Hakim additionally reviewed this document (in very short notice), and they provided valuable and much appreciated feedback that helped us improve it.

Lastly, we thank VMware for sponsoring and hosting the PC meeting (and for paying for drinks at the PC dinner), and Sandra Barreto, Lori Blonn, and Sean Crotty for helping to organize the meeting.

Appendix A Submissions Discussed by Each Member at the Meeting

Let n denote the number of papers that have been submitted to the conference. Let n_2 denoted the total number of R2 submissions that have been promoted from R1. Let m denote one PC member, and assume that m has reviewed exactly r submissions out of the n. Further assume that the number of m's R1 and R2 reviews are r_1 and r_2, respectively ($r = r_1 + r_2$). Let c be the total number of submissions that have been *discussed* at the PC meeting, and let d denote how many of these c submissions have been reviewed by m ($d \leq r$). These notations are summarized in Table 8. Recall that Figure 2 shows that as n grows, d decreases, to the point that m has little to do at the PC meeting because d is small. The computation underlying Figure 2 assumes a typical setup for systems conferences where $n_2 = n/2$ (half of the submissions have been promoted to R2), $r_1 = \frac{2}{3} \cdot r$ and $r_2 = \frac{1}{3} \cdot r$ (two thirds of m's reviews are written during R1), and the number of discussed submissions is $c = 70$. With our assumptions, an intuitive approximation of d on average is

$$d \approx r_1 \cdot \frac{c}{n} + r_2 \cdot \frac{c}{n_2} = (r_1 + 2r_2) \cdot \frac{c}{n} = \frac{4rc}{3n} \quad (1)$$

because (1) the probability that a single R1 submission that has been reviewed by m will be discussed at the meeting is

c/n, and, similarly, (2) the probability that a single R2 submission that has been reviewed by m will be discussed is approximately c/n_2, if disregarding the fact that the latter probability is in fact affected by the specific number of R1 submissions reviewed by m that have made it into R2. (For example, if all the submissions that m reviewed in R1 were promoted to R2, then the latter probability should actually be $\frac{c}{n_2-r_1}$, seeing that m cannot be assigned R2-submissions that she has already reviewed in R1.)
Figure 2, however, does not depict the approximation of d but rather computes it accurately, as follows. Let $p(n,c,r_1,k)$ denote the probability that exactly k of the r_1 submissions that m reviewed in R1 have been discussed at the meeting, then

$$p(n,c,r_1,k) = \binom{r_1}{k} \cdot \binom{n-r_1}{c-k} \div \binom{n}{c}. \tag{2}$$

Thus, $e(n,c,r_1)$, which is the expected number of submissions that m reviewed in R1 and were discussed at the meeting, can (also) be computed with the following summation

$$e(n,c,r_1) = \sum_{k=0}^{r_1} p(n,c,r_1,k) \cdot k. \tag{3}$$

Now, by using Equations 2–3 and the law of total probability, we can compute $e_2(n,c,r_1,r_2)$, which is the expected number of submissions that m reviewed in R2 and were discussed at the meeting, as follows

$$e_2(n,c,r_1,r_2) = \sum_{k=0}^{r_1} p(n,n_2,r_1,k) \cdot e(n_2-k,c,r_2). \tag{4}$$

Notice that Equation 4 uses $p(n,\mathbf{n_2},r_1,k)$ instead of the earlier $p(n,\mathbf{c},r_1,k)$, because here the probability corresponds to the event that k of the r_1 submissions reviewed by m in R1 were promoted to R2. Using Equations 3–4, we conclude that

$$d = e(n,c,r_1) + e_2(n,c,r_1,r_2), \tag{5}$$

which allows us to compute d accurately instead of approximating it. That said, in the range plotted in Figure 2, the difference between the real value of d (Equation 5) and its approximation (Equation 1) is always smaller than 0.52, which is reasonably close.

Given the highly empirical nature of research in cloud computing, networked systems, and related fields, testbeds play an important role in the research ecosystem. In this paper, we cover one such facility, CloudLab, which supports systems research by providing raw access to programmable hardware, enabling research at large scales, and creating a shared platform for repeatable research.

We present our experiences designing CloudLab and operating it for four years, serving nearly 4,000 users who have run over 79,000 experiments on 2,250 servers, switches, and other pieces of datacenter equipment. From this experience, we draw lessons organized around two themes. The first set comes from analysis of data regarding the use of CloudLab: how users interact with it, what they use it for, and the implications for facility design and operation. Our second set of lessons comes from looking at the ways that algorithms used "under the hood," such as resource allocation, have important—and sometimes unexpected—effects on user experience and behavior. These lessons can be of value to the designers and operators of IaaS facilities in general, systems testbeds in particular, and users who have a stake in understanding how these systems are built.

1 Introduction

CloudLab [31] is a testbed for research and education in cloud computing. It provides more control, visibility, and performance isolation than a typical cloud environment, enabling it to support work on cloud architectures, distributed systems, and applications. Initially deployed in 2014, CloudLab is now heavily used by the research community, supporting nearly 4,000 users who have worked on 750 projects and run over 79,000 experiments.

On the surface, CloudLab acts like a provider of cloud computing resources: users request on-demand resources, configure them with software stacks of their choice, and perform experiments. Much like a cloud, the testbed simplifies many of the procedures surrounding access to resources, including selection of hardware configuration, creation of custom images, automation for software installation and configuration, and more. CloudLab staff take care of the construction, maintenance, operation, etc. of the facility, letting users focus on their research. CloudLab gives the benefits of economies of scale and provides a common environment for repeatability.

CloudLab differs significantly from a cloud, however, in that its goal is not only to allow users to build applications, but entire clouds, from the "bare metal" up. To do so, it must give users unmediated "raw" access to hardware. It places great importance on the ability to run fully observable and repeatable experiments. As a result, users are provided with the means not only to *use* but also to *see*, *instrument*, *monitor*, and *modify* all levels of investigated cloud stacks and applications, including virtualization, networking, storage, and management abstractions. Because of this focus on low-level access, CloudLab has been able to support a range of research that cannot be conducted on traditional clouds.

As we have operated CloudLab, we have found that, to a greater extent than expected, "behind the scenes" algorithms have had a profound impact on how the facility is used and what it can be used for. CloudLab runs a number of unique, custom-built services that support this vision and keep the testbed operational. This includes a resource mapper, constraint system, scheduler, and provisioner, among others. CloudLab has had to make several trade-offs between general-purpose algorithms that continue to work well as the system evolves, and more tailored ones that provide a smoother user experience. The right choices for many of these trade-offs were not apparent during the design of the facility, and required experience from the operation of the facility to resolve.

The primary goal of this paper is to provide the architects of large, complex facilities (not only testbeds, but other IaaS-type facilities as well) with lessons from CloudLab's design choices and operational experiences. CloudLab is one of many facilities that serve the research community in various capacities [8, 6, 16, 33, 21, 34, 31, 35], and we aim to generalize the lessons from this specific facility. As a secondary goal, we hope that users of these facilities benefit from a closer look into the way they are designed and operated. With these goals in mind, this paper makes two contributions:

- In Section 2, we describe the CloudLab facility as it

has been built and analyze its basic usage patterns and the research conducted on it. This analysis, and the dataset that goes with it, represent a contribution to the **community understanding of the practical operation of IaaS-type facilities**.

- In Section 3, we analyze specific design choices using data from the operational system, looking at some of the trade-offs inherent in the facility's design. This analysis yields **important insights about how these choices affect user behavior and point to design principles for other facilities.**

Sections 4 and 5 cover related work and conclude.

2 Development and Use of CloudLab

We begin with background on CloudLab; our goal is not a complete summary of its goals, design, and deployment, but to provide sufficient context for the analyses that follow. We then examine usage patterns: how the use of the facility has evolved over time, the availability of resources, and the types of research that are conducted on it. From these analyses, we draw lessons about user behavior and look at the implications for the design of testbeds and IaaS facilities in general.

2.1 The Deployed CloudLab Facility

The primary CloudLab hardware is hosted at three sites: the University of Utah, Clemson University, and the University of Wisconsin–Madison. Though every site supports a wide variety of hardware-agnostic experimentation, each site specializes in a different area of research. Wisconsin's hardware is designed for networking and storage work, Clemson's for analytics and high-performance workloads, and Utah's for scale-out workloads. This equipment has come online in batches as CloudLab has been built out and evolved in response to user demand. Identical nodes in the same batch are all labeled with the same *hardware type* to help users request nodes with specific properties and to enable experiments to be repeated on the same types of resources. Since its initial public availability in December 2014, CloudLab has added devices such as programmable Ethernet switches, GPUs, Infiniband, and high-disk-count servers in response to user feedback. A full description of CloudLab's hardware can be found in its manual [36].

In addition to the hardware that it owns, CloudLab is *federated* [30, 7] with several other facilities, including Emulab [39] and Apt [32]. This brings the total number of servers available to CloudLab users up to about 2,250, and for the rest of the paper we include these resources in our analysis and discussion of CloudLab's hardware.

CloudLab is operated using software developed in-house specifically for running research testbeds: its control software is directly descended from software developed for the Emulab [39], GENI [25, 32], and Apt [32] testbeds. We have extended this software to better support experimentation on clouds and have made a number of improvements (such as those documented in Section 3) based on our experience running the facility.

CloudLab provides access to its devices at the *lowest layer* possible with a *minimum* of virtualization and abstraction between users and hardware. The reason for this is twofold. First, CloudLab's goal is to support research that is not possible on public (or typical private) clouds: it allows users to modify aspects of the software stack that would be fixed on those platforms, such as the storage, virtualization, and networking layers. Second, this supports more repeatable experimentation than facilities that virtualize and share their resources, as it provides strong performance isolation between tenants, factoring out the unpredictable "background noise" that makes it harder to draw sound, scientific conclusions. CloudLab takes pains to ensure that all servers of the same hardware type have comparable performance: in prior work [22], we have developed techniques for identifying servers whose performance is not statistically representative of the whole, and we exclude such servers from the population seen by experimenters. The facility takes the principle of low-level access beyond just servers and also provides "raw" access to other types of hardware such as programmable Ethernet switches [37] and servers with many drives from which users can build their own SANs.

Experiments in CloudLab are instances of *profiles*. A profile contains a description of the hardware resources (servers, switches, etc.) that the experiment will run on, and the software needed to run the experiment (in the form of disk images, `git` repositories, and scripts to run). When a profile is *instantiated*, CloudLab selects available hardware that matches the profile's specification and provisions that hardware with the software and configuration options described in the profile. Every instance of the profile runs on a separate set of hardware resources, and many instances of the same profile can run simultaneously. The CloudLab operators provide standard profiles for popular cloud software stacks, such as OpenStack [28], as well as bare-metal profiles that load standard Linux distributions. Users can also create their own profiles, which they can share with others. A typical workflow for creating a new profile involves starting with CloudLab-provided disk images, installing custom software, and creating a hardware description meeting the experiment's needs. All experiments have an *expiration*: when they are first created, they are set to expire after a few hours. Users can then request that their experiments be *extended* to last longer; short extensions (hours to days) are granted automatically (assuming resources do not need to be reclaimed to satisfy reservations), and administrators evaluate requests for longer periods (weeks to months). When deciding whether to grant these requests, administrators look at coarse-gained *idleness* statistics, such as CPU load and network packet counts, to de-

termine whether the user is using resources efficiently; other than this, CloudLab does not collect information about use *inside* of experiments. It is typical for there to be 200–300 experiments active on CloudLab at any point in time.

It is possible to fully script the workloads that run inside of an experiment, but in practice, most research done on CloudLab involves a great deal of development time and exploratory experiments, so most use is interactive. A key difference between CloudLab and typical cloud (as well as research and academic cyberinfrastructures such as Jetstream [33], Chameleon Cloud [21], and the Mass Open Cloud [35]) is that clouds place emphasis on *elasticity*, and therefore tends to treat ensembles of VMs working together as an *orchestration* problem. CloudLab's profiles place the emphasis instead on describing a *complete, repeatable environment*. This makes it less elastic, but makes it easier to describe entire networks and to repeat experiments in a consistent environment. We have found that some users do have initial confusion regarding this different focus, but that they tend to find it an easier way to run repeated experiments in the long run.

2.2 Hardware Overview

CloudLab Utah has a large number of servers, each with relatively modest specifications. 585 of the servers use HPE's high-density Moonshot platform, which places 45 low-power servers (Intel Xeon-D or ARM64 SoC) in each chassis. Each chassis contains two 10 Gbps switches, which effectively function as "top of rack" switches and are interconnected at 160 Gbps through a core switch. Another 200 servers connect to both a traditional Ethernet network (at 25 Gbps) and to a "layer-1" network. The latter allows control of the physical-layer topology, configurably "wiring" nodes to user-controllable Ethernet switches or directly to each other. These user-controllable Ethernet switches are allocated to one user at a time, allowing users to have full control over their configuration and even, in some cases, to program them.

CloudLab Wisconsin's goal is to reflect the type of technology and architecture found in a typical modern enterprise datacenter. All servers (which come from Cisco) are dual-socket and have a mix of spinning hard drives (HDDs) and solid state drives (SSDs). Several servers have large numbers of disks (up to 14), allowing users to build their own SAN configurations. Many are equipped with GPUs, enabling work on machine learning and applications of GPU computing to other areas, including network packet processing and other systems tasks. The network is arranged in a Clos topology.

CloudLab Clemson focuses on putting more CPU cores in each server (from Dell) and on a greater amount of RAM per core. This makes it suitable for hosting big data analytics (such as Hadoop and Spark), for running high-performance computing workloads, and for hosting large numbers of virtual machines. The Ethernet experiment network topology uses three interconnected core switches, each connected to a companion top-of-rack switch handling direct server connections. In addition to its Ethernet network, CloudLab Clemson has a 40 Gbps QDR Infiniband network used for HPC and RDMA experiments.

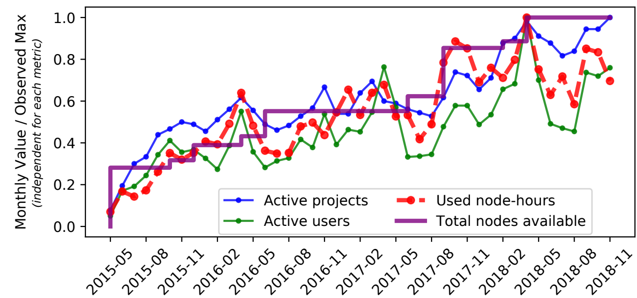

Figure 1: Growing testbed capacity and utilization. To produce a consistent scale, we divide monthly values by the all-time maximum value for each metric.

The hardware at each site has grown over time: the number of servers has increased approximately fourfold over the period covered in this paper. No hardware has yet been retired.

2.3 Usage Patterns

Figure 1 shows how CloudLab's userbase has grown along with its capacity. Starting in early 2015, when CloudLab exited its "preview" phase and became open for general use, it has grown steadily. As its capacity has increased, so too have its users: the more capacity, the more active users there are at a time, and the more projects (roughly corresponding to research groups and classes) are supported. Within the general upward trend, specific yearly cycles can be seen. CloudLab has lower usage during the summer, when there are few classes and research activity is slow. CloudLab's peak usage typically comes in the late spring: this is due to the confluence of major paper deadlines (OSDI, SOSP, SOCC, NSDI spring deadline, etc.) and end-of-year coursework.

CloudLab needs to gracefully handle periods of both high and low utilization. While we expected variation in usage over time, the extent to which it drives user behavior was somewhat surprising. Because most of CloudLab's usage is interactive, periods of low utilization are simply times when users are able to start experiments at will, without having to wait for resources to become available. We have therefore focused on improving user experience during periods of heavy utilization: as detailed in Section 3.3, we have built an *optional* reservation system which allows users to schedule resources ahead of time. Another strategy would be to incentivize users to shift their work from periods of high demand to periods of lower demand. In commercial clouds, one way of doing this is through spot pricing [1], which offers economic incentives. Because CloudLab's users do not pay to use it, economic incentives are not available; while various "virtual currency" approaches have been proposed for use in related facilities such as PlanetLab [18], none have seen widespread

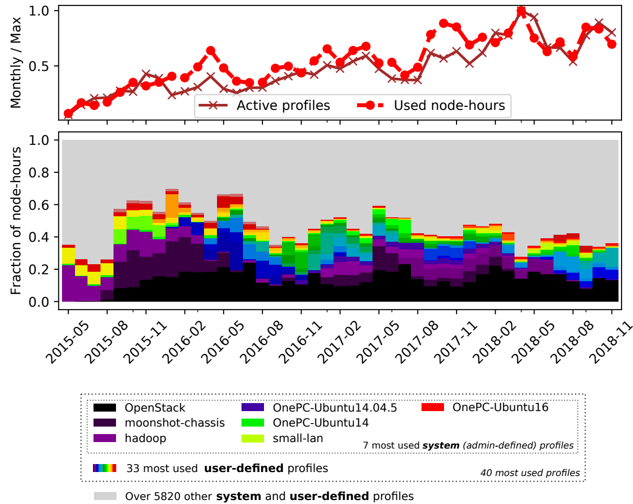

Figure 2: Evolving distribution of profile usage.

success. Demand in CloudLab's core communities appears hard to shift: Figure 1 suggests that CloudLab's users are heavily deadline-driven; it is not feasible to do coursework outside of the school-year, and not many research projects can run their experiments months before conference deadlines. If CloudLab is to "fill in" lightly-loaded periods, it will need to adopt backfill strategies [11, 23] that enable use by work that is easier to shift in time, such as the queueing systems used by high performance and high throughput computing.

Like the number of active users, the number of profiles in use at any time has grown as shown in Figure 2. The bottom half of the figure shows the forty most used profiles, as measured by the cumulative node-hours. We can see that usage patterns vary significantly by month. In some months, such as in early summer 2016, the top forty profiles constitute nearly 70% of the testbed's utilization, while in other months, such as recently, this fraction is less than 40%. The remaining node-hours are allocated by experiments representing over 5,820 other profiles. Users run experiments using up to 572 unique profiles monthly; the median is 233.

The long-tailed distribution we observe indicates that there is a large number of profiles with relatively low and infrequent use, but their combined utilization constitutes most of the user activity. This holds important implications for analysis of usage patterns and for design choices. In Section 2.5, we reflect on the fact that the testbed's major practical value is attributed to facilitating not merely a handful of common use cases, but rather a large variety of experiments in this "long tail." In quantitative analysis, it means we should use medians rather than means as the preferred measure of central tendency due to the highly skewed distributions. The analysis of other percentiles (e.g., 75th or 95th percentiles) provides complementary insights, as we discuss in Section 3.3. Furthermore, this diverse and evolving utilization distribution suggests that we cannot draw reliable conclusions about the impact of testbed's capabilities on usage patterns based solely on comparison of usage statistics from different periods of time. For example, if we compare statistics for 2017 and 2018, it would be difficult to determine the extent to which evolving usage patterns were due to changes in the system or due to the natural evolution of user interests. For the same reason, month-to-month comparisons are also unlikely to provide sufficient evidence for "before and after" analyses for system capabilities.

Fundamentally, periods of time that seem similar by one statistical measure (such as the number of active users) can look very different for other measures (such as the distribution of profile use). We posit that this is likely to be true for many IaaS-type facilities: while multi-tenancy smooths out some measures into predictable shapes (e.g., the top half of Figure 2), others are quite chaotic (e.g., the bottom half of the same figure). Taking these patterns into account when designing facilities can improve their utility and user experience.

2.4 Resource Availability

Availability and diversity of resources play critical roles in the adoption and continued use of a testbed or other IaaS facility. If users' needs frequently cannot be satisfied due to insufficient availability, those users will likely move to other facilities. Users also tend to seek out hardware with cutting-edge features and the highest performance characteristics. New hardware types have been introduced to CloudLab over time in order to satisfy both capacity and the capability requirements. Not only did the new hardware attract new users, but it also reduced contention for older, already deployed resources.

In Figure 3, we show both short- and long-term availability trends for the major CloudLab hardware types. The X-axis represents a fraction of all nodes of a particular type, and the Y-value at each point shows what fraction of the time *at least* that many nodes were available. Lines on these graphs that fall steeply signify the types that are in use most of the time, while higher curves represent more available types. For example, we can compare `d430` and `m400`: the former type is more heavily used across all three graphs.

As we saw in the previous analysis, metrics that look smooth when viewed from a high level show much more variability when we look at the details. This is important because it is often the details that influence users' experience: e.g., for an individual user, availability of the specific node type(s) needed for their experiment is important, rather than the availability of the testbed as whole. To illustrate this, we include the two monthly plots showing the variation that occurs between "slow" and "busy" months. For example, the curves for `pc3000` indicate that in January 2018 users found 80% of these nodes available for use 80% of the time. In contrast, in April of that year, there were *no* times at which 80% of these nodes were available. For several other hardware types (such as `c220g1` and `d710`), resources were even

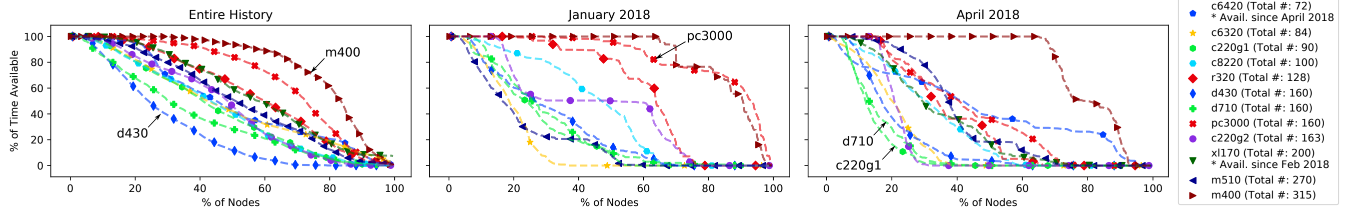

Figure 3: The availability of CloudLab resources. The left plot shows availability over the entire period of time each hardware type was available; the other two plots show availability during low-utilization (center) and high-utilization (right) months.

scarcer, and at no time are more than 30–40% of these nodes free. We also note that d430's low availability is reflected in two ways: it can be seen in these graphs, and we will discuss it in Section 3.3, where we find that users commonly make reservations to schedule access to this in-demand hardware. The curves in these figures highlight that the extent to which system changes and evolving utilization patterns impact individual hardware types varies significantly across the types.

2.5 Research Use of CloudLab

To understand the research conducted on CloudLab, we surveyed 93 papers published in 2017–2018 that used CloudLab for part or all of their experimental evaluations. Table 1 presents a categorization of the papers by the primary area of contribution, using a list of systems and related research areas. These areas are quite broad, and no one area dominates. Given that the most prevalent area, Networking, is an area where typical clouds provide very little transparency [14] and control only as an overlay [2], it is intuitive that research in this area benefits from CloudLab's greater visibility and control. Research in the second area, Security, benefits from the "closed world" of CloudLab, allowing experiments that involve attacks that would be considered hostile in a typical cloud and defenses that need to be implemented within the cloud framework itself.

In this analysis, we found two primary motivations that drove experimenters to CloudLab. The first is low-level access to hardware because of *features* that could not be developed in virtualized environments. Almost every paper in this set used some different aspect of CloudLab, such as the ability to re-configure Ethernet switches, the ability to build an HPC-like environment with root access, the SDN available on most of the CloudLab networks, the ability to monitor power use, the ability to build a complete OpenStack cloud inside the infrastructure, etc. The second motivation is the *performance predictability and isolation* that are difficult to come by in environments that use multi-tenancy on hosts and storage. When the primary metric of interest in a system is its performance, anything that adds variability requires, at a minimum, a far greater number of experiment repetitions to achieve statistical confidence [22, 17]. There is also the

Networking	30%
Security	16%
Storage	11%
Applications	10%
Computing	9%
Virtualization	8%
Databases	7%
Middleware	4%
Energy & Power	2%
Other	15%

Table 1: Research areas in 93 papers that used CloudLab.

question of the extent to which an evaluation is measuring artifacts of the platform vs. the actual system under test: while a more transparent environment does not guarantee that no system artifacts are present, it does give the experimenter more opportunities to observe, understand, and correct for these effects.

The main lesson we take from this analysis is that, as facility operators, we are constantly surprised by the uses to which users put the facility. Had we started from a position of virtualizing everything, then providing lower-level access to specific systems as needed, we think it is unlikely that we would have been able to anticipate all of the use cases found in this survey. Starting from a position of maximizing user control helps to maximize use of the facility.

3 High-Level Effects of Low-Level Decisions

We now move from examining how people use CloudLab to looking at the interactions between design decisions, operational experience, and user behavior. We have found that the *choice of algorithms* deep within the implementation of a system like CloudLab has a profound effect on the ways that users interact with the system, and even what they are able to accomplish. As a result, we have made many changes to the CloudLab facility during its lifetime; in this section, we present individual subsystems that we had to evolve based on facility's usage patterns. The high-level theme of this section is that the choices made at these low levels are not, contrary to what one might expect, simply implementation details, nor are they neutral with respect to the utility of the facility. When building an IaaS facility, designers cannot consider aspects such as resource mapping separately from user goals, require-

ments, and workflows. These aspects of the system must be co-designed, so that users can work *with* these subsystems rather than having to fight *against* them to get work done.

3.1 Resource Mapping

There exist several approaches to the problem of mapping user requests to physical resources. For instance, commercial clouds do not provide control over this mapping within selected instance classes; they manage the placement and consolidation for effective utilization and hide the details from the users. In contrast, Chameleon [21], which is designed as a testbed for repeatable experiments (similar to CloudLab but serving a different research community), has its users do the mapping by asking them to specify IDs of the particular servers they want to use in their requests.

CloudLab takes a unique approach where it recognizes two aspects in this mapping. It is a constraint-satisfaction problem in the sense that the user's request is a specification that must be satisfied; specifically, it resembles the subgraph isomorphism problem [10] in that both the requested and physical topologies are graphs consisting of servers, switches, etc. It is also an optimization problem, because the mapping must be done in a way that maximizes the possibilities for future mappings: it should avoid using scarce resources unless they are specifically requested or there is no available alternative. CloudLab exposes the outcomes of the mapping to the users and allows them to reuse hardware IDs if necessary.

CloudLab's mapping algorithm is derived from the one developed for Emulab [29], and uses simulated annealing to address this NP-hard problem. The advantage of using a powerful, general-purpose algorithm is that it enables the expression of complex constraints and preferences. The disadvantage, however, is that when a mapping *cannot* be found for a request, it can be difficult for users—and even administrators—to understand why. In CloudLab, we have had to evolve this system to improve the intelligibility of the responses that it provides.

The fundamental trade-off exposed here is between a *general* algorithm that makes few assumptions about the facility (and therefore is easily adaptable to new resources) and a more *specialized* algorithm that understands facility semantics and can provide actionable suggestions when a mapping fails. The general algorithm fundamentally lacks semantic information about what the user *may be trying to accomplish* and the *classes of requests that "make sense" on this particular testbed*. A mapping algorithm more tailored to a specific use case could embed such information and make assumptions about user goals.

Our response to this trade-off has been to retain the general algorithm, but to develop a set of heuristics that turn some of the more common failure modes into messages that are easier for users to understand. A major challenge in designing these heuristics is that they must be *conservative*: that is, every mapping that would have succeeded without the heuristic must still succeed. Our experience has been that it is preferable to build such heuristics *around* the mapping algorithm rather than *into* it. Building conservative checks into the *randomized* setting of the mapper itself is extremely difficult and can easily cause unexpected changes in behavior. It is easier—and more informative for the user—to build conservative checks as a *deterministic* wrapper around the mapper. We now describe some of these checks, which we have added over time in response to common error patterns and common questions from users.

In an ideal situation, all mapping errors would be explained to the user by concise, actionable error messages. In theory, the universe of possible mapping errors is so vast that not all have simple explanations. We have found that in practice, however, it is possible to catch most mapping errors with heuristics. We now describe the set of heuristics we have developed over time in response to use patterns and frequent user questions.

Looking in Table 2 at the last year (L.Y.) of mapping errors, approximately 84% of all errors are explained by the top 10 error messages, and of that top 10, only 13.5% are ones that we classify as "unhelpful." If we look at this as a percentage of all experiments, only 1.2% of all attempts to start experiments in the last year have received these four unhelpful mapper messages.

The top two messages (lines 1 and 2 in the table) together account for about half of all mapper errors, and they simply indicate a lack of free nodes (servers or user-controlled switches) at the current time. The first message indicates that there are insufficient nodes free *right now* while the second says that this would occur in the *near future* due to the reservation system described later in this section. There is a third variation on this message (line 7); this is an older version of line 1, which we updated partway through the year to clarify its meaning and provide more specific information. Note that this class of messages are *per-type*, so experiments that request, for example, both servers and user-controlled switches get specific feedback on which is the limitation. The number of available nodes is reported in order to allow the user to decide whether they would prefer to request fewer nodes or to wait until enough nodes become available. When users request specific nodes, in contrast with asking for any nodes of a selected type, they receive explicit messages indicating that those nodes are unavailable (line 10).

Other frequent errors (lines 3, 6, and 8) indicate that there is some node in the request that cannot map to anything available. Our heuristics try to report the specific reason, such as requesting too many physical interfaces, an OS image that is incompatible with the hardware type, or a specific feature (such as a GPU add-on). The distinction between lines 6 and 8 presents an interesting illustration of our use of heuristics: underneath, the mapper uses the same mechanism to handle both of these constraints (support for a particular image is considered a "'feature"). We found that the raw

Error Message	Helpful (actionable)	% of Mapping Errors L.Y.	% of Mapping Errors ALL	% of All Errors L.Y.	% of All Experiments L.Y.
1. Resource reservation violation: X nodes of type HW requested, but only Y available	✓	27.79	14.33	16.07	2.41
2. X nodes of type HW requested, but only Y available nodes of type HW found	✓	21.86	33.01	12.64	1.89
3. No Possible Mapping for X: Too many links of type Y	✓	6.64	6.96	3.84	0.58
4. No Connection	✗	5.22	2.62	3.02	0.45
5. Insufficient Bandwidth	✗	4.88	7.53	2.82	0.42
6. No Possible Mapping for X: OS 'Y' does not run on this hardware type	✓	4.74	3.50	2.74	0.41
7. Not enough nodes because of policy restrictions or existing resource reservations	✓	4.37	2.18	2.53	0.38
8. No Possible Mapping for X: No physical nodes have feature Y	✓	3.54	2.40	2.05	0.31
9. Insufficient Nodes: Unexplained	✗	3.39	2.15	1.96	0.29
10. Fixed physical node X not available.	✓	2.56	3.15	1.48	0.22

Table 2: Distribution of recorded mapping errors. "ALL" denotes the distribution of all errors recorded since October 20, 2015. "L.Y." columns refer to the percentages reported for the last year (starting on August 1, 2017).

message, however, was unhelpful and confusing to users, so we recognize the specific case of image-related mapping failures and transform the message into something that the user can act on: she needs to either pick a different image or a different hardware type.

Lines 4 and 5 are the error messages that are the least helpful to users, and they have a similar cause: the mapper is unable to find a solution that satisfies all links and LANs with the bandwidths specified in the requests. These error messages are produced directly by the simulated annealing portion of the mapper, and it is no coincidence that they are the hardest to explain. They are highly dependent on the details of the topology requested by the user and the switch topology at each CloudLab site. There are many potential actions to take in response to such failures: change the topology, reduce the bandwidth requested, try a different CloudLab site, wait for a different set of physical resources to be free, etc. In essence, the more degrees of freedom the user has with respect to reacting to a failure, the harder it is for the facility to guess which one best addresses the user's actual goals, and the more difficult it is to provide a useful message.

3.2 Interactive Topology Design Feedback

Giving users actionable messages when their profiles don't map is helpful, but it comes fairly late in the process of experiment design. Our experience has been that users can find even the "helpful" mapper errors frustrating, as they come after the user has already invested significant time. A useful analogy is to compile-time errors and syntax checking in IDEs: compiling is complex and slow, and feedback from the editor as the user writes code, while not perfect, leads to a workflow with fewer surprise errors. What we discovered was that we needed the equivalent of realtime syntax checking for network topology design, and our answer to this is CloudLab's *topology constraint system*. The biggest challenge in building it has been to design a system with a simplified model of the mapping process that does not produce a *specific mapping*, but instead checks whether such a solution *should exist*; it must do so quickly enough to run interactively in the browser.

The constraint system is used in two contexts, and has slightly different goals in each. In the first context, it is invoked as part of Jacks: CloudLab's GUI that gives users a "drag and drop" interface for constructing profiles. In this setting, its goal is to assist novice users by disabling UI options that conflict with their existing choices and to warn them when the topology they have drawn is unlikely to be instantiatable. It does not need to admit *every possible* request that can be instantiated on CloudLab (there are more sophisticated interfaces for that), but to provide an assurance that, if a topology passes at this stage, it is virtually guaranteed to succeed in mapping (assuming there are enough resources free). In the second setting, it is used at the final stage of profile instantiation, when the user selects which CloudLab cluster to run their experiment on. Here, it checks the request against each cluster and disables selection of any cluster where the request cannot be instantiated. The goal in this case is the inverse, and we must be more conservative: We want the constraint system to block instantiation if the request will *definitely* fail, but do not want to over-zealously block instantiation that *might* succeed.

The described two-phase experiment design is unique to CloudLab. On the surface, the first phase can be compared to how responsive web interfaces for clouds—e.g., Amazon EC2's dashboard and the OpenStack's Horizon dashboard [27], hide or disable infeasible configurations. At the same time, EC2 goes as far as "attaching" storage characteristics to instance classes (even though networking is actually what is being customized) when listing the storage optimized solutions among the feasible configurations. CloudLab's constraint system makes the design process more explicit by offering interactive control over all components of interconnected experiment environments. In the second phase, requests act analogously to HTCondor's classads [9]. In practice, systems like HTCondor without interactive design capabilities

make working with complex configurations laborious and error-prone.

Generating and checking candidates To check constraints, we generate a set of *candidates* which are tested against a number of *groups*. A candidate is a set of node or link resource properties which we check for mutual compatibility. A group is a whitelist of acceptable combinations relating two or more resource properties. For example, a group might include all allowed combinations of hardware type and disk image. Our constraint system also supports wildcards in both candidates (for unspecified resource properties) and groups (for cases where one resource property is universally allowed). A candidate passes if it matches all groups. Our approach uses a Boolean expression in the *product of sums* form: a set of terms containing conditions that are OR-ed together, with all terms being AND-ed together.

This process is defined in terms of sets and Boolean operations as follows: for a set of candidates $X = \{x_1, x_2, \ldots, x_k\}$, we define an evaluation procedure $f(X)$ that checks all individual candidates. We define $g(x)$ for a given configuration candidate x such that the candidate must match against all groups (A, B, etc.): $g(x) = A(x) \land B(x) \land \ldots$ For each group, the candidate must match at least one condition. As an example, suppose the following table described the conditions allowed for each group:

Group relating `site`, `hardware`, and `type`:	Group relating `hardware` and `image`:
$a_1(x) = \{$`utah`, `m510`, `xen`$\} \subseteq x$	$b_1(x) = \{$`m400`, `ubuntu16-64-ARM`$\} \subseteq x$
$a_2(x) = \{$`utah`, `m400`, `pc`$\} \subseteq x$	$b_2(x) = \{$`m510`, `ubuntu16-64-STD`$\} \subseteq x$
...	...
$a_n(x) = \{$`wisconsin`, `c220g2`, `pc`$\} \subseteq x$	$b_m(x) = \{$`c220g2`, `fbsd110-64-STD`$\} \subseteq x$
$A(x) = a_1(x) \lor a_2(x) \lor \ldots \lor a_n(x)$	$B(x) = b_1(x) \lor b_2(x) \lor \ldots \lor b_m(x)$

In this case, a candidate x=$\{$`utah`, `m400`, `pc`, `ubuntu16-64-ARM`$\}$ evaluates to true, as $a_2(x) \land b_1(x) = 1$.

In the Jacks GUI, the candidates that we generate represent the UI element (node, link, etc.) that the user has selected and the actions they *may* take on it: OS images they may select, other nodes they may connect it to, etc. Each candidate represents a different possible action, and we disable ("gray out") UI elements for candidates that do not pass ($g(x)$ evaluates to false). In the profile instantiation process, the candidates represent *all* nodes as they appear in the request, and the request may only be submitted to clusters for which *all* candidates pass ($f(X)$ evaluates to true).

Checking Constraints Quickly The set of candidates can, in practice, be quite large: in Jacks, it grows with the number of options the user can set on the node (including other nodes to connect to), and in the instantiation process, it grows with the size of the request. We have run containerized experiments with as many as 5,000 nodes. At least one candidate must be evaluated per node in a topology, and if there are LANs, the number of candidates is quadratic in the number of nodes in each LAN. The number of conditions in each group can grow even larger, as it depends in part on the product of the number of hardware types, images, sites, and other node properties. On our current system, every candidate is evaluated against at least 10,000 conditions across all groups. However, the number of groups remains small in all cases (the current number of groups in our testbed is just 7), and in practice, there are several optimizations that allow us to take advantage of the facility environment to make checks fast.

Large requests have many nodes and thus require many candidates to be tested, but many of these candidates will likely be identical. Similarly, when Jacks evaluates which items in a drop-down box are valid, there is no need to re-evaluate combinations that have already been tested on a previous drop-down box instance. Memoizing test results and culling identical candidates yields large speed improvements for our use cases. Even with memoization, every unique candidate has to be checked once, so we have optimized the evaluation of the Boolean expression as well. Naïvely testing each condition in turn using set arithmetic yields a speed that is linear on the number of conditions. Instead, we can uniquely encode conditions as entries in hash tables, and each group can be tested with an (amortized) constant-time lookup. This lookup means that testing a candidate for the first time is linear in the number of *groups* rather than the much larger number of *conditions across all groups*. Together, these optimizations reduce the complexity of the checks from $O(c \cdot g \cdot s)$ (where c is the number of candidates, g is the number of groups, and s is the size of each group) to $O(\text{unique}(c) \cdot g)$.

Impact on User Workflow CloudLab's topology constraint system is built around the idea of using a *quantitative* advantage (fast constraint checking) to provide a *qualitative* improvement in user experience. It has done so by dramatically reducing the number of submitted requests that could not possibly map—even if all resources on the testbed were available. In many situations, builders of IaaS-type facilities face a choice: to ensure that *any* request that a user makes for *any* set of resources configured in *any* way can be instantiated on the facility, or to constrain user requests in some way. While the former is attractive, it can be expensive to guarantee and can result in situations where users *can* request certain combinations but would be better off *not* doing so because these combinations do not perform well together. CloudLab's topology constraint system shows one possible path forward on the latter alternative: constrain users' requests, and give them early, interactive feedback while they design their configurations.

3.3 Reserving Resources

Until recently, resource allocation in CloudLab was done in a First-Come-First-Served (FCFS) manner. While FCFS works well for the interactive "code, compile, debug, gather results" workflow used in the systems research community, it has a number of shortcomings: it favors small experiments

(whatever fits into the available resources at the time the user is active), it can be difficult to plan for deadlines (such as the paper and class deadlines seen in Section 2.3), and it can be problematic for events that must occur at a specific time (such as tutorials and demonstrations). In response to these competing needs, we have developed a *reservation system* to support these use cases while continuing to support the dominant FCFS model.

A reservation is not an experiment scheduled to run at a specific time, but a guarantee of *available resources* at that time. This allows users to run many experiments either in series (e.g., to test different scenarios) or in parallel (e.g., one experiment per student in a class). This *loose experiment-reservation coupling* is one of the key design attributes of our reservation system and the subject of much of the analysis presented in this section.

What we found in designing our reservation system was that it needed to have a fundamentally different design than the resource mapping described in Section 3.1. Resource mapping answers the question, "Given a specific request and a set of available resources, which ones should we use?" The reservation system needs to answer "Given the current schedule of experiments and reservations, would a given action (creating a new experiment, extending an existing one, or creating a new reservation) violate that schedule?" Answering this question must be fast: like the constraint system, we need the reservation system to run at interactive speeds so that we can give users immediate feedback about their ability to create or extend experiments. Our other challenge is to support *late binding* of resources: the reservation system should promise *some* set of resources in the future, but should wait until the time comes to select *specific* ones.

Our approach diverges from the scheduling schemes offered by other facilities. On Chameleon [21], users request specific servers (using server IDs) as mentioned previously; therefore, their requests require only the *early binding*, and the system trades flexibility for simplicity (presumably at the expense of utilization). In contrast, clouds do not offer control over future scheduling decisions. They provide an illusion of infinite resources, and handle all user requests interactively, at the time of submission. In High Performance Computing, solutions are built upon *job queues* where job and user priorities impact scheduling, yet making sure that exact deadlines are met in the future is a constant challenge.

We describe our design using the following terms and operations: A request for reservation r asks for N_r nodes of the specified hardware type h_r to be available within the time window $[s_r, e_r]$. Once `submit`-ed, a request typically requires approval from CloudLab staff, though small requests are auto-approved. In addition to the `approve` operation, staff can `delete` reservations, both pending and active. At any time, users can change their experimentation plans and `delete` their reservations or submit modified requests.

Late Binding Considering that CloudLab's hardware is homogeneous within each hardware type h, the reservation system does not need to decide which *specific* nodes will be counted as N_r nodes of type $h_r \in \{h\}$: any N_r such nodes will satisfy the needs of reservation r with these parameters. This increases efficiency of resource use and helps accommodate FCFS users: it does not require us to force experiments out just because the specific nodes they have allocated happen to be reserved. As long as there are *enough* free nodes for everyone who has requested them, all experiments can continue. Therefore, we spare the reservation system the task of finding exact mappings between reservations and specific nodes and implement reservation operations as node counting tasks. The "binding" occurs later, when the user instantiates their experiment(s) near or within the $[s_r, e_r]$ window. The reservation system simply ensures that the capacity is sufficient.

Checking Reservations Quickly Given the data about active experiments—node counts and their current expiration times—and parameters of approved upcoming reservations, our reservation system constructs a tentative schedule describing how the number of available nodes is expected to change over time. This schedule can be constructed in $O(n \log n)$ time (it must sort upcoming events by time), and takes $O(n)$ time to check. Here, n is the number of events, which is a sum of the number of current experiments (typically hundreds) and the number of future reservations (typically tens). Effectively, this creates a two-phase process, in which the reservation phase involves tasks that are lightweight and fast, while the laborious resource mapping phase runs as part of lengthy resource provisioning process.

This fast checking is enabled by a key design decision: reservations are *per hardware type*—we do not allow reservations for broader categories such as "any server type." While the latter would be attractive, it would also raise the time to check the schedule far above $O(n)$. In our design, we can check the schedule for each type *independently* because the sets of nodes of each type do not overlap. There is only one, binary solution at each point in the schedule: either the sum of nodes in experiments plus the reservations exceeds the total number of nodes of that type, or it does not. If we were to have overlapping sets (e.g., specific and generic types), this would create *dependencies* both between sets and across time. Each point in the schedule would have multiple potential solutions, using different numbers of nodes from each node set. Checking the solution would not only be a matter of checking the solution at each point in time, but ensuring each solution is consistent with the solutions at other time points. The combinatorial complexity that this would entail would prevent us from quickly re-calculating and checking schedules, so we accepted the tradeoff of being more rigid with respect to node types.

Enforcing Reservations The CloudLab reservation system essentially works by "accumulating" free nodes up to the

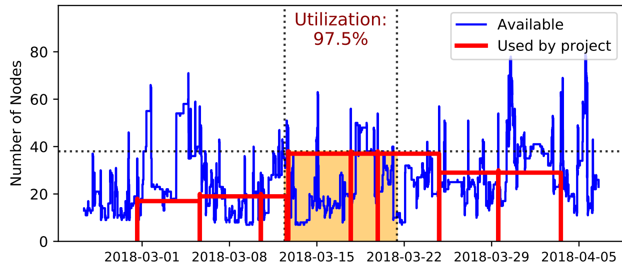

Figure 4: 38 d430 nodes reserved and used for over 9 days. The highlighted box depicts the reserved resources: the number of nodes (up to the horizontal dotted line) reserved for the reservation's time window (between the vertical dotted lines).

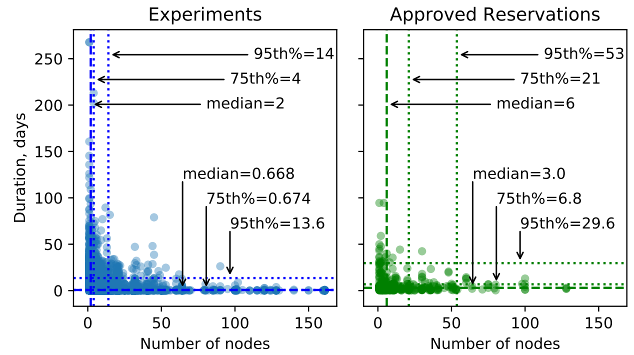

Figure 5: Comparing experiments and reservations. Empirical percentiles are labeled using '%'.

point at which the reservation starts. As the beginning of the reservation approaches, it scrutinizes two types of operations: creation of new experiments, and extending the duration of existing experiments. If either of these operations would overlap with the reservation and would result in there being insufficient free nodes to satisfy it, they are denied. For an illustration, refer to Figure 4, which shows a large reservation *r* requesting over 8200 node-hours worth of d430 nodes. Prior to *r*, d430's availability was insufficient for most of the preceding week (below the horizontal line). As *r*'s start approached, the admission control system began denying overlapping use, and the free nodes rose until the reservation could be satisfied. Almost immediately, the project created a large experiment (the exact size of *r*), and ran two other subsequent experiments. We can see that the final experiment outlasted the reservation: because there were no other reservations directly afterwards, the user was allowed to extend the duration of the experiment. Another interesting behavior visible in this graph is that the project was running smaller experiments before their reservation started; once it did start, they were able to double the size of their experiments.

Parameter Exploration In addition to submit, approve, and delete, CloudLab's reservation system supports a validate operation. validate allows users to explore potential reservations without submitting them, giving them the ability to try different times, hardware types, and reservation sizes to find configurations that fit their needs. If a validation succeeds, the user may submit the reservation. Taking a cue from our mapping and constraint systems, the validation procedure provides users with actionable feedback when the validation fails: messages take the form "Insufficient free nodes at Fri Sep 21 18:00:00 2018 (12 more needed)." This feedback suggests that reducing the number of nodes, shortening the reservation's duration, or moving the reservation further into the future can help the user proceed with submitting a valid reservation.

To understand how users explore different possibilities, we analyzed operations performed on our reservation system between December 6, 2017 and November 30, 2018. Among the 3,500 events in this dataset, there are approximately 1,800 validate and 900 submit operations. These events represent the activity of 200 users working on over 130 unique projects. Nearly 51% of reservation events are validate operations. On average, 2.1 validations preceded each submitted reservation (at least one is required, because users must validate a reservation before they submit it). Further analysis of the operations uncovers infrequent but revealing scenarios. For each submit-ed reservation, we consider validate operations preceding it to be indicative of a user exploring possible candidate reservations. These form a long-tailed distribution: 71% of submit operations were preceded by a single validate, and 14% by two. The remaining 15% of this distribution stretches to a maximum of 32 validate trials. We interpret such cases as empirical evidence for the validation procedure being sufficiently fast to allow users repeatedly *check* and *update* reservation parameters when searching for combinations that satisfy both their needs and the testbed's schedule.

Size and Duration We next compare reservations with experiments, to see whether reservations succeed in enabling larger experiments than are possible with FCFS alone. Using the same time period and reservation data as the previous analysis, we also look at records for 33,300 experiments. Figure 5 illustrates the long-tailed distributions we observe in both. Because these distributions are highly skewed, we characterize and compare them using medians (i.e., 50th percentiles), 75th, and 95th percentiles. The ratios between the pairs of the corresponding percentiles indicate that the reservations are 2.2–10.2 times larger and 3.0–5.3 times longer than experiments. We conclude that reservations do indeed enable larger experiments, though interestingly, the largest experiments were larger than the largest reservations by about 50%. Our analysis of monthly distributions also reveals that the 95th percentile for experiment durations shows significantly less volatility after we introduced the reservation system and stabilizes at its high values, around 300 hours. The same is not true of the node count statistics; the timing of the largest

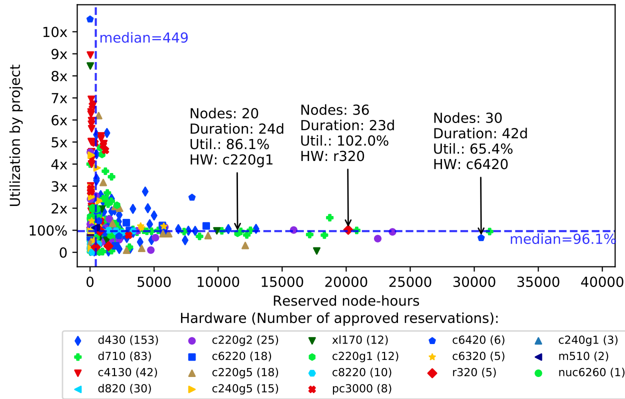

Figure 6: Utilization of reservations.

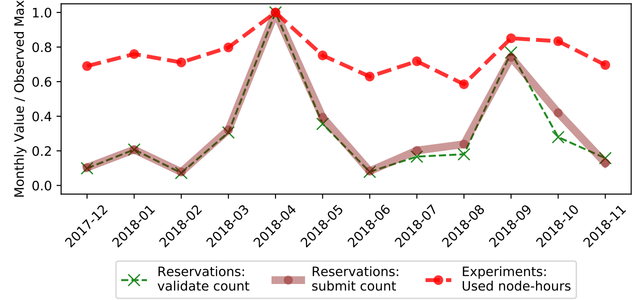

Figure 7: Use of reservations and experiments. For each metric, we divide monthly values by the all-time maximum.

spikes suggests that they are caused by testbed expansions.

Utilization CloudLab does not automatically instantiate experiments for users at the beginning of a reservation, nor does it require the end of a reservation to coincide with the end of an experiment. The current system has no direct penalties for under-using reserved nodes. This leads to an obvious utilization question: *How fully do experimenters use their reservations?* Put another way, this can be framed as a question of trust: *Can we trust users to reserve only what they need and then use what they have reserved?*

Before answering this question, we note several operational nuances that stem from the loose coupling between experiments and reservations in our design. First, we do not stop users from allocating *more* resources than they have reserved: the reservation indicates a minimum guaranteed availability, and if more are available, experimenters are free to use them. Second, if multiple experiments run on h_r hardware within $[s_r, e_r]$, we cannot distinguish experiments that are *meant* to use the studied reservation r from the ones that are run opportunistically, in addition to the planned experiments. Third, reservations are associated with *projects* (groups of users), so the user that creates the reservation may or may not be the one who actually uses it. If users in the same project coordinate their activities, one user submits a reservations on behalf of the group; otherwise, when working independently, one or multiple users submit their reservations and run planned experiments, while others run their unrelated FCFS experiments. Since the studied usage record does not allow us to distill exact user intentions, we estimate aggregate project-specific usage of hardware h_r within $[s_r, e_r]$ and view it as the *upper bound* of the intended r's utilization.

Figure 6 visualizes whole-project resource utilization for nearly 450 approved reservations. The highest point, depicting a utilization of almost 11x the quantity of resources reserved, represents a reservation where a single node was reserved for 33 hours. (The figure omits fifteen small reservations that would stretch the Y axis even further, up to 25x.) That reservation was deleted 3 hours into its time window, and, at the same time, the same or other users from the same project ran multi-node experiments up to 32 node-hours in aggregate. The result is that the project as a whole used far more resources during this time than it had reserved. Labels for several large reservations highlight instances where the utilization is near 100%. We find these and many other large experiments that conform well with the the corresponding reservations. With the median utilization for the shown instances at 96.1%, we conclude that the majority of reservations see high utilization, and we can indeed trust users to reserve what they need and use what they reserve.

In contrast, we found a fairly large number of reservations, 123 (not shown on the graph) with no identified usage. These seem to come from the cases in which the users changed their minds but did not delete their reservations, forgot about the reservations (CloudLab does send reminder emails), or, most interestingly, did run experiments but used wrong types of nodes. This final case seems to stem from misunderstandings about either how the reservation system works (the specific hardware type reserved) or the profile being used (the specific hardware type requested). CloudLab does have measures in place to encourage use of the appropriate node type: when the user has a reservation, the cluster selection box defaults to the relevant cluster, and the mapper applies a preference for nodes of the reserved type. Still, it is clear that this is an area for additional work. With the median size at 96 node-hours, however, these unused reservations add up to less than 12% of all node-hours reserved.

Reservations in Action We conclude our discussion of the reservation system by looking at how its use relates to the use of the testbed as a whole. As shown in Figure 7, rises and falls in use of the testbed (as measured by the number of node-hours used per month) are correlated perfectly with rises and falls in submission of reservations. April 2018, CloudLab's busiest month to date (previously seen in Figures 1 and 3) also saw a large spike in reservations: an astonishing 193 requests were submitted that month, or more than six per day. During that month, there were 140k node-hours of approved reservations, as compared with 724k node-hours used in general, telling us that approximately 19% of all node-hours used

that month were used through reservations. During the preceding January, a lighter month, these numbers were 67k, 552k, and 12%, respectively. Another place where the effects of the reservation system appear is Table 2: if we look at the entire time period, simple resource unavailability is the top reason for mapping failures. If we look at just the last year, however, when the reservation system was more stable, better advertised, and more heavily used, node shortages due to upcoming reservations have become more common than "simple" shortages. The April spike was followed by a similar increase in usage in September 2018.

We postulate that, as the use of the testbed approaches its total capacity, (or, as the free resources approach zero), the notional value of a reservation to a user grows super-linearly. By analogy to queuing theory, as the demand rate approaches the service rate, the expected wait time approaches infinity [20]. Facing the possibility that they may have to wait an unbounded amount of time for the resources they need to become available through the FCFS system, users have far greater incentive to submit reservation requests. This results in the pattern that holds true for the aggregate and also specific hardware types. The demand for specific types of nodes fluctuates over time, and users naturally adjust, using reservations only for the types that are in high demand. Overall, our analysis confirms that the reservation system constitutes a successful "social engineering" project on the part of CloudLab in that the system did change user behavior in the desired way: they use reservations heavily during periods of high demand, but then reservations "fade into the background" when they are not needed, letting the traditional FCFS model dominate.

4 Related Work

There is a body of literature focused on design and analysis of computing testbeds. The work that has shaped the research in this area includes the studies of large-scale experimentation environments such as PlanetLab [8], Grid'5000 [6], Emulab [16], Open Cirrus [5], and PRObE [12]. There are also recent studies that examine the Jetstream [33] "production" cloud for science and engineering research, the Chameleon [21] cloud computing testbed, and the Comet [34] supercomputer, among other facilities. These facility studies describe specific needs of research communities, document major design and implementation efforts, and share the unique lessons learned in the process of deploying and operating each system. Our work complements them by describing different aspects of facility operations and yielding insights into different kinds of design decisions. Studies of relevant commercial installations with similar amounts of detail are scarce.

Another relevant theme relates to using academic and commercial cyberinfrastructures to investigate systems topics and solutions with broad applicability, including the topological issues in testbeds [15], performance and repeatability [26, 22], failure analysis [24], individual subsystems such as disk imaging [19, 4] monitoring infrastructure [38], virtualization [16], and cloud federation [13], among others. Our study complements these by focusing on the way that the *control framework* (the software that manages, assigns, and provisions resources), and the abstractions it offers affect user experience and behavior. The key difference from the related work lies in the unique facility- and user-centered scope of our analysis; none of aforementioned facilities has been studied from this angle. Additionally, this paper describes CloudLab's functionality that extends the control framework used in GENI [25, 32], Emulab [39], and Apt [32].

5 Conclusion

Testbeds for computer science research occupy a unique place in the overall landscape of computing infrastructure. They are often used in an attempt to overcome a basic impasse [3]: as computing technologies become popular, research into their fundamentals becomes simultaneously more valuable and more difficult to do. The existence of production systems such as the Internet and commercial clouds motivates work aimed at improving them, but production deployments offer service at a specific layer of abstraction, making it difficult or impossible to use them for research that seeks to work *under* that layer or to change the abstraction significantly.

The design and operation of testbeds—and other IaaS infrastructures—benefits greatly from analyzing data about how these facilities are used. In this paper, we have presented new analysis of the way that one particular facility, CloudLab, is used in practice. This analysis, and the underlying dataset (which we have made public) have shown that user behavior is highly variable, bursty, and long-tailed. In addition, algorithms that may be thought of as being "deep within" the system have large, visible effects on user experience and on user behavior. Together, these findings point towards design decisions that more carefully take user expectations and behavior into account "end-to-end" throughout the entire facility.

Data and Code

Data and code used for our analyses are available at `https://gitlab.flux.utah.edu/emulab/cloudlab-usage` with the tag `atc19`. This data covers CloudLab's resource availability and events such as experiment instantiations.

Everyone Loves File: File Storage Service (FSS) in Oracle Cloud Infrastructure

Bradley C. Kuszmaul Matteo Frigo Justin Mazzola Paluska Alexander (Sasha) Sandler
Oracle Corporation

Abstract

File Storage Service (FSS) is an elastic filesystem provided as a managed NFS service in Oracle Cloud Infrastructure. Using a pipelined Paxos implementation, we implemented a scalable block store that provides linearizable multipage limited-size transactions. On top of the block store, we built a scalable B-tree that provides linearizable multikey limited-size transactions. By using self-validating B-tree nodes and performing all B-tree housekeeping operations as separate transactions, each key in a B-tree transaction requires only one page in the underlying block transaction. The B-tree holds the filesystem metadata. The filesystem provides snapshots by using versioned key-value pairs. The entire system is programmed using a nonblocking lock-free programming style. The presentation servers maintain no persistent local state, with any state kept in the B-tree, making it easy to scale up and failover the presentation servers. We use a non-scalable Paxos-replicated hash table to store configuration information required to bootstrap the system. The system throughput can be predicted by comparing an estimate of the network bandwidth needed for replication to the network bandwidth provided by the hardware. Latency on an unloaded system is about 4 times higher than a Linux NFS server backed by NVMe, reflecting the cost of replication.

1 Introduction

This paper describes Oracle Cloud Infrastructure File Storage Service (FSS), a managed, multi-tenanted NFS service. FSS, which has been in production for over a year, provides customers with an elastic NFSv3 file service [15]. Customers create filesystems which are initially empty, without specifying how much space they need in advance, and write files on demand. The performance of a filesystem grows with the amount of data stored. We promise customers a convex combination of 100 MB/s of bandwidth and 3000 operations per second for every terabyte stored. Customers can mount a filesystem on an arbitrary number of NFS clients. The size of a file or filesystem is essentially unbounded, limited only by the practical concerns that the NFS protocol cannot cope with files bigger than 16 EiB and that we would need to deploy close to a million hosts to store multiple exabytes. FSS provides the ability to take a snapshot of a filesystem using copy-on-write techniques. Creating a filesystem or snapshot is cheap, so that customers can create thousands of filesystems, each with thousands of snapshots. The system is robust against failures since it synchronously replicates data and metadata 5-ways using Paxos [44].

We built FSS from scratch. We implemented a Paxos-replicated block store, called DASD, with a sophisticated multipage transaction scheme. On top of DASD, we built a scalable B-tree with multikey transactions programmed in a lockless nonblocking fashion. Like virtually every B-tree in the world, ours is a B+-tree. We store the contents of files directly in DASD and store file metadata (such as inodes and directories) in the B-tree.

Why not do something simpler? One could imagine setting up a fleet of ZFS appliances. Each appliance would be responsible for some filesystems, and we could use a replicated block device to achieve reliability in the face of hardware failure. Examples of replicated block devices include [2, 4, 25, 54, 61]. We have such a service in our cloud, so why not use it? It's actually more complicated to operate such a system than a system that's designed from the beginning to operate as a cloud service. Here are some of the problems you would need to solve:

- How do you grow such a filesystem if it gets too big to fit on one appliance?
- How do you partition the filesystems onto the appliance? What happens if you put several small filesystems onto one appliance and then one of the filesystems grows so that something must move?

- How do you provide scalable bandwidth? If a customer has a petabyte of data they should get 100 GB/s of bandwidth into the filesystem, but a single appliance may have only a 10 Gbit/s network interface (or perhaps two 25 Gbit/s network interfaces).
- How do you handle failures? If an appliance crashes, then some other appliance must mount the replicated block device, and you must ensure that the original appliance doesn't restart and continue to perform writes on the block device, which would corrupt the filesystem.

This paper describes our implementation. Section 2 provides an architectural overview of FSS. The paper then proceeds to explain the system from the top down. Section 3 describes the lock-free nonblocking programming style we used based on limited-size multipage transactions. Section 4 shows how we organize metadata in the B-tree. Section 5 explains how we implemented a B-tree key-value store that supports multikey transactions. Section 6 explains DASD, our scalable replicated block storage system. Section 7 describes our pipelined Paxos implementation. Section 8 discusses congestion management and transaction-conflict avoidance. Section 9 describes the performance of our system. Sections 10 and 11 conclude with a discussion of related work and a brief history of our system.

2 FSS Architecture

This section explains the overall organization of FSS. We provision many hosts, some of which act as storage hosts, and some as presentation hosts. The storage hosts, which include local NVMe solid-state-drive storage, store all filesystem data and metadata replicated 5-ways,[1] and provide an RPC service using our internal FSS protocol. The presentation hosts speak the standard NFS protocol and translate NFS into the FSS protocol.

A customer's filesystems appear as exported filesystems on one or more IP addresses, called ***mount targets***. A single mount target may export several filesystems, and a filesystem may be exported by several mount targets. A mount target appears as a private IP address in the customer's virtual cloud network (VCN), which is a customizable private network within the cloud. Most clouds provide VCNs in which hosts attached to one VCN cannot even name hosts in another VCN. Each mount target terminates on one of our presentation hosts. A single mount target's performance can be limited by the network interface of the presentation host, and so to get more performance, customers can create many mount targets that export the same filesystem.

[1]Data is erasure coded, reducing the cost to 2.5, see Section 3.

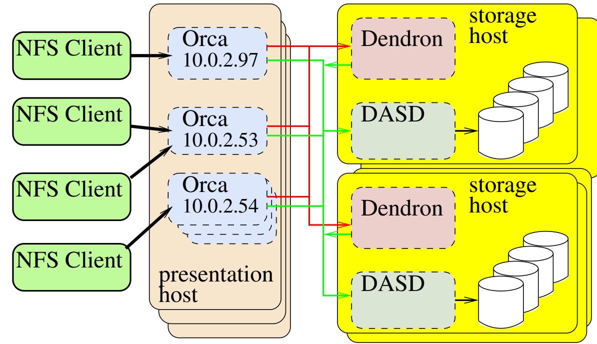

Figure 1: FSS architecture. The NFS clients are on the left, and belong to various customers. Hosts are shown as boxes with solid edges and processes are shown with dashed lines. The presentation hosts are in the middle, each running several Orca processes. The Orca processes are connected to the various customer virtual cloud networks (VCNs) on the left. The IP addresses of each Orca's mount target is shown. The Orca process are also connected to our internal VCN, where they can communicate with the storage hosts. The storage hosts contain NVMe drives and run both the Dendron and DASD processes.

Figure 1 shows how the FSS hosts and processes are organized. The customer sets up NFS clients in their VCN. Our presentation hosts terminate NFS connections from the clients in per-mount-target Orca processes. The Orca processes translate NFS requests into the FSS protocol, and send the FSS to our storage hosts. In the future, the presentation hosts might speak other client protocols, such as SMB [55] or NFSv4 [68].

To ensure isolation between filesystems we depend on a combination of process isolation on our servers, VCN isolation, and encryption. All data stored in the storage hosts or in flight in the FSS protocol is encrypted with a file-specific encryption key that derives from a filesystem master key. The NFSv3 protocol is not encrypted, however, so data arriving at an Orca is potentially vulnerable. To mitigate that vulnerabilty, we rely on VCN isolation while the data is in flight from the NFS client to the presentation host, and use the presentation host's process isolation to protect the data on the presentation host. All data and file names are encrypted as soon as they arrive at an Orca, and each Orca process serves only one mount target.

Each storage host contains NVMe drives and runs two processes, DASD and Dendron. ***DASD***, described in Section 6, provides a scalable block store. ***Dendron*** implements a B-tree (Section 5) in which it maintains the metadata (Section 4) for the filesystem.

We chose to replicate filesystems within a data cen-

ter rather than across data centers within a metropolitan area or across a long distance. There is a tradeoff between latency and failure tolerance. Longer-distance replication means the ability to tolerate bigger disasters, but incurs longer network latencies. We chose local replication so that all of our operations can be synchronously replicated by Paxos without incurring the latency of long-distance replication. It turns out that most of our customers rely on having a functional disaster-recovery plan, and so they're more interested in single-data center file system performance than synchronous replication. In the future, however, we may configure some filesystems to be replicated more widely.

Within a data center, hosts are partitioned into groups called ***fault domains***. We typically employ 9 fault domains. In a small data center, a fault domain might be a single rack. In a large data center, it might be a group of racks. Hosts within a fault domain are likely to fail at the same time (because they share a power supply or network switch). Hosts in different fault domains are more likely to fail independently. We employ 5-way Paxos replicated storage that requires at least 3 out of each group of 5 Paxos instances in order to access the filesystems. We place the Paxos instances into different fault domains. When we need to upgrade our hosts, we can bring down one fault domain at a time without compromising availability. Why 5-way replication? During an upgrade, one replica at a time is down. During that time, we want to be resilient to another host crashing.

We also use the same 5-way-replicated Paxos machinery to run a non-scalable hash table that keeps track of configuration information, such a list of all the presentation hosts, needed for bootstrapping the system.

All state (including NLM locks, leases, and idempotency tokens) needed by the presentation servers is maintained in replicated storage rather than in the memory of the presentation hosts. That means that any Orca can handle any NFS request for the filesystems that it exports. The view of the filesystem presented by different Orcas is consistent.

All memory and disk space is allocated when the host starts. We never run `malloc()` after startup. By construction, the system cannot run out of memory at runtime. It would likely be difficult to retrofit this memory-allocation discipline into old code, but maintaining the discipline was relatively straightforward since the entire codebase is new.

3 Multi-Page Store Conditional

FSS is implemented on top of a distributed B-tree, which is written on top of a a distributed block store with multi-page transactions (see Figure 2). This section describes the programming interface to the distributed block store and how the block store is organized into pages, blocks, and extents.

Customer program
Operating system
NFS
FSS filesystem
B-tree
MPSC
Paxos

Figure 2: Each module is built on the modules below.

The filesystem is a concurrent data structure that must not be corrupted by conflicting operations. There can be many concurrent NFS calls modifying a filesystem: one might be appending to a file, while another might be deleting the file. The filesystem maintains many invariants. One important invariant is that every allocated data block is listed in the metadata for exactly one file. We need to avoid memory leaks (in which an allocated block appears in no file), dangling pointers (in which a file contains a deallocated block), and double allocations (in which a block appears in two different files). There are many other invariants for the filesystem. We also employ a B-tree which has its own invariants. We live under the further constraint that when programming these data structures, we cannot acquire a lock to protect these data structures, since if a process acquired a lock and then crashed it would be tricky to release the lock.

To solve these problems we implemented FSS using a nonblocking programming style similar to that of transactional memory [32]. We use a primitive that we call ***multi-page store-conditional (MPSC)*** for accessing pages in a distributed block store. An MPSC operation is a "mini-transaction" that performs an atomic read-and-update of up to 15 pages. All page reads and writes follow this protocol:

1. Read up to 15 pages, receiving the page data and a ***slot number*** (which is a form of a version tag [38]). A page's slot number changes whenever the page changes. You can read some pages before deciding which page to read next, or you can read pages in parallel. Each read is linearizable [34].
2. Compute a set of new values for those pages.
3. Present the new page values, along with the previously obtained slot numbers, to the MPSC function. To write a page requires needs a slot number from a previous read.
4. The update will either succeed or fail. Success means that all of the pages were modified to the new values and that none of the pages had been otherwise modified since they were read. A successful

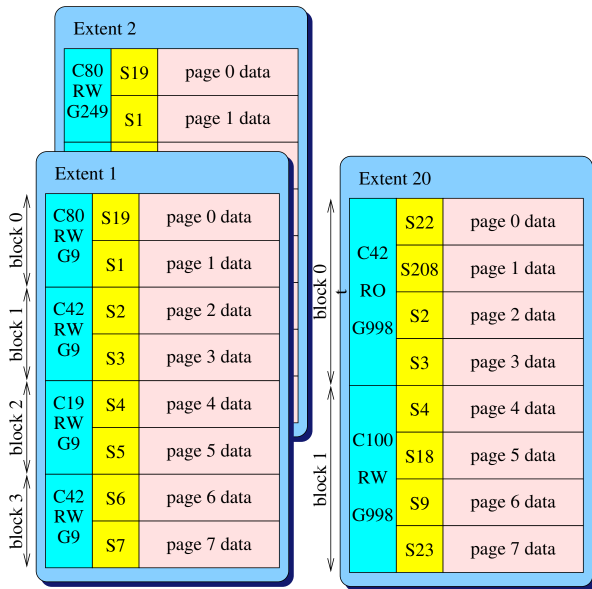

Figure 3: Pages, blocks, and extents. Three extents are shown, each with an array of pages. Each page has a slot. E.g., page 0 of extent 1 has slot 19. Each block has ownership. The first block of extent 1 is owned by customer 80 ("C80"), is read-write ("RW"), and is on its 9th allocation generation ("G9"). Extents 1 and 2 each have 2 pages per block and 4 blocks, whereas extent 20 has 4 pages per block and only 2 blocks.

update linearizes with other reads and MPSC updates. A failure results in no changes.

In addition to reading and writing pages, an MPSC can allocate or free space in the distributed block store.

An MPSC could fail for many reasons. For example, if, between reading a page and attempting an MPSC, some other transaction wrote the page, the MPSC will fail. Even if there is no conflict, an MPSC may fail due to, e.g., packet loss or Paxos leadership changes. Even if a transaction succeeds, the caller may receive an error indication, e.g., if network fails between the update's commit and the caller notification. Our implementation deliberately introduces failures (sometimes called fuzzing [56]) with a small probability rate, so that all of the error-handling code paths are exercised frequently, even in production.

Pages and Blocks. We subdivide the distributed block store into a hierarchy of pages, blocks, and extents, as shown in Figure 3. An MPSC performs an atomic update on a set of ***pages***. A ***block*** includes one or more pages, and is the unit on which we do bookkeeping for allocation. To reduce bookkeeping overheads on small pages, we allocate relatively large blocks. To keep transactions small, we update relatively small pages. An ***extent*** is an array of pages, up to 256 GiB total, and is implemented by a replicated Paxos state machine.

Geometry	Page size	Block size	Extent size	RF	EC
B-tree	8 KiB	1 MiB	16 GiB	5	1
8 KiB	8 KiB	8 KiB	32 GiB	5	5:2
32 KiB	32 KiB	32 KiB	128 GiB	5	5:2
256 KiB	32 KiB	256 KiB	256 GiB	5	5:2
2 MiB	32 KiB	2 MiB	256 GiB	5	5:2

Figure 4: Extent geometries. The B-tree extents contain metadata organized as a B-tree. The other extents contain file contents, and are identified by their block size. For each extent the page size, block size, extent size, replication factor (RF), and erasure-coding (EC) are shown.

For example, one kind of extent contains 256 GiB of disk-resident data, organized in 2 MiB blocks with 32 KiB pages, and is replicated 5 ways using 5:2 erasure coding (an erasure-coding rate of 2/5) [62]. Thus the 256 GiB of disk-resident data consumes a total of 640 GiB of disk distributed across 5 hosts.

An extent's ***geometry*** is defined by its page size, block size, extent size, replication factor, and erasure-coding rate. Once an extent is created, its geometry cannot change. Figure 4 shows the extent geometries that we use for file data and metadata. All of our extents are 5-way replicated within a single data center. The pages in extents used for file contents are erasure coded using a 5:2 erasure coding rate, so that the overhead of storing a page is 2.5 (each replica stores half a page, and there are 5 replicas). The B-tree data is mirrored, which can be thought of as 5:1 erasure coding.

We size our extents so there are hundreds of extents per storage host to ease load balancing. We use parallelism to recover the missing shards when a host crashes permanently—each extent can recover onto a different host.

Block ownership. When operating a storage system as a service, it is a great sin to lose a customer's data. It is an even greater sin to give a customer's data to someone else, however. To avoid the greater sin, blocks have ownership information that is checked on every access.

A block's ownership information includes a version tag, called its ***generation***, as well as 64-bit customer identifier, and a read-only bit. When accessing a block, the generation, customer id, and read-only bit must match exactly. This check is performed atomically with every page access. When a block is allocated or deallocated its generation changes. A ***tagged pointer*** to a page includes the block ownership information, as well as the extent number and page number. A block's pointer is simply the tagged pointer to the block's first page.

The problem that block ownership solves can be illustrated as follows. When data is being written into a new file, we allocate a block and store the block's pointer in the B-tree as a single transaction. To read data from a file, Orca first obtains the block pointer by asking Dendron to read the B-tree. Orca caches that block pointer, so that it can read the data without the overhead of checking the B-tree again on every page access. Meanwhile, another thread could truncate the file, causing the block to be deallocated. The block might then be allocated to a file belonging to a different customer. We want to invalidate Orca's cached pointers in this situation, so we change the block ownership. When Orca tries to use a cached pointer to read a deallocated page, the ownership information has become invalid, and the access fails, which is what we want.

Each of our read operations is linearizable, meaning that they are totally ordered with respect to all MPSC operations and the total ordering is consistent with real time. Although our read operations linearize, if you perform several reads they take place at different times, meaning that the reads may not be mutually consistent. It's easy to trick a transactional-memory-style program into crashing, e.g., due to a failed assertion. For example, if you have two pages in a doubly linked list, you might read one page, and then follow a pointer to the second page, but by the time you read the second page it no longer points back to the first page. Getting this right everywhere is an implementation challenge, leading some [10, 16] to argue that humans should not program transactional memory without a compiler. We have found this problem to be manageable, however, since an inconsistent read cannot lead to a successful MPSC operation, so the data structure isn't corrupted.

4 A Filesystem Schema

This section explains how we represent the filesystem metadata in our B-tree. FSS implements an inode-based write-in-place filesystem using a single B-tree to hold its metadata. What does that mean? "Inode-based" means that each file object has an identifier, called its ***handle***. The handle is used as an index to find the metadata for a file. "Write-in-place" means that updates to data and metadata usually modify an existing block of data. (As we shall see, snapshots introduce copy-on-write behavior.) "Single B-tree to hold the metadata" means there is only one B-tree per data center. Our service provides many filesystems to many customers, and they are all stored together in one B-tree.

The B-tree must support various metadata operations. For example, given an object's handle, we need to find and update the fixed-size part of the object's metadata, which includes the type of the object (e.g., regular, directory, symlink), permissions bits (`rwxrwxrwx`), owner, group, file size, link count, and timestamps. Given a file handle and an offset, we need to find the tagged pointer of the block holding data at that offset, so that reads or write can execute. Given a directory handle and a filename we need to be able perform a directory lookup, yielding a file handle. For a directory, we need to iterate through the directory entries. In NFS this is performed using a 64-bit number called a ***cookie***. Given a directory handle and a cookie we need to find the directory entry with the next largest cookie.

Key-value pairs:

leaderblock:	$0 \to$ next F.
superblock:	$F, 0 \to$ next D, next C, keys.
inode:	$F, 1, D, C, 2, S \to$ stat-data.
name map:	$F, 1, D, C = 0, 3, N, S \to F, D', C', S$.
cookie map:	$F, 1, D, C = 0, 4, c, S \to F, D', C', S, N$.
block map:	$F, 1, D, C, 5, o, S \to$ block ID and size.

Glossary:

F	filesystem number.
D	Directory unique id.
C	File unique id.
S	Snapshot number.
o	Offset in file.
N	Filename in directory.
c	Directory iteration cookie.
F, D', C', S	The handle of a file in a directory.

Figure 5: Filesystem schema showing key $\to$ value pair mappings. The small numbers (e.g., "1") are literal numbers inserted between components of a key to disambiguate key types and force proper B-tree sort ordering. For directories, $C = 0$.

Our strategy is to create B-tree key-value pairs that make those operations efficient. We also want to minimize the number of pages and extents that we access in each transaction. Every B-tree key is prefixed with a filesystem number F, so that all the keys for a given filesystem will be adjacent in the B-tree. Our handles are ordered tuples of integers $\langle F, D, C, S \rangle$, where D a unique number for every directory, C is a unique number for every file ($C = 0$ for directories), and S is a snapshot number. A file's handle depends on the directory in which it was created. The file can be moved to another directory after it is created, but the file's handle will always mention the directory in which the file was originally created.

Figure 5 shows the schema for representing our filesystems. We encode the B-tree keys in a way that disambiguates the different kinds of key value pairs and sorts the key-value pairs in a convenient order. For example, all the pairs for a given filesystem F appear together, with the superblock appearing first because of

the "0" in its key. Within the filesystem, all the non-superblock pairs are sorted by D, the directory number. For a directory, the directory inode sorts first, then come the name map entries for the directory, and then the cookie map, then come all the inodes for the files that were created in that directory. In that set for each file, the file inode sorts first, followed by the block maps for that file. Finally two entries that are the same except for the snapshot number are sorted by snapshot number.

We implement snapshots using copy-on-write at the key-value pair level, rather than doing copy-on-write in the B-tree data structure or at the block level [13, 28, 35, 43, 49, 63, 65, 66, 72]. In the interest of space, we don't show all the details for snapshots, but the basic idea is that each key-value pair is valid for a range of snapshots. When looking up a pair for snapshot S, we find the pair whose key has the largest snapshot number that's no bigger than S.

Our key-value scheme achieves locality in the B-tree. When a file is created it is lexicographically near its parent directory, and the file's block maps and fixed-sized metadata are near each other. (If the file is later moved, it still appears near the original parent directory.) This means that if you create a file in a directory that has only a few files in it, it's likely that the whole transaction to update the directory inode, add directory entries, and create the file inode will all be on the same page, or at least in the same extent, since the B-tree maintains maintains block as well as page locality (see Section 5).

We use multiple block sizes (which are shown in Figure 4) to address the tension between fragmentation and metadata overhead. Small blocks keep fragmentation low for small files. Big blocks reduce the number of block map entries and other bookkeeping overhead for big files. In our scheme the first few blocks of a file are small, and as the file grows the blocks get bigger. For files larger than 16 KiB, the largest block is no bigger than $1/3$ the file size, so that even if the block is nearly empty, we have wasted no more than $1/3$ of our storage. We sometimes skip small-block allocation entirely. For example if the NFS client writes 1 MiB into a newly created file, we can use 256 KiB blocks right away.

5 The B-tree

To hold metadata we built a B-tree [7] on top of MPSC. MPSC provides transactions that can update up to 15 pages, but we want to think about key-value pairs, not pages, and we want B-tree transactions to be able include non-B-tree pages and blocks, e.g., to allocate a data block and store its tagged pointer in a B-tree key-value pair. The B-tree can perform transactions on a total of 15 values, where a value can be a key-value pair, or a non-B-tree page write or block allocation.

Consider the simple problem of executing a B-tree transaction to update a single key-value pair. How many pages must be included in that transaction? The standard B-tree algorithm starts at the root of the tree and follows pointers down to a leaf page where it can access the pair. To update the leaf we need to know that it is the proper page, and the way we know that is by having followed a pointer from the leaf's parent. Between reading the parent and reading the leaf, however, the tree might have been rebalanced, and so we might be reading the wrong leaf. So we we need to include the parent in the transaction. Similarly, we need to include the grandparent and all the ancestors up to the root. A typical B-tree might be 5 or 6 levels deep, and so a single key-value pair update transaction involves 5 or 6 pages, which would limit us to 2 or 3 key-value pairs per transaction. Furthermore, every transaction ends up including the root of the B-tree, creating a scalability bottleneck.

Our solution to this problem is to use ***self-validating pages***, which contain enough information that we can determine if we read the right page by looking at that page in isolation. We arrange every page to "own" a range of keys, for the page to contain only keys in that range, and that every possible key is owned by exactly one page. To implement this self validation, we store in every page a lower bound and upper bound for the set of keys that can appear in the page (sometimes called "fence keys" [26, 47]), and we store the height of the page (leaf pages are height 0). When we read a page to look up a key, we verify that the page we read owns the key and is the right height, in which case we know that if that page is updated in a successful transaction, that we were updating the right page. Thus, we do not need to include the intermediate pages in the MPSC operation and we can perform B-tree transactions on up to 15 keys.

We usually skip accessing the intermediate B-tree nodes altogether by maintaining a cache that maps keys to pages. If the cache steers us to a wrong page, either the page won't self validate or the transaction will fail, in which case we simply invalidate the cache and try again. If a key is missing from the cache, we can perform a separate transaction that walks the tree to populate the cache. It turns out that this cache is very effective, and for virtually all updates we can simply go directly to the proper page to access a key-value pair.

Another problem that could conceivably increase the transaction size is tree rebalancing. In a B-tree, tree nodes must generally be split when they get too full or merged when they get too empty. The usual rule is that whenever one inserts a pair into a node and it doesn't fit, one first splits the node and updates the parent (possibly triggering a parent split that updates the grandparent, and so on). Whenever one deletes a pair, if the node becomes too empty (say less than $1/4$ full), one

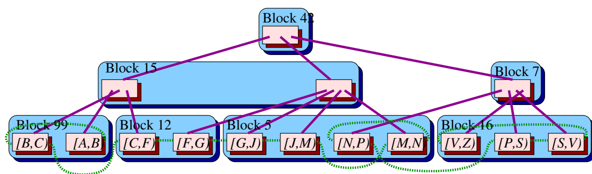

Figure 6: The B-tree comprises block (in blue) and pages (in pink). The pages form a tree. The leaf pages, where the key-value pairs are stored, form a doubly linked list (shown with dashed green lines). Each leaf page is responsible for a range of keys, e.g., $[C,F)$ means the keys from C inclusive to F exclusive. Each block holds a key range of pages for one level. For example, Block 5 has all the leaf pages in the range $[G,P)$.

merges nodes, updating the parent (which can possibly trigger a parent merge that updates the grandparent, and so on). This means that any insertion or deletion can add as many pages to a transaction as the height of the tree. Those rebalancings are infrequent so they don't introduce a scalability bottleneck, but they do make our MPSC operations too big.

Our solution to the rebalancing problem is to rebalance in a separate transaction. When inserting if we encounter a page overflow, we abort the transaction, split the page in a separate transaction, and restart the original transaction. We split the page even if it is apparently nearly empty: as long as there are two keys we can split the page. For merges, we delete keys from the page, and then do a separate transaction afterward to rebalance the tree. It's possible that a page could end up empty, or nearly empty, and that due to some crash or packet loss, we forget to rebalance the tree. That's OK because we fix it up the next time we access the page.

To improve locality we exploit both the page and block structure of MPSC. Figure 6 shows how the B-tree is organized to exploit block locality as well as page locality. Each page is responsible for a key range, and the union of the key ranges in a block is a single key range. When splitting a page, we place the new page into the same block as the old page, and if the block is full, we insert a new block. If the B-tree schema strives to keep keys that will appear in the same transaction lexicographically near each other, locality causes those keys to likely be in the same page, or at least the same block. Our MPSC implementation optimizes for the case where some pages of a transaction are in the same extent. With the schema described in Section 4, this optimization is worth about a 20% performance improvement for an operation such as untarring a large tarball.

The choice of 15 pages per transaction is driven by the B-tree implementation. There is one infrequent operation requiring 15 pages. It involves splitting a page in a full block: a new block is allocated, block headers are updated, and the pages are moved between blocks. Most transactions touch only one or two pages.

6 DASD: Not Your Parent's Disk Drive

This section explains how we implemented MPSC using Paxos state machines (which we discuss further in Section 7). MPSC is implemented by a distributed block store, called ***DASD***[2]. A single extent is implemented by a Paxos state machine, so multipage transactions within an extent is straightforward. To implement transactions that cross extents, we use 2-phase commit.

Given that Paxos has provided us with a collection of replicated state machines, each with an attached disk, each implementing one extent, we implement two-phase commit [29,46,50] on top of Paxos. The standard problem with two-phase commit is that the transaction coordinator can fail and the system gets stuck. Our extents are replicated, so we view the participants in a transaction as being unstoppable.

It would be easy to implement two-phase commit with $3n$ messages. One could send n 'prepare' messages that set up the pages, then n 'decide' messages that switch the state to commited, and then n 'release' messages that release the resources of the transaction. (Each message drives a state transition, which is replicated by Paxos.) The challenge is to implement two-phase commit on n extents with only $2n$ messages and state changes. Every filesystem operation would benefit from the latency being reduced by $1/3$.

To perform an atomic operation with only $2n$ messages, for example on 3 pages, the system progresses through the states shown in Figure 7. The system will end up constructing and tearing down, in the Paxos state machine, a doubly-linked (not circular) list of all the extents in the transaction. Each of these steps is initiated by a message from a client, which triggers a state change in one Paxos state machine (which in turn requires several messages to form a consensus among the Paxos replicas). The client waits for an acknowledgment before sending the next message.

1. Extent A receives a prepare message. A enters the prepared state, indicated by "P(data)", and records its part of the transaction data and its part of the linked list (a null back pointer, and a pointer to B).
2. Extent B receives a prepare message, enters the prepared state, and records its data and pointers to A and C.
3. Extent C receives a prepare-and-decide message, enters the decided state (committing the transac-

[2]Direct-Access Storage Device (DASD) was once IBM's terminology for disk drives [37].

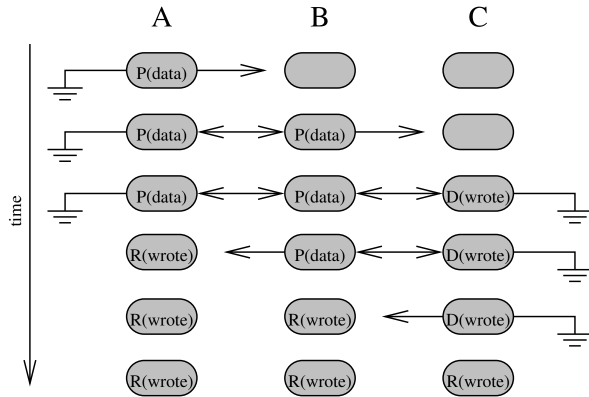

Figure 7: Three extents performing a DASD transaction. Each column is an extent, and each row is a point in time, with time moving downward. A double-arrowed line shows two extents pointing at each other. A single-arrowed line shows one extent pointing at the other, with no pointer back. Ground represents a null pointer.

tion), and records its data and the back pointer to B, indicated by "D(wrote)".

4. Extent A receives a decide-and-release message, notes that the transaction is committed, and releases its resources (such as memory) associated with the transaction, indicated by "R(wrote)". The head of the linked list is now gone.
5. Extent B receives a decide-and-release message, notes the commit, and releases its resources.
6. Extent C receives a release message (it had already decided) and releases its resources.

Thus we implement two-phase commit in exactly $2n$ messages with $2n$ state transitions. Note that the final transition of state C doesn't actually need to be done before replying to the client, and could be piggybacked into the prepare step of the next transaction, potentially reducing the latency to $2n-1$ messages.

The system maintains the invariant that either a prefix or a suffix of the linked list exists, which is useful if the transaction is interrupted. There are two ways that the system can be interrupted, before the commit (in which case the transaction will abort), or after (in which case the cleanup is incomplete). The prefix-suffix property helps in both of these cases. If the transaction gets aborted (at or before step 3) then a prefix exists. If we encounter a prepared state, we can follow the linked list forward until we either find a dangling pointer or a decided state. If we find a dangling pointer, we can delete the prepare record that contained the dangling pointer, preserving a prefix. (At the final point, C, of the linked list, we must extract a promise that C will never decide that the transaction commits. This can be accomplished by introducing a conflict on the read slot for the page.) If we find a decided state then the cleanup was interrupted, so it can proceed back along the linked list until we find the beginning or a dangling pointer, and move the state forward to released.

Our scheme relies on the fact that each state transition occurs one after the other, and hence the critical path of the transition is also $2n$ messages. There are schemes in which one can move the states forward in parallel. For example, one could broadcast "prepare" messages to all the extents, then have one extent decide, and then broadcast decide messages to them all, then release messages, so that the critical path would be only 4 long. This results in $3n$ state transitions (minus one or two, depending on how clever you are.) If you think that big transactions are common, that's valuable, but we have found that most transactions are short so it's better to do the transaction serially.

We optimize the case when there are several pages in a single extent to use fewer messages.

7 Pipelined Paxos

In this section we explain our Paxos implementation, and in particular how we pipeline Paxos operations.

Lamport-Paxos [44, 45] is an algorithm to achieve consensus on a single value. Lamport-Paxos requires two phases, called phase 1 and phase 2 by Lamport.

To achieve consensus on a log (as opposed to one value), one common algorithm is Multi-Paxos [17], which treats the log as an array indexed by slot, running Lamport-Paxos independently on each array element. It turns out that you can run a "vector" phase 1 for infinitely many elements of the array with a single pair of messages, and that you can reuse the outcome of phase 1 for as many phase 2 rounds as you want. In this setup, people tend to call phase-1 "master election" and infer all sorts of wrong conclusions, e.g. that there is only one master at any time and that phase 1 is some kind of "failover".

In Multi-Paxos, if the operation on slot $S+1$ depends on the state after slot S, you must wait for slot S (and all previous slots) to finish phase 2. (We don't say "commit" to avoid confusion with two-phase commit, which is a different protocol.) This Multi-Paxos is not pipelined.

You can pipeline Multi-Paxos with a small modification. You tag each log entry with a unique log sequence number (LSN) and you modify Paxos so that an acceptor accepts slot $S+1$ only if it agrees on the LSN of slot S. Thus, the Paxos phase 2 message is the Lamport phase 2 plus the LSN of the previous slot. By induction, two acceptors that agree on a LSN agree on the entire past history.

Now you can issue phase 2 for $S+1$ depending on S without waiting for S to complete, because the acceptance of $S+1$ retroactively confirms all speculations that you made.

The pipelined Multi-Paxos state, per slot, is the Lamport-Paxos state (a ***ballot*** B and the slot's contents) plus the LSN. You can use whatever you want as LSNs, as long as they are unique, but a convenient way to generate LSNs is to use the pair $\langle E, S \rangle$ where the ***epoch*** E must be unique. As it happens, Lamport phase 1 designates a single winner of ballot B, so you can identify E with the winner of ballot B in phase 1, and be guaranteed that nobody else wins that ballot. In the $E = B$ case, you can reduce the per-slot state to the single-value E, with the dual-role of LSN for pipelining and of ballot for Lamport-Paxos.

Our Paxos algorithm is almost isomorphic to Raft [60]. Essentially Raft is Multi-Paxos plus conditional LSNs plus $E = B$. However, Raft always requires an extra log entry in order to make progress, and cannot be done in bounded space. If you recognize that you are just doing good-old Paxos, then you can make progress by storing a separate ballot B in constant space.

The idea of the acceptance conditional on the previous LSN appeared in viewstamped replication [58] (which didn't discuss pipelining). It is used specifically for pipelining in Zookeeper, except that Zookeeper tries to reinvent Paxos, but incorrectly assumes TCP is an ideal pipe [6]. Conditional acceptance is also used in Raft in the same way as in viewstamped replication, except that Raft lost the distinction between proposer and acceptor, which prevents it from having a speculative proposer state that runs ahead of acceptors.

Recovery. Here we explain how our Paxos system recovers from failures.

The on-disk state of a Paxos acceptor has two main components: the log (of bounded size, a few MB), and a large set of page shards (tens of GB). A shard comprises an erasure-coded fragment of a page and some header information such as a checksum. To write a shard, the Paxos proposer appends the write command to the log of multiple acceptors. When a quorum of acceptors has accepted the command, the write is considered done (or "learned" in Paxos terminology). The proposer then informs acceptors that a command has been learned, and acceptors write the erasure-coded shard to disk.

As long as all acceptors receive all log entries, this process guarantees that all acceptors have an up-to-date and consistent set of shards. However, acceptors may temporarily disappear for long enough that the only way for the acceptor to make progress is to incur a log discontinuity. We now must somehow rewrite all shards modified by the log entries that the acceptor has missed, a process called recovery.

The worst-case for recovery is when we must rewrite the entire set of shards, for example because we are adding a new acceptor that is completely empty. In this ***long-term*** recovery, as part of their on-disk state, acceptors maintain a range of pages that need to be recovered, and they send this ***recovery state*** back to the proposer. The proposer iterates over such pages and overwrites them by issuing a Paxos read followed by a conditional Paxos write, where the condition is on the page still being the same since the read. When receiving a write, the acceptor subtracts the written page range from the to-be-recovered page range, and sends the updated range back to the proposer.

Long-term recovery overwrites the entire extent. For discontinuities of short duration, we use a less expensive mechanism called ***short-term recovery***. In addition to the long-term page range, acceptors maintain a range of log slots that they have lost, they update this range when incurring a discontinuity, and communicate back this slot range to the proposer. The proposer, in the Paxos state machine, maintains a small pseudo-LRU cache of identifiers of pages that were written recently, indexed by slot. If the to-be-recovered slot range is a subset of the slot range covered by the cache, then the proposer issues all the writes in the slot range, in slot order, along with a range R whose meaning is that the present write is the only write that occurred in slot range R. When receiving the write, the acceptor subtracts R from its to-be-recovered slot range and the process continues until the range is empty. If the to-be-recovered slot range overflows the range of the cache, the acceptor falls into long-term recovery.

In practice, almost all normal operations (e.g., software deployments) and unscheduled events (e.g., power loss, network disruption) are resolved by short-term recovery. We need long-term recovery when loading a fresh replica, and (infrequently) when a host goes down for a long time.

Checkpointing and logging. Multi-Paxos is all about attaining consensus on a log, and then we apply that log to a state machine. All memory and disk space in FSS is statically allocated, and so the logs are of a fixed size. The challenge is to checkpoint the state machine so that we can trim old log entries. The simplest strategy is to treat the log as a circular buffer and to periodically write the entire state machine into the log. Although for DASD extents, the state machine is only a few MB, some of our other replicated state machines are much larger. For example we use a 5-way replicated hash table, called Minsk, to store configuration information for bootstrapping the system: given the identity of the five Minsk instances, a Dendron instance can determine the identity of all the other Dendron instances. If the Paxos state machine is large, then checkpointing the state ma-

chine all at once causes a performance glitch.

Here's a simple scheme to deamortize checkpointing. Think of the state machine as an array of bytes, and every operation modifies a byte. Now, every time we log an update to a byte, we also pick another byte from the hash table and log its current value. We cycle through all the bytes of the table. Thus, if the table is K bytes in size, after K update operations we will have logged every byte in the hash table, and so the most recent $2K$ log entries have enough information to reconstruct the current state of the hash table. We don't need to store the state machine anywhere, since the log contains everything we need.

This game can be played at a higher level of abstraction. For example, suppose we think of the hash table as an abstract data structure with a `hash_put` operation that is logged as a logical operation rather than as operations on bytes. In that case every time we log a `hash_put` we also log the current value of one of the hash table entries, and take care to cycle through all the entries. If the hash table contains K key-value pairs, then the entire hash table will be reconstructable using only the most recent $2K$ log entries. This trick works for a binary tree too.

8 Avoiding Conflicts

This section outlines three issues related to transaction conflicts: avoiding too much retry work, avoiding congestion collapse, and reducing conflicts by serializing transactions that are likely to conflict.

In a distributed system one must handle errors in a disciplined fashion. The most common error is when a transaction is aborted because it conflicts with another transaction. Retrying transactions at several different places in the call stack can cause an exponential amount of retrying. Our strategy is that the storage host does not retry transactions that fail. Instead it attempts to complete one transaction, and if it fails the error is returned all the way back to Orca which can decide whether to retry. Orca typically sets a 55 s deadline for each NFS operation, and sets a 1 s deadline for each MPSC. Since the NFS client will retry its operation after 60 s, it's OK for Orca to give up after 55 s.

In order to avoid performance collapse, Orca employs a congestion control system similar to TCP's window-size management algorithm [71]. Some errors, such as transaction conflicts, impute congestion. In some situations the request transaction did not complete because some "housekeeping" operation needed to be run first (such as to rebalance two nodes of the B-tree). Doing the housekeeping uses up the budget for a single transaction, so an error must returned to Orca, but in this case the error does not impute congestion.

When two transactions conflict, one aborts, which is inefficient. We use in-memory locking to serialize transactions that are likely to conflict. For example, when Orca makes an FSS call to access an inode, it sends the request to the storage host that is likely to be the Paxos leader for the extent where that inode is stored. That storage host then acquires an in-memory lock so that two concurrent calls accessing the same inode will run one after another. Orca maintains caches that map key ranges to extent numbers and extent numbers to the leader's IP address. Sometimes one of the caches is wrong, in which case, as a side effect of running the transaction, the storage host will learn the correct cache entries, and inform Orca, which will update its cache. The in-memory lock is used for performance and is not needed for correctness. The technique of serializing transactions that are likely to conflict is well known in the transactional-memory literature [48, 73].

9 Performance

In the introduction we promised customers a convex combination of 100MB/s of bandwidth and 3000 IOPS for every terabyte stored. Those numbers are throughput numbers, and to achieve those numbers the NFS clients may need to perform operations in parallel. This section first explains where those throughput numbers come from, and then discusses FSS latency.

In order to make concrete throughput statements, we posit a simplified model in which the network bandwidth determines performance. The network bottleneck turns out to be on the storage hosts. If VNICs on the NFS clients are the bottleneck, then the customer can add NFS clients. If the presentation host is the bottleneck, then additional mount targets can be provisioned. The performance of the NVMe is fast compared to the several round trips required by Paxos (in contrast to, e.g., Gaios, which needed to optimize for disk latency instead of network latency because disks were so slow [11]).

We define performance in terms of the ratio of bandwidth to storage capacity. There are four components to the performance calculation: raw performance, replication, scheduling, and oversubscription. The ***raw performance*** is the network bandwidth divided by the disk capacity, without accounting for replication, erasure coding, scheduling, or oversubscription.

Replication consumes both bandwidth and storage capacity. Using 5:2 erasure coding, for each page of data, half a page is stored in each of five hosts. This means we can sell only 40% of the raw storage capacity. The network bandwidth calculation is slightly different for writes and reads. For writes, each page must be received by 5 different storage hosts running Paxos. That data is

erasure-coded by each host then written to disk. Thus, for writes, replication reduces the raw network bandwidth by a factor of 5.

For reads we do a little better. To read a page we collect all five erasure-coded copies, each of which is half a page and reconstruct the data using two of the copies. We could probably improve this further by collecting only two of the copies, but for now our algorithm collects all five copies. So for reads, replication reduces the bandwidth by a factor of 5/2.

Scheduling further reduces the bandwidth, but has a negligible effect on storage capacity. Queueing theory tells us that trying to run a system over about 70% utilization will result in unbounded latencies. We don't do quite that well. We find that we can run our system at about 1/3 of peak theoretical performance without affecting latency. This factor of 3 is our ***scheduling overhead***.

Since not all the customers are presenting their peak load at the same time, we can sell the same performance several times, a practice known as oversubscription. In our experience, we can oversubscribe performance by about a factor of 5.

The units of performance simplify from MB/s/TB to s^{-1}, so 100 MB/s/TB is one overwrite per 10 000 s.

For input-outputs per second (IO/s) we convert bandwidth to IOPS by assuming that most IOs are operations on 32 KiB pages, so we provide 3000 IO/s/TB. The cost of other IOs can be expressed in terms of reads: A write costs 2.5 reads, a file creation costs 6 reads, an empty-file deletion costs 8 reads, and a file renaming costs about 10 reads.

This performance model appears to work well on every parallel workload we have seen. To test this model, we measured how much bandwidth a relatively small test fleet can provide. (We aren't allowed to do these sorts of experiments on the big production fleets.) We measured on multiple clients, where each client has its own mount target on its own Orca. This fleet has 41 storage instances each with a 10 Gbit/s VNIC for a total raw performance of 51.25 GB/s. After replication that's 10.25 GB/s of salable bandwidth. Dividing by 3 to account for scheduling overhead is 3.4 GB/s. Those machines provide a total of 200 TB of salable storage, for a ratio of 17 MB/s/TB. According to our model, with 5-fold oversubscription, this fleet should promise customers 85 MB/s/TB.

Figure 8 shows measured bandwidth. The variance was small so we measured only 6 runs at each size. The measured performance is as follows. When writing into an empty file, block allocation consumes some time, and a single client can get about 434 MB/s, whereas 12 clients can get about 2.0 GB/s. When writing into an existing file, avoiding block allocation overhead, the

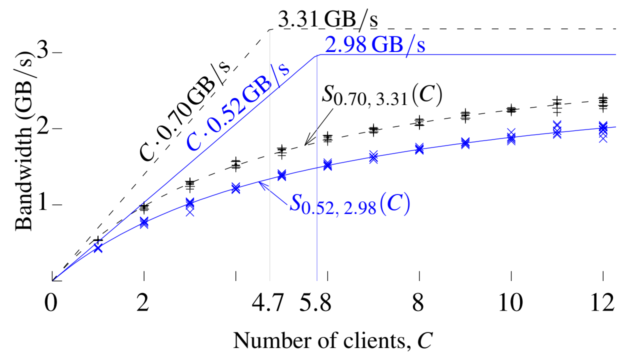

Figure 8: Measured bandwidth. The X-axis is the number of NFS clients. The Y-axis is the cumulative bandwidth achieved. The crosses (in black) show measured performance writing into a preallocated file. The x's (in blue) show measured performance including block allocation. The functions S are the curves fit to a simple-speedup model, with the corresponding linear-speedup shown as lines passing through the origin and the asymptotic speedups shown as horizontal lines. The number of clients at the intercepts are also shown.

performance is about 536 MB/s and 2.4 GB/s for 1 and 12 clients respectively.

We hypothesized that we could model this data as a ***simple-speedup*** curve [9] (a variant of Amdahl's law or of Brent and Graham's Theorem [5,12,27]). In a simple-speedup scenario, as we increase the number of clients, we see a linear speedup which eventually flattens out to give an asymptotic speedup. The curve is parameterized by two numbers l and a. The first value, l, is the ***linear-speedup*** slope which applies when the number of clients C is small where the performance will be $l \cdot C$. The second value, a, is the ***asymptotic speed***, and indicates the performance for large numbers of clients. The simple speedup curve,

$$S_{l,a}(C) = 1/(1/lC + 1/a),$$

is simply half the harmonic mean of the linear-speedup curve lC and the asymptotic speed a.

We fitted of our data to the simple-speedup model and plotted the resulting curves in Figure 8. The asymptotic standard error for the curve fit is less than 1.7%. Visually, the curves fit the data surprisingly well.

We can interpret these curves as follows: When writing to an empty file (which includes block allocation), a few clients can each achieve about 0.52 GB/s, and many clients can achieve a total of 2.98 GB/s. The cutover between "few" and "many" is about 6 clients for this fleet. When writing to a preallocated file, a few clients can each achieve 0.70 GB/s, and many clients can achieve

a total of 3.31 GB/s, which is close to our estimate of 3.4 GB/s. The intercept of the speedup curve lines tells us the ***half-power*** points, where half the peak capacity is consumed: 4.7 clients consume half of the fleet's allocate-and-write capacity, and 5.8 clients consume half of the write-without-allocation capacity.

Low latency is hard to achieve in a replicated distributed system. Latency is the elapsed time from an NFS client's request to response in an otherwise unloaded system. For serial workloads, latency can dominate performance. For example, when running over NFS, the `tar` program creates files one at a time, waiting for an acknowledgment that each file exists on stable storage before creating the next file. After looking at various benchmarks, we concluded that we should simply measure `tar`'s runtime on a well-known tarball such as the Linux 4.19.2 source code distribution, which is 839 MB and contains 65 825 objects. Untarring Linux onto local NVMe device takes about 10 s. The same NVMe served over NFS finishes in about 2.5 minutes. FSS finishes in about 10 minutes. Amazon's EFS, which replicates across a metropolitan region, finishes in about an hour. According to this limited experiment, NFS costs a factor of 15, replication within a datacenter costs another factor of 4, and synchronous replication over metropolitan-scale distances costs another factor of 6. Achieving local-filesystem performance in a replicated distributed fault-tolerant filesystem appears ... difficult.

10 Related Work

MPSC is a variation of load-link/store-conditional [41], and seems less susceptible to the ABA problem (in which the same location is read twice and has the same value for both reads, tricking the user into thinking that no transaction has modified the location in the meanwhile) than compare-and-swap [20,21,33]. Version tagging and the ABA problem appeared in [38, p. A-44].

Sinfonia has many similarities to our system. Sinfonia minitransactions [1] are similar to MPSC. Sinfonia uses uses primary-copy replication [14] and can suffer from the split-brain problem, where both primary and replica become active and lose consistency [19]. To avoid split-brain, Sinfonia remotely turns off power to failed machines, but that's just another protocol which can, e.g., suffer from delayed packets, and doesn't solve the problem. We employ Paxos [44], which is a correct distributed consensus algorithm.

Many filesystems have stored at least some their metadata in B-trees [8, 22, 39, 53, 63, 66, 67] and some have gone further, storing both metadata and data in a B-tree or other key-value store [18, 40, 64, 74, 75]. Our B-tree usage is fairly conventional in this regard, except that we store many filesystems in a single B-tree.

ZFS and HDFS [30,69,70,72] support multiple block sizes in one file. Block suballocation and tail merging filesystems [3,63,66] are special cases of this approach.

Some filesystems avoid using Paxos on every operation. For example, Ceph [42] uses Paxos to run its monitors, but replicates data asynchronously. Ceph's crash consistency can result in replicas that are not consistent with each other. Some systems (e.g., [23, 24, 52]) use other failover schemes that have not been proved correct. Some filesystems store all metadata in memory [24, 31, 36, 42, 57], resulting in fast metadata access until the metadata gets too big to fit in RAM. We go to disk on every operation, resulting in no scaling limits.

11 Conclusion

History: The team started with Frigo and Kuszmaul, and the first code commit was on 2016-07-04. Paxos and DASD were implemented by the end of July 2016, and the B-tree was working by November 2016. Sandler joined and started Orca implementation on 2016-08-03. Mazzola Paluska joined on 2016-09-15 and implemented the filesystem schema in the B-tree. The team grew to about a dozen people in January 2017, and is about two dozen people in spring 2019. Control-plane work started in Spring 2017. Limited availability was launched on 2017-07-01, less than one year after first commit (but without a control plane — all configuration was done manually). General availability started 2018-01-29. As of Spring 2019, FSS hosts over 10,000 filesystems containing several petabytes of paid customer data and is growing at an annualized rate of 8- to 60-fold per year (there's some seasonal variation).

Acknowledgments: In addition to the authors, the team that built and operates FSS has included: the data-plane team of Yonatan (Yoni) Fogel, Michael Frasca, Stephen Fridella, Jan-Willem Maessen, and Chris Provenzano; the control-plane team of Vikram Bisht, Bob Naugle, Michael Chen, Ligia Connolly, Yi Fang, Cheyenne T. Greatorex, Alex Goncharov, David Hwang, Lokesh Jain, Uday Joshi, John McClain, Dan Nussbaum, Ilya Usvyatsky, Mahalakshmi Venkataraman, Viktor Voloboi, Will Walker, Tim Watson, Hualiang Xu, and Zongcheng Yang; the product- and program-management team of Ed Beauvais, Mona Khabazan, and Sandeep Nandkeolyar; solutions architect Vinoth Krishnamurthy; and the engineering-management team of Thomas (Vinod) Johnson, Alan Mullendore, Stephen Lewin-Berlin, and Rajagopal Subramaniyan. Heidi Peabody provided administrative assistance. We further rely on the many hundreds of people who run the rest of Oracle Cloud Infrastructure.

Abstract

Determining whether online users are authorized to access digital objects is central to preserving privacy. This paper presents the design, implementation, and deployment of Zanzibar, a global system for storing and evaluating access control lists. Zanzibar provides a uniform data model and configuration language for expressing a wide range of access control policies from hundreds of client services at Google, including Calendar, Cloud, Drive, Maps, Photos, and YouTube. Its authorization decisions respect causal ordering of user actions and thus provide external consistency amid changes to access control lists and object contents. Zanzibar scales to trillions of access control lists and millions of authorization requests per second to support services used by billions of people. It has maintained 95th-percentile latency of less than 10 milliseconds and availability of greater than 99.999% over 3 years of production use.

1 Introduction

Many online interactions require authorization checks to confirm that a user has permission to carry out an operation on a digital object. For example, web-based photo storage services typically allow photo owners to share some photos with friends while keeping other photos private. Such a service must check whether a photo has been shared with a user before allowing that user to view the photo. Robust authorization checks are central to preserving online privacy.

This paper presents Zanzibar, a system for storing permissions and performing authorization checks based on the stored permissions. It is used by a wide array of services offered by Google, including Calendar, Cloud, Drive, Maps, Photos, and YouTube. Several of these services manage billions of objects on behalf of more than a billion users.

A unified authorization system offers important advantages over maintaining separate access control mechanisms for individual applications. First, it helps establish consistent semantics and user experience across applications. Second, it makes it easier for applications to interoperate, for example, to coordinate access control when an object from one application embeds an object from another application. Third, useful common infrastructure can be built on top of a unified access control system, in particular, a search index that respects access control and works across applications. Finally, as we show below, authorization poses unique challenges involving data consistency and scalability. It saves engineering resources to tackle them once across applications.

We have the following goals for the Zanzibar system:

- *Correctness*: It must ensure consistency of access control decisions to respect user intentions.
- *Flexibility*: It must support a rich set of access control policies as required by both consumer and enterprise applications.
- *Low latency*: It must respond quickly because authorization checks are often in the critical path of user interactions. Low latency at the tail is particularly important for serving search results, which often require tens to hundreds of checks.
- *High availability*: It must reliably respond to requests because, in the absence of explicit authorizations, client services would be forced to deny their users access.
- *Large scale*: It needs to protect billions of objects shared by billions of users. It must be deployed around the globe to be near its clients and their end users.

Zanzibar achieves these goals through a combination of notable features. To provide flexibility, Zanzibar pairs a simple data model with a powerful configuration language. The language allows clients to define arbitrary relations between users and objects, such as `owner`, `editor`, `commenter`, and `viewer`. It includes set-algebraic operators such as intersection and union for specifying potentially complex access control policies in terms of those user-object relations. For example, an application can specify that users granted editing rights on a document are also allowed to comment on the

*Work done while at Google.

document, but not all commenters are given editing rights.

At runtime, Zanzibar allows clients to create, modify, and evaluate access control lists (ACLs) through a remote procedure call (RPC) interface. A simple ACL takes the form of "user U has relation R to object O". More complex ACLs take the form of "set of users S has relation R to object O", where S is itself specified in terms of another object-relation pair. ACLs can thus refer to other ACLs, for example to specify that the set of users who can comment on a video consists of the users who have been granted viewing rights on that specific video along with those with viewing permissions on the video channel.

Group memberships are an important class of ACL where the object is a group and the relation is semantically equivalent to `member`. Groups can contain other groups, which illustrates one of the challenges facing Zanzibar, namely that evaluating whether a user belongs to a group can entail following a long chain of nested group memberships.

Authorization checks take the form of "does user U have relation R to object O?" and are evaluated by a collection of distributed servers. When a check request arrives to Zanzibar, the work to evaluate the check may fan out to multiple servers, for example when a group contains both individual members and other groups. Each of those servers may in turn contact other servers, for example to recursively traverse a hierarchy of group memberships.

Zanzibar operates at a global scale along multiple dimensions. It stores more than two trillion ACLs and performs millions of authorization checks per second. The ACL data does not lend itself to geographic partitioning because authorization checks for any object can come from anywhere in the world. Therefore, Zanzibar replicates all ACL data in tens of geographically distributed data centers and distributes load across thousands of servers around the world.

Zanzibar supports global consistency of access control decisions through two interrelated features. One, it respects the order in which ACL changes are committed to the underlying data store. Two, it can ensure that authorization checks are based on ACL data no older than a client-specified change. Thus, for example, a client can remove a user from a group and be assured that subsequent membership checks reflect that removal. Zanzibar provides these ordering properties by storing ACLs in a globally distributed database system with external consistency guarantees [15, 18].

Zanzibar employs an array of techniques to achieve low latency and high availability in this globally distributed environment. Its consistency protocol allows the vast majority of requests to be served with locally replicated data, without requiring cross-region round trips. Zanzibar stores its data in normalized forms for consistency. It handles hot spots on normalized data by caching final and intermediate results, and by deduplicating simultaneous requests. It also applies techniques such as hedging requests and optimizing computations on deeply nested sets with limited denormalization. Zanzibar responds to more than 95% of authorization checks within 10 milliseconds and has maintained more than 99.999% availability for the last 3 years.

The main contributions of this paper lie in conveying the engineering challenges in building and deploying a consistent, world-scale authorization system. While most elements of Zanzibar's design have their roots in previous research, this paper provides a record of the features and techniques Zanzibar brings together to satisfy its stringent requirements for correctness, flexibility, latency, availability, and scalability. The paper also highlights lessons learned from operating Zanzibar in service of a diverse set of demanding clients.

2 Model, Language, and API

This section describes Zanzibar's data model, configuration language, and application programming interface (API).

2.1 Relation Tuples

In Zanzibar, ACLs are collections of object-user or object-object relations represented as *relation tuples*. Groups are simply ACLs with membership semantics. Relation tuples have efficient binary encodings, but in this paper we represent them using a convenient text notation:

$\langle tuple \rangle$ ::= $\langle object \rangle$'`#`'$\langle relation \rangle$'`@`'$\langle user \rangle$

$\langle object \rangle$ ::= $\langle namespace \rangle$'`:`'$\langle object_id \rangle$

$\langle user \rangle$ ::= $\langle user_id \rangle$ | $\langle userset \rangle$

$\langle userset \rangle$ ::= $\langle object \rangle$'`#`'$\langle relation \rangle$

where $\langle namespace \rangle$ and $\langle relation \rangle$ are predefined in client configurations (§2.3), $\langle object_id \rangle$ is a string, and $\langle user_id \rangle$ is an integer. The primary keys required to identify a relation tuple are $\langle namespace \rangle$, $\langle object_id \rangle$, $\langle relation \rangle$, and $\langle user \rangle$. One feature worth noting is that a $\langle userset \rangle$ allows ACLs to refer to groups and thus supports representing nested group membership.

Table 1 shows some example tuples and corresponding semantics. While some relations (e.g. `viewer`) define access control directly, others (e.g. `parent`, pointing to a folder) only define abstract relations between objects. These abstract relations may indirectly affect access control given userset rewrite rules specified in namespace configs (§2.3.1).

Defining our data model around tuples, instead of per-object ACLs, allows us to unify the concepts of ACLs and groups and to support efficient reads and incremental updates, as we will see in §2.4.

2.2 Consistency Model

ACL checks must respect the order in which users modify ACLs and object contents to avoid unexpected sharing behaviors. Specifically, our clients care about preventing the

Example Tuple in Text Notation	Semantics
`doc:readme#owner@10`	User 10 is an owner of `doc:readme`
`group:eng#member@11`	User 11 is a member of `group:eng`
`doc:readme#viewer@group:eng#member`	Members of `group:eng` are viewers of `doc:readme`
`doc:readme#parent@folder:A#...`	`doc:readme` is in `folder:A`

Table 1: Example relation tuples. "#..." represents a relation that does not affect the semantics of the tuple.

"new enemy" problem, which can arise when we fail to respect the ordering between ACL updates or when we apply old ACLs to new content. Consider these two examples:

Example A: Neglecting ACL update order

1. Alice removes Bob from the ACL of a folder;
2. Alice then asks Charlie to move new documents to the folder, where document ACLs inherit from folder ACLs;
3. Bob should not be able to see the new documents, but may do so if the ACL check neglects the ordering between the two ACL changes.

Example B: Misapplying old ACL to new content

1. Alice removes Bob from the ACL of a document;
2. Alice then asks Charlie to add new contents to the document;
3. Bob should not be able to see the new contents, but may do so if the ACL check is evaluated with a stale ACL from before Bob's removal.

Preventing the "new enemy" problem requires Zanzibar to understand and respect the causal ordering between ACL or content updates, including updates on different ACLs or objects and those coordinated via channels invisible to Zanzibar. Hence Zanzibar must provide two key consistency properties: *external consistency* [18] and *snapshot reads with bounded staleness*.

External consistency allows Zanzibar to assign a timestamp to each ACL or content update, such that two causally related updates $x \prec y$ will be assigned timestamps that reflect the causal order: $T_x < T_y$. With causally meaningful timestamps, a snapshot read of the ACL database at timestamp T, which observes all updates with timestamps $\leq T$, will respect ordering between ACL updates. That is, if the read observes an update x, it will observe all updates that happen causally before x.

Furthermore, to avoid applying old ACLs to new contents, the ACL check evaluation snapshot must not be staler than the causal timestamp assigned to the content update. Given a content update at timestamp T_c, a snapshot read at timestamp $\geq T_c$ ensures that all ACL updates that happen causally before the content update will be observed by the ACL check.

To provide external consistency and snapshot reads with bounded staleness, we store ACLs in the Spanner global database system [15]. Spanner's TrueTime mechanism assigns each ACL write a microsecond-resolution timestamp, such that the timestamps of writes reflect the causal ordering between writes, and thereby provide external consistency. We evaluate each ACL check at a single snapshot timestamp across multiple database reads, so that all writes with timestamps up to the check snapshot, and only those writes, are visible to the ACL check.

To avoid evaluating checks for new contents using stale ACLs, one could try to always evaluate at the latest snapshot such that the check result reflects all ACL writes up to the check call. However, such evaluation would require global data synchronization with high-latency round trips and limited availability. Instead, we design the following protocol to allow most checks to be evaluated on already replicated data with cooperation from Zanzibar clients:

1. A Zanzibar client requests an opaque consistency token called a *zookie* for each content version, via a *content-change* ACL check (§2.4.4) when the content modification is about to be saved. Zanzibar encodes a current global timestamp in the zookie and ensures that all prior ACL writes have lower timestamps. The client stores the zookie with the content change in an atomic write to the client storage. Note that the content-change check does *not* need to be evaluated in the same transaction as the application content modification, but only has to be triggered when the user modifies the contents.
2. The client sends this zookie in subsequent ACL check requests to ensure that the check snapshot is at least as fresh as the timestamp for the content version.

External consistency and snapshot reads with staleness bounded by zookie prevent the "new enemy" problem. In Example A, ACL updates $A1$ and $A2$ will be assigned timestamps $T_{A1} < T_{A2}$, respectively. Bob will not be able to see the new documents added by Charlie: if a check is evaluated at $T < T_{A2}$, the document ACLs will not include the folder ACL; if a check is evaluated at $T \geq T_{A2} > T_{A1}$, the check will observe update $A1$, which removed Bob from the

folder ACL. In Example B, Bob will not see the new contents added to the document. For Bob to see the new contents, the check must be evaluated with a zookie $\geq T_{B2}$, the timestamp assigned to the content update. Because $T_{B2} > T_{B1}$, such a check will also observe the ACL update $B1$, which removed Bob from the ACL.

The zookie protocol is a key feature of Zanzibar's consistency model. It ensures that Zanzibar respects causal ordering between ACL and content updates, but otherwise grants Zanzibar freedom to choose evaluation timestamps so as to meet its latency and availability goals. The freedom arises from the protocol's at-least-as-fresh semantics, which allow Zanzibar to choose any timestamp fresher than the one encoded in a zookie. Such freedom in turn allows Zanzibar to serve most checks at a default staleness with already replicated data (§3.2.1) and to quantize evaluation timestamps to avoid hot spots (§3.2.5).

2.3 Namespace Configuration

Before clients can store relation tuples in Zanzibar, they must configure their namespaces. A namespace configuration specifies its relations as well as its storage parameters. Each relation has a name, which is a client-defined string such as `viewer` or `editor`, and a relation config. Storage parameters include sharding settings and an encoding for object IDs that helps Zanzibar optimize storage of integer, string, and other object ID formats.

2.3.1 Relation Configs and Userset Rewrites

While relation tuples reflect relationships between objects and users, they do not completely define the effective ACLs. For example, some clients specify that users with `editor` permissions on each object should have `viewer` permission on the same object. While such relationships between relations can be represented by a relation tuple per object, storing a tuple for each object in a namespace would be wasteful and make it hard to make modifications across all objects. Instead, we let clients define object-agnostic relationships via *userset rewrite rules* in relation configs. Figure 1 demonstrates a simple namespace configuration with concentric relations, where `viewer` contains `editor`, and `editor` contains `owner`.

Userset rewrite rules are defined per relation in a namespace. Each rule specifies a function that takes an object ID as input and outputs a userset expression tree. Each leaf node of the tree can be any of the following:

- `_this`: Returns all users from stored relation tuples for the ⟨*object#relation*⟩ pair, including indirect ACLs referenced by usersets from the tuples. This is the default behavior when no rewrite rule is specified.
- `computed_userset`: Computes, for the input object, a new userset. For example, this allows the userset expression for a `viewer` relation to refer to the `editor` userset on the same object, thus offering an ACL inheritance capability between relations.
- `tuple_to_userset`: Computes a tupleset (§2.4.1) from the input object, fetches relation tuples matching the tupleset, and computes a userset from every fetched relation tuple. This flexible primitive allows our clients to express complex policies such as "look up the parent folder of the document and inherit its viewers".

```
name: "doc"

relation { name: "owner" }

relation {
 name: "editor"
 userset_rewrite {
  union {
   child { _this {} }
   child { computed_userset { relation: "owner" } }
} } }

relation {
 name: "viewer"
 userset_rewrite {
  union {
   child { _this {} }
   child { computed_userset { relation: "editor" } }
   child { tuple_to_userset {
     tupleset { relation: "parent" }
     computed_userset {
       object: $TUPLE_USERSET_OBJECT  # parent folder
       relation: "viewer"
   } } }
} } }
```

Figure 1: Simple namespace configuration with concentric relations on documents. All owners are editors, and all editors are viewers. Further, viewers of the parent folder are also viewers of the document.

A userset expression can also be composed of multiple sub-expressions, combined by operations such as union, intersection, and exclusion.

2.4 API

In addition to supporting ACL checks, Zanzibar also provides APIs for clients to read and write relation tuples, watch tuple updates, and inspect the effective ACLs.

A concept used throughout these API methods is that of a *zookie*. A zookie is an opaque byte sequence encoding a globally meaningful timestamp that reflects an ACL write, a client content version, or a read snapshot. Zookies in ACL read and check requests specify staleness bounds for snapshot reads, thus providing one of Zanzibar's core consistency properties. We choose to use an opaque cookie instead of the actual timestamp to discourage our clients from choosing arbitrary timestamps and to allow future extensions.

2.4.1 Read

Our clients read relation tuples to display ACLs or group membership to users, or to prepare for a subsequent write. A read request specifies one or multiple *tuplesets* and an optional zookie.

Each *tupleset* specifies keys of a set of relation tuples. The set can include a single tuple key, or all tuples with a given object ID or userset in a namespace, optionally constrained by a relation name. With the tuplesets, clients can look up a specific membership entry, read all entries in an ACL or group, or look up all groups with a given user as a direct member. All tuplesets in a read request are processed at a single snapshot.

With the zookie, clients can request a read snapshot no earlier than a previous write if the zookie from the write response is given in the read request, or at the same snapshot as a previous read if the zookie from the earlier read response is given in the subsequent request. If the request doesn't contain a zookie, Zanzibar will choose a reasonably recent snapshot, possibly offering a lower-latency response than if a zookie were provided.

Read results only depend on contents of relation tuples and do not reflect userset rewrite rules. For example, even if the `viewer` userset always includes the `owner` userset, reading tuples with the `viewer` relation will not return tuples with the `owner` relation. Clients that need to understand the effective userset can use the Expand API (§2.4.5).

2.4.2 Write

Clients may modify a single relation tuple to add or remove an ACL. They may also modify all tuples related to an object via a read-modify-write process with optimistic concurrency control [21] that uses a read RPC followed by a write RPC:

1. Read all relation tuples of an object, including a per-object "lock" tuple.
2. Generate the tuples to write or delete. Send the writes, along with a touch on the lock tuple, to Zanzibar, with the condition that the writes will be committed only if the lock tuple has not been modified since the read.
3. If the write condition is not met, go back to step 1.

The lock tuple is just a regular relation tuple used by clients to detect write races.

2.4.3 Watch

Some clients maintain secondary indices of relation tuples in Zanzibar. They can do so with our Watch API. A watch request specifies one or more namespaces and a zookie representing the time to start watching. A watch response contains all tuple modification events in ascending timestamp order, from the requested start timestamp to a timestamp encoded in a *heartbeat zookie* included in the watch response. The client can use the heartbeat zookie to resume watching where the previous watch response left off.

2.4.4 Check

A check request specifies a userset, represented by $\langle object\#relation \rangle$, a putative user, often represented by an authentication token, and a zookie corresponding to the desired object version. Like reads, a check is always evaluated at a consistent snapshot no earlier than the given zookie.

To authorize application content modifications, our clients send a special type of check request, a *content-change* check. A content-change check request does not carry a zookie and is evaluated at the latest snapshot. If a content change is authorized, the check response includes a zookie for clients to store along with object contents and use for subsequent checks of the content version. The zookie encodes the evaluation snapshot and captures any possible causality from ACL changes to content changes, because the zookie's timestamp will be greater than that of the ACL updates that protect the new content (§2.2).

2.4.5 Expand

The Expand API returns the effective userset given an $\langle object\#relation \rangle$ pair and an optional zookie. Unlike the Read API, Expand follows indirect references expressed through userset rewrite rules. The result is represented by a *userset tree* whose leaf nodes are user IDs or usersets pointing to other $\langle object\#relation \rangle$ pairs, and intermediate nodes represent union, intersection, or exclusion operators. Expand is crucial for our clients to reason about the complete set of users and groups that have access to their objects, which allows them to build efficient search indices for access-controlled content.

3 Architecture and Implementation

Figure 2 shows the architecture of the Zanzibar system. `aclservers` are the main server type. They are organized in clusters and respond to Check, Read, Expand, and Write requests. Requests arrive at any server in a cluster and that server fans out the work to other servers in the cluster as necessary. Those servers may in turn contact other servers to compute intermediate results. The initial server gathers the final result and returns it to the client.

Zanzibar stores ACLs and their metadata in Spanner databases. There is one database to store relation tuples for each client namespace, one database to hold all namespace configurations, and one changelog database shared across all namespaces. `aclservers` read and write those databases in the course of responding to client requests.

`watchservers` are a specialized server type that respond to Watch requests. They tail the changelog and serve a stream of namespace changes to clients in near real time.

Zanzibar periodically runs a data processing pipeline to perform a variety of offline functions across all Zanzibar data in Spanner. One such function is to produce dumps of the relation tuples in each namespace at a known snapshot times-

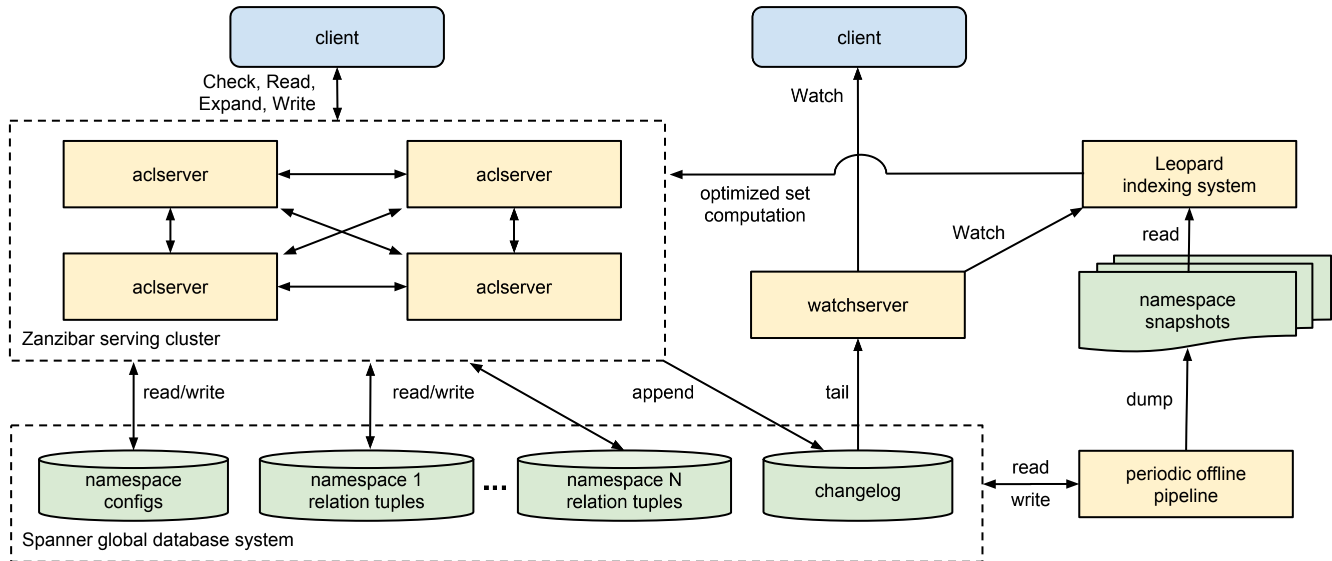

Figure 2: Zanzibar architecture. Arrows indicate the direction of data flow.

tamp. Another is to garbage-collect tuple versions older than a threshold configured per namespace.

Leopard is an indexing system used to optimize operations on large and deeply nested sets. It reads periodic snapshots of ACL data and watches for changes between snapshots. It performs transformations on that data, such as denormalization, and responds to requests from `aclservers`.

The rest of this section presents the implementation of these architectural elements in more detail.

3.1 Storage

3.1.1 Relation Tuple Storage

We store relation tuples of each namespace in a separate database, where each row is identified by primary key *(shard ID, object ID, relation, user, commit timestamp)*. Multiple tuple versions are stored on different rows, so that we can evaluate checks and reads at any timestamp within the garbage collection window. The ordering of primary keys allows us to look up all relation tuples for a given object ID or *(object ID, relation)* pair.

Our clients configure sharding of a namespace according to its data pattern. Usually the shard ID is determined solely by the object ID. In some cases, for example, when a namespace stores groups with very large numbers of members, the shard ID is computed from both object ID and user.

3.1.2 Changelog

Zanzibar also maintains a changelog database that stores a history of tuple updates for the Watch API. The primary keys are *(changelog shard ID, timestamp, unique update ID)*, where a changelog shard is randomly selected for each write.

Every Zanzibar write is committed to both the tuple storage and the changelog shard in a single transaction. We designate the Spanner server hosting the changelog shard as the transaction coordinator to minimize blocking of changelog reads on pending transactions.

3.1.3 Namespace Config Storage

Namespace configs are stored in a database with two tables. One table contains the configs and is keyed by namespace IDs. The other is a changelog of config updates and is keyed by commit timestamps. This structure allows a Zanzibar server to load all configs upon startup and monitor the changelog to refresh configs continuously.

3.1.4 Replication

To reduce latency, Zanzibar data is replicated to be close to our clients. Replicas exist in dozens of locations around the world, with multiple replicas per region. The 5 voting replicas are in eastern and central United States, in 3 different metropolitan areas to isolate failures but within 25 milliseconds of each other so that Paxos transactions commit quickly.

3.2 Serving

3.2.1 Evaluation Timestamp

As noted in §2.4, clients can provide zookies to ensure a minimum snapshot timestamp for request evaluation. When a zookie is not provided, the server uses a default staleness chosen to ensure that all transactions are evaluated at a timestamp that is as recent as possible without impacting latency.

On each read request it makes to Spanner, Zanzibar receives a hint about whether or not the data at that timestamp required an out-of-zone read and thus incurred additional latency. Each server tracks the frequency of such out-of-zone reads for data at a default staleness as well as for fresher

and staler data, and uses these frequencies to compute a binomial proportion confidence interval of the probability that any given piece of data is available locally at each staleness.

Upon collecting enough data, the server checks to see if each staleness value has a sufficiently low probability of incurring an out-of-zone read, and thus will be low-latency. If so, it updates the default staleness bound to the lowest "safe" value. If no known staleness values are safe, we use a two-proportion z-test to see if increasing the default will be a statistically significant amount safer. In that case, we increase the default value in the hopes of improving latency. This default staleness mechanism is purely a performance optimization. It does not violate consistency semantics because Zanzibar always respects zookies when provided.

3.2.2 Config Consistency

Because changes to namespace configs can change the results of ACL evaluations, and therefore their correctness, Zanzibar chooses a single snapshot timestamp for config metadata when evaluating each client request. All `aclservers` in a cluster use that same timestamp for the same request, including for any subrequests that fan out from the original client request.

Each server independently loads namespace configs from storage continuously as they change (§3.1.3). Therefore, each server in a cluster may have access to a different range of config timestamps due to restarts or network latency. Zanzibar must pick a timestamp that is available across all of them. To facilitate this, a monitoring job tracks the timestamp range available to every server and aggregates them, reporting a globally available range to every other server. On each incoming request the server picks a time from this range, ensuring that all servers can continue serving even if they are no longer able to read from the config storage.

3.2.3 Check Evaluation

Zanzibar evaluates ACL checks by converting check requests to boolean expressions. In a simple case, when there are no userset rewrite rules, checking a user U against a userset $\langle object\#relation \rangle$ can be expressed as

$$\begin{aligned} \text{CHECK}(U, \langle object\#relation \rangle) = \\ \exists \text{ tuple } \langle object\#relation@U \rangle \\ \vee \exists \text{ tuple } \langle object\#relation@U' \rangle, \text{ where} \\ U' = \langle object'\#relation' \rangle \text{ s.t. CHECK}(U, U'). \end{aligned}$$

Finding a valid $U' = \langle object'\#relation' \rangle$ involves evaluating membership on all indirect ACLs or groups, recursively. This kind of "pointer chasing" works well for most types of ACLs and groups, but can be expensive when indirect ACLs or groups are deep or wide. §3.2.4 explains how we handle this problem. Userset rewrite rules are also translated to boolean expressions as part of check evaluation.

To minimize check latency, we evaluate all leaf nodes of the boolean expression tree concurrently. When the outcome of one node determines the result of a subtree, evaluation of other nodes in the subtree is cancelled.

Evaluation of leaf nodes usually involves reading relation tuples from databases. We apply a pooling mechanism to group reads for the same ACL check to minimize the number of read RPCs to Spanner.

3.2.4 Leopard Indexing System

Recursive pointer chasing during check evaluation has difficulty maintaining low latency with groups that are deeply nested or have a large number of child groups. For selected namespaces that exhibit such structure, Zanzibar handles checks using Leopard, a specialized index that supports efficient set computation.

A Leopard index represents a collection of named sets using (T, s, e) tuples, where T is an enum representing the set type and s and e are 64-bit integers representing the set ID and the element ID, respectively. A query evaluates an expression of union, intersection, or exclusion of named sets and returns the result set ordered by the element ID up to a specified number of results.

To index and evaluate group membership, Zanzibar represents group membership with two set types, GROUP2GROUP and MEMBER2GROUP, which we show here as functions mapping from a set ID to element IDs:

- $\text{GROUP2GROUP}(s) \rightarrow \{e\}$, where s represents an ancestor group and e represents a descendent group that is *directly or indirectly* a sub-group of the ancestor group.
- $\text{MEMBER2GROUP}(s) \rightarrow \{e\}$, where s represents an individual user and e represents a parent group in which the user is a *direct* member.

To evaluate whether user U is a member of group G, we check whether

$$(\text{MEMBER2GROUP}(U) \cap \text{GROUP2GROUP}(G)) \neq \emptyset$$

Group membership can be considered as a reachability problem in a graph, where nodes represent groups and users and edges represent direct membership. Flattening group-to-group paths allows reachability to be efficently evaluated by Leopard, though other types of denormalization can also be applied as data patterns demand.

The Leopard system consists of three discrete parts: a serving system capable of consistent and low-latency operations across sets; an offline, periodic index building system; and an online real-time layer capable of continuously updating the serving system as tuple changes occur.

Index tuples are stored as ordered lists of integers in a structure such as a skip list, thus allowing for efficient union and intersections among sets. For example, evaluating the intersection between two sets, A and B, requires only $O(\min(|A|, |B|))$ skip-list seeks. The index is sharded by element IDs and can be distributed across multiple servers. Shards are usually served entirely from memory, but they

can also be served from a mix of hot and cold data spread between memory and remote solid-state devices.

The offline index builder generates index shards from a snapshot of Zanzibar relation tuples and configs, and replicates the shards globally. It respects userset rewrite rules and recursively expands edges in an ACL graph to form Leopard index tuples. The Leopard servers continously watch for new shards and swap old shards with new ones when they become available.

The Leopard system described thus far is able to efficiently evaluate deeply and widely nested group membership, but cannot do so at a fresh and consistent snapshot due to offline index generation and shard swapping. To support consistent ACL evaluation, Leopard servers maintain an incremental layer that indexes all updates since the offline snapshot, where each update is represented by a (T, s, e, t, d) tuple, where t is the timestamp of the update and d is a deletion marker. Updates with timestamps less than or equal to the query timestamp are merged on top of the offline index during query processing.

To maintain the incremental layer, the Leopard incremental indexer calls Zanzibar's Watch API to receive a temporally ordered stream of Zanzibar tuple modifications and transforms the updates into a temporally ordered stream of Leopard tuple additions, updates, and deletions. Generating updates for the GROUP2GROUP tuples requires the incremental indexer to maintain group-to-group membership for denormalizing the effects of a relation tuple update to potentially multiple index updates.

In practice, a single Zanzibar tuple addition or deletion may yield potentially tens of thousands of discrete Leopard tuple events. Each Leopard serving instance receives the complete stream of these Zanzibar tuple changes through the Watch API. The Leopard serving system is designed to continuously ingest this stream and update its various posting lists with minimal impact to query serving.

3.2.5 Handling Hot Spots

The workload of ACL reads and checks is often bursty and subject to hot spots. For example, answering a search query requires conducting ACL checks for all candidate results, whose ACLs often share common groups or indirect ACLs. To facilitate consistency, Zanzibar avoids storage denormalization and relies only on normalized data (except for the cases described in §3.2.4). With normalized data, hot spots on common ACLs (e.g., popular groups) may overload the underlying database servers. We found the handling of hot spots to be the most critical frontier in our pursuit of low latency and high availability.

Zanzibar servers in each cluster form a distributed cache for both reads and check evaluations, including intermediate check results evaluated during pointer chasing. Cache entries are distributed across Zanzibar servers with consistent hashing [20]. To process checks or reads, we fan out requests to the corresponding Zanzibar servers via an internal RPC interface. To minimize the number of internal RPCs, for most namespaces we compute the forwarding key from the object ID, since processing a check on ⟨*object#relation*⟩ often involves indirect ACL checks on other relations of the same object and reading relation tuples of the object. These checks and reads can be processed by the same server since they share the same forwarding key with the parent check request. To handle hot forwarding keys, we cache results at both the caller and the callee of internal RPCs, effectively forming cache trees. We also use Slicer [12] to help distribute hot keys to multiple servers.

We avoid reusing results evaluated from a different snapshot by encoding snapshot timestamps in cache keys. We choose evaluation timestamps rounded up to a coarse granularity, such as one or ten seconds, while respecting staleness constraints from request zookies. This timestamp quantization allows the vast majority of recent checks and reads to be evaluated at the same timestamps and to share cache results, despite having microsecond-resolution timestamps in cache keys. It is worth noting that rounding up timestamps does not affect Zanzibar's consistency properties, since Spanner ensures that a snapshot read at timestamp T will observe all writes up to T—this holds even if T is in the future, in which case the read will wait until TrueTime has moved past T.

To handle the "cache stampede" problem [3], where concurrent requests create flash hot spots before the cache is populated with results, we maintain a *lock table* on each server to track outstanding reads and checks. Among requests sharing the same cache key only one request will begin processing; the rest block until the cache is populated.

We can effectively handle the vast majority of hot spots with distributed caches and lock tables. Over time we made the following two improvements.

First, direct membership checks of a user for an object and relation (i.e. ⟨*object#relation@user*⟩) are usually handled by a single relation tuple lookup. However, occasionally a very popular object invites many concurrent checks for different users, causing a hot spot on the storage server hosting relation tuples for the object. To avoid these hot spots, we read and cache *all* relation tuples of ⟨*object#relation*⟩ for the hot object, trading read bandwidth for cacheability. We dynamically detect hot objects to apply this method to by tracking the number of outstanding reads on each object.

Second, indirect ACL checks are frequently cancelled when the result of the parent ACL check is already determined. This leaves the cache key unpopulated. While eager cancellation reduces resource usage significantly, it negatively affects latency of concurrent requests that are blocked by the lock table entry. To prevent this latency impact, we delay eager cancellation when there are waiters on the corresponding lock table entry.

3.2.6 Performance Isolation

Performance isolation is indispensable for shared services targeting low latency and high availability. If Zanzibar or one of its clients occasionally fails to provision enough resources to handle an unexpected usage pattern, the following isolation mechanisms ensure that performance problems are isolated to the problematic use case and do not adversely affect other clients.

First, to ensure proper allocation of CPU capacity, Zanzibar measures the cost of each RPC in terms of generic *cpu-seconds*, a hardware-agnostic metric. Each client has a global limit on maximum CPU usage per second; its RPCs will be throttled if it exceeds the limit *and* there is no spare capacity in the overall system.

Each Zanzibar server also limits the total number of outstanding RPCs to control its memory usage. Likewise it limits the number of oustanding RPCs per client.

Zanzibar further limits the maximum number of concurrent reads per *(object, client)* and per client on each Spanner server. This ensures that no single object or client can monopolize a Spanner server.

Finally, we use different lock table keys for requests from different clients to prevent any throttling that Spanner applies to one client from affecting other clients.

3.2.7 Tail Latency Mitigation

Zanzibar's distributed processing requires measures to accommodate slow tasks. For calls to Spanner and to the Leopard index we rely on request hedging [16] (i.e. we send the same request to multiple servers, use whichever response comes back first, and cancel the other requests). To reduce round-trip times, we try to place at least two replicas of these backend services in every geographical region where we have Zanzibar servers. To avoid unnecessarily multiplying load, we first send one request and defer sending hedged requests until the initial request is known to be slow.

To determine the appropriate hedging delay threshold, each server maintains a delay estimator that dynamically computes an Nth percentile latency based on recent measurements. This mechanism allows us to limit the additional traffic incurred by hedging to a small fraction of total traffic.

Effective hedging requires the requests to have similar costs. In the case of Zanzibar's authorization checks, some checks are inherently more time-consuming than others because they require more work. Hedging check requests would result in duplicating the most expensive workloads and, ironically, worsening latency. Therefore we do not hedge requests between Zanzibar servers, but rely on the previously discussed sharding among multiple replicas and on monitoring mechanisms to detect and avoid slow servers.

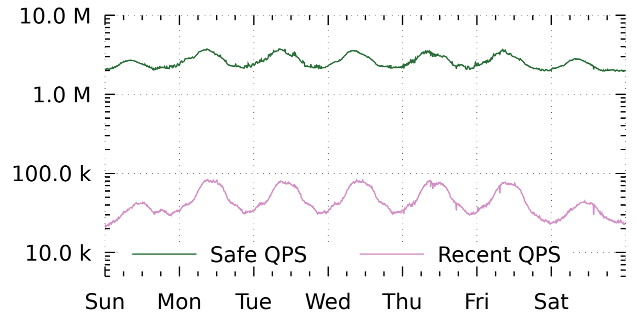

Figure 3: Rate of Check Safe and Check Recent requests over a 7-day period in December 2018.

4 Experience

Zanzibar has been in production use for more than 5 years. Throughout that time, the number of clients using Zanzibar and the load they place on Zanzibar have grown steadily. This section discusses our experience operating Zanzibar as a globally distributed authorization system.

Zanzibar manages more than 1,500 namespaces defined by hundreds of client applications. The size of a namespace configuration file serves as a rough measure of the complexity of the access control policy implemented by that namespace. These configuration files range from tens of lines to thousands of lines, with the median near 500 lines.

These namespaces contain more than 2 trillion relation tuples that occupy close to 100 terabytes. The number of tuples per namespace ranges over many orders of magnitude, from tens to a trillion, with the median near 15,000. This data is fully replicated in more than 30 locations around the world to maintain both proximity to users and high availability.

Zanzibar serves more than 10 million client queries per second (QPS). Over a sample 7-day period in December 2018, Check requests peak at roughly 4.2M QPS, Read at 8.2M, Expand at 760K, and Write at 25K. Queries that read data are thus two orders of magnitude more frequent than those that write data.

Zanzibar distributes this load across more than 10,000 servers organized in several dozen clusters around the world. The number of servers per cluster ranges from fewer than 100 to more than 1,000, with the median near 500. Clusters are sized in proportion to load in their geographic regions.

4.1 Requests

We divide requests into two categories according to the required data freshness, which can have a large impact on latency and availability of the requests. Specifically, Check, Read, and Expand requests carry zookies to specify lower bounds on evaluation timestamps. When a zookie timestamp is higher than that of the most recent data replicated to the region, the storage reads require cross-region round trips to the leader replica to retrieve fresher data. As our storage

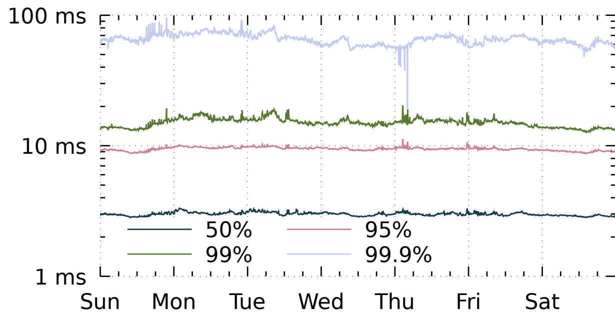

Figure 4: Latency of Check Safe responses at different percentiles over a 7-day period in December 2018.

is configured with replication heartbeats with 8-second intervals, we divide our requests into two categories: *Safe* requests have zookies more than 10 seconds old and can be served within the region most of time, while *Recent* requests have zookies less than 10 seconds old and often require inter-region round trips. We report separate statistics for each.

Figure 3 shows the rate of Check Safe and Check Recent requests over 7 days. Both exhibit a diurnal cycle. The rate of Safe requests is about two orders of magnitude larger than that of Recent requests, which allows Zanzibar to serve the vast majority of ACL checks locally.

4.2 Latency

Zanzibar's latency budget is generally a small fraction of the few hundreds of milliseconds of total response time that its clients must provide to be viable interactive services. Consider for example a client that performs authorization checks on multiple documents before it can show the results of a search on those documents.

We measure latency on the server side using live traffic because (1) latency is heavily influenced by our caching and de-duplication mechanisms so that it is only realistically reflected by live traffic, and (2) accurately measuring latency from clients requires well-behaving clients. Provisioning of client jobs is outside of Zanzibar's control and sometimes client jobs are overloaded.

Figure 4 shows the latency of Check Safe responses over 7 days. At the 50th, 95th, 99th, and 99.9th percentiles it peaks at roughly 3, 11, 20, and 93 msec, respectively. This performance meets our latency goals for an operation that is frequently in the critical path of user interactions.

Table 2 summarizes the latency distributions of Check, Read, Expand, and Write responses over the same 7 days. As intended, the more frequently used Safe versions of Check, Read, and Expand are significantly faster than the less frequently used Recent versions. Writes are the least frequently used of all the APIs, and the slowest because they always require distributed coordination among Spanner servers.

		Latency in milliseconds, μ (σ)		
	API	**50%ile**	**95%ile**	**99%ile**
Safe	Check	3.0 (0.091)	9.46 (0.3)	15.0 (1.19)
	Read	2.18 (0.031)	3.71 (0.094)	8.03 (3.28)
	Expand	4.27 (0.313)	8.84 (0.586)	34.1 (4.35)
Recent	Check	2.86 (0.087)	60.0 (2.1)	76.3 (2.59)
	Read	2.21 (0.054)	40.1 (2.03)	86.2 (3.84)
	Expand	5.79 (0.224)	45.6 (3.44)	121.0 (2.38)
	Write	127.0 (3.65)	233.0 (23.0)	401.0 (133.0)

Table 2: Mean and standard deviation of RPC response latency over a 7-day period in December 2018.

4.3 Availability

We define availability as the fraction of "qualified" RPCs the service answers successfully within latency thresholds: 5 seconds for a Safe request, and 15 seconds for a Recent request as leader re-election in Spanner may take up to 10 seconds. For an RPC to be qualified, the request must be well-formed and have a deadline longer than the latency threshold. In addition, the client must stay within its resource quota.

For these reasons, we cannot measure availability directly with live traffic, as our clients sometimes send RPCs with short deadlines or cancel their in-progress RPCs. Instead, we sample a small fraction of valid requests from live traffic and replay them later with our own probers. When replaying the requests, we set the timeout to be longer than the availability threshold. We also adjust the request zookie, if one is specified, so that the relative age of the zookie remains the same as when the request was received in the live traffic. Finally, we run 3 probers per cluster and exclude outliers to eliminate false alarms caused by rare prober failures.

To compute availability, we aggregate success ratios over 90-day windows averaged across clusters. Figure 5 shows Zanzibar's availability as measured by these probers. Availability has remained above 99.999% over the past 3 years of operation at Google. In other words, for every quarter, Zanzibar has less than 2 minutes of global downtime and fewer than 13 minutes when the global error ratio exceeds 10%.

4.4 Internals

Zanzibar servers delegate checks and reads to each other based on consistent hashing, and both the caller and the callee sides of the delegated operations cache the results to prevent hot spots (§3.2.5). At peak, Zanzibar handles 22 million internal "delegated" RPCs per second, split about evenly between reads and checks. In-memory caching handles approximately 200 million lookups per second at peak, 150 million from checks and 50 million from reads. Caching for

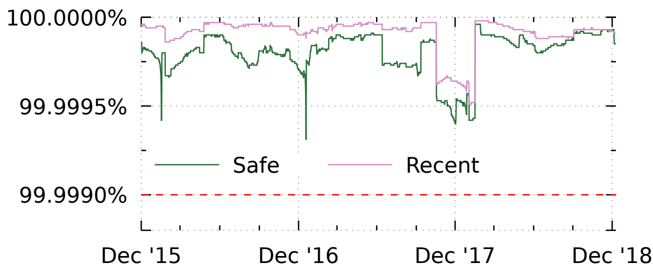

Figure 5: Zanzibar's availability over the past three years has remained above 99.999%.

checks has a 10% hit rate on the delegate's side, with an additional 12% saved by the lock table. Meanwhile, caching on the delegator's side has a 2% hit rate with an additional 3% from the lock table. While these hit rates appear low, they prevent 500K internal RPCs per second from creating hot spots.

Delegated reads see higher hit rates on the delegate's side—24% on the cache and 9% on the lock table—but the delegator's cache is hit less than 1% of the time. For super-hot groups, Zanzibar further optimizes by reading and caching the full set of members in advance—this happens for 0.1% of groups but further prevents hot spots.

This caching, along with aggressive pooling of read requests, allows Zanzibar to issue only 20 million read RPCs per second to Spanner. The median of these requests reads 1.5 rows per RPC, but at the 99th percentile they each read close to 1 thousand rows.

Zanzibar's Spanner reads take 0.5 msec at the median, and 2 msec at the 95th percentile. We find that 1% of Spanner reads, or 200K reads per second, benefit from hedging. We note that Zanzibar uses an instance of Spanner that runs internally to Google, not an instance of Cloud Spanner [6].

The Leopard index is performing 1.56M QPS at the median, or 2.22M QPS at the 99th percentile, based on data aggregated over 7 days. Over the same 7 days, Leopard servers respond in fewer than 150 µsec at the median, or under 1 msec at the 99th percentile. Leopard's incremental layer during those 7 days writes roughly 500 index updates per second at the median, and approximately 1.5K updates per second at the 99th percentile.

4.5 Lessons Learned

Zanzibar has evolved to meet the varied and heavy demands of a growing set of clients, including Google Calendar, Google Cloud, Google Drive, Google Maps, Google Photos, and YouTube. This section highlights lessons learned from this experience.

One common theme has been the importance of flexibility to accommodate differences between clients. For example:

- *Access control patterns vary widely:* Over time we have added features to support specific clients. For instance, we added `computed_userset` to allow inferring an object's owner ID from the object ID prefix, which reduces space requirements for clients such as Drive and Photos that manage many private objects. Similarly, we added `tuple_to_userset` to represent object hierarchy with only one relation tuple per hop. The benefits are both space reduction and flexibility—it allows clients such as Cloud both to express ACL inheritance compactly and to change ACL inheritance rules without having to update large numbers of tuples. See §2.3.1.
- *Freshness requirements are often but not always loose:* Clients often allow unspecified, moderate staleness during ACL evaluation, but sometimes require more precisely specified freshness. We designed our zookie protocol around this property so that we can serve most requests from a default, already replicated snapshot, while allowing clients to bound the staleness when needed. We also tuned the granularity of our snapshot timestamps to match clients' freshness requirements. The resulting coarse timestamp quanta allow us to perform the majority of authorization checks on a small number of snapshots, thus greatly reducing the frequency of database reads. See §3.2.1.

Another theme has been the need to add performance optimizations to support client behaviors observed in production. For example:

- *Request hedging is key to reducing tail latency:* Clients that offer search capabilities to their users, such as Drive, often issue tens to hundreds of authorization checks to serve a single set of search results. We introduced hedging of Spanner and Leopard requests to prevent an occasional slow operation from slowing the overall user interaction. See §3.2.7.
- *Hot-spot mitigation is critical for high availability:* Some workloads create hot spots in ACL data that can overwhelm the underlying database servers. A common pattern is a burst of ACL checks for an object that is indirectly referenced by the ACLs for many different objects. Specific instances arise from the search use case mentioned above, where the documents in the search indirectly share ACLs for a large social or work group, and Cloud use cases where many objects indirectly share ACLs for the same object high in a hierarchy. Zanzibar handles most hot spots with general mechanisms such as its distributed cache and lock table, but we have found the need to optimize specific uses cases. For example, we added cache prefetching of all relation tuples for a hot object. We also delayed cancellation of secondary ACL checks when there are concurrent requests for the same ACL data. See §3.2.5.
- *Performance isolation is indispensable to protect against misbehaving clients:* Even with hot-spot mitigation measures, unexpected and sometimes unin-

tended client behaviors could still overload our system or its underlying infrastructure. Examples include when clients launch new features that prove unexpectedly popular or exercise Zanzibar in unintended ways. Over time we have added isolation safeguards to ensure that there are no cascading failures between clients or between objects of the same client. These safeguards include fine-grained cost accounting, quotas, and throttling. See §3.2.6.

5 Related Work

Zanzibar is a planet-scale distributed ACL storage and evaluation system. Many of its authorization concepts have been explored previously within the domains of access control and social graphs, and its scaling challenges have been investigated within the field of distributed systems.

Access control is a core part of multi-user operating systems. Multics [23] supports ACLs on segments and directories. ACL entries consist of a principal identifier and a set of permissions bits. In the first edition of UNIX [9], file flags indicate whether owner and non-owner can read or write the file. By the 4th edition, the permissions bits had been expanded to read/write/execute bits for owner, group, and others. POSIX ACLs [4] add an arbitrary list of users and groups, each with up to 32 permissions bits. VMS [7, 8] supports ACL inheritance for files created within a directory tree. Zanzibar's data model supports permissions, users, groups, and inheritance as found in the above systems.

Taos [24, 10] supports compound principals that incorporate how an identity has been transformed as it passes through a distributed system. For example, if user U logged into workstation W to access file server S, S would see requests authenticated as "W for U" rather than just U. This would allow one to write an ACL on a user's e-mail that would be accessible only to the user, and only if being accessed via the mail server. Abadi et al. discuss in [11] a model of group-based ACLs with support for compound identities. Their notion of "blessings" are similar to Zanzibar tuples. However, Zanzibar adopts a unified representation for ACLs and groups using usersets, while they are separate concepts in [11].

Role-based access control (RBAC), first proposed in [17], introduced the notion of *roles*, which are similar to Zanzibar relations. Roles can inherit from each other and imply permissions. A number of Zanzibar clients have implemented RBAC policies on top of Zanzibar's namespace configuration language.

A discussion of ACL stores in 2019 would be remiss without mentioning the Identity and Access Management (IAM) systems offered commercially by Amazon [1], Google [5], Microsoft [2], and others. These systems allow customers of those companies' cloud products to configure flexible access controls based on various features such as: assigning users to roles or groups; domain-specific policy languages; and APIs that allow the creation and modification of ACLs. What all of these systems have in common is unified ACL storage and an RPC-based API, a philosophy also core to Zanzibar's design. Google's Cloud IAM system [5] is built as a layer on top of Zanzibar's ACL storage and evaluation system.

TAO [13] is a distributed datastore for Facebook's social graph. Several Zanzibar clients also use Zanzibar to store their social graphs. Both Zanzibar and TAO provide authorization checks to clients. Both are deployed as single-instance services, both operate at a large scale, and both are optimized for read-only operations. TAO offers eventual global consistency with asynchronous replication and best-effort read-after-write consistency with synchronous cache updates. In contrast, Zanzibar provides external consistency and snapshot reads with bounded staleness, so that it respects causal ordering between ACL and content updates and thus protects against the "new enemy" problem.

Lamport clocks [22] provide partially ordered vector timestamps that can be used to determine the order of events. However, Lamport clocks require explicit participation of all "processes", where in Zanzibar's use cases some of the "processes" can be external clients or even human users. In contrast, Zanzibar relies on its underlying database system, Spanner [15], to offer both external consistency and snapshot reads with bounded staleness. In particular, Zanzibar builds on Spanner's TrueTime abstraction [15] to provide linearizable commit timestamps encoded as zookies.

At the same time, Zanzibar adds a number of features on top of those provided by Spanner. For one, the zookie protocol does *not* let clients read or evaluate ACLs at an arbitrary snapshot. This restriction allows Zanzibar to choose a snapshot that facilitates fast ACL evaluation. In addition, Zanzibar provides resilience to database hotspots (e.g. authorization checks on a suddenly popular video) and safe pointer chasing despite potentially deep recursion (e.g. membership checks on hierarchical groups).

The Chubby distributed lock service [14] offers reliable storage, linearizes writes, and provides access control, but it lacks features needed to support Zanzibar's use cases. In particular, it does not support high volumes of data, efficient range reads, or reads at a client-specified snapshot with bounded staleness. Its cache invalidation mechanism also limits its write throughput.

Finally, ZooKeeper offers a high-performance coordination service [19] but also lacks features required by Zanzibar. Relative to Chubby, it can handle higher read and write rates with more relaxed cache consistency. However, it does not provide external consistency for updates across different nodes since its linearizability is on a per-node basis. It also does not provide snapshot reads with bounded staleness.

6 Conclusion

The Zanzibar authorization system unifies access control data and logic for Google. Its simple yet flexible data model and configuration language support a variety of access control policies from both consumer and enterprise applications.

Zanzibar's external consistency model is one of its most salient features. It respects the ordering of user actions, yet at the same time allows authorization checks to be evaluated at distributed locations without global synchronization.

Zanzibar employs other key techniques to provide scalability, low latency, and high availability. For example, it evaluates deeply or widely nested group membership with Leopard, a specialized index for efficient computation of set operations with snapshot consistency. As another example, it combines a distributed cache with a mechanism to deduplicate in-flight requests. It thus mitigates hot spots, a critical production issue when serving data on top of normalized, consistent storage. These measures together result in a system that scales to trillions of access control rules and millions of authorization requests per second.

7 Acknowledgments

Many people have made technical contributions to Zanzibar. We thank previous and recent members of the development team, including Dan Barella, Miles Chaston, Daria Jung, Alex Mendes da Costa, Xin Pan, Scott Smith, Matthew Steffen, Riva Tropp, and Yuliya Zabiyaka. We also thank previous and current members of the Site Reliability Engineering team, including Randall Bosetti, Hannes Eder, Robert Geisberger, Tom Li, Massimo Maggi, Igor Oks, Aaron Peterson, and Andrea Yu.

In addition, a number of people have helped to improve this paper. We received insightful comments from David Bacon, Carolin Gäthke, Brad Krueger, Ari Shamash, Kai Shen, and Lawrence You. IASO: A Fail-Slow Detection and Mitigation Framework for Distributed Storage Services

Biswaranjan Panda, Deepthi Srinivasan, Huan Ke*,
Karan Gupta, Vinayak Khot, and Haryadi S. Gunawi*

Nutanix Inc. University of Chicago*

Abstract

We address the problem of "fail-slow" fault, a fault where a hardware or software component can still function (does not fail-stop) but in much lower performance than expected. To address this, we built IASO, a peer-based, non-intrusive fail-slow detection framework that has been deployed for more than 1.5 years across 39,000 nodes in our customer sites and helped our customers reduce major outages due to fail-slow incidents. IASO primarily works based on timeout signals (a negligible overhead of monitoring) and converts them into a stable and accurate fail-slow metric. IASO can quickly and accurately isolate a slow node within minutes. Within a 7-month period, IASO managed to catch 232 fail-slow incidents in our large deployment field. In this paper, we have also assembled a large dataset of 232 fail-slow incidents along with our analysis. We found that the fail-slow annual failure rate in our field is 1.02%.

1 Introduction

Maintaining high availability of distributed storage services in real deployment fields is challenging due to the various types of faults that can occur. In the last few years, there has been an emphasis on "fail-slow" fault mode [28, 32]. This means that a hardware or software component can still function (does not fail-stop) but in much lower performance than expected. Such faults have been studied under different names such "gray failure" [32], "limping" [24, 37], and "partial failures" [29]. We chose the term "fail-slow" for simplicity and reflecting a recent term [28].

The urgency here is that many distributed systems are still designed based on a binary model of no failure and fail-stop failures. Recent works shows that many distributed systems cannot gracefully tolerate fail-slow mode, i.e. the system cannot isolate and hide a fail-slow component, causing latency spikes or throughput degradation to users [24, 28, 31, 32, 56]. Worse, it has been reported that a fail-slow component can cause *cascade* of performance failures across the cluster, bringing down services for hours [24, 28]. This calls for the importance of designing systems that tolerate not just absolute failure of sub-components but can also gracefully handle the occurrence of performance faults.

In this context, our work in this paper makes the two following contributions:

(1) Design and implementation of a fail-slow mitigation framework. The first contribution of the paper is IASO, our peer-based, non-intrusive fail-slow detection framework that has been deployed for more than 1.5 years across 39,000 nodes in our customer sites. Before the integration with IASO we had more than 25 full outages (IOPS went to zero) due to cascading impacts of fail-slow incidents, not to mention many other occurrences of partial slowdowns. Since the integration with IASO, we had only 2 major outages (false negative cases) caused by fail slow.

Motivation: IASO is motivated by the following reasons.

First, we found that fail-slow faults can be caused by many root causes. Sole dependence on low-level detection tools [38, 40, 15, 4] at various levels of the software and hardware stack might not be sufficient. Thus, we need a fail-slow detection system that works at the service (distributed system) level. Most existing work focuses on hardware level outlier detection or software performance bugs but they might not cover all of the detailed root causes occurring in the field (§4.2.3).

Second, most existing efforts focus only on detection but not mitigation. We are only aware of a handful of works that perform mitigation in real deployments (more in §5). Yet, our findings suggest that if fail-slow incidents are not quickly and automatically isolated, it can cascade and directly affect users for hours or days. For this reason, it is paramount that deployed systems are equipped with fail-slow mitigation.

Third, although some computing frameworks such as MapReduce [1, 23] are equipped with fail-slow mitigation (*e.g.*, via speculative execution [58] or cloning [10]), the tail tolerance is built in their abstractions (*e.g.*, "jobs", "tasks") and not directly generalizable to many other distributed systems. Recent works revealed that many other distributed systems are still not fail-slow tolerant [24, Figure 1][56, Figure 12]. Hence, we need a more general way of addressing fail-slow faults in many distributed storage services.

Challenges and solutions: A fail-slow detection framework must be non-intrusive (negligible overhead), stable and accurate, and not accidentally make wrong decisions (*e.g.*, quarantine healthy nodes). To achieve this, we make IASO peer-based, *i.e.*, a slow service instance should be compared against its peers of the same service (*e.g.*, the performance of Cassandra instance should not be compared to ZooKeeper's). We also make IASO load aware, *i.e.*, the relative performance of a service instance must not be improved or worsen just because the load on the node on which the instance is running on is different.

To achieve all of these, we created an algorithm (§2.2) that can work solely based on timeout signals. Our algorithm can convert timeout and successful-response statistics into a stable and accurate fail-slow detector. Our framework does not need to monitor every request latency, hence achieving a neglibible overhead. IASO can quickly and accurately isolate a slow node within minutes. Within a 7-month period, IASO managed to catch 232 fail-slow incidents in our large deployment field. IASO also automatically quarantined the slow nodes and restored the clusters back to a healthier performance. We only encountered 9 confirmed false positives. Other false positives are because the fail-slowness disappeared when our engineers started diagnosing them (*e.g.*, perhaps caused by unknown external conditions).

(2) A dataset and analysis of fail-slow incidents With IASO integration, we were able to capture many fail-slow incidents in the field. We have assembled a large dataset of fail-slow incidents along with our analysis [7]. To the best of our knowledge, this is the largest dataset of fail-slow cases publicly reported from within a company. Furthermore, existing accounts of fail-slow accidents are anecdotal [12, 28, 32], while our contribution includes some quantitative analysis (*e.g.*, AFR, age correlation).

The dataset: The dataset contains 232 validated cases collected from the deployment of 39,000 nodes throughout a period of 7 months.[1] This data pertains to a type of fully hyperconverged system [9] that we deploy in customer sites.

Findings: Our rich dataset allows us to make some statistical findings. First, given 232 independent cases across 39,000 nodes over 7 months, we can derive that the annual failure rate is 1.02% (232 × 12 / 7 / 39,000), which is relatively significant compared to rates of other types of faults (§4.2.1). Second, we uncovered a wide range of root causes (and the low-level sub-causes), which again accentuates the need for detection at the service level, not just at the individual hardware level. Third, we also observed the "infant mortality" pattern where younger machines exhibit more fail-slow incidents. Fourth, we show that if not mitigated properly, fail-slow cases can take hours or days to fully resolve, which again highlights the importance of automatically quarantining slow nodes.

The following sections present the design and implementation of IASO (§2), experimental results (§3), our dataset and findings (§4), related work and conclusion.

2 IASO

This section presents IASO, our framework for detecting the presence of an unhealthy node and enabling self healing of the cluster. We name our system after "Iaso", the Greek goddess of recuperation from illness [8]. IASO is comprised of three stages:

1. *Detection (§2.1-2.2):* This step reduces the time to detect fail-slow incidents from hours to minutes while keeping false positives low.
2. *Mitigation (§2.3):* This step quarantines the faulty node and brings the cluster back to operation.
3. *Resolution (§2.4):* IASO automatically pages site reliability engineers (SREs) to identify the failed component and help support to do breakfix and assimilate the fixed component back into operation.

When building IASO, we adhere to the following design principles.

- *Non intrusive*: We attempt to reach a near 0% overhead, hence we use raw metrics that the deployed services already collect (*e.g.*, number of timeouts and successful responses).
- *Peer based:* A slow service instance should be compared against its peers of the same service, *e.g.*, the performance of Cassandra instance should be compared to other Cassandra instances, not ZooKeeper instances, as different types of services observe different types of workload. For this reason, we monitor at service-level requests, not at OS or hardware level.
- *Load aware:* The slowdown detection system must be aware of the service load. The relative performance of a peer must not be improved or worsen just because the load on the node the peer is running on is different. This means that the performance of a node must be normalized based on the capacity of the node; in our deployment, a cluster can have different machine capacities with different loads.
- *Stable and accurate:* As a degraded node will be quarantined, it is important to have a stable and accurate algorithm that does not accidentally make wrong decisions (false positives).

[1] For this publication we only have analyzed the dataset for a 7 month period in 2017. Data from 2018 is still being perused and cleaned.

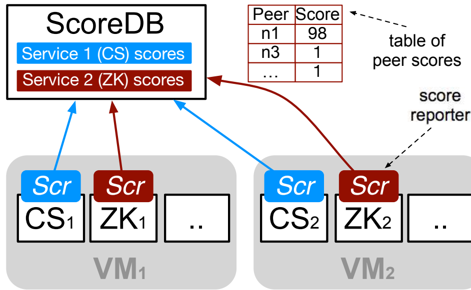

Figure 1: **IASO components.** *The figure is described in the last paragraph of page 2 and also in Section 2.1. "Scr" denotes the hook that sends score table to ScoreDB.*

The following are the terms we use in this paper. As shown in Figure 1, our *system* S is a cluster of high-end *machines* (gray shades) running *VMs* wherein *services* are running (boxes). For example, S comprises a ZooKeeper (ZK) service for cluster configuration manager, a Cassandra service (CS) for storing metadata, and our own blob-store service for storing data. Each VM runs an instance of each of the services (*e.g.*, a VM runs three service instances, Cassandra, ZooKeeper and blob-store instances). These VMs are also known as controller VMs.

2.1 Detection

Our first goal is to detect which service instance is experiencing a slowdown. Currently we only address persistent fault, *i.e.*, the instance is not being slowed down due to an intermittent condition such as a one-off high GC time. This section describes the main components of IASO as shown in Figure 1. The next section (§2.2) presents the detailed algorithm.

RAW METRICS (LATENCY VS. TIMEOUTS): One naive method to measure degradation is to measure the latency of every request. However, with today's high-throughput services it is not amenable (*e.g.*, per-node Cassandra throughput can reach 20,000 IOPS [5]). Sampling can be a solution, but we explored a different method.

In this work, we try a much cheaper method to detect degradation: counting timeouts. Many services such as Cassandra already have a built-in metric that collects how many responses were successful as well as the failed ones due to timeouts. Another advantage of using timeouts is that our monitoring system is not intrusive to the performance of the service itself (a nearly 0% overhead as counting timeouts and successful responses is a simple increment operation).

SCORES: We found that using raw timeout counts as a direct metric to measure outlier is not a stable and accurate way. Thus, we need to introduce the concept of *"score"*. Given a cluster of N nodes with N instances of a service, every instance can observe the performance of its $N-1$ peers and maintain a "score table" (as shown in Figure 1).

STABLE SCORES: The primary challenge we address in this work is *how to convert timeout and success statistics into a stable and accurate degradation detector*. Noisy scores can lead to more false positives where healthy nodes might be accidentally removed and vice versa. Later, the experiment section shows other unsuccessful algorithms that we tried (§3) which then led us to the current algorithm (§2.2). One key to prevent scores from fluctuating along with the number of timeouts is by incorporating additive increase and multiplicative decrease (AIMD) [18] such as used in TCP congestion avoidance. Thus, our custom algorithm employs a technique similar to AIMD.

SCOREDB SERVER: The scores collected from the service instances are stored in a database server called ScoreDB (Figure 1). For every peer, every instance keeps a score, hence in total ScoreDB maintains $N\times(N-1)$ score variables (per every service monitored) including their historical values. Given these scores, ScoreDB runs an outlier detection part of our algorithm and quarantines the outlier. ScoreDB is also a replicated system (to anticipate degradation within itself).

2.2 Detection Algorithm

We now describe how IASO calculates the score metric and detects an outlier. The challenge is to convert timeout and success statistics into a stable and accurate degradation detector. For every equation listed below, the explanation is in the paragraph preceding the equation. Symbols † and ‡ are used for backward references.

2.2.1 Peer Scores

Given a cluster of N instances within a service (*e.g.*, Cassandra), every instance observes the performance of its peers and puts the corresponding scores in a score table containing $N-1$ peer scores. In our scoring system below, a score ranges from 1 to 100 where a higher value implies more severe degradation. For example, in the score table in Figure 1, Cassandra instance on `Node2` believes that Cassandra instane on `Node1` is slow (a score of 98).

As score continues to change, below we use `prev` and `score` to represent the scores in the last and current epoch respectively. An epoch is the interval at which every service instance runs the equations below (*i.e.*, calculates a new score). The `epoch` is set to be 5 seconds and `prev` to 1 in the beginning.

Next, we introduce `ToRespRatio`, the ratio of the number of timeouts and total responses between two peers within an epoch. This is essential to the load-awareness part of our algorithm, that timeout counts should be relative to the num-

ber of total responses as the number of responses will vary across peers.

$\texttt{ToRespRatio} = \texttt{\#timeouts} \, / \, \texttt{\#responses}$

We then set `ratioThresh`, a timeout-response ratio threshold, with a constant value of 0.1 (*e.g.*, 10 timeouts for every 100 responses). In our experience, 10% timeouts from a peer can cause a whole-cluster degradation. A higher value may make IASO react too late, while a lower may lead to more false positives (*i.e.*, too sensitive). If `ToRespRatio` is larger than the `ratioThresh`, it is likely a heavy degradation. Otherwise, it is likely caused by a temporary high load or a benign cause.

$\texttt{ratioThresh} = 0.1$

Next, we introduce `minTTR` as the minimum time to observe zero timeout from a peer before the score assigned to it decreases from 100 to 1 (slow to healthy). We set the time to be 2 minutes. The idea is that when a peer exhibits a zero timeout, it might mean that this peer is temporarily healthy but might suffer degradation again soon. The 2-minute mark is the time window in which a peer must "prove" itself that it is really healthy. A smaller window increases the risk that we may start assigning good scores to a temporarily good peer and thereby creating an unstable score pattern. A larger window has the disadvantage that we may mark a peer as fail-slow even if it has just completely recovered but the 2-minute window hasn't passed. However, the latter scenario should be infrequent.

$\texttt{minTTR} = 2 \text{ mins}$

With all of the values above, now we can stitch them into the score calculation. In every epoch, if `ToRespRatio` is 0 (no timeout), then the `score` will be calculated as shown below. This is the "additive decrease" part of our algorithm – the score will be slowly decreasing back to zero to show that the peer is really healthy.

[if `ToRespRatio` is 0]
$\texttt{score} = \texttt{prev} - (\, 100 \times \texttt{epoch} \, / \, \texttt{minTTR} \,)$

Now, we discuss the case where some timeouts are observed (`ToRespRatio` is not zero). First, we introduce `minRatio` as a higher bound of the timeout-response ratio and threshold values. The idea here is that `ToRespRatio` can be very high (*e.g.*, 90%, when a peer is highly unresponsive). This high value will make our algorithm below unstable. Thus, we cap it to the `ratioThresh` value (0.1), *i.e.*, 10% already represents enough degradation.

$\texttt{minRatio} = \min \left(\texttt{ToRespRatio} \, , \texttt{ratioThresh} \right)^{\dagger}$

Finally, the last variable we introduce is `nearThresh` to measure how far the timeout-response ratio to the threshold (how far from the 10% timeouts). This threshold nearness ranges from 0 to 1.0.

$\texttt{nearThresh} = \texttt{minRatio} \, / \, \texttt{ratioThresh} \; ^{\ddagger}$

With all the new variables above, we now can calculate the score when timeout-response ratio is higher than zero. The equation below represents the "multiplicative increase" part of our algorithm where the score is increased by the threshold nearness. We put more examples below.

[if `ToRespRatio` is not 0]
$\texttt{score} = \texttt{prev} + (\, \texttt{prev} \times \texttt{nearThresh} \,)$

Let's use an example where an instance gave a score of 32 for a peer instance in the last epoch. Now, the current epoch sees too many timeouts beyond the threshold such that `nearThresh` is 1.0. Thus, the current score will jump from 32 to 32+32 (*i.e.*, the score increases multiplicatively).[2]

$\texttt{score} = 32 + (\, 32 \times 1.0 \,) = 64$

Let's imagine another scenario where the `ToRespRatio` is as small as 0.01 (1% timeouts) . Here, the `minRatio` will be 0.01 (see equation †) and the `nearThresh` be 0.1 (see ‡). Thus, the next `score` will only increment fractionally:

$\texttt{score} = 32 + (\, 32 \times 0.1 \,) = 35.2$

To sum up, our algorithm prevents scores from fluctuating along with the number of timeouts. That is, we linearly decrement the score when we do not observe any timeouts from a peer, but multiplicatively increase the score when we observe timeouts from the peer.

2.2.2 Scores Set

Every instance X then sends the scores of its peers (A, B, ...) to the ScoreDB server, which will then maintain a history of the scores. For example for a given peer A, there are $N-1$ scores for A collected in every 5-second epoch.

For every peer, all the scores given for that peer are collected within a 10-minute sliding window, where ScoreDB then picks the 30th-percentile value to be the *representative* score for that peer, such as for instance A. The 30th-percentile value implies that the peer instance must have 70% high score values within a 10-minute interval such that we do not inadvertently quarantine instances with mere transient faults. In our deployments, we have observed that a 10-minute window is wide enough to detect persistent faults. It may not be the absolute minimum but it does put an upper bound on the time to isolate a fail-slow peer.

At this point, ScoreDB has N representative scores for all the instances in the cluster and it submits these scores to the DBSCAN algorithm [6]. ScoreDB performs this every minute, but using the data from the past 10 minutes (a sliding window). DBSCAN [6] is an algorithm that takes a set of

[2] To make the score multiplication increases faster/slower (*i.e.*, more configurable), we can introduce a score multiplier with a usage such as: *e.g.*, 32 + `scoreMultiplier` × 32. We use `scoreMultiplier` =1.

points and groups them such that points that are spatially close are grouped together while points which do not have enough close neighbors are classified as outliers. Thus, we configure DBSCAN to output a binary decision (whether an instance is "fast" or "slow"). We also only mark at most one outlier at a time to make sure we do not remove too many service instances (explained later in §2.3).

Finally, we emphasize that we only compare instances (scores) of the same service. We do not compare instance scores of Cassandra with those of ZooKeeper, thus the algorithm above runs for every service deployed. For example in Figure 1, the ScoreDB server maintains history of Cassandra and ZooKeeper peer scores separately.

2.3 Mitigation

After a service instance is marked as an outlier, IASO starts the mitigation process. Below are the three options that our customers can set in IASO configuration. The first one (service instance reboot) is the default configuration. The philosophy of our mitigation is that it is better to remove a highly degraded instance than allowing it to induce a cascading problem to the entire cluster. Other works [24, 56] already show how running with one less instance ($N-1$) can give a better performance than running a full cluster (N) with a degraded instance. IASO only quarantines at most one instance to prevent the cluster drops below its fault-tolerant level.

(1) SERVICE INSTANCE REBOOT AND LEADERSHIP REMOVAL: Here, IASO will restart the slow instance and remove leadership leases (if any) from the service instance running on that node. We emphasize here that we only remove the service instance (*e.g.*, Cassandra/ZooKeeper slow instance), but not the underlying VM or the machine. As a reason, imagine a machine where an instance of service X uses the underlying slow disk, but another instance of service Y only utilizes the memory (still fast). Here, we want X to be rebooted and its leadership removed, but let Y continue to run normally as it is not affected by the slow disk.

Regarding the removal of leadership, in ZooKeeper, if the instance is a leader, rebooting the instance will automatically make ZooKeeper choose a new leader. This way the old slow leader is no longer the single point of performance failure. The only cost associated with this action is the rebuilding of leader state on some other healthy peer.

In Cassandra, every instance is responsible for a key range (our deployment does not use Cassandra's virtual node feature). Here, we have two opposing options for mitigation. The expensive option is to remove the instance from the ring and trigger a whole-cluster key-range rebalancing, which might be a premature action as the instance perhaps can be fixed soon. The cheaper option is to let the slow instance be in the ring but not allow it to be part of the data transfer.

We chose the latter option and modified Cassandra slightly to achieve this. In this mode, the slow instance is no longer the primary owner of its key range, but rather one of the other replicas becomes the primary owner. The upside is that we postpone the need for whole-cluster key-range rebalancing. The downside is that the fault tolerance of newly added data will be down by one (*e.g.*, we can only write to two replica nodes as the instance on the slow node is being isolated) and read throughput may be degraded due to the loss of one instance. We note that the fault tolerance of old data does not go down as the data is still there in the slow instance.

Regardless of the limitations of this default option, customers who have smaller clusters tend to choose this option as they do not have options to migrate the instance or VMs to another healthy machine. Below we discuss other options for customers with larger clusters.

(2) VM SHUTDOWN: This is a more severe action than the default option above. In this mode, the controller VM of the slow service instance is shut down and no services are started on the VM. The difference between this action and the default one above is that when VM is shut down, the services above will automatically run their recovery protocols (*e.g.*, whole ring rebalancing). Thus, the fault tolerance of the data stays the same (*e.g.*, 3-way replication is still maintained). The similarity is that there may also be a performance drop to the loss of a VM. When the problem is fixed, the VM is added backed and full performance can be restored.

(3) HOST MACHINE SHUTDOWN: This option is similar to VM shutdown. The difference is that our system will automatically migrate the entire VM from this host to another, which is a process transparent to the services running on the VM. There may be a potential VM rebalancing issue (*e.g.*, a machine has too many VMs). For VM balancing, we employ our own proprietary VM rebalancing that is outside the scope of the paper. We also emphasize that in our deployment, these machines are running the services that we deploy. The machines are not shared with other tenants, hence we have a full control of when to shut down the machine.

2.4 Resolution

The last stage, resolution, is the manual part of the whole IASO operational procedure, which we describe here for completeness.

When detecting a fail-slow node, IASO generates a user alert on the customer monitoring UI. IASO also pages our site-reliability engineers (SREs) such that they can work with the affected customer to fix the problem. If there had been a cluster outage (*i.e.*, cluster IOPS went to almost zero) before the mitigation, IASO helps the customer and our SREs in identifying the faulty node and service.

It is also possible that before the SREs perform the full

Table 1: **Implementation complexity (§2.5).** *The table shows our* IASO *integration effort.*

diagnosis, the problem already went away by itself from rebooting the slow node. We see this happens in cases such as CPU locks-ups or high heap usage levels. In such cases, IASO will no longer mark the node as a degraded node. In overall, when the problem is fixed, IASO immediately rolls back the fail-slow node actions executed before, and service instances on the newly recovered node regain their leadership responsibilities.

Temporary fail-slow faults can be recurrent (*e.g.*, high heap usage level). To prevent such recurrent faults, the root cause must be fixed. For example, we could apply some custom optimizations to our services to prevent it from entering such a state again.

2.5 Other Implementation Details

INTEGRATION: So far we have integrated IASO with Cassandra and ZooKeeper. The implementation complexity is shown in Table 1. The changes to the target services are non-intrusive (less than 600 LOC). The service instances use IASO library to measure local scores and send them to the ScoreDB server where the rest of the complexity lies. The total score data size of ScoreDB server is only 0.27 MB per day per cluster on average as it only needs to keep the score history of the last 10 minutes. The CPU overhead is near 0%.

We envision that IASO can be easily integrated to other master-worker systems where data flows across workers. For example, in HDFS, write replication forms a pipeline of datanodes where each datanode can sense the performance of its peers. For systems like ZooKeeper, the integration involves a different type of modification due to ZooKeeper's "pure" leader-follower architecture (*i.e.*, followers do not interact with each other). We describe these changes later below. As mentioned before, we also run our own blob-store service which can be integrated with IASO as well. This process is still in progress, not because of integration difficulty, but because so far our IASO integration in Cassandra and Zookeper seems to be sufficient. One limitation of our deployment is that a single blob-store instance can be misconfigured causing a fail-slow fault, but goes undetected (which again so far never happened).

ZOOKEEPER MODIFICATION: In our deployment, the Cassandra-side IASO so far has been very effective. But as we deal with deployments of tens of thousands of nodes, we can potentially cover a wider set of failure types if we can integrate IASO with another service as well. Hence, we attempted to integrate IASO to ZooKeeper, but ZooKeeper employs a pure leader-follower architecture where followers do not transfer data with each other (*i.e.*, 3-way writes flow from the leader to three followers, unlike in HDFS or Cassandra). The leader is a single point of performance failure [24]; if the leader's NIC is slow, the writes to all the followers will slow down, hence no outlier.

For this, we add a simple, lightweight background ping-pong thread between ZooKeeper peers (only <200 LOC). Every 10 seconds, every instance picks a maximum of 7 random peers and makes an RPC that includes a synchronous disk write. Checking the disk latency this way is also beneficial since most data operations in Cassandra hit the cache, hence disk monitoring is a bit lacking. Besides these small changes, we emphasize that the rest of the algorithm is the same – the instances send the median latencies of their peers (median of 1 minute window) to ScoreDB and the DBSCAN algorithm will compute the outlier.

THRESHOLDS: We would like to emphasize that the threshold values we use in our algorithms (§2.2) are based on our specific deployment experiences. It is possible that the values might not work in other cases.

3 Results

This section presents our experimental results, starting with unsuccessful experiences (§3.1) and then the successful ones (§3.2) and the false positive rates (§3.3).

3.1 Unsucessful Attempts

The first strawman approach we tried was to use the raw timeout count as a metric to sense service instance level performance degradation. Figure 2 shows the number of timeouts observed in three samples of real degraded instances (in different time periods and clusters). As shown, the timeouts observed occur in bursts although the fault is severe throughout the time interval. Thus, without saving the ratio of timeouts and responses for every peer over a given period, there is no way to detect whether these high scores were merely transient or if they were truly persistent and possibly catastrophic faults.

For this reason, we next attempted to create a more stable algorithm by defining a score to be the percentage of timeouts over the total responses in every epoch. The first line below is the same as the first equation in §2.2, and in the second line, a peer score is essentially the `ToRespRatio`.

```
ToRespRatio = #timeouts / #responses
score = ToRespRatio
```

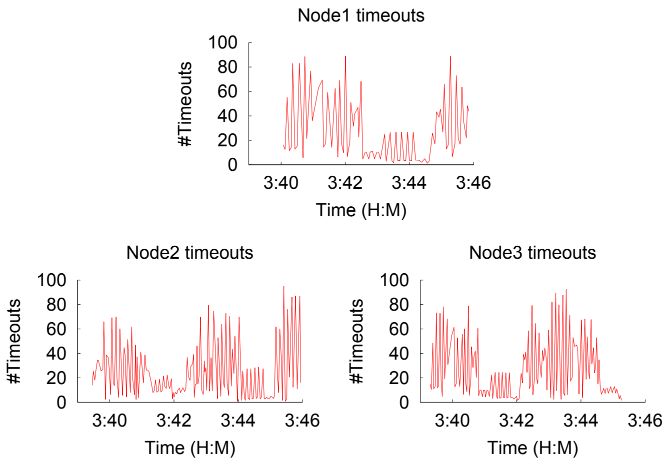

Figure 2: **Timeout fluctuations** (§3.1). *The figures show the number of timeouts observed over time in three samples of degraded nodes (different time period).*

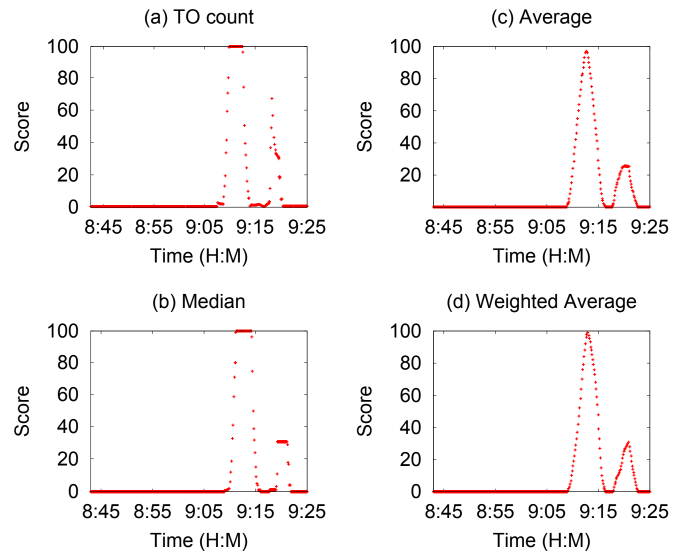

Figure 3: **Unstable scores** (§3.1). *Other attempts to create stable scores using timeout-response ratio as explained in §3.1.*

Figure 3a shows the result. Ideally the score should stay high throughout the degraded period, but instead we see one big spike and one small spike. We then modified the scoring algorithm slightly by using the median of the last 3-minute window:

$$\texttt{score} = \texttt{median}\left(\texttt{ToRespRatio in last 3 mins}\right)$$

The result, as shown in Figure 3b, still shows the same behavior (a dip between the two spikes). We tried replacing the median using average and weighted average and the result is similar (Figures 3c-d).

3.2 Successful Results

The previous section provides the reason we invented our custom outlier detection. Figure 4a shows the resulting scores from our custom algorithm, as detailed in Section 2.2. We can see that the metadata service (Cassandra/MS) instance on the degraded node has high scores assigned to it from 11:30 to 13:15 hours. Note that this is the case where we have not enabled the mitigation procedure, *i.e.*, the customer was experiencing degradation for almost 2 hours!

Correspondingly, to check that the scores are accurate, we checked the standard network performance graphs and we found that there had been a network issue at the exact time interval. Figure 4b shows the TCP SEND_Q size on the network connection between another node with this unhealthy node. Furthermore, Figure 4c shows the ping latencies to the degraded machine.

From these graphs, we can see that bad network performance on the slow machine correlated perfectly with the bad scores assigned to the nodes running on it. As a side note, we can see that the two metrics in Figures 4b-c cannot be used as raw scores as they also fluctuate.

Next, Figure 5 shows what is happening in the ScoreDB server side for a different fail-slow incident. The picture shows the representative scores by instance X measured for its $N-1$ peers on other nodes. For simplicity, the data here is from a cluster of 4 nodes. Figure 5a shows that `Node3` has a high score compared to other peers. But at this point `Node3` has not been marked as a definite outlier because its 30^{th}percentile score is not high yet. However, two minutes later, as shown in Figure 5b, we have sufficient scores for the 30^{th}percentile score to be high. When we plug this score into the DBSCAN algorithm, `Node3` was marked as a definite outlier.

IASO automatically quarantines an outlier to prevent it slowing down the entire cluster. Figure 6 shows another case after we deploy IASO. Here, the figure shows that the cluster-level IOPS drops to almost zero with the presence of one degraded machine, essentially showing how a degraded node can impact the entire cluster, as also shown by other works [24, 56]. Packet losses and the cluster-level degradation started occurring at around 09:15am but just after 10 minutes, IASO's mitigatory actions kicked in and the performance of the cluster was completely restored. Thus, with IASO, the time taken to quarantine a degraded node has now been brought down to the order of *minutes*. Note that the IOPS returns to "normal" although we lost a node, which is because in this scenario the 100K IOPS were far from the maximum throughput of the cluster.

3.3 True and False Positives

Figures 7a and 7b show the number of true and false positives we encountered every month across the 7 months, re-

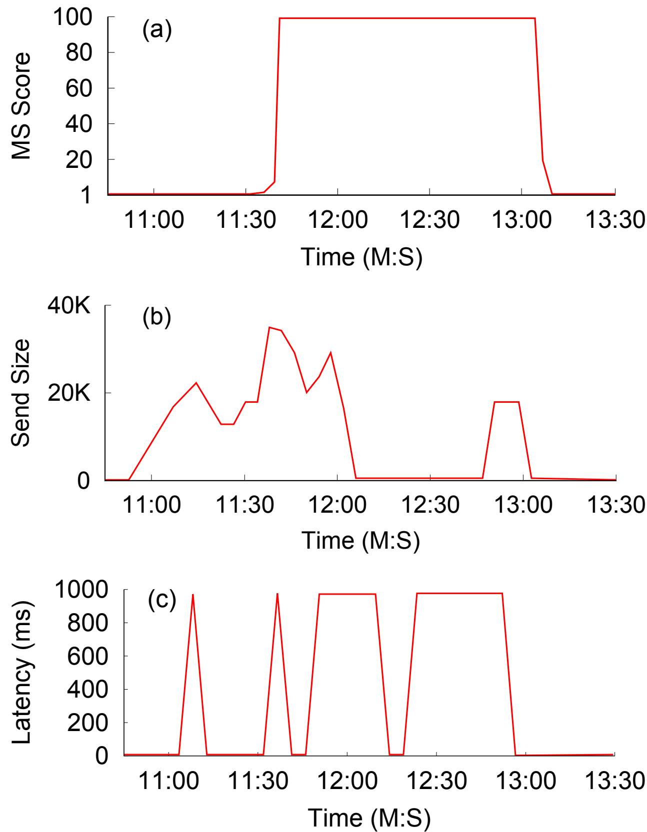

Figure 4: **Stable scores** (§3.2). *The figures show (a) the score of a degraded peer over time, (b) the SEND_Q size of the network connection to the degraded node, and (c) ping latencies to the degraded node monitored by our* `systat` *collector.*

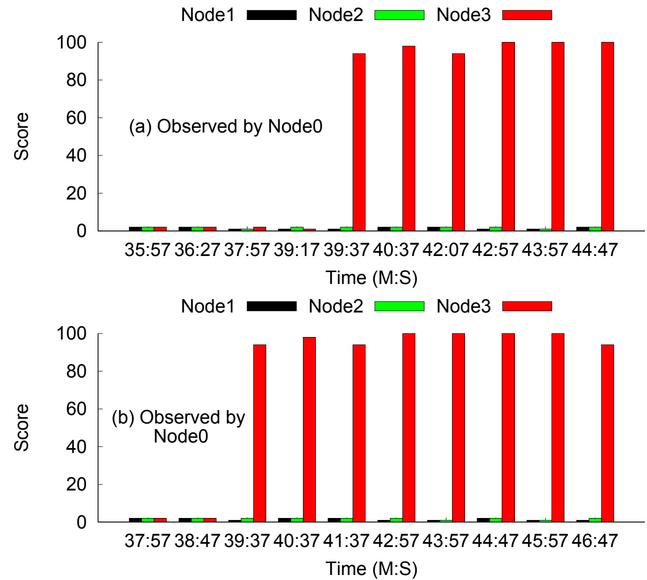

Figure 5: **Mitigation** (§3.2). *The top figure shows that* `Node3`*'s score is high as observed by* `Node0` *however it is not being marked as an outlier yet as its* 30th *percentile score is still low. In the bottom figure,* `Node3` *is marked as a definite outlier.*

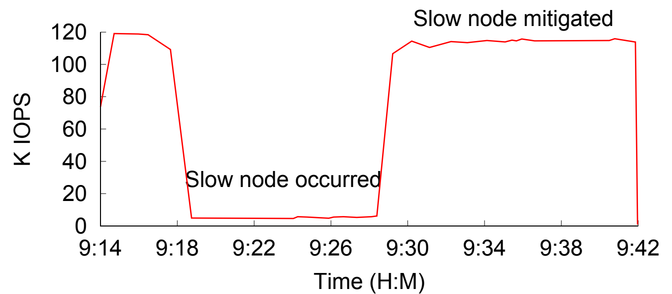

Figure 6: **Restored performance** (§3.2). *Within 10 minutes,* IASO *made the cluster-level IOPS return back to normal after isolating the slow node.*

spectively. For Figure 7b, the figure combines the number of "confirmed" and "probable" false positives as explained below.

Over a 7-month period, we encountered 9 *confirmed* false positives over the 232 true positives (confirmed fail-slow incidents), which brings our false positive rate to 3.7%. One major reason for our false positive is in our earlier versions of IASO where the cluster still sends data to a dead service instance and a healthy instance already becomes affected and "looks" slow as well. Here IASO incorrectly marks the healthy instance as an outlier. Due to space constraints, we put more false positive stories in our anonymized supplemental material [7].

We also encountered 41 *probable* false positives. We label these cases as "probable" because they do *not* necessarily suggest that IASO is imprecise. In these cases, by the time our SREs started debugging, the issue was no longer present and the service instances, VMs, and machines were healthy. Existing works gave some hints on the reasons behind this, for example, fail-slow incidents can be triggered by temporary environmental causes such as high temperature [28].

While we managed to record the false positives, we were not able to collect many false-negative reports (*i.e.*, undetected fail-slow incidents). This is because the reality of a large company and our SREs have their own priorities and might not contact us when they found cases that were not but should have been detected by IASO. The false negatives we were aware of came from two 2 outages that happened after the deployment of IASO, which can be found in our supplemental material [7]. Other false negatives we noticed include low workloads as fail-slow faults with low workloads might not necessarily result in timeouts. We did not fix this problem as almost all our customers heavily utilize their clusters.

From our perspective, we prefer false positives over false negatives as in our system IASO pages site-reliability engineers whenever it detects a fail-slow failure. This gives

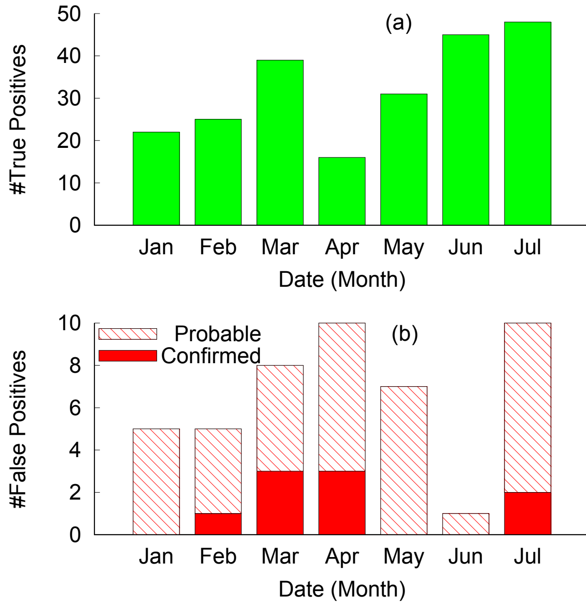

Figure 7: **True and false (confirmed+probable) positives (§3.3).** *The figure shows the number of (a) true and (b) false positives every month. The false positives include the "confirmed" and "probable" false positives as described in §3.3.*

us a way to easily track and investigate such issues and improve our system over time. As for the worst case impact, a false positive can cause a cluster to temporarily operate in a reduced fault tolerance state as IASO's extreme mitigation strategy can bring down a node. However, in case of a false negative, there can be an entire cluster outage which can stay undetected for hours.

4 Fail-Slow Dataset and Analysis

The deployment of IASO allows us to analyze fail-slow incidents in our vast field of clusters, which then enables us to perform new statistical studies. This section first describes our dataset (§4.1) followed with our findings (§4.2).

4.1 Dataset

We first describe our deployment settings. Our field consists of 39,000 nodes spread across many clusters. A cluster size ranges from 3 to 56 nodes. Our various cluster models and configurations (RAM size, storage, etc.) can be found in our supplemental material [7]. A cluster can contain heterogeneous nodes as we support heterogeneous applications and a broken hardware can be replaced with a higher-end one. Each node in a cluster runs a special VM called a controller VM where our data and control path services run. Among these services, Cassandra and Zookeeper run with IASO integration.

Failure	AFR	Notes
SSD error	5-15.7%	$\geq$ one uncorrectable error [53]
SSD failure	1-2%	Dead SSDs [16]
Disk error	1.7-8.6%	$\geq$ one failure event [46, 52]
DRAM error	2.2-9.0%	$\geq$ one memory error [33, 54]
fail-slow	**1.02%**	Node-level fail-slow faults

Table 2: **Fail-slow AFR (§4.2.1).** *Comparisons of annual failure rates of different types of failures*

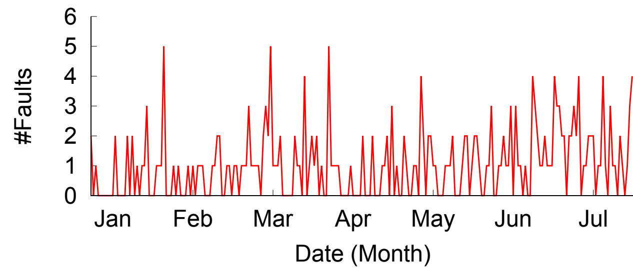

Figure 8: **Fail-slow per day (§4.2.1).** *The figure shows the number of fail-slow incidents per day in our field over 7 months.*

As mentioned before, every time IASO detects a fail-slow fault, it raises an alert that triggers the opening of a *support ticket* to investigate the issue. The support case is investigated by a team of trained site reliability engineers (SREs), who in turn coordinate with the customer and debug the issue. Once the problem is identified, the SREs update the support ticket with a category of the root cause found and the steps to resolve the issue. Other information that is updated as part of the case includes the time of the incident, a cluster identification number, the software version on the customer's cluster, the model family of the node that was affected and the number of months the node has been with the customer at the time of the incident.

With 232 fail-slow related tickets, our dataset can be seen as the largest fail-slow data from within a company. The previous largest dataset was 101 cases from 12 different institutions (more in §5). The next section presents our findings from studying the support tickets. The dataset that we will make public and discuss here comes from a period of seven months in 2017. The dataset for 2018 is still being perused and cleaned, hence not part of this submission.

4.2 Findings

4.2.1 Frequency

With a large dataset, we are able to measure the annual failure rate (AFR) of fail-slow incidents. Given 232 independent cases across 39,000 nodes over 7 months, we can derive that fail-slow AFR is 1.02% (232 $\times$ 12 / 7 / 39,000).

Table 2 compares fail-slow AFR with the rates of other types of failures. As shown, fail-slow fault frequency is rel-

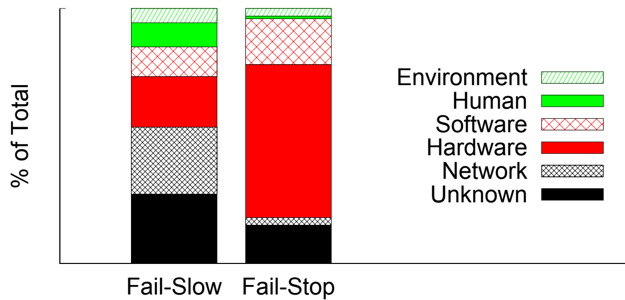

Figure 9: **Fail-slow root causes** (§4.2.2). *The figure shows the breakdown of fail-slow root causes (and the comparison to fail-stop causes).*

atively significant and cannot be ignored. Figure 8 breaks down the number of fail-slow incidents observed per day in our field over the 7 months. We see that barring a couple of days in between, there is at least one failure per day. These statistics accentuate the importance of fail-slow detection and mitigation frameworks such as IASO.

4.2.2 Root Causes

Next, we analyze the root causes of fail-slow incidents. To compare the frequencies of various different root causes of fail-slow incidents with those of fail-stop failures [51], we group the causes into six categories: `Hardware`, `Software`, `Network`, `Environment`, `Human` and `Unknown`. For example, all issues that had a tag of "memory" or "disk" in our support tickets are grouped under `Hardware`.

Figure 9 shows the breakdown of fail-slow root causes (and the comparison to fail-stop causes from a related work [51, Figure 4a]). `Hardware` and `Network` failures turn out to be the highest contributors of fail-slow incidents in our field. Their total is roughly the same as in the fail-stop cases. In the next section, we break down the *sub*-causes to understand more about the root causes.

The `Unknown` count is quite significant because of a couple of reasons. One common reason is when a customer becomes unresponsive during the support case or does not want the issue to be investigated further without providing a clear reason. We believe this can be either because the customer did not notice any issue around the time the fail-slow alert was generated (thereby a false positive) or fixed the issue themselves without our help. The other reason is when the SREs could not find a specific root cause for the issue or did not tag the support case with a clear cause.

4.2.3 Root Sub-Causes

Table 3 shows further the breakdown of the sub-causes within each of the five root categories in the previous section. The numbers in the parentheses are the count of tickets.

Root	Sub-causes
Hardware	Faulty dimm (15), ECC error (10), low memory (9), SATADOM (5), CRC error (1), RAID controller (1), LSI controller (1), unknown (5)
Software	Software upgrade (8), VM issue (6), GC (3), BIOS (1), scheduler (1), unknown (6)
Network	Faulty device (13), network outage (9), device replace(7), unreachability (6), packet drop (5), network contention (2), device reboot (1), unknown (18)
Environment	Incorrect setting (11), high load (1), energy issue (1)
Human error	Misconf (10), network migration (4), install /deploy (3), unplugged cable (2), unknown (4)

Table 3: **Root *sub*-causes** (§4.2.3). *The table shows the sub-causes within each of the five categories of known root causes. The dataset will be released publicly.*

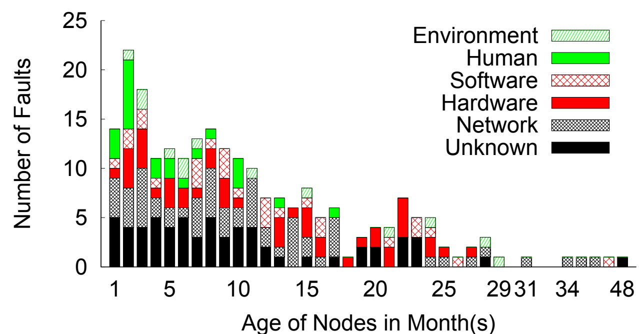

Figure 10: **Fail-slow vs. age** (§4.2.4). *The figure correlates fail-slow incidents with machine ages.*

For example, for hardware-induced slowdown, it can be because of faulty dimm, ECC/CRC errors, low memory, etc., while network-induced slowdown can be because of faulty NICs/switches, bad cables, packet drops, and network contention.

Our goal here is to show that fail-slow root causes *vary widely*. We believe this is a strong motivation why fail-slow detection and mitigation should be also deployed at the service level (not just low-level hardware level). Our findings are also consistent with those reported in a recent paper [28]; we observed in our field how fault conversions take place and how different failure types such as fail-stop (*e.g.*, disk/SSD failure), fail-transient (*e.g.*, GC), and fail-partial (ECC errors) can transform into fail-slow failures at the service level [28, §3.2].

4.2.4 Age and Model

As our ticketing system automatically collects machine age data, we are able to correlate fail-slow failures with machine ages, as shown in Figure 10, bucketed into months ranging

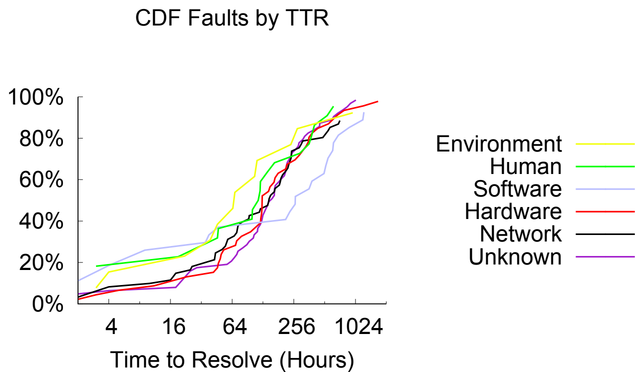

Figure 11: **Tickets TTR (§4.2.5).** *The figure shows the CDF of time to resolve tickets across different root-cause categories.*

	Net	Unk	HW	SW	Human	Env
Median	79	145	126	234	108	65
Mean	149	220	244	323	165	149
Max	721	1033	1705	1238	625	964

Table 4: **TTR tickets (§4.2.5).** *The table shows the median, mean, and maximum values of the data in Figure 11.*

from 1 to 48. We can see the "infant mortality" trend where younger machines exhibit more issues, but older (perhaps more stable) machines exhibit fewer issues. This follows the same failure trend in fail-stop failures [51, Figure 4]. This also supports a continuous paradigm where when the rate of fail-stop errors drops so does the fail-slow ones.

We also attempted to correlate fail-slow failures with the node model family and found no significant correlation, that every node model family suffers from faults across a majority of component types (see [7] for more).

4.2.5 Tickets TTR

Finally, Figure 11 shows the distribution of time to resolve the tickets (in hours) across different root causes. Table 4 shows the median, mean, and max values of the data in Figure 11. We emphasize that this metric does *not* represent the time for IASO to mitigate the issues (which is in the order of 10 minutes), but rather how long it takes to close a ticket. When a ticket is closed, the customer's cluster is guaranteed to be back fully healthy.

The reason we show this data is to point out that a fail-slow root cause can take *days* to be fully resolved. This is consistent with anecdotal experiences shared by large-scale operators from various institutions [28, §3.5]). Hence, it is important to quickly quarantine the fail-slow component before the performance problem cascades to the entire cluster.

Table 5: **Related work (IASO).** *The table categorizes works that relate to fail-slow detection, diagnosis, and mitigation across hardware-, software-, and service levels.*

5 Related Work

We now discuss related work beyond the papers that we already cited earlier. In particular, we break the discussion here to two categories: (1) works related to fail-slow detection and mitigation systems and (2) publications that release information about fail-slow incidents.

Table 5 shows that there are many tools, frameworks, and approaches that have been introduced or deployed for different levels of the hardware, software, and service stack. First, there are many *bug-finding* tools such as MacePC [38], PCatch [40], and Orca [15], but they are offline approaches. Second, there are online fail-slow *detection* tools across the hardware/software stack. For example, SMART [4] is a monitoring tool that can be used to detect hardware degradation but does not include diagnosis capability. Third, Pip [48], PivotTracing [41] and many others provide *diagnosis* approaches that work at the service level (not just one particular software) but they do not make quarantine decisions. Finally, IASO is in a category that performs detection and automated *mitigation*. In this space, we are not aware of many published works. The limitation of IASO is that it does not come with diagnosis tools. Thus, the diagnosis approaches in the 3rd row of Table 5 are orthogonal to our work.

Table 6 shows publications that release datasets on performance problems. The table shows the year span (Yr), number of fail-slow failures/bugs reported ($\#F$), deployment size/number of nodes ($\#N$), the number of systems/services the data is collected from ($\#S$) and the scope of the root-cause analysis (A). The top part of the table represents incidents that appear in live deployments while the bottom of the

Table 6: **Related work (fail-slow dataset).** *For each related work, the columns show the year span (Yr), number of fail-slow failures/bugs reported ($\#F$), deployment size/number of nodes ($\#N$), the number of systems/services the data is collected from ($\#S$) and the scope of the root-cause analysis (A). In the last column (analysis), "h" represents hardware, "s" software, "n" network, "e" environment, and "m" human. Papers with "s"-only label implies bug-study papers.*

paper represents works that study/test software bugs. In the former category, our dataset can be considered as the largest dataset of fail-slow cases publicly reported from within a company. Our work strongly supplements existing anecdotes that fail-slow faults at all levels, hardware and software, have to be addressed.

6 Conclusion

We have described our successful 1.5-year deployment of IASO. We found fail-slow detection and automated mitigation schemes are crucial in preventing fail-slow induced outages in our large deployment field. We would like to emphasize again that automatic fail-slow mitigation/quarantine schemes (beyond detection only) are relatively a new area of research. We hope our paper can provide insights to the development of better frameworks in the future.

As future work, we look forward to building a more aggressive algorithm that can quarantine a slow node shorter than our current 10-minute interval (and do so with low false positives) as well as automatically marking fail-slow faults that are resolved by themselves without depending on our customers or SREs (more in [7]). Furthermore, as we continue to collect peer scores reported in the field, we hope to learn more detailed characteristics.

7 Acknowledgments

We thank Ric Wheeler, our shepherd, and the anonymous reviewers for their tremendous feedback and comments. We also would like to thank Roger Liao and Anshul Purohit for their significant contributions during the development of IASO. We learnt a lot from the actual customer cases where IASO was effective and also from a few scenarios where we hit false positives. Thanks to Rob Savino and Mark Czarnecki for their effort to make this information available to us and help us with quite some root cause analysis. University of Chicago authors were supported by funding from NSF grant No. CNS-1350499.

PARTISAN: Scaling the Distributed Actor Runtime

Christopher S. Meiklejohn, Heather Miller
Carnegie Mellon University

Peter Alvaro
UC Santa Cruz

Abstract

We present the design of an alternative runtime system for improved scalability and reduced latency in actor applications called PARTISAN. PARTISAN provides higher scalability by allowing the application developer to specify the network overlay used at runtime without changing application semantics, thereby specializing the network communication patterns to the application. PARTISAN reduces message latency through a combination of three predominately automatic optimizations: *parallelism*, *named channels*, and *affinitized* scheduling. We implement a prototype of PARTISAN in Erlang and demonstrate that PARTISAN achieves up to an order of magnitude increase in the number of nodes the system can scale to through runtime overlay selection, up to a 38.07x increase in throughput, and up to a 13.5x reduction in latency over Distributed Erlang.

1 Introduction

Building distributed applications remains a difficult task for application developers today due to the challenges of concurrency, state management, and parallelism. One promising approach to building these types of applications is by using distributed actors; the actor-based programming paradigm is one where actors can live on different nodes and communicate transparently to actors running on other nodes. Actor-based programming is well suited to the challenges of distributed systems; actors encapsulate state, allowing controlled, serial access for state manipulation. A single machine can typically run hundreds of thousands of actors, allowing efficient use of resources per machine and thereby enabling high-scalability and high-concurrency by elastically scaling the number of machines in a cluster. Taken together with the fact that actors communicate through unidirectional asynchronous message passing with no shared memory between them, the actor-based programming paradigm is well suited to the nature of distributed systems. In addition to providing developers of distributed systems with a convenient programming model, distributed actor systems can also be efficiently implemented, which has resulted in significant adoption and large-scale success in many areas of industry.

There exist three primary industrial-grade distributed actor systems; Distributed Erlang [31], Akka [21] (for Scala) and Microsoft's Orleans [8, 10] (for C#). Distributed Erlang has been used as the underlying infrastructure for message brokers [2, 25], distributed databases [4, 6, 18], and has provided infrastructure for the chat functionality for applications like *WhatsApp*, *Call of Duty*, and *League of Legends*. [14, 15, 27] Similarly, Akka has been used by Netflix for the management of time series data [23], and Microsoft's Orleans has been used as the underlying infrastructure for Microsoft's popular online multiplayer games, *Halo* and *Gears of War* for the Xbox [24]. In all of these cases, these applications have benefited from both the state encapsulation and pervasive concurrency that actors provide and the fault isolation of actors by reducing the use of shared memory. However, these distributed actor systems are still limited in terms of both *scalability* and *latency*.

Scalability. Compared to other distributed frameworks which can support hundreds to thousands of nodes, these production-grade distributed actor systems are still limited in the number of nodes that they can support. Distributed Erlang, for instance, has not been operated on clusters larger than 200 nodes [1], whereas one of the more popular applications built on Distributed Erlang, the distributed database Riak, has been demonstrated to not scale beyond 60 nodes [15]. As we will later show, this limited scalability is related to the rigidity of the overlay network—the communication pattern between the nodes in the application—used in the runtime system. This rigidity has been the subject of previous research on alternative designs to improve the scalability of the system [11], and efforts to find a "one-size-fits-all" overlay, which can equally serve all types of distributed applications, have not been successful [28]. Thus, especially in the context of Distributed Erlang, scalability is still a major challenge.

Latency. Due to their underlying model of computation—unidirectional asynchronous message passing between ac-

tors with independent queues that are multiplexed onto a single queue between nodes—distributed actor systems frequently suffer from the problem of head-of-line blocking. For example, the distributed database Riak avoids using Distributed Erlang for background data synchronization (e.g., hinted and ownership handoff) to avoid head-of-line blocking in the read/write request path. While alleviating head-of-line blocking has been the subject of much research [12, 30] and remains a relevant problem in today's large-scale systems [9], the general solution of introducing more queues and partitioning communication across those queues does not necessarily yield better performance without a priori knowledge of the application's workload.

Application-specific information exists that can be used to reduce the effects of head-of-line blocking. Given (i) the knowledge of the identities of the actors that are sending messages, (ii) the identities of the recipients, and (iii) the knowledge that actors will process their messages sequentially, this application-specific information can be provided in the form of a small number of lightweight annotations to the runtime. These annotations can help the runtime to separate network traffic over specialized channels (e.g., cluster maintenance, high-priority application behavior, failure detection), in turn leading to the reduction of head-of-line blocking in an application-specific manner.

In this paper, we present the design of an alternative runtime system for improving the scalability and performance of distributed actor systems, along with an implementation of this runtime called PARTISAN. PARTISAN enables greater scalability by allowing the application developer to specialize the overlay network to the communication pattern required by the application at runtime without altering application semantics. PARTISAN facilities lower latency by providing the application developer with three ways to customize messaging behavior, without altering application semantics or requiring changes to application code. PARTISAN enables the application developer to (i) customize *parallelism* (for increasing the number of communication channels between nodes), (ii) utilize *named channels* (for separating different types of messages sent between actors), and (iii) *affinitize* scheduling (for partitioning traffic across communication channels depending on message source, destination and type).

We implement PARTISAN using Erlang without requiring changes to the Erlang VM, in an effort to make these scalability and latency benefits immediately available to production Erlang applications with minimal changes to application code. We provide a detailed experimental evaluation which, beyond microbenchmarks, includes a port of an existing widely-deployed Erlang distributed computing framework to take advantage of PARTISAN's optimizations. In our evaluation, we demonstrate that the use of each of these optimizations independently results in latency reduction, but the combination of these techniques yields significant reductions in latency.

The contributions of this paper are the following:

- We present the design of the PARTISAN runtime system that enables the runtime selection of overlay, enabling greater scalability by specializing the overlay to the application's communication patterns (Sections 3 & 5);
- We present a collection of predominantly automatic optimizations for latency reduction, realized in PARTISAN, that enable more efficient scheduling of messages on the network, specifically by exploiting (i) *parallelism*, (ii) *named channels*, and (iii) *affinitized* scheduling (Sections 4 & 5);
- We provide an open source implementation of PARTISAN that supports the runtime selection of overlay with implementations of four different overlay networks (Section 5);
- We port an existing widely-deployed open source distributed computing framework, Riak Core, from Distributed Erlang to PARTISAN, and provide an analysis of the process (Section 6);
- We present a detailed empirical evaluation of PARTISAN on (i) microbenchmarks, (ii) an industrial-grade actor-based distributed programming framework (Riak Core), and (iii) a research framework for distributed programming over replicated shared state (Lasp). We go on to show that PARTISAN demonstrates greater scalability (in some experiments, an order of magnitude increase in the number of nodes the system can scale to) through runtime overlay selection and lower latency (in some experiments, up to a 38.07x increase in throughput, and a 13.5x reduction in latency) through latency reduction optimizations (Section 6).

2 Background: Distributed Actors

Actors provide a simple programming model for building highly concurrent applications. Programming with actors involves two primary concepts: actors: lightweight processes that act sequentially, respond to messages from other actors, and sent messages to other actors; and asynchronous message passing: unidirectional, asynchronous messages that are sent between actors. Applications built using the actor model typically achieve their task through the cooperation of many actors sending messages to one another. No state is shared between actors: the only way for data to be shared between actors is through message passing[1]. Actors are designed to be extremely lightweight and typically implementations allow for ten to hundreds of thousands of actors per machine. As no data is shared, and actors are relatively independent with loose coupling to other actors – strictly through message passing – if a particular actor happens to fail, the fault remains isolated to that actor. Actors are not static: actors are allowed to "spawn" other actors as the system is running.

[1] Pony is a unique exception here, which uses a capability system to know when it is safe to share memory. However, this is an implementation detail as the programming model remains that of message passing.

Actors are a popular mechanism for building highly concurrent applications as they allow both users and user actions to be modeled as actors themselves. For instance, in the aforementioned *Halo* and *Call of Duty* examples, actors are use for modeling the presence service for the online functionality of the game. Therefore, a single actor, dynamically created, is used to model a connection to the service for a single user. In the Riak distributed database, an actor is spawned for every single read or write request made to the database. As the number of actors can range several orders of magnitude higher than the parallel computing capacity of a single machine, preemptive (e.g., Erlang) or cooperative scheduling (e.g., Orleans) is used for actor scheduling within the runtime.

Distributed actor systems extend the actor functionality from a single machine to a cluster of machines. Distribution adds a number of complexities to the model: (i) *failure detection*: actors may be unavailable under network partitions or crash failures of remote machines; (ii) *message omission*: messages are no longer guaranteed to arrive at a destination due to failure; (iii) *membership*: or what nodes are currently members of the cluster and how the membership overlay is organized; (iv) *binding*: the location of actors may not be known at runtime when actors are dynamically created; (v) *contention*: contention for access to network resources may slow down actors; (vi) *congestion*: and the varying location of actors results in non-uniform latency with inter-actor messaging when actors are located on different machines.

2.1 Framework Commonalities

These concerns are addressed by the contemporary industrial distributed actor systems through various mechanisms. Each of these mechanisms introduces additional network overhead that the application developer may not be aware of, contributing to reduced scalability and higher latencies.

Failure detection. Actors may become unreachable due to crash failures or network partitions. To detect failures, nodes typically send heartbeat messages to the other nodes in the cluster. When a node is suspected as failed, it's assumed that the actors that were running on that node failed.

Message omission. Distributed actor systems try to address the problem of message omission by using TCP. With a single connection, TCP ensures FIFO ordering of messages between pairs of actors and best-effort delivery using retransmission based on sequence numbers and acknowledgements.

However, as failure detection is imperfect and nodes may be disconnected and reconnected under network partitions or crash failures, message delivery is not guaranteed by the runtime system. Therefore, distributed actor systems typically require the user to program as if message omission is always a possibility. Put more generally, TCP connections are session-oriented and in these frameworks delivery guarantees do not hold across sessions.

Membership. Membership determines which nodes are part of the cluster and are available for hosting actors. Failure detection is combined with membership to determine who the active members of the cluster are at any given moment.

Binding. When sending a message from one actor to another, the location of that actor may or may not be known at a given time. Most of these systems encode a node identifier into the process identifier, or leverage a replicated, global process registry, for determining the location of an actor by a registered name instead of a process identifier.

2.2 Challenges

The problems of both network contention and network congestion remain challenges for distributed actor systems.

Network contention. All of the aforementioned actor systems support inter-machine communication through the use of a single TCP connection, therefore multiplexing actor-to-actor communication on a single channel. Not only does actor-to-actor communication (data) use this channel, but background communication from the membership and failure detection systems (control) also contribute to congestion on this link. Taken together with CPU-intensive activities that may block access to the socket (message serialization/deserialization, for example) and non-uniform distribution of message load (slow-senders vs. fast-senders), the possibility for contention increases, which in turn increases latency and reduces throughput of the system. This is further exacerbated by certain overlays; for example, the full-mesh overlay must perform failure detection from all nodes to all other nodes.

Network congestion. Network congestion, in the form of latency or congestion control, may further impact performance. Under situations where the frequency of message sends exceeds what can be transmitted over the network, causing queueing delays on these multiplexed connections between nodes, other senders on the same node may be penalized and forced to wait for other senders to transmit.

3 Overlay Networks

To address the problems that arise from a fixed overlay, PARTISAN supports the selection of overlay at runtime. PARTISAN's API exposes an overlay agnostic programming model – only asynchronous messaging and cluster membership operations – that easily allows programmers to build applications that can operate over any of the supported overlays. Selection of the overlay at runtime only affects the performance of the application, and does not change the application semantics. Selection of the overlay is done with a configuration parameter specified at runtime; therefore, changing the overlay does not require recompilation and the selection is fixed for the lifetime of the application.

PARTISAN supports four overlays and exposes an API for developers to extend the system with their own overlays: *static*, *full-mesh*, *client-server*, and *peer-to-peer*.

3.1 Static, Full-mesh, Client-server Overlays

The static, full-mesh, and client-server overlays are similar. Each overlay uses a single connection for communication between each node in the cluster. Failure detection is performed by monitoring this connection; when this connections is dropped, the node is reported as down.

With the static overlay, membership is fixed at runtime whereas with the full-mesh overlay, membership is dynamic and can be altered while the system is running. With the client-server overlay, connections are only maintained between servers and from servers to clients, similar to a traditional hub-and-spoke topology.

3.2 Peer-to-peer Overlay

The peer-to-peer overlay builds upon the HyParView [20] membership protocol and the Plumtree [19] broadcast protocol, both of which use a two-phase approach to pair an efficient dissemination protocol with a resilient repair protocol used to ensure operation during network partitions.

HyParView. HyParView is an algorithm that provides a resilient membership protocol by using partial views to provide global system connectivity in a scalable way. Using partial views ensures scalability; however, since each node only sees part of the system, it is possible that node failures break connectivity. To overcome this, HyParView uses two different partial views that are maintained with different strategies.

Plumtree. Plumtree is an algorithm that provides reliable broadcast by combining a deterministic tree-based broadcast protocol with a gossip protocol. The tree-based protocol constructs and uses a spanning tree to achieve efficient broadcast. However, it is not resilient to node failures. The gossip protocol is able to repair the tree when node failures occur.

Semantics. However, with partial views, nodes may want to message other nodes that are not directly connected. To maintain the existing semantics of existing actor systems, PARTISAN needs to support messaging between any two nodes in a cluster. To achieve this, PARTISAN's peer-to-peer membership backend uses an instance of the Plumtree protocol to compute a spanning tree rooted at each node. When sending to a node that is not directly connected, the spanning tree is used to forward the message down the leaves of the tree in a best-effort method for delivering the message to the desired node. This is similar to the approach taken by Cimbiosys [26] to prevent livelocks in their anti-entropy system.

4 Latency Reduction

In Section 2, we discussed a number of features of distributed actor systems that operate in the background to maintain cluster operation. These included *binding*, *membership*, and *failure detection*. Each of these features of actor systems can be expensive in terms of network traffic and contributes to increasing the overall message latency by delaying application-specific messaging behind cluster maintenance messaging. In addition to background traffic, it's also possible that one type of application-specific messaging may also delay different types of application-specific messaging, as in the case where a slow sender is arbitrarily delayed behind a fast sender. These are all specific cases of head-of-line blocking.

To alleviate these issues, we provide the application developer with three ways to customize messaging behavior in a distributed actor system; by (i) customizing *parallelism*, (ii) utilizing *named channels*, and (iii) *affinitized* scheduling.

4.1 Parallelism

To reduce the effects of head-of-line blocking with a single message queue, additional message queues can be introduced in an attempt to parallelize as much work as possible. We refer to this mechanism as *parallelism*. With little input from the application developer—only a specification of the number of queues to operate at each node for each destination node—the system can either use random or round-robin scheduling to assign work to queues. In most cases, the system can optimally choose this parameter based on available system resources.

4.2 Named Channels

While parallelism serves to increase the amount of work performed in parallel, background messages may be queued in front of application-specific messages, resulting in diminishing returns if this is the only technique used to reduce latency.

If we further classify these message queues as either queues for background messaging or application-specific messaging, we can be more intelligent in our scheduling. This can be achieved using *named channels*, and it is similar to Quality-of-Service (QoS) present in many modern networking systems. This mechanism only requires the application developer to annotate what type of message is being sent, and dedicated queues based on type are used for scheduling these messages. This mechanism allows the system to automatically place background messaging on a queue where it will not interfere with application-specific messaging.

4.3 Affinity

While named channels prevent background messaging from directly interfering with application-specific messaging, application-specific messaging may still suffer from interference between actors that send at different rates.

Under the assumption that multiple outgoing queues are available (parallelism), random or round-robin scheduling may still produce schedules that lead of head-of-line blocking issues. With the knowledge that actors have (i) a distinct identity (unique references which point to each actor and which can itself be exchanged), (ii) and act sequentially, we can further refine our message scheduling algorithm by selecting an outgoing message queue based on the sending actor's identity.

Feature	API	Analogous Call (Erlang)
Join node to cluster	`join(Node)`	`net_kernel:connect_node(Node)`
Remove self from the cluster	`leave()`	`net_kernel:stop()`
Return locally known peers	`members()`	`nodes()`
Forward message to registered name	`forward(Node, Name, Msg, Opts)`	`erlang:send({Name, Node}, Msg)`
Forward message to process id	`forward(Pid, Msg, Opts)`	`erlang:send(Pid, Msg)`

Table 1: PARTISAN's API

```
call(Dst, Msg, Timeout) ->
  Dst ! Msg,

  receive
    Response ->
      Response
  after
    Timeout ->
      {error, timeout}
    end
end.
```

(a) Distributed Erlang

```
call(Dst, Msg, Timeout) ->
  partisan_pluggable_peer_service_manager:forward(Dst, Msg, []),

  receive
    Response ->
      Response
  after
    Timeout ->
      {error, timeout}
    end
end.
```

(b) PARTISAN

Listing 1: Sending messages using Distributed Erlang and PARTISAN. PARTISAN's API is designed to be a drop-in replacement for Distributed Erlang.

```
%% Use `N' to partition with affinitized scheduling.
partisan_pluggable_peer_service_manager:forward(
    Dst, Msg, [ {partition_key, N} ])

%% Use `Channel' to partition by channel.
partisan_pluggable_peer_service_manager:forward(
    Dst, Msg, [ {channel, Channel} ])
```

Listing 2: Sending messages using PARTISAN. PARTISAN's API allows both affinitized scheduling and channels to be specified for a single message send.

This scheduling technique is known as *affinitized* scheduling and results in a further reduction in latency for network intensive processes by avoiding interference between different actors that send messages at different rates—for example, two actors on the same node sending at different rates to the same remote actor can be scheduled on different queues.

The application developer can take advantage of affinitized scheduling either by enabling affinitized scheduling for all messages, where a partition key is automatically derived by the system, or by annotating individual message sends with a partition key. This partition key is then concatenated with the identity of the recipient and, using a hash function, is used to select the appropriate queue. By hashing both the sender and the recipient together, the system will attempt to collocate pairwise communication between the same two actors together, providing best-effort FIFO when the system is not operating under failure.

5 PARTISAN

PARTISAN is a runtime system that enables greater scalability and reduced latency for distributed actor applications. PARTISAN improves scalability by allowing the application developer to specialize the overlay network to the application's communication patterns. PARTISAN achieves lower latency by leveraging several predominately automatic optimizations that result in the efficient scheduling of messages. PARTISAN is the first distributed actor system to expose this level of control to the application developer, improving the performance of existing actor application and enabling new types of actor applications.

5.1 Design

All three industrial-grade actor systems follow the same underlying assumptions that define the actor model. The design of PARTISAN is therefore based upon a lowest-common-denominator view of distributed actor systems. In all cases:

- actors will act sequentially, sending and receiving unidirectional, asynchronous messages;
- actors can be located on any node on the network, known only at runtime, and the system will be able to locate, though a system specific mechanism, on which machine an actor is located;
- message delivery is not guaranteed and node failures will be detected eventually.

PARTISAN follows this lowest-common-denominator view of distributed actor systems for the sake of portability of these

ideas; the same principles behind our work can be applied to realizations of PARTISAN for the other industrial-grade actor systems, such as Akka and Orleans. Applying these ideas to Akka would be straightforward, given the programming model is directly inspired by Erlang. Orleans has a slightly different programming model involving remote method invocations, but the underlying execution model is composed of unidirectional, asynchronous message sends and receives, the same as the Erlang programming model (and, extremely similar to Erlang's included RPC abstraction.)

Based on this view of actor systems, PARTISAN adds (i) the runtime selection of overlay network, and (ii) a collection of predominantly automatic latency reduction optimizations.

Latency Reduction Optimizations. PARTISAN applies the above three optimizations, *parallelism*, *named channels*, and *affinitized* scheduling (Section 4) to this lowest-common-denominator view of actor systems to achieve sometimes significant latency reduction (demonstrated in Section 6).

While some of these ideas for latency reduction have been explored in the context of networking, these optimizations are not exposed to the developer in distributed actor systems–this work is the first to do so, to the best of our knowledge.

In order to enable the application developer to directly take advantage of these optimizations when it makes sense for their application, application developers only need to specify the number of outgoing message queues (parallelism) and the types of messages that are being sent (named channels); affinitized scheduling is automatically performed by the runtime.

5.2 API

PARTISAN is designed to be a drop in replacement for Distributed Erlang, with each API command in PARTISAN providing a 1-to-1 correspondence with Distributed Erlang. The API of PARTISAN, and its corresponding calls in Distributed Erlang, is provided in Table 1 and an example of the transformation of a program from using Distributed Erlang to PARTISAN is provided in Listing 1. Performing this 1-to-1 transformation converts a Distributed Erlang application to use PARTISAN with optimizations disabled.

Like all distributed actor systems, PARTISAN's API provides both membership operations, that are used for joining/removing nodes from the cluster, and messaging operations, that are used for asynchronously sending messages. PARTISAN's programming model is both overlay-agnostic and asynchronous. Therefore, all operations return immediately and have overlay-specific behavior.

5.3 Implementation

PARTISAN is implemented as a library for Erlang and requires no modifications to the Erlang VM. This was in an effort to make PARTISAN's scalability and latency benefits immediately available to production Erlang applications with minimal changes to application code. PARTISAN is implemented in 6.7 KLOC and is available as an open source project on GitHub. This implementation of PARTISAN has several industry adopters and a growing community.

```
{partisan, [%% Enable affinity scheduling for all messages.
            {affinity, enabled},

            %% Enable parallel connections.
            {parallel, enabled},

            %% Optional: override default.
            {parallel_connections, 16},

            %% Specify available channels.
            {channels, [vnode, gossip, broadcast]},

            %% Selection of overlay.
            {membership_strategy,
             partisan_full_mesh_membership_strategy}]}.
```

Listing 3: Riak Core configuration for PARTISAN using options in Table 2 for experiments run in Section 6.2.

5.4 Configuration

Configuration options to select overlay, enable parallelism, and specify named channels are outlined in Table 2. Listing 3 demonstrates a configuration used in our Riak Core evaluation which enables parallelism, named channels, and affinitized scheduling for all messages. Users can choose to annotate message sends with a channel for targeted use of named channels and affinitized scheduling can be enabled for all messages or for an individual message; these options are demonstrated in Listing 2.

If the number of parallel connections is not specified by the user, the system will default to a reasonable value for this parameter based on the number of Erlang schedulers available. Under a default configuration of the Erlang VM, a single scheduler maps to a single vCPU. This default configuration and heuristic is discussed in detail in our experimental evaluation. (Section 6.1).

5.5 Bring Your Own Overlay

PARTISAN exposes an API for users to implement their own overlays; application developers must simply implement the `membership_strategy` interface for handling messages. PARTISAN automatically uses this membership strategy for processing incoming and outgoing messages to the system – the application developer only needs to handle internal state transitions and supplying the system with an updated list of members. PARTISAN automatically sets up required connections, serializes and deserializes messages, performs failure detection, and message forwarding. This makes it possible to implement protocols with very little code; our implementation of the full-mesh membership protocol is 152 LOC.

6 Experimental Evaluation

To evaluate PARTISAN, we designed a set of experiments to answer the following questions:

Feature	Configuration Option
Enable parallelism with default number of connections	`{parallel, enabled}`
Specify number of *N* connections to each peer	`{parallel_connections, N}`
Open *N* parallel connections for each of the named channels	`{channels, [Channel1, Channel2]}`
Enable affinitized scheduling for all messages	`{affinity, enabled}`
Specification of overlay	`{membership_strategy, MembershipStrategy}`

Table 2: PARTISAN's configuration options

- **RQ1:** What are the benefits of affinitizing actor messaging across a number of parallel TCP connections?
- **RQ2:** Can these optimizations be used on real-world applications to achieve reduction in message latencies?
- **RQ3:** Does the selection of the overlay at runtime provide better scaling properties for the application?

We begin with a set of microbenchmarks (Section 6.1), where we seek to examine the benefits of affinitizing actor communication across a number of parallel connections. We demonstrate that PARTISAN's optimizations can provide reductions in latency for workloads containing large objects, or when deployed in high latency scenarios.

Next, we examine the applicability of these optimizations on real-world applications (Section 6.2). Using a real-world distributed programming framework with an example key-value store, we show a significant reduction in latency under both high latency scenarios (datacenter-to-datacenter communication) and large object workloads through the use of a combination of optimizations: *parallelism*, *named channels*, and *affinitized* scheduling.

Finally, we explore the selection of the overlay on scaling to larger clusters (Section 6.3). We demonstrate that we can scale to order-of-magnitude larger clusters while maintaining the same application semantics by specializing the overlay at runtime to the application.

6.1 Microbenchmarks

To evaluate the optimizations in PARTISAN around latency reduction (**RQ1**), we set out to answer the following questions: (i) what is the effect of affinitizing actors; (ii) how does one know how many parallel connections to use when affinitizing actors; (iii) does affinitized parallelism benefit workloads in high latency scenarios; and (iv) does affinitized parallelism benefit workloads with large object sizes? We present a set of microbenchmarks that address each of these questions.

Experimental Setup. For the microbenchmarks, we used a single Linux virtual machine with 16 vCPUs with 64 GB of memory. On this machine, we ran two instances of the Erlang VM that communicate with one another using TCP with either a simulated RTT latency of 1ms (RTT within a single AWS availability zone) or 20ms (RTT between two availability zones in the same AWS region.) A single Linux VM is used for hosting both instances of the Erlang VM to ensure no interference from the external network and to guarantee a fixed latency during the duration of the experiment. This virtual machine is purposely kept underloaded, as to not see the effects of resource contention inside the Linux VM on latency. Each Erlang VM is configured to run 16 schedulers with kernel polling enabled.

Each of the microbenchmarks runs multiple configurations of PARTISAN under both increasing latency and payload size, with a fixed number of $10,000$ messages per actor, per experiment. We consider PARTISAN with parallelism disabled, PARTISAN with parallelism, and PARTISAN with affinitized parallelism. We do not consider named channels in the microbenchmarks, as named channels and affinitized parallelism serve the same function: partitioning communication across a number of TCP connections either automatically or by using a user-specified partitioning key.

At the start of each experiment, *N* actors are spawned on each of two instances of the Erlang VM (unless otherwise specified, as in Figure 2), based on the desired concurrency level. Each actor will send a single message to an actor on the other node and wait for acknowledgement before proceeding. Experiments were run using the *full-mesh* overlay, but the optimizations are implemented for all overlays. Latency is reported as the time to send a single message from the source to the destination.

Results. We start by showing a baseline configuration of Distributed Erlang compared with PARTISAN in Figure 1. Our results show that leveraging additional connections and affinitizing communication increases performance regardless of concurrency. With 128 actors, 512KB payload, and 1ms RTT, PARTISAN with affinitized parallelism performs 1.69x better than Distributed Erlang. Considering parallelism, but without affinity, yields a 1.90x performance improvement. With a uniform workload and without the network as a bottleneck, affinitized scheduling yields a performance benefit over Distributed Erlang, but introduces a slight performance penalty when compared to purely random scheduling.

In Figure 1, the number of parallel connections is specified as 16; however, picking this number is not necessarily trivial! Figure 2 shows the effects on outliers based on the number of connections the system needs to maintain to its peers. Here, we demonstrate that 16 connections is a good choice for connections (and, the number selected as our best case in all experiments.) But why 16? 16 is selected using the heuristic that each Erlang VM is running 16 schedulers, one mapped

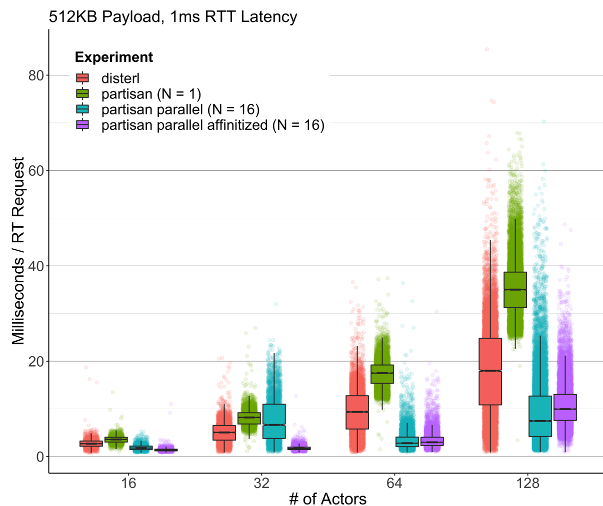

Figure 1: Performance of Distributed Erlang and PARTISAN broken out by optimization.

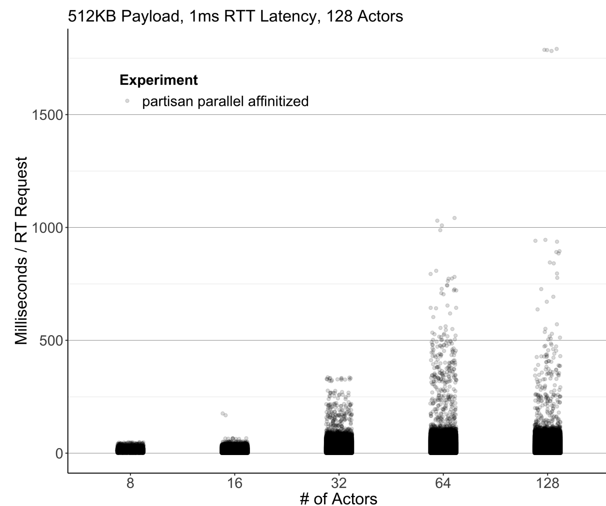

Figure 2: Effects of scaling connections with the number of actors on outliers.

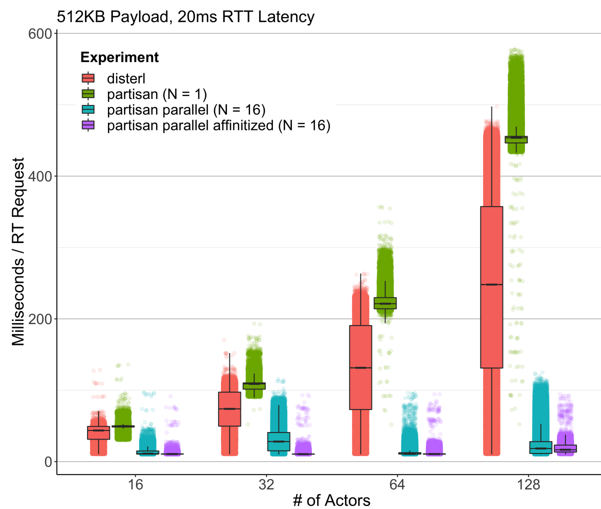

Figure 3: Performance of Distributed Erlang and PARTISAN broken out by optimization under a high latency workload: round trip time between actors is set at 20ms, object size is set at 512KB.

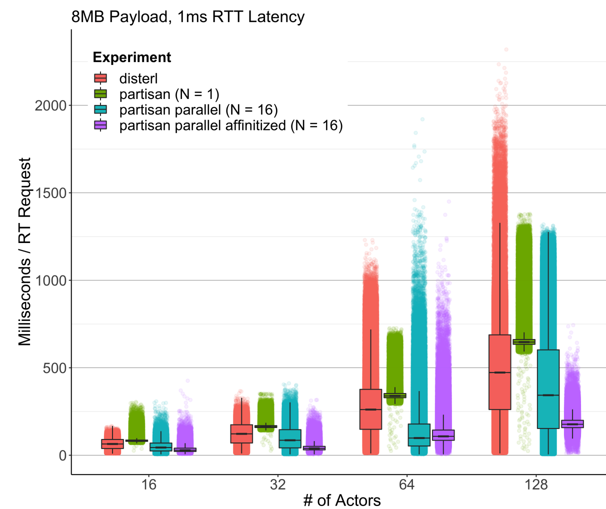

Figure 4: Performance of Distributed Erlang and PARTISAN broken out by optimization under a large payload workload: round trip time between actors is set at 1ms, object size is set at 8MB.

to a particular vCPU, and when the system needs to maintain more connections than available schedulers, context switching penalties manifest themselves as outliers (shown in Figure 2).

Focusing on these outliers, we might ask how bad does it get? With 128 actors, 512KB payload, and 1ms RTT, moving from 16 connections to 128 connections increases outliers from a max value of 176ms to 1791ms, a 10.17x increase!

In Figure 3, we turn our attention to the question of network conditions. In our first experiment (Figure 1), we chose a 1ms RTT to explore performance in a scenario where we can assume our application is running within a single AWS availability zone. But what happens if we don't have such favorable network conditions? What if our application is spread out between two AWS availability zones and suffers from RTTs closer to 20ms instead? Figure 3 shows the effects of running our earlier experiment this time with a 20ms RTT latency between actors located on different nodes. As we can see, as the latency increases, the system can take advantage of more communications channels to parallelize inter-actor communication on the network. With 128 actors, 512KB payload, and 20ms RTT, PARTISAN with parallelism performs 10.92x better than Distributed Erlang. By affinitizing parallelism, per-

formance increases to 13.50x better than Distributed Erlang.

In the Erlang community, large message sizes are not uncommon. Consider again Riak, the distributed key-value store which could contain user-stored and arbitrary-sized data. An Erlang message then could contain a user-provided piece of data megabytes in size. However, it's well-known in the Erlang community that Distributed Erlang doesn't handle large message sizes well. In fact, the Riak documentation suggests to avoid storing objects larger than 1-2MB due to the performance degradation that occurs due to Distributed Erlang [5,15]. Cognizant of this, we turn our attention to question of how large payload size affects performance in PARTISAN. Can PARTISAN overcome some of the performance issues faced by Distributed Erlang with large payloads?

Figure 4 explores the effects of increasing payload size on PARTISAN as compared to Distributed Erlang. Keeping in line with the community-observed limits of Distributed Erlang, we vary the message size from 512kb (below the 1MB performance degradation threshold) to 8MB (far above the 1MB performance degradation threshold). With 128 actors, 8MB payload, and 1ms RTT, PARTISAN with parallelism performs 1.20x better than Distributed Erlang! By affinitizing parallelism, performance increases to 2.63x.

Discussion. So far, we've seen that PARTISAN outperforms Distributed Erlang in all of our microbenchmarks. We've shown that the collection of optimizations made available to Erlang applications by PARTISAN (that is, leveraging additional connections, and affinitizing work to those connections based on the type of message and the node that the message is being sent to), can drastically improve performance by reducing latency, in some cases by over 30x.

But what does this mean practically? From these experiments, it's clear that Distributed Erlang was designed when the sort of applications being written was limited as compared to what we would like to write today; i.e., applications that send small payloads within a single data center.

As we have shown in these experiments, PARTISAN goes beyond this, and seems to be well-suited for enabling new types of applications, such as: (i) applications that operate with large data-centric workloads; (ii) applications that operate at a geo-distributed scale; (iii) the combination of both.

6.2 Evaluation: Latency Reduction in Riak

To determine the applicability of these optimizations to real-world programs (**RQ2**), we asked the following questions: (i) is it possible to modify existing application code to take advantage of the PARTISAN optimizations through the use of PARTISAN's API, and (ii) do these optimizations result in the reduction of latency for these programs?

To answer these, we ported the distributed systems framework, Riak Core, to PARTISAN and built two example applications: (i) a simple echo service – an application that's designed to only be bound by the speed of the actor receiving messages and the network itself; and (ii) a memory-based key-value store that operates using read/write quorums – more representative of a workload where more data is being transmitted and more CPU work has to occur.

6.2.1 Background: Riak Core

Riak Core is a distributed programming framework written in Erlang and based on the Amazon Dynamo [13] system that influenced the design of the distributed database Riak, Apache Cassandra, and the distributed actor framework Akka.

In Riak Core, a distributed hash table is used to partition a hash space across a cluster of nodes. These *virtual nodes*—the division of the hash space into N partitions—are claimed by a node in the cluster, and the resulting ownership is stored in a data structure known as the ring that is periodically gossiped to all nodes in the cluster. Requests for a given key are routed to a node in the cluster based on the current partitioning of virtual nodes to cluster nodes in the ring structure using consistent hashing, which minimizes the impact of reshuffling when nodes join and leave the cluster. Background processes are used for cluster maintenance; ownership handoff, (transferring virtual node ownership) metadata anti-entropy (an internal KVS for configuration metadata) and ring gossip (information about the cluster's virtual node to node mapping.)

In our experimental configuration we use 1,024 virtual nodes, the largest possible ring configuration for Riak Core. This ring size requires the largest amount of system resources – we account for this in our experiment – however, provides the most fine-grained partitioning for individual requests.

6.2.2 Modifications to Riak Core to Support PARTISAN

To perform our evaluation of PARTISAN using Riak Core, it was necessary to modify the existing application to take advantage of PARTISAN's APIs. Our changeset to Riak Core in order to use PARTISAN instead of Distributed Erlang is fairly minimal: 290 additions and 42 removals including additional logging for debugging, additional tests, and configuration.

The authors of Riak Core already realized that request traffic and background traffic could be problematic, so one mechanism inside of Riak Core—ownership handoff, responsible for moving data between virtual nodes when partitioning changes—already manages it's own set of connections. This mechanism alone contains roughly 900 LOC for connection maintenance – code that could be eliminated and replaced with calls to the PARTISAN API.

6.2.3 Echo Service

Experimental Setup. Our first application is a simple echo service, implemented on a three node Riak Core cluster. For each request, we generate a binary object, uniformly select a partition to send the request to, and wait for a reply containing the original message before issuing the next request. For each request, we draw a key from a uniform distribution over 1,024 keys – matching the ring size of the cluster – and run the key through Riak Core's consistent hashing algorithm for placement of the request. Requests originate at all of the nodes

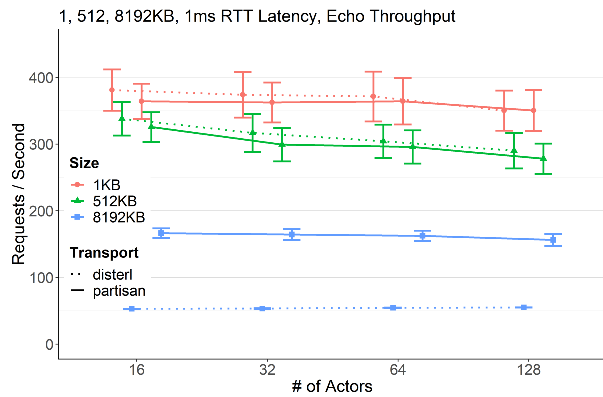

Figure 5: Performance of Distributed Erlang and PARTISAN with affinitized parallelism using the echo service / low latency workload: round trip time between actors is set at 1ms, object size varies 1, 512, and 8192KB.

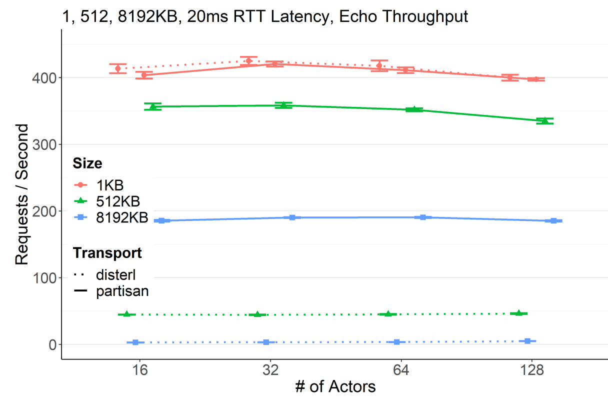

Figure 6: Performance of Distributed Erlang and PARTISAN with affinitized parallelism using the echo service / high latency workload: round trip time between actors is set at 20ms, object size varies 1, 512, and 8192KB.

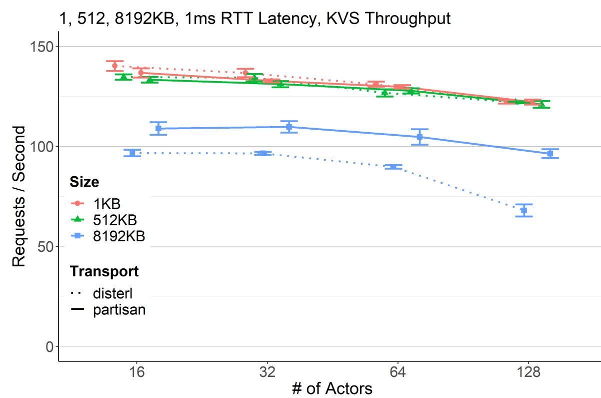

Figure 7: Performance of Distributed Erlang and PARTISAN with affinitized parallelism using the KVS / low latency workload: round trip time between actors is set at 1ms, object size varies 1, 512, and 8192KB.

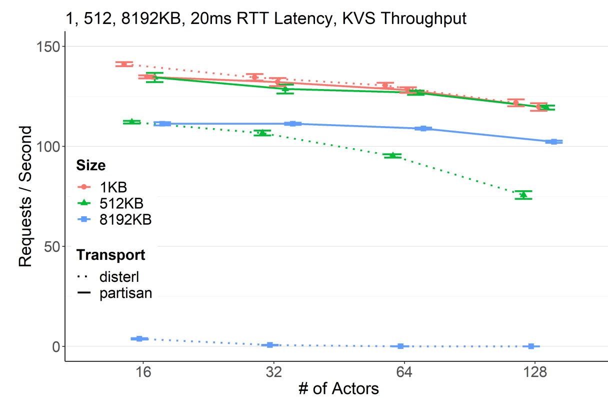

Figure 8: Performance of Distributed Erlang and PARTISAN with affinitized parallelism using the KVS / high latency workload: round trip time between actors is set at 20ms, object size varies 1, 512, and 8192KB.

in the cluster, and based on the key placement, are routed to the node responsible for handling the request. To ensure we can compare the results between runs, we wait for the cluster to stabilize before beginning the experiment.

Binary objects are generated for three payload sizes, 1KB, 512KB and 8192KB. Concurrency is increased during the test execution and parallelism is configured at 16. We test two latency configurations: 1ms, shown in Figure 5, and 20ms, shown in Figure 6. We run a fixed duration of 120 seconds.

Results. Figure 5 demonstrates that with 128 actors, 1ms RTT, and large payloads (8MB), PARTISAN is 2.84x faster than Distributed Erlang. With medium (512KB) and small payloads (1KB), PARTISAN is on par with Distributed Erlang (0.95x - 1.00x).

Figure 6 demonstrates that with 128 actors, 20ms RTT, and larger payloads (8MB), PARTISAN is 38.07x faster than Distributed Erlang (which achieves only 5 ops/second before reaching peak throughput). With medium payloads (512KB), PARTISAN is 7.25x faster than Distributed Erlang. With small payloads (1KB), PARTISAN is on par with Distributed Erlang (0.99x).

6.2.4 Key-Value Store

Experimental Setup. Our second application is a memory-based key-value store, similar to the Riak database, implemented on a three node Riak Core cluster.

Each key is hashed and mapped to a virtual node using the ring structure that is gossiped in the cluster. The virtual node that the key is hashed to, along with that virtual nodes' two clockwise neighbors on the ring, represent the three virtual nodes that contain the three replicas for the data item. Each request (either a get operation or put operation) to the key-value store uses a quorum request pattern, where requests are

made to these three replicas, and the response is returned to the user when a majority (2 out of 3) replicas reply.

This pattern involves multiple nodes in the request path, and each partition simulates a 1ms storage delay in the request path. We reuse the aforementioned benchmarking strategy: test execution is fixed at 120 seconds.

For each request, we draw a key from a normal distribution across 10,000 keys and run the key through Riak Core's consistent hashing algorithm for placement. The consistent hashing placement algorithm aims for uniform partitioning of keys across the cluster. Requests originate at all of the nodes in the cluster, and based on the key placement, are routed to the node(s) responsible for handling the request. To ensure we can compare the results between runs, we wait for the cluster to stabilize before beginning the experiment. We use a 10:1 read/write ratio for the experimental workload. Concurrency is varied in our experiments (x-axis) and parallelism is configured at 16. We test two latency configurations: 1ms, shown in Figure 7, and 20ms, shown in Figure 8.

Results. Figure 7 demonstrates that with 128 actors, 1ms RTT, and both medium (512KB) and small (1KB) payloads, PARTISAN performs on par with Distributed Erlang (0.99x-1.00x). With larger payloads (8MB), PARTISAN is 1.42x faster than Distributed Erlang.

Figure 8 demonstrates that with 128 actors, 20ms RTT, and small (1KB) payloads, PARTISAN performs on par with Distributed Erlang (0.98x). With medium payloads (512KB), PARTISAN is 1.50x faster than Distributed Erlang. With large payloads (8MB), PARTISAN far exceeds the performance of Distributed Erlang, achieving 102 ops/second; Distributed Erlang only completes 1 operation during the entire 120s execution.

6.2.5 Discussion

As we have shown in these experiments, PARTISAN is not only well-suited as a replacement for Distributed Erlang, given its similar performance under workloads that Distributed Erlang was designed for, but PARTISAN also enables new classes of applications in distributed actor frameworks. Our experiments have shown increased throughput in applications with large data-centric workloads: an example of this would be the Riak distributed database without 1MB storage limitations.

6.3 Evaluation: Improving Scalability in Lasp

In our previous experiment on latency reduction in Riak Core, we demonstrated optimizations for latency reduction in a distributed database that communicates with all of the nodes in the cluster. This is one example of an application that benefits from the *full-mesh* overlay. However, not all applications benefit from, nor require, the full-mesh model that is default case in Distributed Erlang. In this section, we address the question of whether or not an application can benefit from selection of the overlay at runtime (**RQ3**): specifically, the *client-server* and *peer-to-peer* overlays.

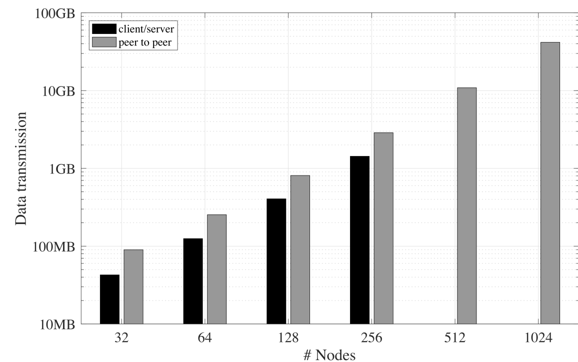

Figure 9: Comparison of data transmission for Lasp deployed on the client-server and peer-to-peer overlays for different cluster sizes (32 to 1024 nodes).

In order to understand the effect of overlay on scalability, we focus on how many nodes we can scale our application to under each overlay for an advertisement counter application implemented with Lasp.

6.3.1 Lasp

Lasp [22] is a programming framework designed for large scale coordination-free programming. Applications in Lasp are written using shared state; this shared state is stored in an underlying key-value store and is replicated between all nodes. Applications modify their own replica and propagate the effects of their changes to their peers. Lasp ensures that applications converge to the same result on every node through the use of data structures known as Conflict-Free Replicated Data Types [29], combined with monotone programming [3].

For our Lasp evaluation, the application is a simulated advertisement counter, modeled after the Rovio counter scenario for Angry Birds [22]. In this application, each client keeps a replica of a distributed counter that is incremented every time an advertisement is displayed to the user and whose state is periodically propagated to other peers in the system. When a certain number of impressions is reached, the advertisement is disabled and no longer displayed to the user.

The distributed counter used was a particular type of CRDT: a Grow-Only Counter (G-Counter). The G-Counter maps node identifiers at each of the clients to a monotonically increasing counter. Clients increment their position in the map and when merging state propagated from other nodes in the system, the pair-wise maximum is taken for each component in the map. To determine when an advertisement can be disabled, a lower bound is checked according to the sum of the components in the map: this represents a lower bound on the total number of times an advertisement has been displayed.

Experimental Setup. For this evaluation, a total of 70 m3.2xlarge Amazon EC2 instances in the same region and availability zone. Mesos [16], is used to subdivide each of these machines into smaller, fully-isolated machines. Each

container in Mesos represents a single Lasp node that communicates with other nodes in the cluster using PARTISAN.

The increment interval for each counter was fixed at 10s, and the propagation interval for the counter was fixed at 5s. The total number of impressions was configured to ensure that the experiment would run for 30 minutes under all configurations. The evaluation is performed on both the *client-server* and *peer-to-peer* overlays for different cluster sizes, ranging from 32 all the way up to 1,024 node clusters. For both overlays, the system propagates the full state of the counter to the node's peers at each propagation interval.

Note that since the Rovio advertisement counter scenario was designed for mobile applications, we do not run the full-mesh topology because it would be unrealistic. That is, in the context of mobile apps, clients would not connect to all other nodes, nor will they have knowledge of who all of the clients in the system are. Rather, either mobile apps will communicate with some number of nearby peers (peer-to-peer) or they will communicate through a server (client-server). Client-server also serves as the standard model of deploying mobile applications today. Thus, we designed our experiments to reflect this—we examine client-server and peer-to-peer overlays for this application in our experiments.

Results. Figure 9 presents the total data transmission required for the experiment to finish as we scale the size of the cluster from 32 to 1024 nodes. For smaller clusters of nodes, client-server is the more efficient overlay in terms of the amount of data that must be transmitted to finish the experiment. However, this improved efficiency comes at a cost: the client-server configuration is unable to scale beyond 256 nodes. More specifically, the experiment fails to complete because of a crash failure of the server. This crash failure occurs because of unbounded message queues: when the server is unable to process the incoming messages from the clients quickly enough, the Erlang VM allocates all available memory for storage of the message queue. This unbounded allocation results in termination of the Erlang by the Linux OOM killer once the instance runs out of available memory.

Peer-to-peer is more resilient in the face of a node failure allowing it to support larger clusters of nodes—up to 1024! However, peer-to-peer is less efficient due to this—the redundancy of communication links used by the overlay causes it to transmit more data in order to complete the experiments.

Discussion. Perhaps the most interesting takeaway from the results of this real-world large-scale experiment is that the experiment was even possible at all with Erlang. As Distributed Erlang permits one to only use a full-mesh overlay, it's possible that the previous results observed by Ericsson [1] on the maximum size of Erlang clusters–only 200 nodes–are due to this full-mesh-only restriction.

This experiment suggests that PARTISAN may enable the development of new applications with actors systems that have not been previously possible by enabling the application developer to, at runtime, change the pattern of communication between nodes, without altering application semantics. Perhaps the lack of mobile applications or even IoT applications written using distributed actor systems is a symptom of the full-mesh-only restriction.

7 Related Work

Head-of-line blocking is a well-known issue in the systems and networking community, especially in systems that use multiplexed connections. Facebook's TAO [9] relies on multiplexed connections but allows out-of-order responses to prevent head-of-line blocking issues. Riak CS [7], an S3-API compatible object storage system build on Riak, arbitrarily chunks data into 1MB segments to prevent head-of-line blocking. Geo-replicated Riak [6] contains an ad hoc implementation of node-to-node messaging to avoid Distributed Erlang at cross-region latencies. Distributed Erlang now includes a feature for arbitrarily segmenting messages into smaller chunks to reduce the impact of head-of-line blocking [17].

Ghaffari *et al.* [15] identified several factors limiting Erlang's scalability: (i) increasing payload size and (ii) head-of-line blocking with Erlang's RPC mechanism – two of the limiting factors in Riak 1.1.1's ≈ 60 node limit on scalability. Chechina *et al.* [11] proposed partitioning the graph of nodes into subgraphs and using supernodes for connecting the groups, avoiding the problems of full-mesh connectivity.

8 Conclusion

We presented PARTISAN, an alternative runtime system for improved scalability and reduced latency in actor applications. PARTISAN provides higher scalability by allowing the application developer to specify the network overlay used at runtime without changing application semantics, thereby specializing the network communication patterns to the application. PARTISAN reduces message latency through a combination of three predominately automatic optimizations: *parallelism*, *named channels*, and *affinitized* scheduling. We implemented PARTISAN in Erlang and showed that PARTISAN achieves up to an order of magnitude increase in the number of nodes the system can scale to through runtime overlay selection, up to a 38.07x increase in throughput, and up to a 13.5x reduction in latency over Distributed Erlang.

Abstract

Dynamic binary translation (DBT) is a key system technology that enables many important system applications such as system virtualization and emulation. To achieve good performance, it is important for a DBT system to be equipped with high-quality translation rules. However, most translation rules in existing DBT systems are created manually with high engineering efforts and poor quality. To solve this problem, a learning-based approach was recently proposed to automatically learn semantically-equivalent translation rules, and symbolic verification is used to prove the semantic equivalence of such rules. But, they still suffer from some shortcomings.

In this paper, we first give an in-depth analysis on the constraints of prior learning-based methods and observe that the equivalence requirements are often unduly restrictive. It excludes many potentially high-quality rule candidates from being included and applied. Based on this observation, we propose an enhanced learning-based approach that relaxes such equivalence requirements but supplements them with constraining conditions to make them semantically equivalent when such rules are applied. Experimental results on SPEC CINT2006 show that the proposed approach can improve the dynamic coverage of the translation from 55.7% to 69.1% and the static coverage from 52.2% to 61.8%, compared to the original approach. Moreover, up to 1.65X performance speedup with an average of 1.19X are observed.

1 Introduction

Dynamic binary translation (DBT) is a key enabling technology for many critical system applications such as system virtualization and emulation [20, 28], whole program/system analysis [6, 13], software development and debugging [14], security vulnerability detection and defense [15, 17], computer architecture simulation [22, 27, 29], and mobile computation offloading [26]. There have been many widely-used DBT systems, such as Pin [18], Valgrind [21] and QEMU [2].

In general, a DBT system takes an executable binary code in one instruction set architecture (called *guest* ISA) and dynamically translates it into the binary code in another instruction set architecture (called *host* ISA). The translation process is mostly driven by *translation rules* that translate guest instructions into a sequence of semantically-equivalent host instructions [23].

For a DBT system, its performance is dominated by the quality of the translated host binary code [25]. Therefore, it is very important for a DBT system to be equipped with high-quality translation rules. However, due to the complexity and opacity of modern ISAs, it is difficult to *manually* construct such high-quality translation rules as it poses a significant engineering challenge. Even worse, to support retargetable DBTs (from multiple guest ISAs into multiple host ISAs) in the same framework, a set of pseudo-instructions are commonly used as their internal representations [2]. As the execution time is directly proportionate to the number of host instructions executed, such a multiplying effect has a significant impact on the overall DBT performance.

To improve the quality of translation rules and reduce engineering efforts, a learning-based approach [23] is recently proposed to learn automatically binary translation rules. Since the translation rules are learned from the optimized binary codes generated by the compiler, this approach is capable of yielding higher quality translation rules than existing manual schemes. Moreover, the whole learning process can be fully automated without manual intervention. Although the above approach is attractive, it still suffers from some fundamental limitations. That is, a translation rule can be harvested (i.e., learned) only if the guest and the host binary code that correspond to the same program source statement(s) are strictly semantically equivalent. This is enforced through a symbolic verification process.

On the surface, this equivalence verification process is necessary and appropriate because it guarantees the *correctness* of the learned rules. However, further investigation reveals that this equivalence requirement is often unduly restrictive. It excludes many potentially high-quality rule candidates from being harvested and applied. In particular, such restrictions usually keep architecture-specific instructions in guest and/or

host ISAs from being included for more efficient translation as they are mostly architecturally specific, and thus inherently different and more challenging to prove semantic equivalence.

To overcome this limitation, this paper presents an enhanced learning-based approach that relaxes such restrictions and allows more translation rules to be harvested and applied. More specifically, it purposely relaxes the requirements of semantic equivalence and allows semantic discrepancies between the guest and host instructions to exist in the translation rules, e.g., different condition codes or the different number of operands in matching guest and host instructions. Symbolic verification process is no longer just to check the *strict* semantic equivalence between the matching guest and host instructions, but also to identify the specific semantic discrepancies between them that can be used during the rule application phase to verify whether such discrepancies either will not cause ill effect, or are satisfied in the context of the rules being applied (for more details see Section 4). We call such semantic equivalence in the translation rules *constrained semantic equivalence* as the specific semantic discrepancies of the translation rules become the *constraining conditions* for such rules to be safely applied. This requires some runtime program analysis (mostly in a very limited scope) during the rule application phase, which usually incurs very small overhead. Those with very complicated constraining conditions that require extensive runtime program analysis will be discarded.

To demonstrate the feasibility and the benefit of such constrained-equivalent translation rules, we have implemented a prototype based on the proposed approach. The prototype includes an enhanced learning framework and a DBT system that applies the constrained-equivalent translation rules to generate host binary code. We evaluate the implemented prototype using SPEC CINT2006. Experimental result shows that the proposed approach can significantly improve the harvest rate of the learning process from 20.3% to 25.1% and dynamic coverage from 55.7% to 69.1% while static coverage from 52.2% to 61.8%, compared to the original learning approach in [23]. Moreover, no degradation is observed for the learning efficiency, i.e., around 2 seconds to yield a translation rule, which is the same as the original learning process. After applying the enhanced translation rules, we achieve up to 1.65X performance speedup with an average of 1.19X compared to the original approach.

In summary, this paper makes the following contributions:

- We propose an enhanced learning-based approach that can harvest and apply constrained-equivalent translation rules discarded by the original approach, and allows DBT systems to generate more efficient host binary code.
- We implement the proposed learning-based approach in a prototype, which includes a learning framework based on LLVM and a DBT system extended from QEMU to accept the constrained-equivalent translation rules.
- We conduct some experiments to evaluate the proposed learning-based approach. Experimental results on SPEC CINT2006 shows that our approach can achieve up to 1.65X speedup with an average of 1.19X compared to the original learning approach.

The rest of this paper is organized as follows. Section 2 presents some background of the original non-constrained semantically-equivalent learning-based approach. In Section 3, we identify some technical challenges in learning and applying constrained-equivalent translation rules. Section 4 presents the design issues of our enhanced learning-based approach. In Section 5, we describe some implementation details of the prototype and evaluate the proposed approach and show some experimental results. Section 6 presents some related work and Section 7 concludes the paper.

2 Background

In this section, we introduce some background information on how a DBT and a learning-based approach such as the one proposed in [23] work.

2.1 Dynamic Binary Translation (DBT)

Typically, a DBT system adopts a guest *basic block* (or *block* for short) as the translation unit to translate guest binary code into host binary code. A basic block comprises a sequence of instructions with only one entry and one exit, and thus whenever the first instruction of a basic block is executed, the rest of the instructions in this block will be executed exactly once in order. It is worth noting that, due to the semantic differences between the guest and host ISAs, one guest block may be translated into multiple host blocks by the DBT system.

To translate a guest basic block, the DBT system firstly disassembles the guest binaries to obtain guest assembly instructions. Then, it tries to match the guest instructions with available *translation rules*. After a matched translation rule is found, the corresponding guest instructions are translated into host instructions as specified in the translation rule. This process could be iterated multiple times until all instructions in the guest block are translated. Finally, the generated host instructions are assembled into host binaries and executed directly on host machines. Figure 1 shows an example of such a translation process, where ARM is the guest ISA, and x86 is the host ISA. In this example, two translation rules are applied to translate two ARM instructions into two x86 instructions, respectively.

To mitigate the performance overhead incurred during the translation process, especially for short-running guest applications, the translated host binary code is stored into a memory region called *code cache*, and reused in the later execution. After all instructions in a guest block are translated, the execution flow of the DBT system is transferred to the code cache.

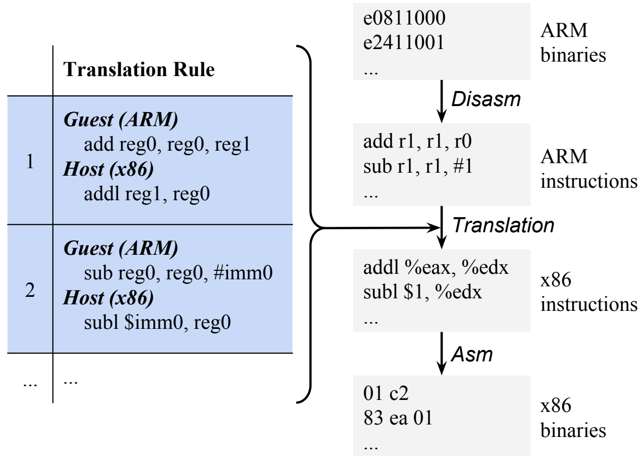

Figure 1: Dynamic binary translation from ARM to x86 driven by manually-constructed translation rules. Here, for simplicity, we assume the guest registers `r0` and `r1` are emulated using the host registers `eax` and `edx`, respectively.

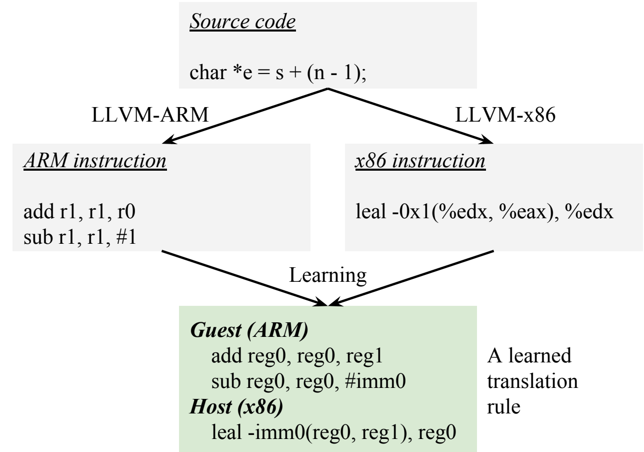

Figure 2: Automatically learning binary translation rules during the compilation process of program source code. Compared to the translation rules used in Figure 1, the learned translation rule can generate more efficient host binary code.

A *hash table* is employed to establish the mapping between the guest binary code and the corresponding translated host binary code in the code cache. Each time a guest block is encountered, the hash table is looked up to find out whether there exists a host code in the code cache that corresponds to this guest block. If yes, the translation process will be skipped, and the stored host binary code will be executed. Otherwise, the guest block is translated, and the hash table is updated with the added translated host binary.

2.2 Learning Translation Rules

As mentioned earlier, the translation process in a DBT system is mainly directed by translation rules, which also determine the quality (i.e., performance) of the translated host binary code. Therefore, it is vital for a DBT system to have high-quality translation rules for better performance. However, in practice, it is a significant engineering challenge to develop high-quality translation rules as most translation rules in existing DBT systems are constructed manually by developers. Moreover, modern ISAs are often documented in obscure and tediously long manuals. For example, Intel's manual has around 1500 pages for the x86 ISA. It requires substantial engineering efforts to understand both the guest and the host ISAs to construct high-quality translation rules.

To solve this problem, a recent approach proposes to automatically learn binary translation rules [23]. More specifically, this approach uses the same compiler for different ISAs, i.e., LLVM-ARM and LLVM-x86, to compile the same source program. During the compilation process, it extracts binary translation rules from ARM and x86 binary code that correspond to the same program source statement(s). This is inspired by the observation that the binary code compiled by the same compiler for different ISAs from the same program source code should be equivalent in program semantics. To further enforce such equivalence requirement, a symbolic verification engine is developed to filter out rule candidates in which guest and host binary code are not semantically equivalent.

Figure 2 illustrates an example of the above learning process, In this example, the program source statement is compiled into two ARM instructions and one x86 instruction by LLVM-ARM and LLVM-x86, respectively. Using symbolic execution, we can verify that the guest ARM register `r1` and the host x86 register `edx` should have the same value assuming the same initial condition. We can thus prove that the sequence of the two ARM instructions is semantically equivalent to the single x86 instruction in the example. A translation rule that maps the sequence of the two ARM instructions into one x86 instruction can then be harvested. Recall the example in Figure 1. If we use this learned rule to translate the guest binaries, we only need one host instruction instead of two as shown in the example, i.e. more efficient host binary code can be generated.

3 Issues and Challenges

The significance of the above learning approach is two folds. Firstly, it can automatically learn binary translation rules for DBT systems with less burden on developers. Secondly, given that the translation rules are learned directly from binary code generated by the native compilers, it is more likely that the harvested translation rules are more optimized than the translation rules naïvely constructed by hand, as shown in Figure 2 and Figure 1.

Theoretically, if we keep training such a learning-based

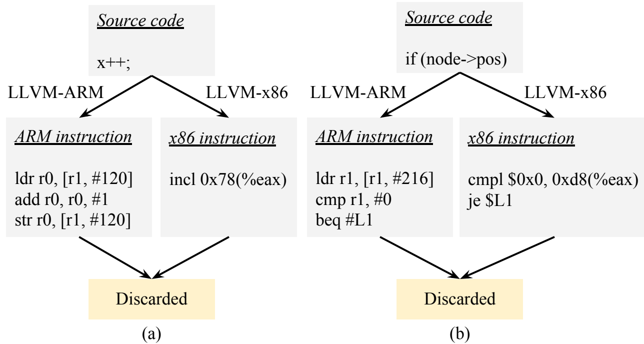

Figure 3: Two examples to demonstrate the limitation of the learning approach in [23]. These two rule candidates are discarded because the guest registers `r0` in (a) and `r1` in (b) have no equivalent host register.

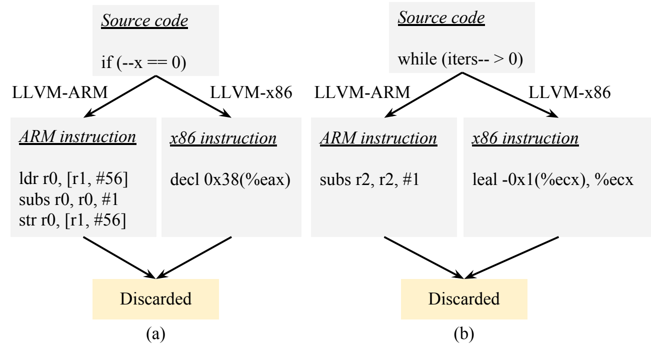

Figure 4: Another two rule candidates discarded by the learning approach in [23] because of the different condition codes in guest and host ISAs.

system with a large number of source programs, we should be able to harvest a large number of translation rules and apply them to guest binaries with good coverage. Unfortunately, after a more thorough study of this approach, we found it suffers from a fundamental limitation that prohibits it from harvesting many high-quality translation rules. In this section, we explain in more details such limitations and identify some technical challenges if we want to overcome them.

A Fundamental Limitation. To guarantee the correctness of the learned translation rules, it employs a symbolic verification engine to check the exact semantic equivalence between the guest and host binary code sequences. More specifically, the semantic equivalence is verified in three aspects that include matching register operands, memory operands and branch conditions. More details can be found in [23].

If the verification results show that the guest and host binary code sequences are not strictly equivalent, the rule candidate is discarded and no translation rule is harvested. Undoubtedly, such a verification process is necessary and appropriate. However, by a more detailed study on the discarded rule candidates, we found that the requirement of *exact* semantic equivalence is too restrictive. Many high-quality rule candidates are forced to be discarded, especially those guest and host binary code sequences that are more architecturally specific and their ISAs are significantly different, such as ARM (a reduced instruction set computer (RISC)) and Intel x86 (a complex instruction set computer (CISC)) in our example.

Figure 3 shows two examples of this limitation. Here, similar to the previous examples, the guest ISA is ARM and the host ISA is Intel x86. In Figure 3(a), the value of the variable `x` is increased by one through the increment operator as shown in the source code. With its RISC ISA, the ARM compiler generates three instructions for this source statement: loading the original value of `x`, performing the addition, and then storing the result back to `x`. In contrast, the Intel x86 compiler needs only one instruction, `incl`, with its CISC ISA.

Similarly, in Figure 3(b), the x86 instruction `cmpl` can have a memory operand, but an ARM `ldr` instruction is required before the `cmp` instruction. In these two cases, the verification will fail because there is a mismatch of register operands between the guest and the host code sequences, i.e. there is no host register that matches and holds the same value as the guest register `r0`.

However, if we examine these two examples more carefully, we will find that the root cause of the failed verification stems from the inherent differences between the guest and the host ISAs. In practice, such architectural differences are quite common and pervasive in different ISAs, even if they are both RISCs or CISCs. For instance, a post-indexed memory load instruction in ARM will modify the address register after the loading operation, while there is no similar instruction in MIPS, which is another representative RISC ISA.

In fact, these differences represent the essence of the architectural design unique to each ISAs. It is indeed a huge loss for a learning-based approach to discard such rule candidates simply because of their ISA differences. As they are architecturally specific, they are often the most efficient code sequences selected by the native compilers for specific program contexts and thus have a high potential to turn into high-quality translation rules.

Another shortcoming resulted from the aforementioned limitation is that it also excludes many rule candidates that contain instructions associated with architecture-specific hardware support. For instance, many architectures have condition codes (also known as *eflags* in x86 machines). They are single-bit registers used to store the execution summary of an instruction and can influence the control flow of the later instructions. In particular, ARM has four condition codes: negative (NF), zero (ZF), carry (CF), and overflow (VF), while x86 has seven condition codes: carry (CF), parity (PF), adjust (AF), zero (ZF), sign (SF), direction (DF), and overflow (OF).

Figure 4 shows two examples with instructions related to condition codes. In Figure 4(a), the source code decreases the

value of `x` by one and then checks the result to see whether it is zero or not. An ARM instruction `subs` is generated to perform the subtraction and update the condition codes. Here, `subs` updates all four ARM condition codes, including CF. Similarly, an x86 instruction `decl` is used to decrease the value stored in the memory operand by one and update the condition codes. However, `decl` updates all x86 condition codes, except CF. As a result, the verification process in the original learning-based approach will consider the ARM and x86 code are not semantically equivalent and discard this rule candidate. Similarly, the rule candidate in Figure 4(b) is also discarded because the x86 instruction `leal` does not update any condition code. In fact, the source code in Figure 4(a) only needs to check whether the result is zero or not, which only requires the condition code ZF. Thus, it is unnecessary to update the condition code CF, as it is never used in this context. That means, it is still possible to harvest this translation rule and apply it, if the ARM condition code CF is not used (i.e. *dead*) in the later code before it is updated. Similarly, the rule candidate in Figure 4(b) can also be harvested.

Technical Challenges. Although such limitations could exclude many high-quality translation rules during the learning process, it faces several technical challenges if we want to harvest them and apply them in a DBT system for a better performance and higher coverage.

First, we have to relax the original verification objectives as they are designed to verify the *exact* equivalence between the guest and host code sequences.

Second, given that most of those translation rules are not strictly equivalent, it is imperative that we have a mechanism to enforce their correctness when we apply them. Equally important is that the performance overhead incurred by such enforcement should be less than the performance gain they can provide.

Last but not least, in the original learning approach, a learned translation rule only needs to include two parts, i.e., the guest and host instructions, and this is typically sufficient for a DBT system. However, for the constrained-equivalent translation rules, whether we can apply these rules at runtime or not depends on the context they are being applied. As a result, we need to extend the structure of translation rules to include such constraining requirements.

4 An Enhanced Learning-Based Approach

In this section, we present the design of the proposed enhanced learning-based scheme, starting with an overview of the system framework.

4.1 Overview

The major goal of our enhanced learning-based approach is to learn and apply high-quality translation rules excluded by the original learning approach. These translation rules contain constrained-equivalent guest and host instructions, and thus cannot be harvested using the original learning approach. To this end, we redesign the learning process, reorganize the structure of the learned translation rules, and make necessary extensions to the DBT system to allow the application of the constrained-equivalent translation rules.

Figure 5 illustrates the workflow of our enhanced learning-based approach. To learn translation rules, we also compile the same program source code using the same compiler for guest and host ISAs to generate two versions of the binary code. We then extract guest and host code sequences that correspond to the same *learning scope* and consider them as the candidates for the translation rules. The learning scope is defined at the program source code level. In the original learning system, the default learning scope is set to be one source statement. The extracted guest and host code sequences then form a *rule candidate*. For each rule candidate, the next step is to verify whether the corresponding guest and host code sequences are *constrained equivalents* or not. If yes, a translation rule can be harvested. Otherwise, the rule candidate is discarded.

As an example to demonstrate our approach and by studying the rule candidates discarded by the original learning scheme, we consider the guest and host code sequences in a rule candidate as *constrained equivalent* if every modified guest *storage operand* contains the same value as a modified host storage location at the end of the code sequences and vice versa. Here the *storage operand* is broadly defined, as it can be either a register, a memory location, or a condition code (i.e., eflag). Furthermore, it is allowed that there is no corresponding modified storage location in the *host* code sequences, e.g., a corresponding condition code as mentioned earlier.

Using this relaxed and constrained equivalence definition, the guest and host code sequences can be semantically equivalent only if all *modified* guest storage operands without the corresponding host storage operands (e.g., condition codes) are not used in the following guest binaries before they are modified again. These modified guest storage operands without the corresponding host storage operands can be considered as the *constraining condition* of this constrained-equivalent translation rule.

In our framework, the semantic equivalence can be relaxed in other ways as long as the *discrepancies* can be identified and shown either having no ill effect in the context they are applied or can be compensated to make them semantically equivalent when they are applied. In other words, their *constraining conditions* can be identified and satisfied when these rules are applied. To simplify our prototype design, we only consider relaxing the requirement of exact mapping of the storage operands as defined earlier. The identified constraining conditions are integrated into the learned translation rules to determine whether it is safe to apply them or not. It is worth noting that for strictly equivalent translation rules the constraining condition is null.

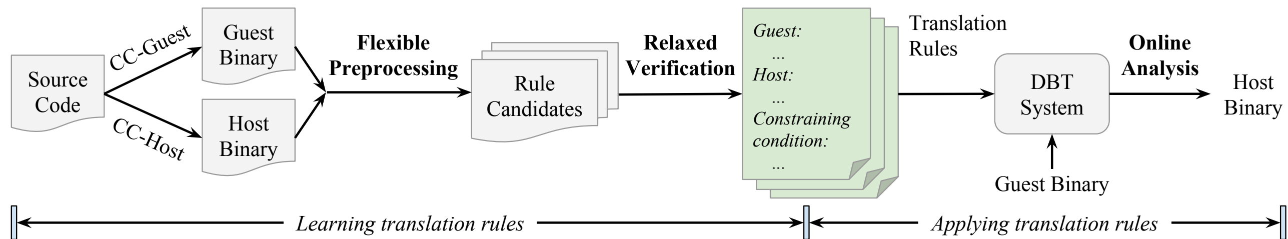

Figure 5: The work flow of the proposed enhanced learning-based approach.

To determine whether the constraining condition is met or not, a lightweight runtime analysis is employed to determine the program context in which the guest instructions is to be translated. In our case, the program context includes the information about which guest storage operand is modified by the guest instructions and used in the later code before it is modified again. The program context is then used to verify whether the constraining condition is satisfied or not. If yes, the translation rule can be applied, otherwise, it is discarded.

4.2 Varying Learning Scopes

In the original learning scheme, the learning scope is limited to one source statement. Although it appears to be reasonable, it may miss potential rule candidates as it is very common for compilers to perform optimization across multiple source statements. Therefore, our enhanced learning approach varies the learning scope from one to n source statements, and apply each learning scope over the source program.

More specifically, a *sliding window* is employed. The sliding window of size n covers n contiguous source statements, i.e. the sliding window covers the learning scope of n statements. Guest and host instructions that correspond to the n statements in this window are extracted as a rule candidate. The sliding window moves from the first line of the source code toward the end of the code. The window size is initially set to 1, and incremented by one after each pass through the sources code. When the window of size i is moved through all the source code, the number of rules learned from current window size will be compared to the number of rules learned from window sizes 1 to $i-1$. If new rules learned from window size i are less than 10% of all learned rules from window sizes 1 to $i-1$, the learning process will be stopped.

4.3 Learning Constrained-Equivalent Rules

To verify the constrained equivalence of the guest and host instructions in a rule candidate, we use the same symbolic verification engine, but relax the requirements for semantic equivalence.

First, we establish an *initial mapping* between guest and host live-in operands the same way as the original learning approach, i.e., guest registers $\mapsto$ host registers, guest memories $\mapsto$ host memories, and guest immediate values $\mapsto$ host immediate values (i.e. constants). Then, we initialize the mapped guest and host operands with the same symbol values and symbolically execute the guest and host code sequences, respectively. After the symbolic execution, we extract the symbol results of the modified guest and host registers, memories, and condition codes. These results are then fed into a SMT solver to figure out, for each modified guest register/memory/condition code, whether there exists a modified host register/memory/condition code corresponding to it or not. If each modified guest operand is mapped to a modified host operand, an original rule is generated.

If the SMT solver indicates that there exists a modified guest memory operand that does not have a matching host memory operand, we discard this rule candidate. If a modified guest register/condition code has no matching modified host register/condition code, we can harvest this rule candidate as the guest and host instructions can still be constrained equivalent. Moreover, such unmatched guest registers/condition codes are recorded as constraining conditions of the learned rules and will be checked when the rules are applied. The reason for discarding candidate rules with unmatched memory operands is that the resulting constraining conditions will require time-consuming data dependence analysis to determine whether the constrained equivalence is satisfied or not when such rules are applied.

Otherwise, all other rules are considered as a non-equivalent rule and be discarded.

4.4 Lightweight Online Analysis

For each constrained-equivalent rule to be applied, an online analysis is invoked to analyze the program context of the guest code sequence. The context information includes the data flow of the guest registers and condition codes, which can be obtained by statically analyzing the guest instructions. The context information is then used to determine whether the constraining condition of the matched constrained-equivalent rule is satisfied. For instance, if the analysis shows that a modified guest register is not mapped to any modified host register in the rule, and this modified guest register is not used in the following guest code, we can determine that the constraining condition has been satisfied in the program context, and the

translation rule can be applied.

In general, to collect the context information, the online analysis examines guest instructions that are executed after the matched guest instruction sequence. Each instruction is examined to see whether it defines or uses the register(s) or condition code(s) specified in the constraining condition of the matched translation rule. If a definition can be found before usage on *all* paths following the matched guest code sequence, the matched rule can be applied safely. Otherwise, if usage is found, the matched rule should not be applied as the modified guest register/condition code is used but the matched rule does not update it.

For indirect branch instructions, it is quite difficult to identify all possible branch targets statically. For simplicity, we stop the online analysis when an indirect branch is encountered and the translation rule will not be applied for safety consideration.

4.5 Handling Predicated Instructions

Predicated instructions are very common in many ISAs, e.g., ARM and MIPS. A predicated instruction executes only if its predicate bit is "True". Otherwise, the instruction is a "nop". For example, "add ne r0, r0, r1" in ARM will be executed only when the condition code is not equal ("ne"). Some ISAs like x86 do not support predication, and conditional branches are used instead. It is worth noting that the original learning approach cannot handle predicated instructions. So how to efficiently support predicated instructions is another important design issue for a learning-based approach because the predicate tag in predicated instructions and conditional branch are not equivalent although the execution results are the same.

In translation, we use a lightweight analysis to divide predicated instructions into multiple blocks and generate conditional branches around those blocks according to their predicate information to support the translation of predicate instructions. Before translating a basic block, we first check the predicated condition of all instructions and divide the basic block into multiple *condition blocks*. Each condition block includes instructions with the same predicated condition. In one condition block, the translation rules can be directly applied without considering the predicated condition. After a condition block is translated, a branch instruction with the opposite condition is added to the host basic block before the translated condition block is added to the host block. The branch target is the instruction following the end of the host block. This analysis is very lightweight and each basic block only needs to be checked once.

Note that an instruction with a predicated condition may change the condition codes itself. For example, `cmp ne r0, 0` will update the condition code if the last condition code is *not equal*. So, instructions after these instructions that may change condition codes should be divided into a new condition block even the predicated condition is the same.

4.6 Discussion

Our enhanced learning approach currently only supports user-level applications. The translation for full-system level applications is not supported because full-system translation is more complex with mechanisms such as system calls, interrupts and device I/O. These mechanisms make the learning and matching of rules more difficult. It is left in our future work.

ABIs and many instructions such as *indirect branches* are not supported either. For ABIs, the calling conventions, such as how parameters are passed and how many parameters are used, are difficult to be identified and translated by rules. For example, ARM use registers to pass parameters but no specific instructions are used. But in X86, the *push* instructions will be used for passing parameters. For indirect branches, DBT systems usually search the branch target address according to a branch table maintained at runtime, which is not available at compile time. It makes it impossible to translate by our learned rules.

5 Experimental Results

In this section, we evaluate our prototype and address the following research questions:

1. How much performance improvement can be obtained by our enhance learning scheme in which we relax the requirement of matching storage operands as described in Section 4?
2. Where does the performance improvement come from when we include the added constrained-equivalent translation rules?
3. What is the effect of relaxing the strict semantic equivalence requirement?
4. How much overhead will the dynamic analysis incur?

5.1 Experimental Setup

Our enhanced learning-based DBT prototype is implemented based on QEMU (version 2.6.0) which is the same as the original learning scheme. The guest ISA is ARM, and the host ISA is x86. The LLVM compiler (version 3.8.0) is used to generate binary code for guest/host ISAs. All binary codes are generated using the same optimization level -O2. The same version of source code and guest/host binary code are used for comparison. One machine with 3.33GHz Intel Core i7-980x with six cores (12 threads) and 16GB memory is set up exclusively for performance evaluation. The operating system is the 32-bit Ubuntu 14.04 with Linux 3.13 for both machines. We used an older version of the system because we need to compare our new approach with the original approach, which used the same older version of the system. Besides, our

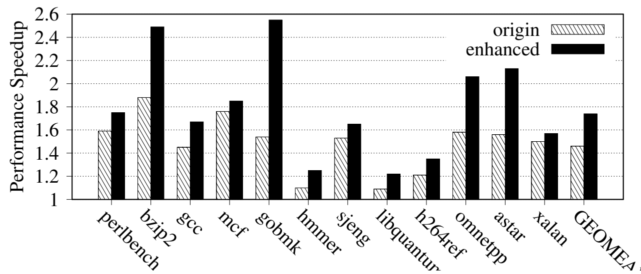

Figure 6: Performance comparison of the original and enhanced learning-based approaches.

experimental results are valid regardless of the system version used.

We use the 12 benchmarks in SPEC CPU INT 2006 with the reference inputs in our studies. To be as close to the real-world usage scenarios as possible, the performance of each benchmark is evaluated by the rules learned from other 11 benchmarks excluding evaluated benchmark itself. Each benchmark is run three times to reduce the random influence. The enhanced learning scheme described earlier is implemented in Python. The enhanced verification is implemented based on FuzzBALL [19], a symbolic execution engine. The tiny code generator (TCG) in QEMU is also enhanced to support the translation of predicated instructions as described in the last subsection, As mentioned earlier, to apply the constrained-equivalent translation rules, the dynamic analysis should be performed before such rules are applied.

5.2 Performance Results

Figure 6 shows the performance comparison of our enhanced learning-based scheme (marked as *enhanced*) and the original learning-based approach (marked as *origin*). The performance of QEMU without using any of the learning schemes is used as the baseline. Table 1 shows the MIPS of performance of original and enhanced approaches.

Using the *ref* input for all SPEC benchmarks, the quality of the translated host code is the major factor that impacts the overall performance. As shown in Figure 6, our enhanced learning scheme can achieve a performance improvement of up to 2.55X with an average of 1.74X compared to QEMU, which is a 1.19X improvement over the original learning approach on average.

By studying the learned translation rules and how they are applied using our enhanced learning approach, we have the following observations on how they impact the overall performance. First, constrained-equivalent translation rules can usually be applied quite successful. The modified guest registers/condition codes that have no matching modified host registers/condition codes will usually be modified quickly again. This means they are only used to hold temporary value as we expected. Hence, relaxing strict matching requirements

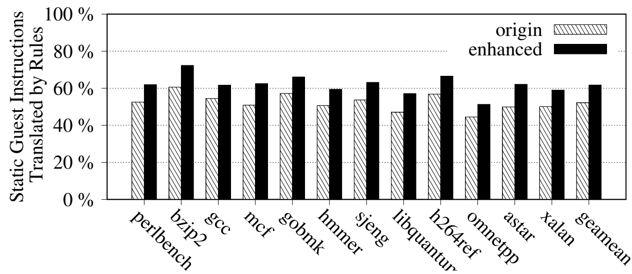
Table 1: MIPS of the original and enhanced learning-based approaches

Benchmarks	Original	enhanced
perlbench	221.63	250.15
bzip2	1211.32	1388.92
gcc	521.78	575.09
mcf	603.99	739.93
gobmk	372.18	616.31
hmmer	1448.56	1632.93
sjeng	474.71	485.23
libquantum	1469.59	1532.97
h264ref	189.99	215.69
omnetpp	195.28	284.74
astar	396.10	562.51
xalan	283.19	290.52
GEOMEAN	475.15	567.29

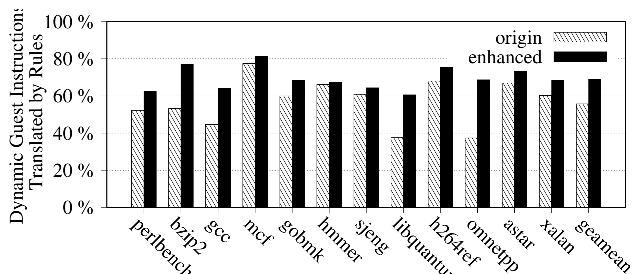
for storage operands can yield more translation rules, albeit constrained-equivalent rules, and can be applied quite effectively.

Second, by relaxing the equivalence constraints to allow constrained-equivalent translation rules that can include predicated and condition instructions greatly improve the overall performance. This is because typical DBTs such as QEMU usually use memory locations to emulate the condition codes. Such an approach will incur many additional memory operations to access and update those condition codes in memory and incur very high overhead. But the constrained-equivalent translation rules can take advantage of the host condition codes to emulate guest condition codes, which can significantly reduce such overheads.

Figure 7(a) and Figure 7(b) show the static and dynamic coverage of the guest binaries using the origin and our enhanced learning-based schemes, respectively. The *"Coverage"* here is defined as the percentage of guest instructions that can be translated by the learned rules. So the *"static"* coverage is the percentage of static code translated by learned rules and *"dynamic"* coverage here is the percentage of *"executed"* guest instructions translated by learned rules. Compare to the original learning-based scheme, our enhanced learning scheme can improve the static coverage from 52.2% to 61.8%, and the dynamic coverage from 55.7% to 69.1% on average. It is worth noting that *gcc* and *libquantum* have a much higher dynamic coverage improvement than others, but do not get an expected higher performance improvement. Conversely, *gobmk* attains a high performance improvement but not as much coverage improvement. The reason is that many high-quality rules are applied when translating *gobmk*, but in *gcc* and *libquantum*, the applied rules can only attain moderate improvement. This seems to indicate that the coverage improvement does not translate directly to the overall performance improvement, but could be an important secondary effect.

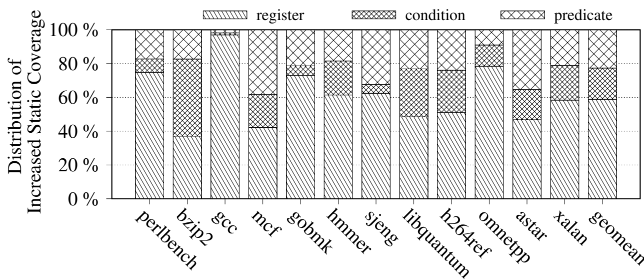


(a) Static coverage

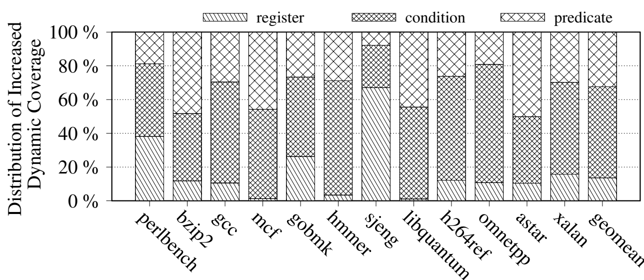


(b) Dynamic coverage

Figure 7: Static and dynamic coverage of translation rules.



(a) Distribution of increased static coverage



(b) Distribution of increased dynamic coverage

Figure 8: Distribution of the improved rule coverage.

To address the question of "where does the performance improvement come from when we include the added constrained-equivalent translation rules?", we analyze the coverage of the added translation rules when they are applied in each program. The results are shown in Figure 8. As described in Section 4, there are three major components in our relaxed equivalence constraints, i.e. we remove the strict requirement of exact matching. They are (1) register operands (marked as *register*), (2) condition-code operands (marked as *condition*), and (3) predicated-related instructions (marked as *predicate*). We did not include memory operands because they require more complicated data dependence analysis when they are applied.

A very interesting observation is that, among the added constrained-equivalent translation rules (their increased coverage is shown in Figure 7), the register-related constrained-equivalent translation rules constitute 58.83% of the static instructions on average. However, they only constitute 13.58% of added dynamic coverage. But the dynamic coverage of condition-code related rules is increased to 54.02% on average, while their static coverage is only 18.52%. This is because the condition codes are usually associated with the bound check, such as at the end of a loop. So, these instructions will be executed more frequently than others in their dynamic coverage.

To study the quality/efficiency of translated rules, Figure 9 shows the percentages of the reduced host instructions. On average, our enhanced learning scheme can reduce 11.28% of the total dynamic host instructions compared to the original learning scheme. We observe that the reduction in the host

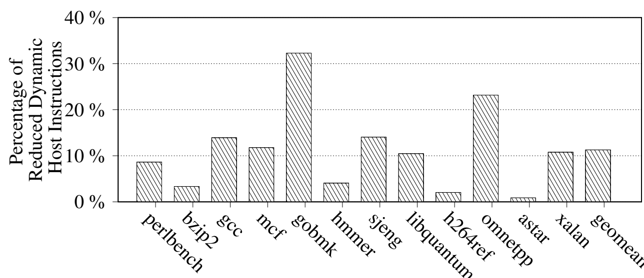


Figure 9: Reduction in dynamic host instruction counts by enhanced learning and translation.

instructions of *gobmk* is higher than 30%, and in *omnetpp*, it is higher than 20%. However, in *gcc* and *libquantum*, the reduction is only about 10%. This also confirm our observation that rules applied in *gobmk* and *omentpp* translation have a higher quality, i.e. fewer host instructions in those translation rules, than rules in *gcc* and *libquantum*. But, we also notice that *bzip2* and *astar* attain a high performance improvement but only a moderate number of host instructions are reduced. One probable explanation is that even though they may have similar dynamic host instruction counts, more efficient and architecture-specific host instructions may have been used.

5.3 Learning Results

We further study the effect of our proposed relaxed learning scheme in other related aspects. The first is about the "yield" obtained during the learning phase, which shows how

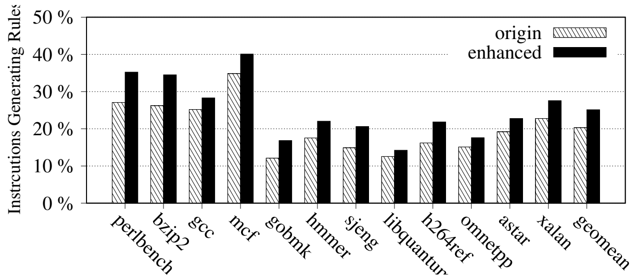

Figure 10: The yields of rule learning.

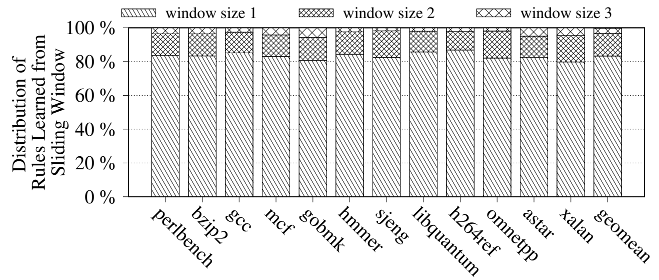

Figure 11: Rules distribution of sliding windows.

many translation rules can be harvested among the candidate rules during the learning phase. The other aspects include the effect of using the sliding window, and the distribution of the constrained-equivalent rules learned based on our relaxed equivalence constraints, i.e. relaxing the strict matching requirement on three storage operand types described in Section 4.

Figure 10 shows the yield obtained during the learning phase using the original learning scheme (marked as *origin*) and our enhanced learning scheme (marked as *enhanced*). The learning yield is increased from 20.3%to 25.1%. Even though the improvement in learning yield is moderate as we only made moderate relaxation on the semantic equivalence requirements, but as the obtained performance results show the quality of these rules is quite high. The moderate yield improvement also shows that there is a high potential for more high-quality rules to be learned and harvested. Another interesting question is that if a significant number of more source programs is used in the training phase, even with a low yield, how much more rules can be learned, and how much more performance improvement can be achieved by applying those added rules. These questions are beyond the scope of this paper.

Figure 11 shows the distribution of the translation rules learned using a flexible sliding window. We only show the data for a window size of up to three source statements because significantly fewer rules can be learned beyond 3 source statements. As the result shows, 13.16% of new rules can be learned from a window size of 2 and 3 source statements. The rules learned from window size 3 and beyond are less than 3.31%. So, a larger learning window is not necessary.

Figure 12 shows the distribution of the rules we learned using our enhanced learning scheme. On average, 16.84% of the learned rules are register-related (marked as *register*), while 8.16% are condition-code related (marked as *condition*) rules. We find that many constrained-equivalent rules related to local registers are used to load values from the memory before some computation, and are stored back to the memory after the computation. This is because RISCs are primarily "load/store" architectures, i.e. values in memory must be loaded into registers before computation and stored back to memory when the computation is completed. So many

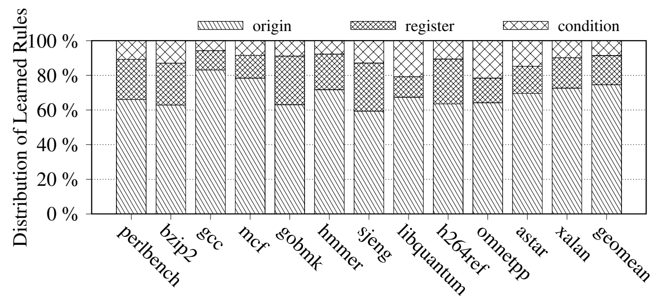

Figure 12: Distribution of rules learned by enhanced learning.

temporary/local registers are used. Another observation is that the amount of register reuse is minimal on RISCs, only 3.57% in total. So, only in rare situations, the compiler will use multiple registers instead of only one register. Such behavior is reflected in the use of the learned rules in the application phase.

5.4 Performance Overhead of Online Analysis

As the lightweight dynamic analysis is needed in the application of the constrained-equivalent translation rules, its runtime overhead needs to be evaluated. Figure 13 shows such runtime overhead with and without dynamic analysis. To measure such overheads, we collected the performance data with original approach and compare them with those with only the online analysis but without applying the constrained-equivalent rules. As Figure 13 shows, the dynamic analysis will introduce very little overhead, which is less than 1% on average. The low overhead is due to two main reasons. First, the dynamic analysis typically only needs to check a few registers and condition codes. And the percentage of the rules that requires dynamic analysis is not very high. Second, the relaxed register and condition-code operands are usually updated very quickly, so only a very small number of instructions need to be analyzed in practice. Both factors greatly reduce the analysis overhead.

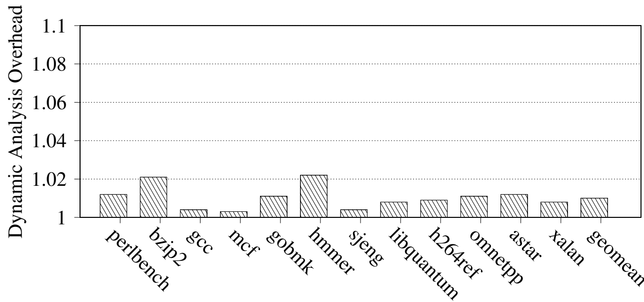

Figure 13: The performance overhead of dynamic analysis.

6 Related Work

To improve the efficiency of the translated host binaries, many manual optimization techniques have been proposed. For example, some try to efficiently translate guest single-instruction-multiple-data (SIMD) instructions [7, 10, 16]. Another work proposes to leverage host hardware features to apply post-optimization to host binary code after the translation [30]. Some recent work also proposes to optimize dynamically-generated guest binary code [8]. Different from those approaches, most of which rely on manually constructed translation rules, our enhanced learning-based approach proposed in this paper can automatically learn binary translation rules.

Previous work in [1] also proposes to use peephole superoptimizer to generate binary translation rules for static binary translators. For each potential guest code sequence, an exhaustive search is employed to explore all possible sequences of host instructions to examine their equivalence. However, it takes a very long time to collect sufficient translation rules, i.e., could be up to one week as mentioned in the paper. Moreover, due to the exponential increase in the number of possible instruction sequences, this approach can only generate translation rules with a guest code sequence of up to 3 instructions. This can significantly limit the quality of the generated translation rules because many high-quality translation rules have more than 3 guest instructions.

Although the learning-based approach was originally proposed in [23], our enhanced learning-based approach differs from the original approach in a significant way. Our proposed enhanced approach allows relaxation of semantic equivalence, thus can learn constrained-equivalent translation rules while the original approach simply discards them. These relaxed translation rules can improve the total coverage of the guest binaries and improve the yield of rule generation. More importantly, these constrained-equivalent translation rules can further improve the performance of the translated host binary code.

Another DBT system, HQEMU [9], which is also based on QEMU, translates guest binary code into LLVM intermediate representation (IR) and then leverages LLVM JIT to generate more optimized binary code. However, the overhead introduced by the LLVM optimization can offset the benefit gained from the optimized host binary code, especially for short-running guest binaries. Moreover, due to the lack of source-level information in the LLVM IR translated from the guest binary code, e.g., type information, it is quite challenging to take full advantage of the LLVM optimization. In contrast, the translation overhead for applying the learned translation rules are much smaller, and no additional information is required to apply the learned rules.

There has been a lot of research to improve the performance of the DBT system itself [3–5, 11, 12, 24, 25]. These methods can typically be used in conjunction with our approach to further improve their performance.

7 Conclusion

As one of the core enabling technologies, DBT has been extensively used in many important applications. To improve the efficiency of DBT systems, this paper proposes an enhanced learning-based approach, which can automatically learn optimized binary translation rules. The learned translation rules can then be applied to a DBT system to generate more efficient host binary code. Compared to the original learning approach, our enhanced learning-based approach relaxes the semantic equivalence requirements to allow more efficient constrained-equivalent translation rules. We redesign the original learning process and the verification engine to accommodate such constrained equivalence. Moreover, to preserve the correct semantics of the translated code when such constrained-equivalent translation rules are applied, a lightweight online analysis is employed in the enhanced DBT system to check the constraining conditions. The constrained-equivalent translation rules are applied only when the constraining conditions are satisfied. We have implemented the proposed approach in a prototype and extended a widely-used DBT system, i.e., QEMU, to accept such enhanced translation rules through learning.

Experimental results on SPEC CINT2006 show that the proposed approach can improve the dynamic coverage of the translation from 55.7% to 69.1% and the static coverage from 52.2% to 61.8%, compared to the original approach. Moreover, up to 1.65X performance speedup with an average of 1.19X are observed.

Abstract

A large class of IoT applications read sensors, execute application logic, and actuate actuators. However, the lack of high-level programming abstractions compromises correctness especially in presence of failures and unwanted interleaving between applications. A key problem arises when operations on IoT devices or the application itself fails, which leads to inconsistencies between the physical state and application state, breaking application semantics and causing undesired consequences. Transactions are a well-established abstraction for correctness, but assume properties that are absent in an IoT context. In this paper, we study one such environment, smart home, and establish inconsistencies manifesting out of failures. We propose an abstraction called *transactuation* that empowers developers to build reliable applications. Our runtime, *Relacs*, implements the abstraction atop a real smart-home platform. We evaluate programmability, performance, and effectiveness of transactuations to demonstrate its potential as a powerful abstraction and execution model.

1 Introduction

Building reliable IoT applications that interact with the physical world on top of existing solutions is difficult. Current IoT solutions (e.g., Smartthings [14] and OpenHAB[12]) provide simple abstractions that allow developers to easily read sensors and actuate actuators. However, they lack high-level abstractions for writing reliable and fault-tolerant applications that can tolerate different types of failures that might happen. Therefore, application programmers need to implement tedious and error-prone code for not only handling all kinds of failures happening in the physical world, but also to guarantee consistency between operations on application states (called soft states hereafter) and states of IoT devices (called hard states). For instance, an actuation to turn on an alarm might fail while the alarm state in an application might have been set to true.

The use of serverless functions as a de facto platform for running IoT applications has exacerbated the reliability issues of these applications even further. This is because serverless computing infrastructure can terminate running applications at any point [2]. This again leaves incomplete operations on some hard states (e.g., lock all doors) inconsistent with an operation on soft state inside the application (e.g., set the home state to `safe` after all doors are locked).

Transactions seem like the right mechanism for addressing the above issues. Interestingly though, a transactional abstraction cannot fix these issues because of intrinsic properties of IoT devices (and their associated hard states). A transactional abstraction is ideal for ensuring isolation and all-or-nothing guarantees among soft states. Moreover, a transactional system can easily rollback soft states without other transactions or users noticing effects of a rolled back transaction. However, rolling back a hard state has consequences. The state might have already been observed by a user and rolling it back may be undesirable. Or even worse, some states cannot be rolled back (e.g., undoing actuation of a water dispenser).

This paper proposes an abstraction called *transactuation*. Transactuations hide the complexity of handling various failures and allow developers to easily maintain soft states to be consistent with respect to reads and writes to hard states – states of sensors and actuators. Objectively, transactuations allow a developer to specify dependencies among operations on soft and hard states along with a *sensing/actuating policy* which specifies the conditions under which soft states can commit despite failures.

We provide a runtime system called *Relacs* that implements the abstraction for the smart home environment. Relacs transforms an application into a serverless function, and reliably executes the application in the cloud while enforcing transactuation specific semantics. We note that while the focus of this paper is on smart homes, the transactuation abstraction is not particularly specific to smart homes, and can be applied to other IoT environments as well.

[†] Work done at Samsung Research America. Now at Uber Technologies.
[‡] Work done at Samsung Research America.

Concretely, this paper has the following contributions:

1. *Study of smart-home applications.* Using static analysis, we conduct a comprehensive study of smart-home applications written for two popular platforms [12, 14] and identify drawbacks of existing platforms in writing reliable and fault-tolerant applications (Section 3).

2. *Transactuations.* We present our abstraction that allows developers to simply write reliable IoT applications. Transactuations preserve the dependencies between operations on hard states and soft states, which when broken, break application semantics (Section 4).

3. *Relacs.* Our runtime, Relacs, enforces a serializable execution of transactuations without rolling back hard states (i.e., states of actuators) while enforcing the specified sensing and actuating policies (Section 4 and Section 5).

4. *Evaluation.* We evaluate representative smart-home applications to reveal the correctness issues due to lack of appropriate abstractions. Our evaluation further demonstrates that (a) Transactuations are an effective high-level abstraction for building reliable IoT applications and reduce lines of code significantly compared to manually handling failures. (b) Relacs guarantees reliable execution of transactuations while imposing reasonable overheads over a baseline that does not provide consistency between operations on hard states and soft states (Section 6).

2 Background & Model

In this section, we first review existing smart-home platforms and their programming models. We focus on smart homes as a case study of class of IoT environments that deal with real world state since many smart home applications and platforms are publicly available. We then discuss different types of failures that occur in IoT environments.

2.1 Smart-home Platforms

To setup a smart home, a user installs centralized gateways, called smart-home hubs or simply hubs, to connect in-home devices (e.g., light bulbs, outlet strip, and motion sensor) that typically communicate through low-energy wireless protocols (e.g., Zigbee [17], ZWave [16], and Bluetooth Low Energy [4]). The user then installs smart-home applications to create her desired home automation. For instance, to turn on a balcony light when motion is detected outside.

Currently, cloud-centric smart-home solutions (e.g., Smartthings [14]) are the most widely used architecture [28]. In this model, a hub is only responsible for collecting device events, and forwarding them to the cloud, where applications run. The applications running in the cloud then process events and send actuation commands back to the hub, which forwards the commands to corresponding devices. An alternative architecture is to run applications inside hubs. OpenHAB [12] follows this hub-centric approach.

```
1   preferences {
2     input(sensor, "capa.co2", req:true)
3     input(switches, "capa.switch", multi:true)
4     input(level, "number", req:true)
5   }
6   def initialize() {
7     state.active = false;
8     subscribe(sensor, "co2", handleLevel)
9   }
10  def handleLevel(evt) {
11    def co2 = sensor.currentValue("co2");
12    if(co2 >= level && !state.active) {
13      switches.each { it.on(); }
14      state.active = true;
15    } else if(co2 < level && state.active) {
16      switches.each { it.off(); }
17      state.active = false;
18    }
19  }
```

Listing 1: CO_2 vent application that turns exhaust fans on when CO_2 level is high and turns off otherwise.

2.2 Programming Model

In most smart-home platforms, an application is written in a trigger-action programming model [45] where an application comprises event handlers. Handlers can subscribe to changes in sensor/actuator states, updates to shared states, or timer-based events. Handlers can issue the following operations:

- Hard read: reading sensor/actuator values.
- Hard write: sending actuation commands to actuators.
- Soft read: reading application states from shared storage.
- Soft write: writing application states to shared storage.

In the remainder of this section, and for simplicity, we solely detail SmartThings [14] programming model. Yet, we note that other platforms have very similar constructs.

SmartThings uses capabilities, attributes, and commands to manage devices. Each device has one or more capabilities, and each capability has one or more associated attributes and commands. For example, a smart light bulb has two capabilities, switch and color. The switch capability allows an application to control the bulb status via `on`/`off` commands. The color capability has three attributes, color, hue and saturation that can be controlled via `setColor`, `setHue`, and `setSaturation` commands.

Listing 1 shows a SmartThings application, named CO_2 vent, written in the Groovy language [5]. It reads CO_2 level from sensors, and turns on an exhaust fan if the level is high. Similarly, it turns off an exhaust fan if the level is low. A developer first declares mapping of variable names to capabilities in the preference section (lines 1-5). Consequently, a variable is mapped to an array of devices with the same capability. For example, variable `switches` (line 3) gets mapped to an array of exhaust fans having the switch capability.

A developer then subscribes event handlers to value changes of some capabilities or timer schedules. In line 8, she subscribes an event handler called `handleLevel` to co2 capability. Observe that inside the handler, she can perform

hard read on sensor data (`sensor.currentValue()` in line 11) and soft read on shared states (reading `state.active` in line 12 and 15). Also, the developer can issue hard writes to list of actuators (line 13 and 16). She can also perform soft writes to application states (assignments to `state.active` in line 14 and 17).

2.3 Failures in IoT Environments

Previous work [20, 33] have shown a variety of failures in IoT environments. For instance, hubs can fail due to plug disconnection, hardware failure, and driver crash. IoT devices can fail due to battery drainage, plug disconnection, and failure in a sensor subsystem. Additionally, network loss occurs due to RF interference, concrete slab flooring and copper siding. These failures lead to permanent or intermittent unavailability of devices in an IoT environment.

Although, these failures are common, existing platforms do not provide a simple way to detect and handle them. A failed hard read can produce a null or stale value that a developer needs to handle or explicitly validate its timestamp (freshness). Detecting a failed hard write is even more difficult due to the asynchronous nature of IoT programming model. For instance, a developer needs to subscribe to an event triggered by a hard write, and periodically check if the event is fired. As shown in other systems [30, 35, 37], inserting failure detection and handling code for asynchronous environments is challenging and error prone. Moreover, due to inherent event-driven concurrency in applications, it is notoriously difficult to prevent interleaving and concurrency-related bugs in IoT platforms [40].

3 Problem Study

Existing smart-home solutions do not guarantee any consistency between soft reads/writes (i.e., reads/writes from/to shared storage) and reads/writes to hard states (i.e., sensor reads and actuation commands sent to actuators) in case of failures. Application developers need to carry the burden and ensure the correctness of an application when a failure occurs.

In this section, we present a systematic study of open source smart-home applications, using static analysis, in order to unearth various inconsistencies, that surface under failure, between operations on soft and hard states.

3.1 Inconsistency

Listing 2 shows a simplified code excerpt from a smart security application. This application associates a soft state named `alarmActive` with the status of an alarm. If the application detects an intruder when the alarm is not active, it activates the alarm and sets `alarmActive` to `true`. However, an inconsistency arises if the alarm is not activated properly. For example, RF interference may cause an actuation command to be lost. This problem is so common that some brands (e.g., Fortrezz [15]) give warnings regarding RF interference, and explicitly ask consumers to not use the alarm in life supporting situations. Observe that even though `alarmActive` is set, the states of the physical world and application have diverged. Further, if the sensors detect the intruder again, the application will not retry to activate the alarm because as per the application's state the alarm is ringing. Clearly, the developer does not anticipate such a failure, and this divergence is irreversible without manual intervention. Such inconsistencies cause changes in application semantics and compromise correctness, and may severely affect smart-home users.

```
1  def intruderMotion(evt) {
2    ...
3    if (isIntruder(evt) && !state.
         alarmActive) {
4      alarm.strobe();
5      state.alarmActive = true;
6    }
7    ...
8  }
```

Listing 2: A simplified code excerpt from Smart Security application that detects an intruder using sensors, and activates an alarm if it has not been activated previously.

Moreover, stale hard reads may also break correctness of an application. For example, recent CO_2 level events might never get delivered to the CO_2 vent application in Listing 1. By reading a stale CO_2 level, the application may incorrectly turn off the exhaust fans.

Besides device failures, similar issues arise if an application crashes. For instance, an inconsistency arises if the smart security application fails between sending a command to set the alarm (line 4) and setting the active state to true (line 5).

Finally, applications may modify shared soft and hard states concurrently [40] which can cause canonical interleaving based inconsistencies [39].

As an example, the following quote from a disgruntled SmartThings customer [9] who got robbed during his vacation shows the impact of the inconsistency problem: "*More importantly, we were robbed when we were out on vacation. ... The logs show the motion of the robbers, but it never sounded the alarm ... I no longer trust it to do what it is supposed to do when it is supposed to do.*"

3.2 Dependency

In the previous section, we showed connections between hard states and soft states that are potential sources of inconsistencies due to hard read/write failure. We call these connections between two operations on hard states or two operations between soft and hard states that are semantically associated, a *dependency*. By identifying dependencies in an application, we can study the effects of failures on its correctness.

In order to systematically analyze smart-home applications, and understand how failures can affect them, we categorize

dependencies into four classes, using the following notations: we represent a hard read to device D as HR_D, and denote a hard write to device D with value V as $HW_D(V)$. A soft read from application state X is denoted as SR_X, and a soft write to state X with value V is represented as $SW_X(V)$.

1. $HR_D \rightarrow HW_{D'}(V)$: a dependency in this category captures the effect of a failure in a HR_D. The read might fail to return any value if device D is unavailable, or it might return a stale value. In either case, it implies that the application may exercise the dependency incorrectly, thus breaking its semantic. Such a dependency in an application can be because of a control dependence [27] or a data dependence.

If the dependency is a control-dependence [27], the value of HR_D controls the execution of $HW_{D'}(V)$. For example, in Listing 1, the dependency between lines 12 and 13, and also between lines 15 and 16 are control dependences. The hard read in line 11 flows into the control statements in lines 12 and 15. Therefore, a stale read at line 12 might incorrectly switch off the exhaust fans, and update the soft state even though the CO_2 levels are unsafe. A read value can also flow into a hard write via data dependencies. For example:
`a =` HR_{D_1}`; c = foo(a, b);` $HW_{D_2}(c)$.

2. $HR_D \rightarrow SW_X(V)$: this dependency affects the execution of a soft write. Analogous to $HR_D \rightarrow HW_{D'}(V)$, this results in a missing soft write or an incorrect soft write, because of control and data dependences. In turn, the incorrect soft write leads to unexpected program behavior when the state is read elsewhere. In our running example, this dependency exists between lines 12 and 14, and also lines 15 and 17.

3. $HW_D(V) \rightarrow SW_X(V')$: a hard write to soft write dependency is more subtle since $SW_X(V')$ is not a control or a data dependence on a $HW_D(V)$. Nevertheless, we observe that semantically tying a soft state with a hard state — meaning the soft state is an indicator of the hard state — is a common practice in many smart-home applications. Developers use this technique mainly to save battery: by associating a soft state with an actuation, developers can use the soft state elsewhere in the code instead of reading hard states.

For example, in the CO_2 Vent application, the developer implicitly creates a $HW_{switches}(ON) \rightarrow SW_{active}(true)$ dependency between lines 13 and 14, and also between lines 16 and 17. Thus, a failure in turning on `switches`, even if temporary, leaves a permanent inconsistency. Any subsequent change in the CO_2 level, even above the `level`, precludes turning on the exhaust fans.

To find a $HW \rightarrow SW$ dependency in the code, we compute the postdominance relation [23]: a code point b postdominates a code point a, if b is executed on every path from a to the end of the analyzed entity, which in our case, is an event handler. After computing postdominance instances, we manually look at all instances to confirm if the pair is semantically tied. Accordingly, we infer a case for semantic error if the soft state is read elsewhere in the application.

4. $SW_X(V) \rightarrow HW_D(V')$: this dependency has the same semantic effect as $HW_D(V) \rightarrow SW_X(V')$.

Note that all dependencies with soft reads (i.e., $SR_X \rightarrow *$), are not directly related to device failures. However, we still statically compute all such control and data dependences as an incorrect soft read can produce unintended behavior. Concretely, a soft read can be on a state determined by an incorrect, inconsistent, or missing soft write originating from the dependencies described above.

3.3 Analysis and Findings

We statically analyzed 147 SmartThings applications [19] and 35 OpenHAB applications chosen from IoTBench [10] by adding phases to the Groovy compiler. The AST visitors, `GroovyClassVisitor` [8], allow us to build a call graph per entry point and an intermediate representation (IR) amenable to data and control-flow analysis.

We analyzed the applications using inter-procedural data and control-flow analysis to understand the dependencies and their implications. Our analysis yields two key benefits: (i) understand the implications and the extent of failures on a large set of smart-home applications, and (ii) mitigate or eliminate the problems with our programming abstraction, called transactuation.

On average, the studied applications have three triggers, and manage a diverse set of devices (4–5 capabilities). In order to get a holistic view of the home state, on average, the applications perform three hard reads. They also perform between seven to nine hard writes on average. This shows that many of these applications try to provide automation among a set of devices (e.g., turning on restroom light, preparing coffee, and playing music, when a user wakes up), instead of managing a single device. Additionally, our analysis revealed that developers regularly use soft states to share states not only among handlers, but also among different applications. These results indicate that smart-home applications are fairly complex, and their behavior could be complicated through the use of handlers triggered by events that read/write both hard and soft states.

More specifically, we observed that, on average, applications have 3–10 instances of $HR \rightarrow HW$, 1–2 instances of $HR \rightarrow SW$ and 1–2 instances of $HW \rightarrow SW$ dependencies. We inspected these dependencies to find their potential implications on systems lacking appropriate abstractions to capture failures. We categorized the implications as follows: (i) missing actuation, (ii) wrong actuation, (iii) inconsistent soft state, (iv) missing notification, and (v) wrong notification . These implications can lead to unwanted outcomes, some of which have serious consequences such as security threats, health hazards, and missing critical alerts, e.g., a fire alarm not rung. They may also cause inconveniences, e.g., erroneous automation, incorrect notifications, sirens not turned off. Out of all 182 applications, our analysis unearthed 67 SmartThings and 32 OpenHAB applications, that have unintended effects. Due

Application	Type	Consequence	Dependency	Correction/Mitigation
Smart Humidifer (ST)	Automation	Wrong status flag causes humidifier to never be turned on/off. Incorrect notification.	*HW*→ *SW* *SR*→ *	Correct status flag to retry turning humidifier on/off later. Notify glitch to user.
Thermostat Auto Off (ST)	Energy	Wrong status flag causes thermostat to never be turned on/off.	*HW*→ *SW*	Correct status flag to retry turning thermostat on/off later.
CO2 Vent (ST)	Safety	Wrong status flag causes exhaust fans to never be turned on/off.	*HW*→ *SW* *SR*→ *	Correct status flag to retry turning exhaust fans on/off later.
Elder Care (ST)	Safety	Missing elder inactivity notification	*HR*→ *HW*	Notify glitch to user.
Smart Care (ST)	Safety	Alarm not armed. Missing notification.	Bad interleaving *HW*→ *SW*	Notify glitch to user.
Alarm (OH)	Security	Wrong status flag causes sirens to never be turned off.	*HR*→ *SW* *SR*→ *HW*	Correct status flag to retry turning sirens off.
Fire Detection (OH)	Security	Wrong status flag causes fire alarm to never ring	*HW*→ *SW* *SR*→ *	Correct status flag to retry ringing alarm later.
Forgiving Security (ST)	Security	Alarm does not ring. Incorrect notification.	*HW*→ *SW* *SR*→ *	Notify glitch to user.
Lock It When I Leave (ST)	Security	Door not locked but home vacant.	*HR*→ *HW*	Notify user to lock manually.

Table 1: Critical undesirable consequences in smart-home applications if failures are not handled and how developers can correct or mitigate the problems. ST and OH are abbreviations for SmartThings and OpenHAB, respectively.

to space constraint, we only show a subset of them with unintended semantics and potential fixes in Table 1.

To address these implications, a developer needs to preserve the semantic invariants of the dependencies to avoid discrepancy between the physical and application realms. One key trait of these applications is that their semantics tolerate different numbers of failed hard reads and writes. For example, for *HR*→*HW* in the application that computes average humidity level and reacts accordingly, even if some hard reads are stale based on their timestamp (i.e., some humidity sensors fail), the application can proceed with correct semantics as long as some sensors function properly. On the other hand, for *HW*→*SW* in the application that locks all doors and set the home state to `safe`, the developer needs to ensure that the home state is not set, even if only one door fails to be locked. To summarize, the following two key aspects are missing in existing IoT abstractions: 1. identifying the inherent connection between application semantics and *number* of failed operations, and 2. recomputing application states to preserve invariants under failed hard reads/writes.

4 Transactuations

To address the issues discussed in the previous section, we introduce a new abstraction called *transactuation* that allows a developer to build a reliable smart-home application. Transactuations provide the following two guarantees: (1) preserve dependencies between reads/writes to hard states and soft writes (i.e., *HR*→*SW* and *HW*→*SW*) even in cases of hardware and communication failures. (2) ensure isolation among transactuations that execute concurrently.

The concept of transactuations is very similar to database transactions. Yet, due to the intrinsic nature of physical world, it is impossible to ensure similar transactional guarantees. We note that transactuations are not meant to replace transactions completely. Instead, they are designed to address a similar problem in a cyber-physical environment which inherently prevents us from making strong assumptions. Precisely, transactuations and transactions differ as follows:

1. *Atomic durability:* atomic durability [36] guarantees that either all updates inside a transaction eventually become durable, or none of them becomes durable. Since IoT devices can neither be locked nor rolled back (e.g., in case of some failures), transactuation cannot guarantee atomic durability of hard writes. More specifically, unlike a transaction, a transactuation only guarantees atomic durability of soft writes but not hard writes inside it. Thus, if a hard write fails, a transactuation still commits by forcing its soft states to be consistent with its hard states, as per developer specified policies (see Section 4.1).

2. *Isolation & Atomic visibility:* strong isolation models (e.g., serializability or snapshot isolation) requires a transaction to read a consistent snapshot of a system (e.g., the last committed state) and precludes a use of partially committed states. A transactuation executes on the latest known consistent snapshot of the physical world, in isolation from other concurrent transactuations. However, two concurrent transactuations can execute on different snapshots of the physical world in absence of any committing transactuation. Additionally, (internal) atomic visibility ensures that effects of all updates in a transaction become visible to another transaction atomically [36]. Transactuations are also capable of guaranteeing internal atomic visibility: effects of a transactuation become atomically visible to other transactuation. However, in a smart home domain, consumers will unavoidably observe the effect of a hard write operation the moment it gets

executed in an actuator. Thus, it is impossible to provide *external* atomic visibility. For instance, one cannot expect that a smart-home user to observe all door locks become locked instantaneously.
Transactuations, further add to the definition of consistency based on consistency between hard reads/writes and soft writes. Transactuations preserve two invariants as follows:
(D1) A transactuation guarantees that if it executes, the staleness of its hard reads is bounded, as per the developer specified tolerance. A developer leverages this invariant to ensure inconsistencies arising out of breaking *HR*→ * dependencies are detected, and appropriate actions are taken.
(D2) If writes to soft states are committed, it implies that sufficient number of hard writes as per developer specification have successfully executed. A developer leverages this invariant to enforce consistency of *HW*→ *SW* dependencies.

4.1 Abstraction & API

Transactuations contain three pieces of logic which a developer writes as lambda expressions. A lambda expression is a function that can be passed as an argument to another function [1, 7, 11]. In the rest of this paper, we refer to these lambda expressions as lambdas. A transactuation can have the following three lambdas: perform lambda, onSuccess lambda, and onFailure lambda.

perform lambda. A perform lambda contains the core logic of a transactuation. Inside a perform lambda, a developer can perform hard writes (`actuate(Device, Value)`), soft reads (`read(State)`), and soft writes (`write(State, Value)`) as shown in Listing 3.

To assign a perform lambda to a certain transactuation, a developer calls the `perform()` method and passes the lambda as an argument as shown in lines 5–15 of Listing 3. The method signature is `perform(performLambda, [sensorList, timeWindow, sensingPolicy], [actuatingPolicy])`.

A developer cannot explicitly issue a hard read inside a perform lambda. Instead, she has to specify a list of required hard states as an argument (i.e., `sensorList`) to `perform()` method. The required hard states are read before perform lambda is executed, and a list of available hard states are accessible as key-value pairs to perform lambda, using `sensors` parameter of a perform lambda (line 5). Disallowing explicit hard reads inside a transactuation prevents reading stale or null sensor values, which can break application semantics.

To preserve consistency between hard reads and soft writes in case of a sensor unavailability, a developer can use a time window along with a sensing policy. The time window specifies that the sensor list must be validated such that, after validation, the list of available sensors includes those that have received events close in time. Specifically, a time window defines the duration when the transactuation triggering event and read hard states remain valid. For instance, a window of

```
1  function handler(evt) {
2    let tx = Transactuation(evt);
3    // executes if all CO2 sensors received
4    // events in past 5s w.r.t. triggering event
5    tx.perform(func(sensors){
6      let co2 = sensors['co2'];
7      let active = read('active');
8      if (co2 >= threshold && !active) {
9    //if all fans can be on, set active to true
10       actuateAll('fans', 'on');
11       write('active', true);
12     } else if (co2 < threshold && active) {
13       ...
14     }
15   }, ['co2'], 5, 'all', 'all');
16   // executes if both policies are met
17   tx.onSuccess(func(evt) {
18     let txs = Transactuation(evt);
19     txs.perform({
20       actuate('msg', 'CO2 is high');
21     }, 'none', 'none');
22     txs.execute();
23   });
24   // executes if either one policy is not met
25   tx.onFailure(func(evt) {
26     let txf = Transactuation(evt);
27     ...
28   });
29   tx.execute(); }
```

Listing 3: CO2 Vent written with transactuation. The code presented here is in synchronous style but our implementation uses asynchronous Node JS.

10 seconds has the following intent: a hard state passes validation if its most recent event and the transactuation triggering event are not more than 10 seconds apart.

A sensing policy is an acceptable level of hard-read failures that a transactuation can tolerate. It specifies that under what condition a perform lambda can be executed over a returned list of window-validated sensors. The perform lambda in turn may or may not execute depending on the sensing policy. Transactuations support three sensing policies:

- *All*: ensures that the perform lambda executes only if all hard states in the sensor list pass validation. Consider an application that reads presence sensors of every user and turns on cameras if no one is present. For privacy, *all* sensors need to pass validation. If even one presence sensor fails, it should not risk turning on the cameras since it violates privacy.
- *Any*: guarantees the execution of the perform lambda as long as at least one hard state in the sensor list passes validation. For example, an application that computes average humidity level from multiple sensors to control fans, executes accordingly with correct semantics, even if some sensors fail, but not all.
- *None*: states that the perform lambda executes over the returned validated list of hard states regardless of how many hard states are unavailable.

Observe that a time window along with a sensing policy helps preserve *HR*→* dependency as per the developer's intention to preserve invariant (D1). To preserve invariant (D2),

a developer needs to specify an *actuating policy*. The actuating policy is an acceptable level of hard-write failures that is tolerable. To meet an actuating policy in case of a failure, soft writes inside a transactuation roll back to their initial values, and onFailure lambda executes. Similar to a sensing policy, an actuating policy supports the following semantics:

- *All*: states that modifications to soft states commit if all hard writes successfully finish. An example of this policy is an application that locks all doors and sets home state to `safe`. If even one door fails, the home state should not be set.
- *Any*: guarantees that soft state modifications inside a lambda commits if at least one hard write succeeds. For example, an application that actuates all sirens and sets the flag `ringing`. Even if only one siren rings, the flag should be set.
- *None*: states that soft writes commit despite of failures.

onSuccess lambda. An onSuccess lambda executes if the perform lambda of a transactuation succeeds (i.e., sensing and actuating policies are met). A developer can assign an onSuccess lambda to a transactuation via `onSuccess()` as shown in line 17 of Listing 3.

onFailure lambda. An onFailure lambda executes if a transactuation cannot meet its sensing or actuating policies. It is assigned to a transactuation via `onFailure()` as depicted in line 25 of Listing 3.

When a developer has set up all the lambdas for a transactuation, she executes the transactuation by invoking `execute()` (line 29), which is an asynchronous call that executes the perform lambda in the background.

Listing 3 illustrates the CO_2 Vent rewritten with the transactuation abstraction. The perform lambda is parameterized with 5s time window. The transactuation only reads one hard state, `co2`. The lambda executes if the latest sensor update from `co2`, and the triggering event, which is also `co2` fall in the 5 second time interval. `switches`, which binds to an array of fans, requires the "all" policy if we want the soft writes to be consistent with the actuations. The soft state `active` will be set to true only if all fans can be turned on, otherwise, `active` remains unchanged.

4.2 Chaining transactuations

A transactuation can be chained to other transactuations by invoking it in their onSuccess and onFailure lambdas. As we shall see in the next section, the runtime guarantees to execute chained transactuations sequentially: if a transactuation τ_j is invoked in onSuccess lambda of τ_i, τ_j is guaranteed to see the updates τ_i makes. We call this ordered execution of transactuations as T-Chain. This is particularly relevant in an asynchronous runtime where high latency operations can finish in arbitrary order, executing outside the critical path such as in worker threads [25, 44]. Thus, if τ_j wants to use a soft state written by τ_i, τ_j needs to be invoked in onSuccess lambda of τ_i. In addition, if τ_j requires actuations of τ_i to complete before it, these two transactuations must form a T-Chain.

5 Relacs

In this section, we detail the design of our runtime, called Relacs, that execute smart-home applications, along with a supporting key-value store called *Relacs Store*.

5.1 Relacs Store

All soft and hard states inside a transactuation are stored in a key-value store called Relacs Store. It hides all complexities of working with sensors and actuators by allowing developers to not only perform read/write operations on soft states inside a transactuation, but also to issue hard reads/writes.

Conceptually, every state inside the Relacs Store maintains two values, *speculative* and *final*. A speculative value means that the state has been updated logically in the Relacs Store, but is not confirmed to be final (i.e., issued to an IoT device). For example, a transactuation that wants to unlock a door will have the speculative value of the door set to `unlocked`, before the actuation command succeeds. When Relacs receives an ack event confirming the success of an actuation command, it updates the final value and discards the speculative value. Along with setting the final value, the Relacs Store also logs the timestamp of the ack event for validating a time window of a transactuation reading that hard state. In Section 5.2, we explain how speculative states help Relacs to speculatively execute transactuations.

Since multiple hard writes on the same state can execute before the system receives an ack from the corresponding device, Relacs Store needs to record all versions of speculative values that have not been finalized yet. When reading a state, Relacs Store returns the latest speculative value, or the final value if no speculative value exists. For instance, consider the following transactuations: a transactuation τ_i sets a lamp color to red. While the lamp is changing its color, τ_j changes the lamp color to green. In this example, Relacs Store logs both speculative values. Thus, if τ_k tries to read the state of the lamp, Relacs Store returns green, even if the lamp has not completed executing the first actuation command to change its color to red.

5.2 Execution Model

A transactuation execution model comprises of the following three phases:

1. *Hard read phase*: to start executing a transactuation, the system first needs to determine if it can read the required hard states in the sensor list which satisfy the specified window and the sensing policy. If so, the system proceeds to the next phase. For a poll-based sensor, if Relacs fails to validate the

window, it polls the sensor to check if it can get a fresh value. For a push-based sensor, Relacs simply waits, as long as the window is valid, to receive an event from the sensor. Observe that the window is valid as long as the specified time window has not passed since the transactuation triggering event. If the window becomes invalid, and the list of received events fails staleness validation, it cannot execute the perform lambda, and proceeds to execute the onFailure lambda.

2. *Speculative Commit Phase*: since IoT devices cannot roll back, Relacs needs to make sure that a transactuation will definitely commit before performing real actuations. Therefore, it employs a speculative execution model where a perform lambda first executes speculatively, without performing any real actuation. Once the perform lambda finishes, it tries to speculatively commit like a normal transaction inside Relacs Store. Therefore, new speculative values are committed for modified soft and hard states. Additionally, committing new speculative values may trigger other handler functions subscribed to these states. Finally, Relacs starts executing the onSuccess lambda of the transactuation when it commits. Note that these lambdas triggered by speculative commit execute their transactuations speculatively.

3. *Final Commit Phase*: in the last phase, Relacs sends actuation commands that correspond to hard writes. A transactuation τ_i can start its final phase, when the following three conditions hold: first, all transactuations that precede τ_i in the T-Chain finally commit. Second, all transactuations updating states that τ_i read, finally commit. Third, no other finally committing τ_j conflicts with τ_i. More specifically, the readset of τ_i does not have any intersection with the writeset of some finally committing transactuation, and the writeset of τ_i does not intersect with both readset and writeset of some finally committing transactuation.

Relacs finally commits the transactuation when sufficient acks are received from actuators to satisfy its actuating policy. If the transactuation times out without satisfying its actuating policy, all soft writes inside the transactuation roll back to their initial state, and the transactuation finally commits. Next, onFailure lambda executes if it has been defined. Moreover, all speculative transactuations invoked by the failed transactuation abort (e.g., chained transactuations), and transactuations that bear data dependencies with the failed transactuation need to re-execute.

5.3 Relacs Runtime

Relacs is built atop serverless computing [32, 42]. The runtime comprises two classes of functions namely application functions and system functions. We explain these functions in detail here.

Application Functions. An application can comprise several handlers which are triggered when particular states in the Relacs Store change (publish-subscribe model), and each handler can comprise several transactuations. An application submitted to run by Relacs system is transformed into a set of application functions to run on serverless instances as follows:

1. For each handler, Relacs transforms the logic of an embedded transactuation (i.e., perform lambda) into a transaction that can execute transactionally inside the Relacs Store.
2. The logic inside onSuccess lambda and onFailure lambda are transformed into stand-alone serverless functions called *success* and *failure* functions, respectively, hereafter. If onSuccess lambda or onFailure lambda is comprised of transactuations with their own onSuccess lambda and onFailure lambda (T-Chain), the transformations are applied recursively.
3. Finally, every handler is transformed into a runnable stand-alone serverless function, called *handler* function.

System Functions. Relacs comprises a serverless function called *updater* function that is invoked whenever the state of a sensor or an actuator changes. Upon receiving a notification, the updater updates the hard state corresponding to the event in Relacs Store, and launches an instance of subscribed handler function(s).

Final-committer is a designated function to perform the final commits. It selects speculative transactuations that can finally commit without breaking the final commit rules, issues all of their actuation commands, and marks the actuations as issued. When a successful actuation receives a notification (ack) from an IoT device, the updater function updates its corresponding state in Relacs Store, and marks the actuation command as done transactionally.

In order to detect an actuation failure, Relacs has a *failure-detector* function that runs periodically, and checks whether an ack is received for an actuation command. If after certain threshold no ack is received, the failure detector marks the actuation as failed. If actuating policy is not met, the enclosing transactuation commits with rollback of soft writes, which triggers a *re-executor* function to re-execute transactuations that have data dependencies with the failed transactuation.

5.4 Fault Tolerance

A function in serverless computing is not guaranteed to complete, and can terminate at any arbitrary point of execution. Yet, Relacs guarantees applications to execute reliably despite failures as follows.

Relacs ensures that all transactuations are executed exactly-once even if an application function (handler, success, or failure) fails during its execution. To this end, Relacs maintains two logs: function log and transactuation log. Function log is a write-ahead log for application functions. The function name along with ID of the triggering event is recorded in the function log before the function executes. Transactuation log atomically records a transactuation name and the event ID during the speculative commit of a transactuation along with updates to soft/hard states.

A system function called *serverless checker* runs periodically, and inspects the function log to execute functions which have failed. In either case, the serverless checker invokes the failed functions again. This might lead to duplicated executions of transactuations that have executed. To prevent this, Relacs checks if a particular transactuation is in the transactuation log, and skips its execution if present. [1]

Currently, the updater failure is treated as an equivalent of sensor or actuator failure and it is handled by transactuation semantics. To address final committer failure, Relacs runs the final committer periodically to complete pending final commits by actuating unissued actuations. To preclude contention between the periodic and the regular final committer that can run concurrently, Relacs uses leases and ETAGS à la Tuba [21] in the final committer to ensure correctness.

5.5 Implementation

We implemented Relacs runtime and Relacs Store on top of Microsoft Azure. We used Azure Function (serverless computing) to implement the runtime, and used Azure Cosmos DB to build Relacs Store. All serverless functions were implemented with Azure Function. Application functions are triggered by HTTP calls and system functions are triggered on Cosmos DB updates or periodic timers. The parts of the protocol that need to update Relacs Store transactionally (including perform lambda) are transformed into Cosmos DB stored procedures [3].

Currently, Relacs has only been integrated with Samsung SmartThings. SmartThings allows a developer to build a web service that connects with devices in a home [18]. We built a gateway that forwards actuation commands from Relacs to actuators and also polls sensor data.

5.6 Discussion

As described, Relacs validates sensor failures through event timestamps and actuator failures through timeouts. For sensor validation, as explained, if validation fails and a device is pollable, Relacs polls the device within the window constraints. If a device is push-based but pollable, Relacs polls the device and if the validation fails again, it waits for its push-interval within the time window. However, if the device is purely push-based, Relacs cannot differentiate between inactivity and failure. We inspected 188 SmartThings-compatible devices and found that 113 of them are pollable. Likewise, actuation failures are detected with timeouts, first on initial ack from smart-home connector, followed by notification on final actuator state change. Again, if the ack message is lost, Relacs can incorrectly rollback soft states. However, transactuations can still help developers to prioritize home safety over convenience such as always setting a soft state to a conservative value; e.g., in Smart Security (Listing 2) to ensure that the alarm eventually rings.

[1] Note that any failure during the speculative commit results in a regular transactional abort and transactuation log is not updated. Hence the transactuation is retried when the function reexecutes.

6 Evaluation

In this section, we report our evaluation results on programmability, effectiveness of transactuations in enforcing correctness, and the overhead incurred by Relacs to provide transactuation semantics.

We selected 10 SmartThings applications from the applications that we statically analyzed. These applications are publicly available on SmartThings repository [19]. The applications cover the four most common categories—Security (Sc), Safety (Sf), Convenience (Cn), and Energy Efficiency (Ee). Instead of using the original version that runs on SmartThings cloud, we implemented the following three versions of the applications, that run on Azure Functions, using Javascript Node JS [44]. This allows us to compare an application with transactuations against an application without transactuations in an apple-to-apple fashion.

- *BE:* we wrote a best-effort version (BE) of the applications without the transactuation abstraction. The BE version follows the default semantics that ignores device failure, exactly-once execution, and isolation.
- *BE+Con:* since the BE version ignores potential failures in devices or applications, we implemented a *best-effort with consistency* (BE+Con) version of an application which adds code that keeps device states consistent with application states. More specifically, BE+Con introduces both sensor window validation and soft state rollback code. However, it ignores the isolation guarantee that transactuations provide.
- *TN:* we also implemented these applications with the transactuation abstraction (TN). 5 applications out of the evaluated 10 applications used T-Chain to establish order among hard and soft states.

Experimental setup. We set up SmartThings compatible devices and measured the round trip latency of four devices in a typical smart home: a door lock, a bulb, a power strip, and a smart power plug. The door lock has a significant latency of nearly 3.6s on average and maximum of nearly 9.8s, over 100 trials. The other devices incur an average latency of nearly 0.7s with the maximum at nearly 3.7s. Since we had a limited set of devices, we parallelized our experiments by simulating the devices using latency data on a Raspberry Pi Model 3 [13]. It comes with a 1.2 GHz 32-bit quadcore ARM Cortex-A53 processor and 1 GB RAM. In addition, the simulator also allowed us to easily inject failures for our experiments.

Application	#HR	#HW	Transactuation Policy	LOC		
				BE	BE+Con	TN
Rise And Shine (Cn1)	1 (*)	1	2 (none, none)	72	195	68
Whole House Fan (Cn2)	1 (*), 3	2 (*)	1 (none, none)	29	176	26

CO2 Vent (Sf1)	1	2 (*)	1 (all, all)	29	152	26
Lock It When I Leave (Sf2)	3 (*)	2 (*), 2	2 (none, none), 1 (all, none)	51	180	54

Table 2: Properties of each benchmark application including the number of hard reads and hard writes (* denotes an operation to an array of devices with a single command, for example, 2 (*) means 2 operations, each accessing a device group); the fault-tolerance policies for the TN configuration in a format of (sensing, actuating) (Col 4); and programability shown by LOC comparison among transactuation (TN), best effort (BE), and best effort with consistency (BE+Con) (Col 5).

6.1 Programmability

In order to evaluate the programmability and convenience of using transactuation in contrast to manually writing failure handling code, we compare lines of code (LOC) of applications, using CLOC [6].

Table 2 shows the programmability evaluation (LOC) along with the number of hard reads and writes, and transactuation policies we employ for each application. Observe that TN and BE versions are comparable in LOC despite no guarantees in the BE version, except in Ee1 where we introduce new soft states and four transactuations, each part of T-Chains, in order to ensure consistency. BE+Con version requires substantial code to explicitly handle failures. As mentioned earlier, BE+Con version validates sensor freshness similar to transactuation and may roll back soft states after determining the outcome of actuations for hard write to soft write dependencies. Finally, although transactuations require more code in order to create T-Chains, it automatically handles failure, and simplifies writing reliable applications considerably.

6.2 Correctness

Table 3 shows the applications that we evaluated with their inherent undesirable behaviors on transient or longer duration failures. The second column shows the undesirable behaviors, and the third column shows the outcome of using transactuations. The last column explains the mechanism transactuations use to resolve or mitigate the issue. We considered different types of failures that transactuations can address (i.e., unavailable sensors and failed actuations), and injected these failures by dropping event or actuation messages. Transactuation addresses these issues with three techniques. First, sensor staleness validation prevents the execution of perform lambda and executes onFailure lambda that can notify a user. Second, actuation losses are detected automatically and associated soft writes are rolled back to ensure consistency. Third, when one actuation depends on another, we used an intermediate soft state to chain two transactuations each having actuations. For example, in Sc3 (Smart Security) application, inconsistency between the alarm actuation and the soft write is resolved using roll back to eliminate the issue. However, some applications need to use multiple chained transactuations to correctly address actuation dependencies.

6.3 Overhead

To evaluate the overhead of transactuations, we measured execution time of the applications as follows. We started timing when an application began executing, and stopped when every soft write committed and all actuations completed. Our performance results are summarized in Figure 1. Each value is the mean of 30 runs, with 95% confidence intervals.

Failure-free. We first compare the execution times of TN and BE versions without any injected failures. The overhead of transactuations is attributed to (1) safeguarding against inconsistencies due to inherently concurrent execution, (2) providing fault tolerance, and (3) enforcing actuation orders of T-Chains. We note that the final committer function imposes significant overhead on Relacs since it is invoked[2] automatically by CosmosDB updates. For instance, we observed that its start may be delayed between zero to five seconds. The periodic final committer which we set to run every second helps to mitigate this overhead.

Figure 1a shows that, on average (geomean), the TN version incurs 1.5 times slowdown compared to BE. Observe that the

[2]Other functions except the re-executor are invoked by HTTP calls.

App	Undesirable consequence	Transactuation effect	Mechanism used
Cn1	Mode not set permanently	✓	Soft state rollback
Cn2	Incorrect behavior Fans not ON irreversibly	Issue detected and user notified ✓	Sensor staleness validation Soft state rollback
Cn3	Thermostat not OFF Incorrect mode	✓ ✓	Soft state rollback Soft state rollback
Ee1	Incorrect energy and operation time reported Incorrect behavior	✓ Issue detected and user notified	Soft state rollback and chaining Sensor staleness validation
Ee2	Incorrectly turning lights ON/OFF	Issue detected and user notified	Sensor staleness validation
Sc1	Incorrect behavior Actuation failure	Issue detected and user notified ✓	Sensor staleness validation Chaining
Sc2	Incorrect mode set Home mode change w/o notification	Issue detected and user notified ✓	Sensor staleness validation soft state rollback
Sc3	Intruder motion not detected Alarm not active irreversibly	Issue detected and user notified ✓	Sensor staleness validation soft state rollback
Sf1	Incorrect behavior Exhauts not ON irreversibly	Issue detected and user notified ✓	Sensor staleness validation soft state rollback
Sf2	Door unlocked but home vacant Door locked at arrival	Issue detected and user notified ✓	Sensor staleness validation Chaining

Table 3: Applications with undesirable consequences on induced failures. Column 3 shows failure avoidance or mitigation when written with transactuations. Column 4 shows the internal mechanism used by the transactuations. A checkmark implies that transactuation automatically resolves the issue.

speculative commit duration (TN.SC) is significantly smaller than the final commit duration (TN.FC). Figure 1a also breaks down the final commit time into actuation time (TN.FC.ACT) and the final-committer triggering overhead (TN.FC.TRIG). As mentioned earlier, the triggering overhead is significantly large, especially, in the case of a long T-Chain like Ee1 (4 transactuations).

With failure. In this scenario, we conducted two experiments. In each experiment, we used a dummy application that issued a dummy actuation, and updated a dummy soft state. In the first experiment, the dummy actuation turned on a smart switch (low-latency actuation). In the second one, it actuated a door lock (high-latency actuation). We introduced an artificial data dependency (RAW) by forcing all benchmark applications to read the dummy soft state before executing their core logic. Lastly, we injected a failure to the dummy actuation to trigger failure detection and handling in the dummy application and re-execution of the benchmark applications to repair the broken data dependency. Because devices have different actuation latencies, the timeout thresholds to declare failed actuations are specific to each device. More specifically, we used the maximum observed latency for each device (i.e., 4s for the smart switch and 10s for the door lock).

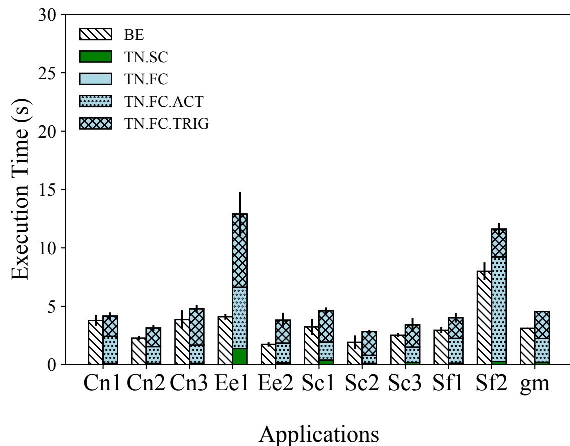
Figure 1b compares the execution time of the failure-free case against the two failure experiments. The additional overhead we observe here is the failure detection overhead which includes the timeout (TN.FD.TO) and the overhead of triggering the re-executor function (TN.FD.TRIG). Similar to the final committer, the re-executor is invoked automatically by Cosmos DB when actuations are marked as `failed`, thus it incurs similar overhead. Observe that the failure experiments have two stacked bars of speculative commits. The second bar shows the re-execution of transactuations with broken dependencies.

As expected, introducing a failure results in longer execution times for the applications. This slowdown is caused by the timeout threshold plus the re-executor triggering overhead (~2s). Moreover, the difference between the middle and right bars for each application is the difference in timeout thresholds for low and high latency actuations (~6s).

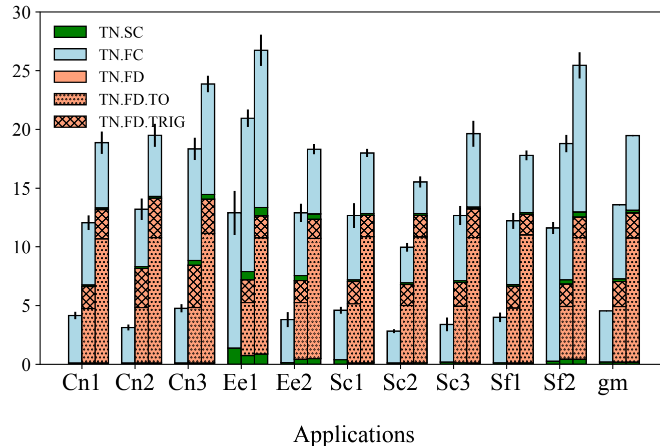
7 Related Work

Checking Correctness. Soteria [22] employs model checking to identify contradicting interactions between IoT applications. For example, water leak detection turns off a water valve while smoke detection attempts to turn on a fire sprinkler. Prior work like DeLorean [24] models absolute and relative time to find timing bugs in event driven programs, e.g., door open at unsafe times. In contrast, our work tackles a different problem, the lack of reliability and isolation, using a dynamic technique. IoT analyses also use dynamic taint analyses like techniques to detect source of security breaches [46] and dynamic program slicing to explain behaviors [40]. We use static dependence analysis to report potential problems.

Programming abstractions. Using speculative execution for improving latency and performance is a common technique in many transactional and replicated systems. These can be classified into two categories: systems [34, 41, 47]



(a) Execution times for BE and TN versions in failure-free case. We break down the execution time of TN into speculative commit (TN.SC) and final commit (TN.FC). TN.FC is shown as actuation time (TN.FC.ACT) and as overhead to trigger the final-committer function (TN.FC.TRIG).



(b) Execution time comparison for failure-free and failure cases. For each application, we show 3 bars, failure-free case (the left bar), low-latency actuation failure case (the middle bar), and high-latency actuation failure case (the right bar). For the failure cases, the breakdown includes failure detection time (TN.FD) which is subdivided into timeout detection (TN.FD.TO) and re-execution triggering overhead (TN.FD.TRIG).

Figure 1: The execution time of 10 applications chosen from SmartThings repository and their geomean (gm) for BE and TN versions of applications in failure-free and failure scenarios.

that hide the effects of speculation from applications, and work [29, 31, 43] that expose speculation results to applications. While certain applications in the latter case can benefit by reading speculative values, they need to handle possible side effects of acting on misspeculated values. With Relacs, effects of speculatively committed transactuations are exposed to other transactuations. Yet, no transactuation can finally commit, and actuate devices until all transactuations that it speculatively read from finally commit.

Planet [43] provides a mechanism to speculate on partial state of a transaction in distributed environments. The abstraction allows a developer to continue based on a predictive outcome, and later receive a confirmation or an apology. In contrast, we target a different environment and problem, and provide a simplified way to address device failure handling.

Execution semantics and conflict detection. IOTA [40] defines a calculus for programs in IoT domain. They also define an execution semantics to eliminate races on actions against the same physical event. Similar races can be resolved in our system by reordering transactuations according to programmer annotations similar to Zave et al. [48]. IOTA also shows offline analyses to detect device conflicts. Conflict detection in a home can include static model checking [38] or dynamic analyses [48] to detect feature interactions [38] and accesses to the same device [26]. They detect commands due to single event or concurrent independent events to the same device, e.g., simultaneous turning on and off on a device. The execution semantics of our system provides isolation naturally and can easily be enhanced to report device interactions by intersecting read-write sets of transactuations dynamically.

8 Conclusion

In this paper, we identified a fundamental problem that arises due to failures in IoT systems that interact with the physical world. We analyzed smart-home applications, and showed how application semantics is broken due to different failures that occur in an IoT environment. We introduced an abstraction, called transactuation, that allows a developer to build reliable IoT applications. Our runtime, called Relacs, enforces the semantic guarantees of transactuations. Our evaluation demonstrated programmability, performance, and effectiveness of the transactuation abstraction on top of our runtime.

Not So Fast: Analyzing the Performance of WebAssembly vs. Native Code

Abhinav Jangda, Bobby Powers, Emery D. Berger, and Arjun Guha
University of Massachusetts Amherst

Abstract

All major web browsers now support WebAssembly, a low-level bytecode intended to serve as a compilation target for code written in languages like C and C++. A key goal of WebAssembly is performance parity with native code; previous work reports near parity, with many applications compiled to WebAssembly running on average 10% slower than native code. However, this evaluation was limited to a suite of scientific kernels, each consisting of roughly 100 lines of code. Running more substantial applications was not possible because compiling code to WebAssembly is only part of the puzzle: standard Unix APIs are not available in the web browser environment. To address this challenge, we build BROWSIX-WASM, a significant extension to BROWSIX [29] that, for the first time, makes it possible to run unmodified WebAssembly-compiled Unix applications directly inside the browser. We then use BROWSIX-WASM to conduct the first large-scale evaluation of the performance of WebAssembly vs. native. Across the SPEC CPU suite of benchmarks, we find a substantial performance gap: applications compiled to WebAssembly run slower by an average of 45% (Firefox) to 55% (Chrome), with peak slowdowns of 2.08× (Firefox) and 2.5× (Chrome). We identify the causes of this performance degradation, some of which are due to missing optimizations and code generation issues, while others are inherent to the WebAssembly platform.

1 Introduction

Web browsers have become the most popular platform for running user-facing applications, and until recently, JavaScript was the only programming language supported by all major web browsers. Beyond its many quirks and pitfalls from the perspective of programming language design, JavaScript is also notoriously difficult to compile efficiently [12, 17, 30, 31]. Applications written in or compiled to JavaScript typically run much slower than their native counterparts. To address this situation, a group of browser vendors jointly developed *WebAssembly*.

WebAssembly is a low-level, statically typed language that does not require garbage collection, and supports interoperability with JavaScript. The goal of WebAssembly is to serve as a universal compiler target that can run in a browser [15, 16, 18].[1] Towards this end, WebAssembly is designed to be fast to compile and run, to be portable across browsers and architectures, and to provide formal guarantees of type and memory safety. Prior attempts at running code at native speed in the browser [4, 13, 14, 38], which we discuss in related work, do not satisfy all of these criteria.

WebAssembly is now supported by all major browsers [8, 34] and has been swiftly adopted by several programming languages. There are now backends for C, C++, C#, Go, and Rust [1, 2, 24, 39] that target WebAssembly. A curated list currently includes more than a dozen others [10]. Today, code written in these languages can be safely executed in browser sandboxes across any modern device once compiled to WebAssembly.

A major goal of WebAssembly is to be faster than JavaScript. For example, the paper that introduced WebAssembly [18] showed that when a C program is compiled to WebAssembly instead of JavaScript (`asm.js`), it runs 34% faster in Google Chrome. That paper also showed that the performance of WebAssembly is competitive with native code: of the 24 benchmarks evaluated, the running time of seven benchmarks using WebAssembly is within 10% of native code, and almost all of them are less than 2× slower than native code. Figure 1 shows that WebAssembly implementations have continuously improved with respect to these benchmarks. In 2017, only seven benchmarks performed within 1.1× of native, but by 2019, this number increased to 13.

These results appear promising, but they beg the question: *are these 24 benchmarks representative of WebAssembly's intended use cases*?

[1] The WebAssembly standard is undergoing active development, with ongoing efforts to extend WebAssembly with features ranging from SIMD primitives and threading to tail calls and garbage collection. This paper focuses on the initial and stable version of WebAssembly [18], which is supported by all major browsers.

The Challenge of Benchmarking WebAssembly The aforementioned suite of 24 benchmarks is the PolybenchC benchmark suite [5], which is designed to measure the effect of polyhedral loop optimizations in compilers. All the benchmarks in the suite are small scientific computing kernels rather than full applications (e.g., matrix multiplication and LU Decomposition); each is roughly 100 LOC. While WebAssembly is designed to accelerate scientific kernels on the Web, it is also explicitly designed for a much richer set of full applications.

The WebAssembly documentation highlights several intended use cases [7], including scientific kernels, image editing, video editing, image recognition, scientific visualization, simulations, programming language interpreters, virtual machines, and POSIX applications. Therefore, WebAssembly's strong performance on the scientific kernels in PolybenchC do not imply that it will perform well given a different kind of application.

We argue that a more comprehensive evaluation of WebAssembly should rely on an established benchmark suite of large programs, such as the SPEC CPU benchmark suites. In fact, the SPEC CPU 2006 and 2017 suite of benchmarks include several applications that fall under the intended use cases of WebAssembly: eight benchmarks are scientific applications (e.g., `433.milc`, `444.namd`, `447.dealII`, `450.soplex`, and `470.lbm`), two benchmarks involve image and video processing (`464.h264ref` and `453.povray`), and all of the benchmarks are POSIX applications.

Unfortunately, it is not possible to simply compile a sophisticated native program to WebAssembly. Native programs, including the programs in the SPEC CPU suites, require operating system services, such as a filesystem, synchronous I/O, and processes, which WebAssembly and the browser do not provide. The SPEC benchmarking harness itself requires a file system, a shell, the ability to spawn processes, and other Unix facilities. To overcome these limitations when porting native applications to the web, many programmers painstakingly modify their programs to avoid or mimic missing operating system services. Modifying well-known benchmarks, such as SPEC CPU, would not only be time consuming but would also pose a serious threat to validity.

The standard approach to running these applications today is to use Emscripten, a toolchain for compiling C and C++ to WebAssembly [39]. Unfortunately, Emscripten only supports the most trivial system calls and does not scale up to large-scale applications. For example, to enable applications to use synchronous I/O, the default Emscripten `MEMFS` filesystem loads the entire filesystem image into memory before the program begins executing. For SPEC, these files are too large to fit into memory.

A promising alternative is to use BROWSIX, a framework that enables running unmodified, full-featured Unix applications in the browser [28, 29]. BROWSIX implements a Unix-compatible kernel in JavaScript, with full support for

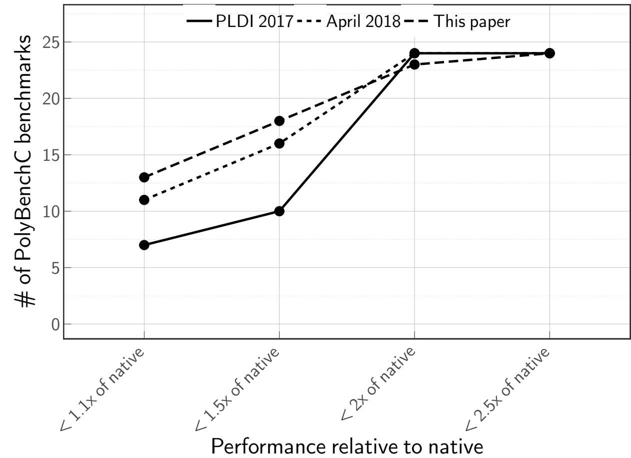

Figure 1: Number of PolyBenchC benchmarks performing within $x\times$ of native. In 2017 [18], seven benchmarks performed within $1.1\times$ of native. In April 2018, we found that 11 performed within $1.1\times$ of native. In May 2019, 13 performed with $1.1\times$ of native.

processes, files, pipes, blocking I/O, and other Unix features. Moreover, it includes a C/C++ compiler (based on Emscripten) that allows programs to run in the browser unmodified. The BROWSIX case studies include complex applications, such as LaTeX, which runs entirely in the browser without any source code modifications.

Unfortunately, BROWSIX is a JavaScript-only solution, since it was built before the release of WebAssembly. Moreover, BROWSIX suffers from high performance overhead, which would be a significant confounder while benchmarking. Using BROWSIX, it would be difficult to tease apart the poorly performing benchmarks from performance degradation introduced by BROWSIX.

Contributions

- **BROWSIX-WASM:** We develop BROWSIX-WASM, a significant extension to and enhancement of BROWSIX that allows us to compile Unix programs to WebAssembly and run them in the browser with no modifications. In addition to integrating functional extensions, BROWSIX-WASM incorporates performance optimizations that drastically improve its performance, ensuring that CPU-intensive applications operate with virtually no overhead imposed by BROWSIX-WASM (§2).

- **BROWSIX-SPEC:** We develop BROWSIX-SPEC, a harness that extends BROWSIX-WASM to allow automated collection of detailed timing and hardware on-chip performance counter information in order to perform detailed measurements of application performance (§3).

- **Performance Analysis of WebAssembly:** Using BROWSIX-WASM and BROWSIX-SPEC, we conduct the first comprehensive performance analysis of WebAssembly using the SPEC CPU benchmark suite (both 2006 and 2017). This evaluation confirms that WebAssembly does run faster than JavaScript (on average 1.3× faster across SPEC CPU). However, contrary to prior work, we find a substantial gap between WebAssembly and native performance: code compiled to WebAssembly runs on average 1.55× slower in Chrome and 1.45× slower in Firefox than native code (§4).

- **Root Cause Analysis and Advice for Implementers:** We conduct a forensic analysis with the aid of performance counter results to identify the root causes of this performance gap. We find the following results:

  1. The instructions produced by WebAssembly have more loads and stores than native code (2.02× more loads and 2.30× more stores in Chrome; 1.92× more loads and 2.16× more stores in Firefox). We attribute this to reduced availability of registers, a sub-optimal register allocator, and a failure to effectively exploit a wider range of x86 addressing modes.
  2. The instructions produced by WebAssembly have more branches, because WebAssembly requires several dynamic safety checks.
  3. Since WebAssembly generates more instructions, it leads to more L1 instruction cache misses.

  We provide guidance to help WebAssembly implementers focus their optimization efforts in order to close the performance gap between WebAssembly and native code (§5, 6).

BROWSIX-WASM and BROWSIX-SPEC are available at `https://browsix.org`.

2 From BROWSIX to BROWSIX-WASM

BROWSIX [29] mimics a Unix kernel within the browser and includes a compiler (based on Emscripten [33, 39]) that compiles native programs to JavaScript. Together, they allow native programs (in C, C++, and Go) to run in the browser and freely use operating system services, such as pipes, processes, and a filesystem. However, BROWSIX has two major limitations that we must overcome. First, BROWSIX compiles native code to JavaScript and not WebAssembly. Second, the BROWSIX kernel has significant performance issues. In particular, several common system calls have very high overhead in BROWSIX, which makes it hard to compare the performance of a program running in BROWSIX to that of a program running natively. We address these limitations by building a new in-browser kernel called BROWSIX-WASM, which supports WebAssembly programs and eliminates the performance bottlenecks of BROWSIX.

Emscripten Runtime Modifications BROWSIX modifies the Emscripten compiler to allow processes (which run in WebWorkers) to communicate with the BROWSIX kernel (which runs on the main thread of a page). Since BROWSIX compiles native programs to JavaScript, this is relatively straightforward: each process' memory is a buffer that is shared with the kernel (a `SharedArrayBuffer`), thus system calls can directly read and write process memory. However, this approach has two significant drawbacks. First, it precludes growing the heap on-demand; the shared memory must be sized large enough to meet the high-water-mark heap size of the application for the entire life of the process. Second, JavaScript contexts (like the main context and each web worker context) have a fixed limit on their heap sizes, which is currently approximately 2.2 GB in Google Chrome [6]. This cap imposes a serious limitation on running multiple processes: if each process reserves a 500 MB heap, BROWSIX would only be able to run at most four concurrent processes. A deeper problem is that WebAssembly memory cannot be shared across WebWorkers and does not support the `Atomic` API, which BROWSIX processes use to wait for system calls.

BROWSIX-WASM uses a different approach to process-kernel communication that is also faster than the BROWSIX approach. BROWSIX-WASM modifies the Emscripten runtime system to create an auxiliary buffer (of 64MB) for each process that is shared with the kernel, but is distinct from process memory. Since this auxiliary buffer is a `SharedArrayBuffer` the BROWSIX-WASM process and kernel can use `Atomic` API for communication. When a system call references strings or buffers in the process's heap (e.g., `writev` or `stat`), its runtime system copies data from the process memory to the shared buffer and sends a message to the kernel with locations of the copied data in auxiliary memory. Similarly, when a system call writes data to the auxiliary buffer (e.g., `read`), its runtime system copies the data from the shared buffer to the process memory at the memory specified. Moreover, if a system call specifies a buffer in process memory for the kernel to write to (e.g., `read`), the runtime allocates a corresponding buffer in auxiliary memory and passes it to the kernel. In case the system call is either reading or writing data of size more than 64MB, BROWSIX-WASM divides this call into several calls such that each call only reads or writes at maximum 64MB of data. The cost of these memory copy operations is dwarfed by the overall cost of the system call invocation, which involves sending a message between process and kernel JavaScript contexts. We show in §4.2.1 that BROWSIX-WASM has negligible overhead.

Performance Optimization While building BROWSIX-WASM and doing our preliminary performance evaluation,

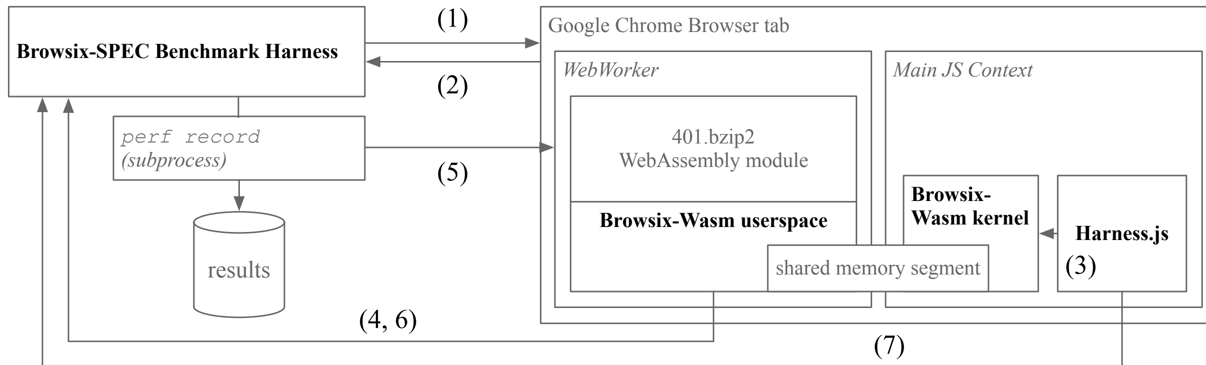

Figure 2: The framework for running SPEC benchmarks in browsers. **Bold** components are new or heavily modified (§3).

we discovered several performance issues in parts of the BROWSIX kernel. Left unresolved, these performance issues would be a threat to the validity of a performance comparison between WebAssembly and native code. The most serious case was in the shared filesystem component included with BROWSIX/BROWSIX-WASM, BROWSERFS. Originally, on each append operation on a file, BROWSERFS would allocate a new, larger buffer, copying the previous and new contents into the new buffer. Small appends could impose substantial performance degradation. Now, whenever a buffer backing a file requires additional space, BROWSERFS grows the buffer by at least 4 KB. This change alone decreased the time the `464.h264ref` benchmark spent in BROWSIX from 25 seconds to under 1.5 seconds. We made a series of improvements that reduce overhead throughout BROWSIX-WASM. Similar, if less dramatic, improvements were made to reduce the number of allocations and the amount of copying in the kernel implementation of pipes.

3 BROWSIX-SPEC

To reliably execute WebAssembly benchmarks while capturing performance counter data, we developed BROWSIX-SPEC. BROWSIX-SPEC works with BROWSIX-WASM to manage spawning browser instances, serving benchmark assets (e.g., the compiled WebAssembly programs and test inputs), spawning `perf` processes to record performance counter data, and validating benchmark outputs.

We use BROWSIX-SPEC to run three benchmark suites to evaluate WebAssembly's performance: SPEC CPU2006, SPEC CPU2017, and PolyBenchC. These benchmarks are compiled to native code using Clang 4.0, and WebAssembly using BROWSIX-WASM. We made no modifications to Chrome or Firefox, and the browsers are run with their standard sandboxing and isolation features enabled. BROWSIX-WASM is built on top of standard web platform features and requires no direct access to host resources – instead, benchmarks make standard HTTP requests to BROWSIX-SPEC.

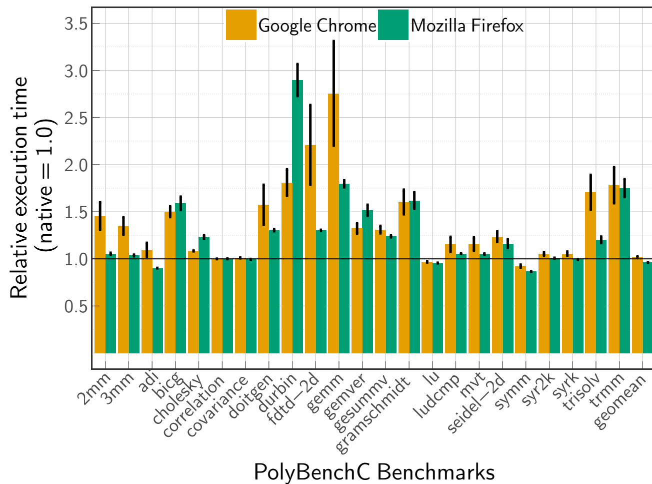
3.1 BROWSIX-SPEC Benchmark Execution

Figure 2 illustrates the key pieces of BROWSIX-SPEC in play when running a benchmark, such as `401.bzip2` in Chrome. First (1), the BROWSIX-SPEC benchmark harness launches a new browser instance using a WebBrowser automation tool, Selenium.[2] (2) The browser loads the page's HTML, harness JS, and BROWSIX-WASM kernel JS over HTTP from the benchmark harness. (3) The harness JS initializes the BROWSIX-WASM kernel and starts a new BROWSIX-WASM process executing the `runspec` shell script (not shown in Figure 2). `runspec` in turn spawns the standard `specinvoke` (not shown), compiled from the C sources provided in SPEC 2006. `specinvoke` reads the `speccmds.cmd` file from the BROWSIX-WASM filesystem and starts `401.bzip2` with the appropriate arguments. (4) After the WebAssembly module has been instantiated but before the benchmark's `main` function is invoked, the BROWSIX-WASM userspace runtime does an XHR request to BROWSIX-SPEC to begin recording performance counter stats. (5) The benchmark harness finds the Chrome thread corresponding to the Web Worker `401.bzip2` process and attaches `perf` to the process. (6) At the end of the benchmark, the BROWSIX-WASM userspace runtime does a final XHR to the benchmark harness to end the `perf record` process. When the `runspec` program exits (after potentially invoking the test binary several times), the harness JS POSTs (7) a `tar` archive of the SPEC results directory to BROWSIX-SPEC. After BROWSIX-SPEC receives the full results archive, it unpacks the results to a temporary directory and validates the output using the `cmp` tool provided with SPEC 2006. Finally, BROWSIX-SPEC kills the browser process and records the benchmark results.

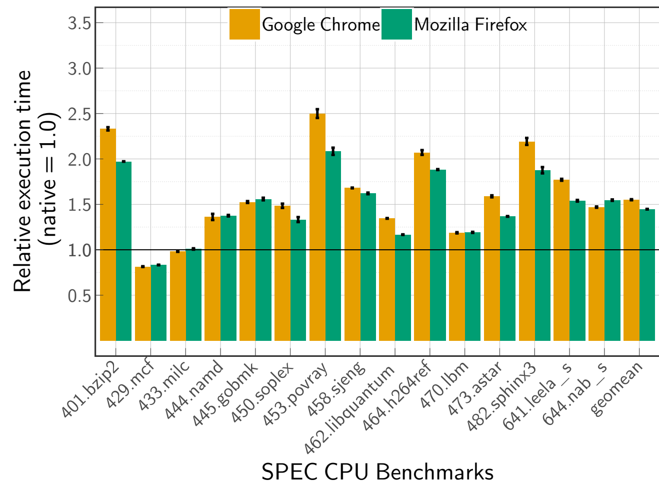
4 Evaluation

We use BROWSIX-WASM and BROWSIX-SPEC to evaluate the performance of WebAssembly using three benchmark

[2] `https://www.seleniumhq.org/`



(a)



(b)

Figure 3: The performance of the PolyBenchC and the SPEC CPU benchmarks compiled to WebAssembly (executed in Chrome and Firefox) relative to native, using BROWSIX-WASM and BROWSIX-SPEC. The SPEC CPU benchmarks exhibit higher overhead overall than the PolyBenchC suite, indicating a significant performance gap exists between WebAssembly and native.

suites: SPEC CPU2006, SPEC CPU2017, and PolyBenchC. We include PolybenchC benchmarks for comparison with the original WebAssembly paper [18], but argue that these benchmarks do not represent typical workloads. The SPEC benchmarks are representative and require BROWSIX-WASM to run successfully. We run all benchmarks on a 6-Core Intel Xeon E5-1650 v3 CPU with hyperthreading and 64 GB of RAM running Ubuntu 16.04 with Linux kernel v4.4.0. We run all benchmarks using two state-of-the-art browsers: Google Chrome 74.0 and Mozilla Firefox 66.0. We compile benchmarks to native code using Clang 4.0[3] and to WebAssembly using BROWSIX-WASM (which is based on Emscripten with Clang 4.0).[4] Each benchmark was executed five times. We report the average of all running times and the standard error. The execution time measured is the difference between wall clock time when the program starts, i.e. after WebAssembly JIT compilation concludes, and when the program ends.

4.1 PolyBenchC Benchmarks

Haas et al. [18] used PolybenchC to benchmark WebAssembly implementations because the PolybenchC benchmarks do not make system calls. As we have already argued, the PolybenchC benchmarks are small scientific kernels that are typically used to benchmark polyhedral optimization techniques, and do not represent larger applications. Nevertheless, it is still valuable for us to run PolybenchC with BROWSIX-WASM, because it demonstrates that our infrastructure for system calls does not have any overhead. Figure 3a shows the execution time of the PolyBenchC benchmarks in BROWSIX-WASM and when run natively. We are able to reproduce the majority of the results from the original WebAssembly paper [18]. We find that BROWSIX-WASM imposes a very low overhead: an average of 0.2% and a maximum of 1.2%.

4.2 SPEC Benchmarks

We now evaluate BROWSIX-WASM using the C/C++ benchmarks from SPEC CPU2006 and SPEC CPU2017 (the new C/C++ benchmarks and the speed benchmarks), which use system calls extensively. We exclude four data points that either do not compile to WebAssembly[5] or allocate more memory than WebAssembly allows.[6] Table 1 shows the absolute execution times of the SPEC benchmarks when running with BROWSIX-WASM in both Chrome and Firefox, and when running natively.

WebAssembly performs worse than native for all benchmarks except for `429.mcf` and `433.milc`. In Chrome, WebAssembly's maximum overhead is 2.5× over native and 7 out of 15 benchmarks have a running time within 1.5× of native. In Firefox, WebAssembly is within 2.08× of native and performs within 1.5× of native for 7 out of 15 benchmarks. On average, WebAssembly is 1.55× slower than native in Chrome, and 1.45× slower than native in Firefox. Table 2 shows the time required to compile the SPEC benchmarks

[3] The flags to Clang are `-O2 -fno-strict-aliasing`.

[4] BROWSIX-WASM runs Emscripten with the flags `-O2 -s TOTAL_MEMORY=1073741824 -s ALLOW_MEMORY_GROWTH=1 -fno-strict-aliasing`.

[5] `400.perlbench`, `403.gcc`, `471.omnetpp`, and `456.hmmer` from SPEC CPU2006 do not compile with Emscripten.

[6] From SPEC CPU2017, the `ref` dataset of `638.imagick_s` and `657.xz_s` require more than 4 GB RAM. However, these benchmarks do work with their `test` dataset.

Benchmark	Native	Google Chrome	Mozilla Firefox
401.bzip2	370 ± 0.6	864 ± 6.4	730 ± 1.3
429.mcf	221 ± 0.1	180 ± 0.9	184 ± 0.6

Slowdown: geomean	–	**1.55×**	**1.45×**
Slowdown: median	–	**1.53×**	**1.54×**

Table 1: Detailed breakdown of SPEC CPU benchmarks execution times (of 5 runs) for native (Clang) and WebAssembly (Chrome and Firefox); all times are in seconds. The median slowdown of WebAssembly is 1.53× for Chrome and 1.54× for Firefox.

using Clang and Chrome. (To the best of our knowledge, Firefox cannot report WebAssembly compile times.) In all cases, the compilation time is negligible compared to the execution time. However, the Clang compiler is orders of magnitude slower than the WebAssembly compiler. Finally, note that Clang compiles benchmarks from C++ source code, whereas Chrome compiles WebAssembly, which is a simpler format than C++.

4.2.1 BROWSIX-WASM Overhead

It is important to rule out the possibility that the slowdown that we report is due to poor performance in our implementation of BROWSIX-WASM. In particular, BROWSIX-WASM implements system calls without modifying the browser, and system calls involve copying data (§2), which may be costly. To quantify the overhead of BROWSIX-WASM, we instrumented its system calls to measure all time spent in BROWSIX-WASM. Figure 4 shows the percentage of time spent in BROWSIX-WASM in Firefox using the SPEC benchmarks. For 14 of the 15 benchmarks, the overhead is less than 0.5%. The maximum overhead is 1.2%. On average, the overhead of BROWSIX-WASM is only 0.2%. Therefore, we conclude that BROWSIX-WASM has negligible overhead and does not substantially affect the performance counter results of programs executed in WebAssembly.

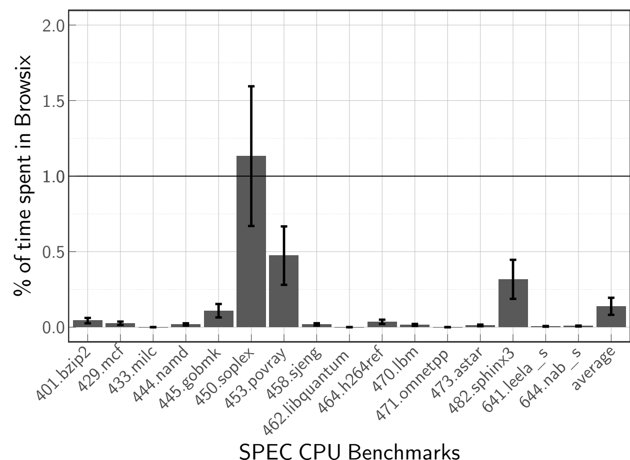

Figure 4: Time spent (in %) in BROWSIX-WASM calls in Firefox for SPEC benchmarks compiled to WebAssembly. BROWSIX-WASM imposes a mean overhead of only 0.2%.

4.2.2 Comparison of WebAssembly and `asm.js`

A key claim in the original work on WebAssembly was that it is significantly faster than `asm.js`. We now test that claim using the SPEC benchmarks. For this comparison, we modified BROWSIX-WASM to also support processes compiled to `asm.js`. The alternative would have been to benchmark the `asm.js` processes using the original BROWSIX. However, as we discussed earlier, BROWSIX has performance problems that would have been a threat to the validity of our results. Figure 5 shows the speedup of the SPEC benchmarks using WebAssembly, relative to their running time using `asm.js` using both Chrome and Firefox. WebAssembly outperforms `asm.js` in both browsers: the mean speedup is 1.54× in

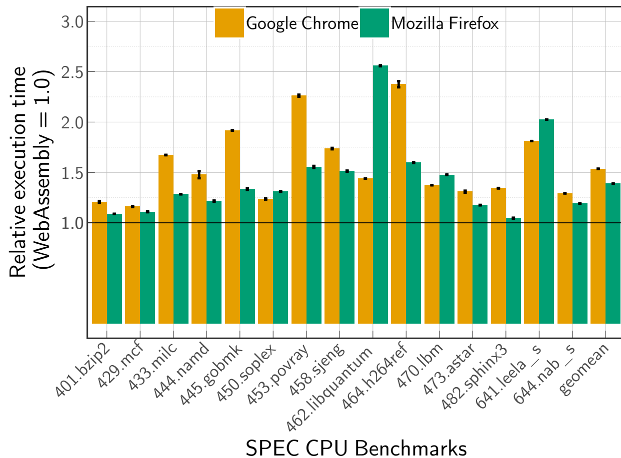

Figure 5: Relative time of `asm.js` to WebAssembly for Chrome and Firefox. WebAssembly is 1.54× faster than `asm.js` in Chrome and 1.39× faster than `asm.js` in Firefox.

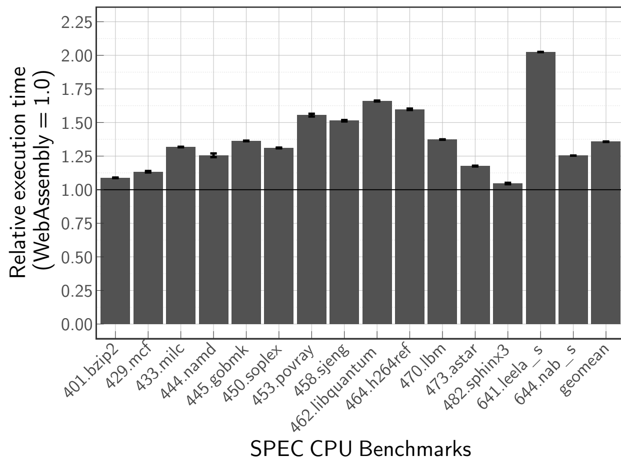

Figure 6: Relative *best* time of `asm.js` to the best time of WebAssembly. WebAssembly is 1.3× faster than `asm.js`.

Chrome and 1.39× in Firefox.

Since the performance difference between Chrome and Firefox is substantial, in Figure 6 we show the speedup of each benchmark by selecting the best-performing browser for WebAssembly and the best-performing browser of `asm.js` (i.e., they may be different browsers). These results show that WebAssembly consistently performs better than `asm.js`, with a mean speedup of 1.3×. Haas et al. [18] also found that WebAssembly gives a mean speedup of 1.3× over `asm.js` using PolyBenchC.

5 Case Study: Matrix Multiplication

In this section, we illustrate the performance differences between WebAssembly and native code using a C function that performs matrix multiplication, as shown in Figure 7a. Three matrices are provided as arguments to the function, and the results of `A` ($N_I \times N_K$) and `B` ($N_K \times N_J$) are stored in `C` ($N_I \times N_J$), where N_I, N_K, N_J are constants defined in the program.

In WebAssembly, this function is 2×–3.4× slower than native in both Chrome and Firefox with a variety of matrix sizes (Figure 8). We compiled the function with `-O2` and disabled automatic vectorization, since WebAssembly does not support vectorized instructions.

Figure 7b shows native code generated for the `matmul` function by `clang-4.0`. Arguments are passed to the function in the `rdi`, `rsi`, and `rdx` registers, as specified in the System V AMD64 ABI calling convention [9]. Lines 2 - 26 are the body of the first loop with iterator `i` stored in `r8d`. Lines 5 - 21 contain the body of the second loop with iterator `k` stored in `r9d`. Lines 10 - 16 comprise the body of the third loop with iterator `j` stored in `rcx`. Clang is able to eliminate a `cmp` instruction in the inner loop by initializing `rcx` with $-N_J$, incrementing `rcx` on each iteration at line 15, and using `jne` to test the zero flag of the status register, which is set to 1 when `rcx` becomes 0.

Figure 7c shows x86-64 code JITed by Chrome for the WebAssembly compiled version of `matmul`. This code has been modified slightly – `nop`s in the generated code have been removed for presentation. Function arguments are passed in the `rax`, `rcx`, and `rdx` registers, following Chrome's calling convention. At lines 1– 3, the contents of registers `rax`, `rdx`, and `rcx` are stored on the stack, due to registers spills at lines 7 - 9. Lines 7–45 are the body of the first loop with iterator `i` stored in `edi`. Lines 18–42 contain the body of second loop with iterator `k` stored in `r11`. Lines 27–39 are the body of the third loop with iterator `j` stored in `eax`. To avoid memory loads due to register spilling at lines 7– 9 in the first iteration of the first loop, an extra jump is generated at line 5. Similarly, extra jumps are generated for the second and third loops at line 16 and line 25 respectively.

5.1 Differences

The native code JITed by Chrome has more instructions, suffers from increased register pressure, and has extra branches compared to Clang-generated native code.

5.1.1 Increased Code Size

The number of instructions in the code generated by Chrome (Figure 7c) is 53, including `nop`s, while clang generated code (Figure 7b) consists of only 28 instructions. The poor instruction selection algorithm of Chrome is one of the reasons for increased code size.

Additionally, Chrome does not take advantage of all available memory addressing modes for x86 instructions. In Figure 7b Clang uses the `add` instruction at line 14 with register addressing mode, loading from and writing to a memory address in the same operation. Chrome on the other hand loads

```
1 void matmul (int C[NI][NJ],
2              int A[NI][NK],
3              int B[NK][NJ]) {
4   for (int i = 0; i < NI; i++) {
5     for (int k = 0; k < NK; k++) {
6       for (int j = 0; j < NJ; j++) {
7         C[i][j] += A[i][k] * B[k][j];
8       }
9     }
10  }
11 }
```

(a) `matmul` source code in C.

```
1 xor  r8d, r8d           #i <- 0
2 L1:                     #start first loop
3   mov  r10, rdx
4   xor  r9d, r9d         #k <- 0
5   L2:                   #start second loop
6     imul  rax, 4*NK, r8
7     add   rax, rsi
8     lea   r11, [rax + r9*4]
9     mov   rcx, -NJ     #j <- -NJ
10    L3:                 #start third loop
11      mov   eax, [r11]
12      mov   ebx, [r10 + rcx*4 + 4400]
13      imul  ebx, eax
14      add   [rdi + rcx*4 + 4*NJ], ebx
15      add   rcx, 1      #j <- j + 1
16    jne L3              #end third loop
17
18    add   r9,  1        #k <- k + 1
19    add   r10, 4*NK
20    cmp   r9,  NK
21  jne L2                #end second loop
22
23  add  r8,  1           #i <- i + 1
24  add  rdi, 4*NJ
25  cmp  r8,  NI
26 jne L1                 #end first loop
27 pop  rbx
28 ret
```

(b) Native x86-64 code for `matmul` generated by Clang.

```

5 jmp L1'
6 L1:                          #start first loop
7   mov ecx,[rbp-0x18]
8   mov edx,[rbp-0x20]
9   mov eax,[rbp-0x28]
10  L1':
11  imul r8d,edi,0x1130
12  add r8d,eax
13  imul r9d,edi,0x12c0
14  add r9d,edx
15  xor r11d,r11d              #k <- 0
16  jmp L2'
17  L2:                        #start second loop
18    mov ecx,[rbp-0x18]
19    L2':
20    imul r12d,r11d,0x1130
21    lea r14d,[r9+r11*4]
22    add r12d,ecx
23    xor esi,esi              #j <- 0
24    mov r15d,esi
25    jmp L3'
26    L3:                      #start third loop
27      mov r15d,eax
28      L3':
29      lea eax,[r15+0x1]      #j <- j + 1
30      lea edx,[r8+r15*4]
31      lea r15d,[r12+r15*4]
32      mov esi,[rbx+r14*1]
33      mov r15d,[rbx+r15*1]
34      imul r15d,esi
35      mov ecx,[rbx+rdx*1]
36      add ecx,r15d
37      mov [rbx+rdx*1],ecx
38      cmp eax,NJ             #j < NJ
39    jnz L3                   #end third loop
40  add r11,0x1                #k++
41  cmp r11d,NK                #k < NK
42  jnz L2                     #end second loop
43 add edi,0x1                 #i++
44 cmp edi,NI                  #i < NI
45 jnz L1                      #end first loop
46 retl
```

(c) x86-64 code JITed by Chrome from WebAssembly `matmul`.

Figure 7: Native code for `matmul` is shorter, has less register pressure, and fewer branches than the code JITed by Chrome. §6 shows that these inefficiencies are pervasive, reducing performance across the SPEC CPU benchmark suites.

the address in `ecx`, adds the operand to `ecx`, finally storing `ecx` at the address, requiring 3 instructions rather than one on lines 35–37.

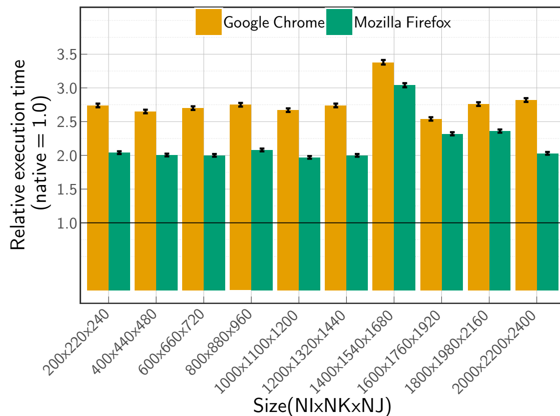

Figure 8: Performance of WebAssembly in Chrome and Firefox for different matrix sizes relative to native code. WebAssembly is always between 2× to 3.4× slower than native.

`perf` Event	Wasm Summary
`all-loads-retired (r81d0)` (Figure 9a) `all-stores-retired (r82d0)` (Figure 9b)	Increased register pressure
`branches-retired (r00c4)` (Figure 9c) `conditional-branches (r01c4)` (Figure 9d)	More branch statements
`instructions-retired (r1c0)` (Figure 9e) `cpu-cycles` (Figure 9f) `L1-icache-load-misses` (Figure 10)	Increased code size

Table 3: Performance counters highlight specific issues with WebAssembly code generation. When a raw PMU event descriptor is used, it is indicated by `rn`.

5.1.2 Increased Register Pressure

Code generated by Clang in Figure 7b does not generate any spills and uses only 10 registers. On the other hand, the code generated by Chrome (Figure 7c) uses 13 general purpose registers – all available registers (`r13` and `r10` are reserved by V8). As described in Section 5.1.1, eschewing the use of the register addressing mode of the `add` instruction requires the use of a temporary register. All of this register inefficiency compounds, introducing three register spills to the stack at lines 1–3. Values stored on the stack are loaded again into registers at lines 7–9 and line 18.

5.1.3 Extra Branches

Clang (Figure 7b) generates code with a single branch per loop by inverting the loop counter (line 15). In contrast, Chrome (Figure 7c) generates more straightforward code, which requires a conditional jump at the start of the loop. In addition, Chrome generates extra jumps to avoid memory loads due to register spills in the first iteration of a loop. For example, the jump at line 5 avoids the spills at lines 7– 9.

6 Performance Analysis

We use BROWSIX-SPEC to record measurements from all supported performance counters on our system for the SPEC CPU benchmarks compiled to WebAssembly and executed in Chrome and Firefox, and the SPEC CPU benchmarks compiled to native code (Section 3).

Table 3 lists the performance counters we use here, along with a summary of the impact of BROWSIX-WASM performance on these counters compared to native. We use these results to explain the performance overhead of WebAssembly over native code. Our analysis shows that the inefficiences described in Section 5 are pervasive and translate to reduced performance across the SPEC CPU benchmark suite.

6.1 Increased Register Pressure

This section focuses on two performance counters that show the effect of increased register pressure. Figure 9a presents the number of *load* instructions retired by WebAssembly-compiled SPEC benchmarks in Chrome and Firefox, relative to the number of load instructions retired in native code. Similarly, Figure 9b shows the number of *store* instructions retired. Note that a “retired” instruction is an instruction which leaves the instruction pipeline and its results are correct and visible in the architectural state (that is, not speculative).

Code generated by Chrome has 2.02× more load instructions retired and 2.30× more store instructions retired than native code. Code generated by Firefox has 1.92× more load instructions retired and 2.16× more store instructions retired than native code. These results show that the WebAssembly-compiled SPEC CPU benchmarks suffer from increased register pressure and thus increased memory references. Below, we outline the reasons for this increased register pressure.

6.1.1 Reserved Registers

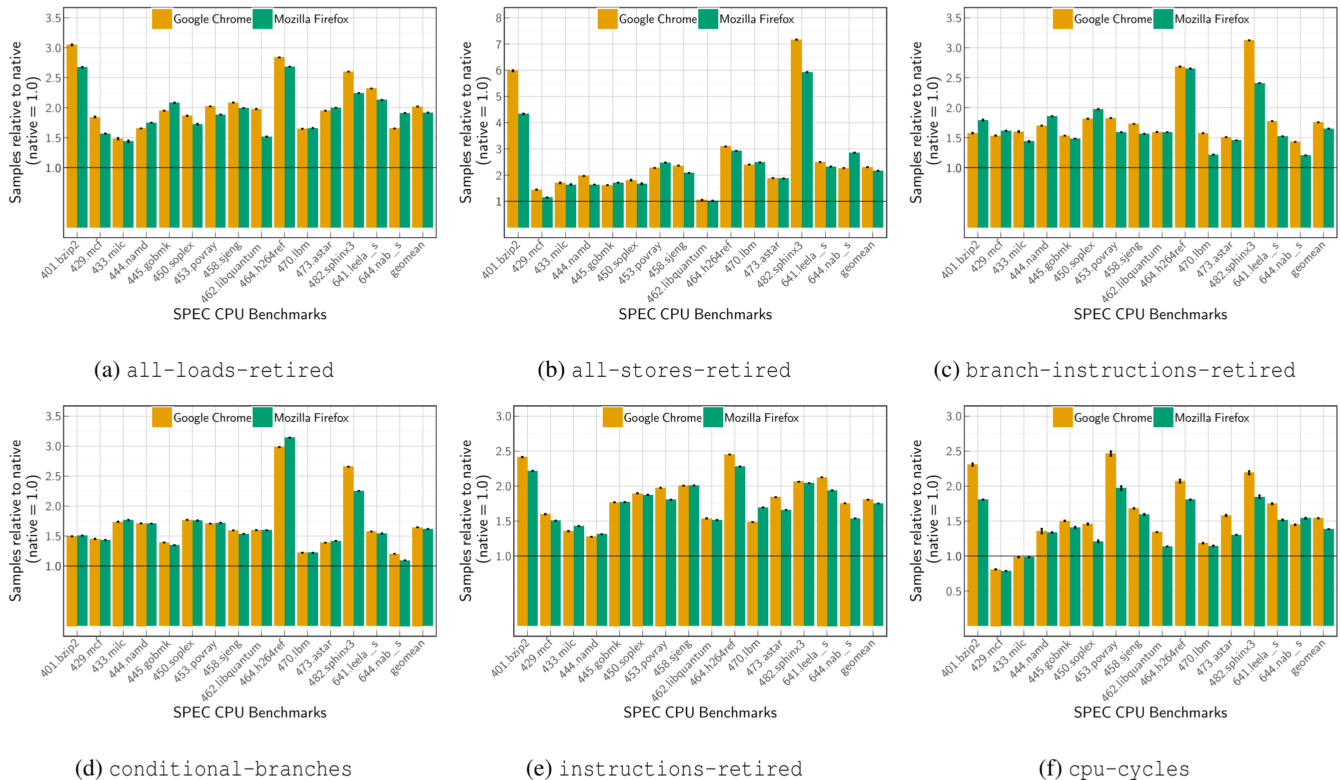
In Chrome, `matmul` generates three register spills but does not use two x86-64 registers: `r13` and `r10` (Figure 7c, lines 7– 9). This occurs because Chrome reserves these two registers.[7] For the JavaScript garbage collector, Chrome reserves `r13` to point to an array of GC roots at all times. In addition, Chrome uses `r10` and `xmm13` as dedicated scratch registers. Similarly, Firefox reserves `r15` as a pointer to the start of the heap, and `r11` and `xmm15` are JavaScript scratch registers.[8] None of these registers are available to WebAssembly code.

6.1.2 Poor Register Allocation

Beyond a reduced set of registers available to allocate, both Chrome and Firefox do a poor job of allocating the registers

[7] `https://github.com/v8/v8/blob/7.4.1/src/x64/register-x64.h`

[8] `https://hg.mozilla.org/mozilla-central/file/tip/js/src/jit/x64/Assembler-x64.h`



(a) `all-loads-retired` (b) `all-stores-retired` (c) `branch-instructions-retired`

(d) `conditional-branches` (e) `instructions-retired` (f) `cpu-cycles`

Figure 9: Processor performance counter samples for WebAssembly relative to native code.

they have. For example, the code generated by Chrome for `matmul` uses 12 registers while the native code generated by Clang only uses 10 registers (Section 5.1.2). This increased register usage—in both Firefox and Chrome—is because of their use of fast but not particularly effective register allocators. Chrome and Firefox both use a linear scan register allocator [36], while Clang uses a greedy graph-coloring register allocator [3], which consistently generates better code.

6.1.3 x86 Addressing Modes

The x86-64 instruction set offers several addressing modes for each operand, including a *register* mode, where the instruction reads data from register or writes data to a register, and memory address modes like *register indirect* or *direct offset* addressing, where the operand resides in a memory address and the instruction can read from or write to that address. A code generator could avoid unnecessary register pressure by using the latter modes. However, Chrome does not take advantage of these modes. For example, the code generated by Chrome for `matmul` does not use the register indirect addressing mode for the `add` instruction (Section 5.1.2), creating unnecessary register pressure.

6.2 Extra Branch Instructions

This section focuses on two performance counters that measure the number of branch instructions executed. Figure 9c shows the number of branch instructions retired by WebAssembly, relative to the number of branch instructions retired in native code. Similarly, Figure 9d shows the number of *conditional* branch instructions retired. In Chrome, there are 1.75× and 1.65× more unconditional and conditional branch instructions retired respectively, whereas in Firefox, there are 1.65× and 1.62× more retired. These results show that all the SPEC CPU benchmarks incur extra branches, and we explain why below.

6.2.1 Extra Jump Statements for Loops

As with `matmul` (Section 5.1.3), Chrome generates unnecessary jump statements for loops, leading to significantly more branch instructions than Firefox.

6.2.2 Stack Overflow Checks Per Function Call

A WebAssembly program tracks the current stack size with a global variable that it increases on every function call. The programmer can define the maximum stack size for the program. To ensure that a program does not overflow the stack,

both Chrome and Firefox add stack checks at the start of each function to detect if the current stack size is less than the maximum stack size. These checks includes extra comparison and conditional jump instructions, which must be executed on every function call.

6.2.3 Function Table Indexing Checks

WebAssembly dynamically checks all indirect calls to ensure that the target is a valid function and that the function's type at runtime is the same as the type specified at the call site. In a WebAssembly module, the function table stores the list of functions and their types, and the code generated by WebAssembly uses the function table to implement these checks. These checks are required when calling function pointers and virtual functions in C/C++. The checks lead to extra comparison and conditional jump instructions, which are executed before every indirect function call.

6.3 Increased Code Size

The code generated by Chrome and Firefox is considerably larger than the code generated by Clang. We use three performance counters to measure this effect. (i) Figure 9e shows the number of *instructions retired* by benchmarks compiled to WebAssembly and executed in Chrome and Firefox relative to the number of instructions retired in native code. Similarly, Figure 9f shows the relative number of *CPU cycles* spent by benchmarks compiled to WebAssembly, and Figure 10 shows the relative number of *L1 instruction cache load misses*.

Figure 9e shows that Chrome executes an average of 1.80× more instructions than native code and Firefox executes an average of 1.75× more instructions than native code. Due to poor instruction selection, a poor register allocator generating more register spills (Section 6.1), and extra branch statements (Section 6.2), the size of generated code for WebAssembly is greater than native code, leading to more instructions being executed. This increase in the number of instructions executed leads to increased L1 instruction cache misses in Figure 10. On average, Chrome suffers 2.83× more I-cache misses than native code, and Firefox suffers from 2.04× more L1 instruction cache misses than native code. More cache misses means that more CPU cycles are spent waiting for the instruction to be fetched.

We note one anomaly: although `429.mcf` has 1.6× more instructions retired in Chrome than native code and 1.5× more instructions retired in Firefox than native code, it runs *faster* than native code. Figure 3b shows that its slowdown relative to native is 0.81× in Chrome and 0.83× in Firefox. The reason for this anomaly is attributable directly to its lower number of L1 instruction cache misses. `429.mcf` contains a main loop and most of the instructions in the loop fit in the L1 instruction cache. Similarly, `433.milc` performance is better due to fewer L1 instruction cache misses. In `450.soplex` there are 4.6× more L1 instruction cache misses in Chrome and Firefox than native because of several virtual functions being executed, leading to more indirect function calls.

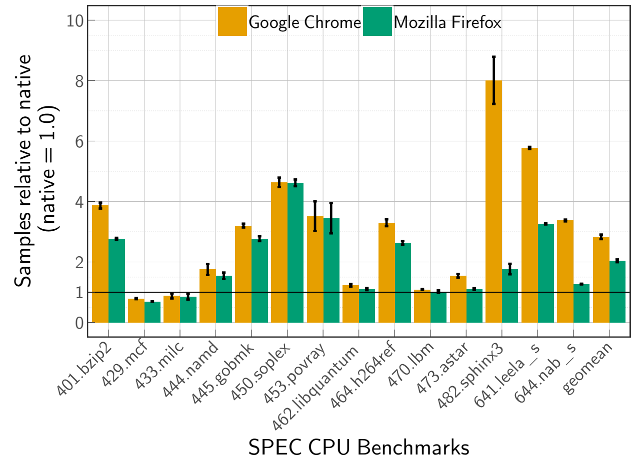


Figure 10: `L1-icache-load-misses` samples counted for SPEC CPU compiled to WebAssembly executed in Chrome and Firefox, relative to native. `458.sjeng` not shown in the graph exhibits 26.5× more L1 instruction cache misses in Chrome and 18.6× more in Firefox. The increased code size generated for WebAssembly leads to more instruction cache misses.

Performance Counter	Chrome	Firefox
`all-loads-retired`	2.02×	1.92×

`cpu-cycles`	1.54×	1.38×
`L1-icache-load-misses`	2.83×	2.04×

Table 4: The geomean of performance counter increases for the SPEC benchmarks using WebAssembly.

6.4 Discussion

It is worth asking if the performance issues identified here are fundamental. We believe that two of the identified issues are not: that is, they could be ameliorated by improved implementations. WebAssembly implementations today use register allocators (§6.1.2) and code generators (§6.2.1) that perform worse than Clang's counterparts. However, an offline compiler like Clang can spend considerably more time to generate better code, whereas WebAssembly compilers must be fast enough to run online. Therefore, solutions adopted by other JITs, such as further optimizing hot code, are likely applicable here [19, 32].

The four other issues that we have identified appear to

arise from the design constraints of WebAssembly: the stack overflow checks (§6.2.2), indirect call checks (§6.2.3), and reserved registers (§6.1.1) have a runtime cost and lead to increased code size (§6.3). Unfortunately, these checks are necessary for WebAssembly's safety guarantees. A redesigned WebAssembly, with richer types for memory and function pointers [23], might be able to perform some of these checks at compile time, but that could complicate the implementation of compilers that produce WebAssembly. Finally, a WebAssembly implementation in a browser must interoperate with a high-performance JavaScript implementation, which may impose its own constraints. For example, current JavaScript implementations reserve a few registers for their own use, which increases register pressure on WebAssembly.

7 Related Work

Precursors to WebAssembly There have been several attempts to execute native code in browsers, but none of them met all the design criteria of WebAssembly.

ActiveX [13] allows web pages to embed signed x86 libraries, however these binaries have unrestricted access to the Windows API. In contrast, WebAssembly modules are sandboxed. ActiveX is now a deprecated technology.

Native Client [11, 37] (NaCl) adds a module to a web application that contains platform specific machine code. NaCl introduced sandboxing techniques to execute platform specific machine code at near native speed. Since NaCl relies on static validation of machine code, it requires code generators to follow certain patterns, hence, supporting only a subset of the x86, ARM, and MIPS instructions sets in the browser. To address the inherent portability issue of NaCl, Portable NaCl (PNaCl) [14] uses LLVM Bitcode as a binary format. However, PNaCl does not provide significant improvement in compactness over NaCl and still exposes compiler and/or platform-specific details such as the call stack layout. Both have been deprecated in favor of WebAssembly.

`asm.js` is a subset of JavaScript designed to be compiled efficiently to native code. `asm.js` uses type coercions to avoid the dynamic type system of JavaScript. Since `asm.js` is a subset of JavaScript, adding all native features to `asm.js` such as 64-bit integers will first require extending JavaScript. Compared to `asm.js`, WebAssembly provides several improvements: (i) WebAssembly binaries are compact due to its lightweight representation compared to JavaScript source, (ii) WebAssembly is more straightforward to validate, (iii) WebAssembly provides formal guarantees of type safety and isolation, and (iv) WebAssembly has been shown to provide better performance than `asm.js`.

WebAssembly is a stack machine, which is similar to the Java Virtual Machine [21] and the Common Language Runtime [25]. However, WebAssembly is very different from these platforms. For example WebAssembly does not support objects and does not support unstructured control flow.

The WebAssembly specification defines its operational semantics and type system. This proof was mechanized using the Isabelle theorem prover, and that mechanization effort found and addressed a number of issues in the specification [35]. RockSalt [22] is a similar verification effort for NaCl. It implements the NaCl verification toolchain in Coq, along with a proof of correctness with respect to a model of the subset of x86 instructions that NaCl supports.

Analysis of SPEC Benchmarks using performance counters Several papers use performance counters to analyze the SPEC benchmarks. Panda et al. [26] analyze the SPEC CPU2017 benchmarks, applying statistical techniques to identify similarities among benchmarks. Phansalkar et al. perform a similar study on SPEC CPU2006 [27]. Limaye and Adegija identify workload differences between SPEC CPU2006 and SPEC CPU2017 [20].

8 Conclusions

This paper performs the first comprehensive performance analysis of WebAssembly. We develop BROWSIX-WASM, a significant extension of BROWSIX, and BROWSIX-SPEC, a harness that enables detailed performance analysis, to let us run the SPEC CPU2006 and CPU2017 benchmarks as WebAssembly in Chrome and Firefox. We find that the mean slowdown of WebAssembly vs. native across SPEC benchmarks is 1.55× for Chrome and 1.45× for Firefox, with peak slowdowns of 2.5× in Chrome and 2.08× in Firefox. We identify the causes of these performance gaps, providing actionable guidance for future optimization efforts.

Extension Framework for File Systems in User space

Ashish Bijlani
Georgia Institute of Technology

Umakishore Ramachandran
Georgia Institute of Technology

Abstract

User file systems offer numerous advantages over their in-kernel implementations, such as ease of development and better system reliability. However, they incur heavy performance penalty. We observe that existing user file system frameworks are highly general; they consist of a minimal interposition layer in the kernel that simply forwards all low-level requests to user space. While this design offers flexibility, it also severely degrades performance due to frequent kernel-user context switching.

This work introduces EXTFUSE, a framework for developing extensible user file systems that also allows applications to register "thin" specialized request handlers in the kernel to meet their specific operative needs, while retaining the complex functionality in user space. Our evaluation with two FUSE file systems shows that EXTFUSE can improve the performance of user file systems with less than a few hundred lines on average. EXTFUSE is available on GitHub.

1 Introduction

User file systems not only offer better security (i.e., unprivileged execution) and reliability [46] when compared to in-kernel implementations, but also ease the development and maintenance/debugging processes. Therefore, many approaches to develop user space file systems have also been proposed for monolithic Operating Systems (OS), such as Linux and FreeBSD. While some approaches target specific systems [25, 45, 53], a number of general-purpose frameworks for implementing user file systems also exist [3, 14, 29, 33, 47]. FUSE [47], in particular, is the state-of-the-art framework for developing user file systems. Over a hundred FUSE file system have been created in academic/research [11, 32, 37, 41, 44, 49], as well as in production settings [9, 24, 40, 52].

Being general-purpose, the primary goal of the aforementioned frameworks is to enable easy, yet fully-functional implementation of file systems in user space supporting multiple different functionalities. To do so, they implement a minimal kernel driver that interfaces with the Virtual File System (VFS) operations and simply forwards all low-level requests to user space. For example, when an application (app) makes an `open()` system call, the VFS issues a `lookup` request for each path component. Similarly, `getxattr` requests are issued to read security labels while serving `write()` system calls. Such low-level requests are simply forwarded to user space. This design offers flexibility to developers to easily implement their functionality and apply custom optimizations, but also incurs a high overhead due to frequent user-kernel switching and data copying. For example, despite several recent optimizations, even a simple passthrough FUSE file system can introduce up to 83% overhead on an SSD [50]. As a result, some FUSE file systems have been replaced by alternative implementations in production [8, 22, 24].

There have been attempts to address performance issues of user file system frameworks, for example, by eliminating user-kernel switching in FUSE under certain scenarios [28, 34]. Nevertheless, the optimizations proposed pertain to their specific use cases and do not address the inherent design limitations of existing frameworks.

We observe that the interfaces exported by existing user file system frameworks are too low-level and general-purpose. As such, they fail to match the specific operative needs of file systems. For example, `getxattr` requests during `write()` can be completely eliminated for files containing no security labels. `lookup` replies from the daemon could be cached and validated in the kernel to reduce context switches to user space. Similarly, when stacking sandboxing functionality for enforcing custom permissions checks in `open()` system call, I/O requests (e.g., `read/write`) could be passed directly through the host file system. Nevertheless, modifying existing frameworks to efficiently address specific functional and performance requirements of each use case is impractical.

We borrow the idea of safely extending system services at runtime from past works [6, 13, 43, 56] and propose to address the performance issues in existing user file systems frameworks by allowing developers to safely extend the functionality of the kernel driver at runtime for specialized handling of their use case. This work introduces EXTFUSE, an extension framework for file systems in user space that allows developers to define specialized "thin" *extensions* along with auxiliary data structures for handling low-level requests in the kernel. The extensions are safely executed under a sandboxed runtime environment in the kernel immediately as the requests are issued from the upper file system layer (e.g., VFS), thereby offering a fine-grained ability to either serve each request entirely in the kernel (*fast path*) or fall back to the existing complex logic in user space (*slow path*) to achieve the desired operative goals of functionality and performance. The fast and slow paths can access (and modify) the auxiliary data structures to define custom logic for handling requests.

ExtFUSE consists of three components. First, a helper user library that provides a familiar set of file system APIs to register extensions and implement custom fast-path functionality in a subset of the C language. Second, a wrapper (no-ops) interposition driver that bridges with the low-level VFS interfaces and provides the necessary support to forward requests to the registered kernel extensions as well as to the lower file system, as needed. Third, an in-kernel Virtual Machine (VM) runtime that safely executes the extensions.

We have built ExtFUSE to work in concert with existing user file system frameworks to allow both the fast and the existing slow path to coexist with no overhauling changes to the design of the target user file system. Although there are several user file system frameworks, this work focuses only on FUSE because of its wide-spread use. Nonetheless, we have implemented ExtFUSE as in a modular fashion so it can be easily adopted for others.

We added support for ExtFUSE in four popular FUSE file systems, namely LoggedFS [16], Android sdcard daemon, MergerFS, and BindFS [35]. Our evaluation of the first two shows that ExtFUSE can offer substantial performance improvements of user file systems by adding less than a few hundred lines, on average.

This paper makes the following contributions:

- We identify optimization opportunities in user file system frameworks for monolithic OSes (§2) and propose extensible user file systems.
- We present the design (§3) and architecture (§3.4) of ExtFUSE, an extension framework for user file systems that offers the performance of kernel file systems, while retaining the safety properties of user file systems.
- We demonstrate the applicability of ExtFUSE by adopting it for FUSE, the state-of-the-art user file system framework, and evaluating it on Linux (§6).
- We show the practical benefits and limitations of the ExtFUSE with two popular FUSE file systems, one deployed in production (§6.2).

2 Background and Extended Motivation

This section provides a brief technical background on FUSE and its limitations that motivate our work.

2.1 FUSE

FUSE is the state-of-the-art framework for developing user file systems. It consists of a loadable kernel driver and a helper user-space library that provides a set of portable APIs to allow users to implement their own fully-functional file system as an unprivileged daemon process on Unix-based systems with no additional kernel support. The driver is a simple interposition layer that only serves as a communication channel between the user-space daemon and the VFS. It registers a new file system to interface with the VFS operations and directly forwards all low-level requests to the daemon, as received.

The library provides two different sets of APIs. First, a `fuse_lowlevel_ops` interface that exports all VFS operations such as `lookup` for path to inode mapping. It is used by file systems that need to access low-level abstractions (e.g., inodes) for custom optimizations. Second, a high-level `fuse_operations` interface that builds on the low-level APIs. It hides complex abstractions and offers a simple (e.g., path-based) API for the ease of development. Depending on their particular use case, developers can adopt either of the two APIs. Furthermore, many operations in both APIs are optional. For example, developers can choose to not handle extended attributes (xattrs) operations (e.g., `getxattr`).

As apps make system calls, the VFS layer forwards all low-level requests to the kernel driver. For example, to serve the `open()` system call on Linux, the VFS issues multiple `lookup` requests to the driver, one for each input path component. Similarly, every `write()` request is preceded by a `getxattr` request from the VFS to fetch the security labels. The driver queues up all requests, along with the relevant parameters, for the daemon through `/dev/fuse` device file and blocks the calling app thread until the requests are served. The daemon, through the `libfuse` interface, retrieves the requests from the queue, processes them as needed, and enqueues the results for the driver to read. The driver copies the results, populating VFS caches, as appropriate (e.g., page cache for `read`/`write`, dcache for dir entries from `lookup`), and wakes the app thread and returns the results to it. Once cached, the subsequent accesses to the same data are served with no user-kernel round-trip communication.

In addition to the common benefits of user file systems such as ease of development and maintenance, FUSE also provides app-transparency and fine-grained control to developers over the low-level API to easily support their custom functionality. Furthermore on Linux, the FUSE driver is GPL-licensed, which detaches the implementation in user space from legal obligations [57]. It also supports multiple language bindings (e.g., Python, Go, etc.), thereby enabling access to ecosystem of third-party libraries for reuse.

Given its general-purpose design and numerous advantages, over a hundred FUSE file systems with different functionalities have been created. A large majority of them are stackable; that is, they introduce incremental functionality on the host file system [38]. FUSE has long served as a popular tool for quick experimentation and prototyping new file systems in academic and research settings [11, 32, 37, 41, 44, 49]. However, more recently a host of FUSE file systems have also been deployed in production. Both Gluster [40] and Ceph [52] cluster file systems use a FUSE network client implementation. Android v4.4 introduced FUSE sdcard daemon (stackable) to add multi-user support and emulate FAT functionality on the EXT4 file system [24].

While exporting low-level abstractions and VFS interfaces offers more control and flexibility to developers, this design comes with a cost. It induces frequent user-kernel round-

Media	W/ xattr (%Diff)		W/O xattr (%Diff)	
	SW	RW	SW	RW
HDD	-0.29	-3.80	-0.17	-2.83
SSD	-11.5	-23.38	+0.31	-12.24

Table 1: Percentage difference between I/O throughput (ops/sec) for EXT4 vs FUSE StackfsOpt (see §6) under single thread 4K Seq Write (SW), and Rand Write (RW) settings on a 60GB file across different storage media as reported by Filebench [48]. Received 15 million getxattr requests.

trip communication and data copying, and thus inevitably yields poor runtime performance. Nonetheless, FUSE has evolved significantly over the years; several optimizations have been added to minimize the user-kernel communication: zero-copy data transfer (splicing), and utilizing system-wide shared VFS caches (page cache for data I/O and dentry cache for metadata). However, despite these optimizations, FUSE severely degrades runtime performance in a host of scenarios. For instance, data caching improves I/O throughput by batching requests (e.g., read-aheads, small writes), but it does not help apps that perform random reads or demand low write latency (e.g., databases). Splicing is only used for over 4K requests. Therefore, apps with small writes/reads (e.g., Android apps, etc.) will incur data copying overheads. Worse yet, the overhead is higher with faster storage media. Even a simple passthrough (no-ops) FUSE file system can introduce up to 83% overhead for metadata-heavy workloads on SSD [50].

The performance penalty incurred by user file systems overshadows their benefits. Consequently, some user file systems have been replaced with alternative implementations in production. For instance, Android v7.0 replaced the sdcard daemon with its in-kernel implementation after several years [24]. Ceph [52] adopted an in-kernel client for Linux kernel [8].

2.2 Generality vs Specialization

We observe that being highly general-purpose, the FUSE framework induces unnecessary user-kernel communication in many cases, yielding low throughput and high latency. For instance, `getxattr` requests generated by the VFS during `write()` system calls (one per `write`) can double the number of user-kernel transitions, which decreases the I/O throughput of sequential writes by over 27% and random writes by over 44% compared to native (EXT4) performance (Table 1). Moreover, the penalty incurred is higher with the faster media.

Nevertheless, simple filtering or caching metadata replies in the kernel can substantially reduce user-kernel communication. For instance, by caching the last `getxattr` reply in the FUSE driver and simply validating the cached state for every subsequent `getxattr` request from the VFS on the same file, unnecessary user-kernel transitions can be eliminated to achieve significant improvement in `write` performance. Similarly, replies from other metadata operations, such as `lookup` and `getattr` can be cached, validated, and served entirely within the kernel. Note that custom validation of cached metadata is imperative, and lack of support to do so may result in incorrect behavior as happens in the case of optimized FUSE that leverages VFS caches to serve requests (§5.1).

Many stackable user file systems add a thin layer of functionality; they perform simple checks in a few operations and pass remaining requests directly through the host (lower) file system. LoggedFS [16] filters requests that must be logged and do so by accessing host file system services. Union file systems such as MergerFS [20] determine the backend host file in `open()` and redirects I/O requests to it. Android sdcard daemon performs access permission checks only in metadata operations (e.g., `open`, `lookup`), but data I/O requests (e.g., `read`, `write`, etc.) are simply forwarded to the lower file system. Thin functionality that realizes such use cases does not need any complex processing in user space, and therefore can easily be stacked in the kernel, thereby avoiding expensive user-kernel switching to yield lower latency and higher throughput for the same functionality. Furthermore, data I/O requests could be directly forwarded to the host file system.

The FUSE framework offers a few configuration (config) options to the developers to tune the behavior of its kernel driver for their use case. However, those options are coarse-grained and implemented as fixed checks embedded in the driver code; thus, it offers limited static control. For example, for file systems that do not support certain operations (e.g., `getxattr`), the FUSE driver caches this knowledge upon first `ENOSUPPORT` reply and does not issue such requests subsequently. While this benefits the file systems that completely omit certain functionality (e.g., security xattr labels), it does not allow custom and fine-grained filtering of requests that may be desired by some file systems supporting only partial functionality. For example, file systems providing encryption (or compression) functionality may desire a fine-grained custom control over the kernel driver to skip the decryption (or decompression) operation in user space during `read()` requests on non-sensitive (or unzipped) files.

As such, the FUSE framework proves to be too low-level and general-purpose in many cases. While it enables a number of different use cases, modifying the framework to efficiently handle special needs of each use case is impractical. This is a typical unbalanced generality vs. specialization problem, which can be addressed by extending the functionality of the FUSE driver in the kernel [6, 13, 43].

3 Design

In this section, we 1) present an overview of EXTFUSE, 2) discuss the design goals and challenges we faced, and 3) mechanisms we adopted to address those challenges.

3.1 Overview

EXTFUSE is a framework for developing extensible FUSE file systems for UNIX-like monolithic OSes. It allows the

unprivileged FUSE daemon processes to register "thin" extensions in the kernel for specialized handling of low-level file system requests, while retaining their existing complex logic in user space to achieve the desired level of performance.

The registered extensions are safely executed under a sandboxed eBPF runtime environment in the kernel (§3.3), immediately as requests are issued from the upper file system (e.g., VFS). Sandboxing enables the FUSE daemon to safely extend the functionality of the driver at runtime and offers a fine-grained ability to either serve each request entirely in the kernel or fall back to user space, thereby offering safety of user space and performance of kernel file systems.

EXTFUSE also provides a set of APIs to create shared key-value data structures (called maps) that can host abstract data blobs. The user-space daemon and its kernel extensions can leverage maps to store/manipulate their custom data types as needed to work in concert and serve file system requests in the kernel without incurring expensive user-kernel round-trip communication if deemed unnecessary.

3.2 Goals and Challenges

The over-arching goal of EXTFUSE is to carefully balance the safety and runtime extensibility of user file systems to achieve the desired level of performance and specialized functionality. Nevertheless, in order for developers to use EXTFUSE, it must also be easy to adopt. We identify the following concrete design goals.

Design Compatibility. The abstractions and interfaces offered by EXTFUSE framework must be compatible with FUSE without hindering existing functionality or properties. It must be general-purpose so as to support multiple different use cases. Developers must further be able to adopt EXTFUSE for their use case without overhauling changes to their existing design. It must be easy for them to implement specialized extensions with little to no knowledge of the underlying implementation details.

Modular Extensibility. EXTFUSE must be highly modular and limit any unnecessary new changes to FUSE. Particularly, developers must be able to retain their existing user-space logic and introduce specialized extensions only if needed.

Balancing Safety and Performance. Finally with EXTFUSE, even unprivileged (and untrusted) FUSE daemon processes must be able to safely extend the functionality of the driver as needed to offer performance that is as close as possible to the in-kernel implementation. However, unlike Microkernels [2, 23, 30] that host system services in separate protection domains as user processes or the OSes that have been developed with safe runtime extensibility as a design goal [6, 13], extending system services of general-purpose UNIX-like monolithic OSes poses a design trade-off question between the safety and performance requirements.

Untrusted extensions must be as lightweight as possible, with their access restricted to only a few well-defined APIs to guarantee safety. For example, kernel file systems offer near-native performance, but executing complex logic in the kernel results in questionable reliability. Additionally, most OS kernels employ Address Space Randomization [36], Data Execution Prevention [5], etc. for code protection and hiding memory pointers. Providing unrestricted kernel access to extensions can render such protections useless. Therefore, extensions must not be able to access arbitrary memory addresses or leak pointer values to user space.

However, severely restricting extensibility can prevent user file systems from fully meeting their operative performance and functionality goals, thus defeating the purpose of extensions in the first place. Therefore, EXTFUSE must carefully balance safety and performance goals.

Correctness. Furthermore, specialized extensions can alter the existing design of user file systems, which can lead to correctness issues. For example, there will be two separate paths (fast and slow) both operating on the requests and data structs at the same time. The framework must provide a way for them to synchronize and offer safe concurrent accesses.

3.3 eBPF

EXTFUSE leverages extended BPF (eBPF) [26], an in-kernel Virtual Machine (VM) runtime framework to load and safely execute user file system extensions.

Richer functionality. eBPF is an extension of classic Berkeley Packet Filters (BPF), an in-kernel interpreter for a pseudo machine architecture designed to only accept simple network filtering rules from user space. It enhances BPF to include more versatility, such as 64-bit support, a richer instruction set (e.g., call, cond jump), more registers, and native performance through JIT compilation.

High-level language support. The eBPF bytecode backend is also supported by Clang/LLVM compiler toolchain, which allows functionality logic to be written in a familiar high-level language, such as C and Go.

Safety. The eBPF framework provides a safe execution environment in the kernel. It prohibits execution of arbitrary code and access to arbitrary kernel memory regions; instead, the framework restricts access to a set of kernel helper APIs depending on the target kernel subsystem (e.g., network) and required functionality (e.g., packet handling). The framework includes a static analyzer (called verifier) that checks the correctness of the bytecode by performing an exhaustive depth-first search through its control flow graph to detect problems, such as infinite loops, out-of-bound, and illegal memory errors. The framework can also be configured to allow or deny eBPF bytecode execution request from unprivileged processes.

Key-Value Maps. eBPF allows user space to create *map* data structures to store arbitrary key-value blobs using system calls and access them using file descriptors. Maps are also accessible to eBPF bytecode in the kernel, thus providing a communication channel between user space and the bytecode

to define custom key-value types and share execution state or data. Concurrent accesses to maps are protected under read-copy update (RCU) synchronization mechanism. However, maps consume unswappable kernel memory. Furthermore, they are either accessible to everyone (e.g., by passing file descriptors) or only to `CAP_SYS_ADMIN` processes.

eBPF is a part of the Linux kernel and is already used heavily by networking, tracing, and profiling subsystems. Given its rich functionality and safety properties, we adopt eBPF for providing support for extensible user file systems. Specifically, we define a white-list of kernel APIs (including their parameters and return types), and abstractions that user file system extensions can safely use to realize their specialized functionality. The eBPF verifier utilizes the whitelist to validate the correctness of the extensions. We also build on eBPF abstractions (e.g., maps) and apply further access restrictions to enable safe in-kernel execution, as needed.

3.4 Architecture

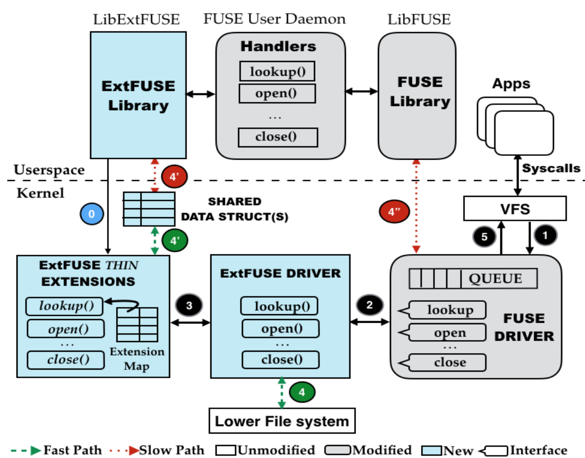

Figure 1: Architectural view of the EXTFUSE framework. The components modified or introduced have been highlighted.

Figure 1 shows the architecture of the EXTFUSE framework. It is enabled by three core components, namely a kernel file system (`driver`), a user library (`libExtFUSE`), and an in-kernel eBPF virtual machine runtime (`VM`).

The EXTFUSE driver uses interposition technique to interface with FUSE at low-level file system operations. However, unlike the FUSE driver that simply forwards file system requests to user space, the EXTFUSE driver is capable of directly delivering requests to in-kernel handlers (extensions). It can also forward a few restricted set of requests (e.g., `read`, `write`) to the host (lower) file system, if present. The latter is needed for stackable user file systems that add thin functionality on top of the host file system. `libExtFUSE` exports a set of APIs and abstractions for serving requests in the kernel, hiding the underlying implementation details.

Use of `libExtFUSE` is optional and independent of `libfuse`. The existing file system handlers registered with `libfuse` continue to reside in user space. Therefore, their invocation incurs context switches, and thus, we refer to their execution as the *slow* path. With EXTFUSE, user space can also register kernel extensions that are invoked immediately as file system requests are received from the VFS in order to allow serving them in the kernel. We refer to the in-kernel execution as the *fast* path. Depending upon the return values from the fast path, the requests can be marked as served or be sent to the user-space daemon via the slow path to avail any complex processing as needed. Fast path can also return a special value that instructs the EXTFUSE driver to interpose and forward the request to the lower file system. However, this feature is only available to stackable user file systems and is verified when the extensions are loaded in the kernel.

The fast path interfaces exported by `libExtFUSE` are the same as those exported by `libfuse` to the slow path. This is important for easy transfer of design and portability. We leverage eBPF support in the LLVM/Clang compiler toolchain to provide developers with a familiar set of APIs and allow them to implement their custom functionality logic in a subset of the C language.

The extensions are loaded and executed inside the kernel under the eBPF VM sandbox, thereby providing user space a fine-grained ability to safely extend the functionality of FUSE kernel driver at runtime for specialized handling of each file system request.

FS Interface	API(s)	Abstractions	Description
Low-level	`fuse_lowlevel_ops`	`Inode`	FS Ops
Kernel Access	**API(s)**	**Abstractions**	**Description**
eBPF Funcs	`bpf_*`	`UID, PID, etc.`	Helper Funcs
FUSE	`extfuse_reply_*`	`fuse_reply_*`	Req Output
Kernel	`bpf_set_pasthru`	`FileDesc`	Enable Pthru
Kernel	`bpf_clear_pasthru`	`FileDesc`	Disable Pthru
DataStructs	**API(s)**	**Abstractions**	**Description**
SHashMap	`CRUD`	`Key/Val`	Hosts arbitrary data blobs
InodeMap	`CRUD`	`FileDesc`	Hosts upper-lower inode pairs

Table 2: APIs and abstractions provided by EXTFUSE. It provides FUSE-like file system interface for easy portability. CRUD (create, read, update, and delete) APIs are offered for map data structures to operate on Key/Value pairs. Kernel accesses are restricted to standard eBPF kernel helper functions. We introduced APIs to access the same FUSE request parameters as available to user space.

3.5 EXTFUSE APIs and Abstractions

`libExtFUSE` provides a set of high-level APIs and abstractions to the developers for easy implementation of their specialized extensions, hiding the complex implementation details. Table 2 summarizes the APIs. For handling file system operations, `libExtFUSE` exports the familiar set of FUSE interfaces and corresponding abstractions (e.g., inode) for design compatibility. Both low-level as well as high-level file system interfaces are available, offering flexibility and development ease. Furthermore, as with `libfuse`, the daemon can reg-

ister extensions for a few or all of the file system APIs, offering them flexibility to implement their functionality with no additional development burden. The extensions receive the same request parameters (`struct fuse_[in,out]`) as the user-space daemon. This design choice not only conforms to the principle of least privilege, but also offers the user-space daemon and the extensions the same interface for easy portability.

For hosting/sharing data between the user daemon and kernel extensions, `libExtFUSE` provides a secure variant of eBPF `HashMap` key/value data structure called `SHashMap` that stores arbitrary key/value blobs. Unlike regular eBPF maps that are either accessible to all user processes or only to `CAP_SYS_ADMIN` processes, `SHashMap` is only accessible by the unprivileged daemon that creates it. `libExtFUSE` further abstracts low-level details of `SHashMap` and provides high-level `CRUD` APIs to create, read, update, and delete entries (key/value pairs).

EXTFUSE also provides a special `InodeMap` to enable passthrough I/O feature for stackable EXTFUSE file systems (§5.2). Unlike `SHashMap` that stores arbitrary entries, `InodeMap` takes open file handle as key and stores a pointer to the corresponding lower (host) inode as value. Furthermore, to prevent leakage of inode object to user space, the `InodeMap` values can only be read by the EXTFUSE driver.

3.6 Workflow

To understand how EXTFUSE facilitates implementation of extensible user file systems, we describe its workflow in detail. Upon mounting the user file system, FUSE driver sends `FUSE_INIT` request to the user-space daemon. At this point, the user daemon checks if the OS kernel supports EXTFUSE framework by looking for `FUSE_CAP_ExtFUSE` flag in the request parameters. If supported, the daemon must invoke `libExtFUSE init` API to load the eBPF program that contains specialized handlers (extensions) into the kernel and register them with the EXTFUSE driver. This is achieved using `bpf_load_prog` system call, which invokes eBPF verifier to check the integrity of the extensions. If failed, the program is discarded and the user-space daemon is notified of the errors. The daemon can then either exit or continue with default FUSE functionality. If the verification step succeeds and the JIT engine is enabled, the extensions are processed by the JIT compiler to generate machine assembly code ready for execution, as needed.

Extensions are installed in a `bpf_prog_type` map (called *extension map)*, which serves effectively as a jump table. To invoke an extension, the FUSE driver simply executes a `bpf_tail_call` (far jump) with the FUSE operation code (e.g., `FUSE_OPEN`) as an index into the extension map. Once the eBPF program is loaded, the daemon must inform EXTFUSE driver about the kernel extensions by replying to `FUSE_INIT` containing identifiers to the extension map.

Once notified, EXTFUSE can safely load and execute the extensions at runtime under the eBPF VM environment. Every request is first delivered to the fast path, which may decide to 1) serve it (e.g., using data shared between the fast and slow paths), 2) pass the request through to the lower file system (e.g., after modifying parameters or performing access checks), or 3) take the slow path and deliver the request to user space for complex processing logic (e.g., data encryption), as needed. Since the execution path is chosen per-request independently and the fast path is always invoked first, the kernel extensions and user daemon can work in concert and synchronize access to requests and shared data structures. It is important to note that the EXTFUSE driver only acts as a thin interposition layer between the FUSE driver and kernel extensions, and in some cases, between the FUSE driver and the lower file system. As such, it does not perform any I/O operation or attempts to serve requests on its own.

Component	Version	Loc Modified	Loc New
FUSE kernel driver	4.11.0	312	874
FUSE user-space library	3.2.0	23	84
EXTFUSE user-space library	-	-	581

Table 3: Changes made to the existing Linux FUSE framework to support EXTFUSE functionality.

4 Implementation

To implement EXTFUSE, we provided eBPF support for FUSE. Specifically, we added additional kernel helper functions and designed two new map types to support secure communication between the user-space daemon and kernel extensions, as well as support for passthrough access in read/write. We modified FUSE driver to first invoke registered eBPF handlers (extensions). Passthrough implementation is adopted from WrapFS [54], a wrapper stackable in-kernel file system. Specifically, we modified FUSE driver to pass I/O requests directly to the lower file system.

Since with EXTFUSE developers can install extensions to bypass the user-space daemon and pass I/O requests directly to the lower file system, a malicious process could stack a number of EXTFUSE file systems on top of each other and cause the kernel stack to overflow. To guard against such attacks, we limit the number of EXTFUSE layers that could be stacked on a mount point. We rely on `s_stack_depth` field in the super-block to track the number of stacked layers and check it against `FILESYSTEM_MAX_STACK_DEPTH`, which we limit to two. Table 3 reports the number of lines of code for EXTFUSE. We also modified `libfuse` to allow apps to register kernel extensions.

5 Optimizations

Here, we describe a set of optimizations that can be enabled by leveraging custom kernel extensions in EXTFUSE to implement in-kernel handling of file system requests.

```
1  void handle_lookup(fuse_req_t req, fuse_ino_t pino,
2              const char *name) {
3      /* lookup or create node @cname parent @pino */
4      struct fuse_entry_param e;
5      if (find_or_create_node(req, pino, name, &e)) return;
6  +   lookup_key_t key = {pino, name};
7  +   lookup_val_t val = {0/*not stale*/, &e};
8  +   extfuse_insert_shmap(&key, &val); /* cache this entry */
9      fuse_reply_entry(req, &e);
10 }
```

Figure 2: FUSE daemon `lookup` handler in user space. With EXTFUSE, lines 6-8 (+) enable caching replies in the kernel.

5.1 Customized in-kernel metadata caching

Metadata operations such as `lookup` and `getattr` are frequently issued, and thus form high sources of latency in FUSE file systems [50]. Unlike VFS caches that are only reactive and fixed in functionality, EXTFUSE can be leveraged to proactively cache metadata replies in the kernel. Kernel extensions can be installed to manage and serve subsequent operations from caches without switching to user space.

Example. To illustrate, let us consider the `lookup` operation. It is the most common operation issued internally by the VFS for serving `open()`, `stat()`, and `unlink()` system calls. Each component of the input path string is searched using `lookup` to fetch the corresponding inode data structure. Figure 2 lists code fragment for FUSE daemon handler that serves `lookup` requests in user space (slow path). The FUSE `lookup` API takes two input parameters: the parent node ID and the next path component name. The node ID is a 64-bit integer that uniquely identifies the parent inode. The daemon handler function traverses the parent directory, searching for the child entry corresponding to the next path component. Upon successful search, it populates the `fuse_entry_param` data structure with the node ID and attributes (e.g., size) of the child, and sends it to the FUSE driver, which creates a new inode for the dentry object representing the child entry.

With EXTFUSE, developers could define a `SHashMap` that hosts `fuse_entry_param` replies in the kernel (lines 7-10). A composite key generated from the parent node identifier and the next path component string arguments is used as an index into the map for inserting corresponding replies. Since the map is also accessible to the extensions in the kernel, subsequent requests could be served from the map by installing the EXTFUSE `lookup` extension (fast path). Figure 3 lists its code fragment. The extension uses the same composite key as an index into the hash map to search whether the corresponding `fuse_entry_param` entry exists. If a valid entry is found, the reference count (`nlookup`) is incremented and a reply is sent to the FUSE driver.

Similarly, replies from user space daemon for other metadata operations, such as `getattr`, `getxattr`, and `readlink` could be cached using maps and served in the kernel by respective extensions (Table 4). Network FUSE file systems, such as SshFS [39] and Gluster [40] already perform aggressive metadata caching and batching at client to reduce the number of remote calls to the server. SshFS [39], for example,

```
1  int lookup_extension(extfuse_req_t req, fuse_ino_t pino,
2              const char *name) {
3      /* lookup in map, bail out if not cached or stale */
4      lookup_key_t key = {pino, name};
5      lookup_val_t *val = extfuse_lookup_shmap(&key);
6      if (!val || atomic_read(&val->stale)) return UPCALL;
7      /* EXAMPLE: Android sdcard daemon perm check */
8      if (!check_caller_access(pino, name)) return -EACCES;
9      /* populate output, incr count (used in FUSE_FORGET) */
10     extfuse_reply_entry(req, &val->e);
11     atomic_incr(&val->nlookup, 1);
12     return SUCCESS;
13 }
```

Figure 3: EXTFUSE `lookup` kernel extension that serves valid cached replies, without incurring any context switches. Customized checks could further be included; Android sdcard daemon permission check is shown as an example (see Figure 10).

implements its own directory, attribute, and symlink caches. With EXTFUSE, such caches could be implemented in the kernel for further performance gains.

Invalidation. While caching metadata in the kernel reduces the number of context switches to user space, developers must also carefully invalidate replies, as necessary. For example, when a file (or dir) is deleted or renamed, the corresponding cached `lookup` replies must be invalidated. Invalidations can be performed in user space by the relevant request handlers or in the kernel by installing their extensions before new changes are made. However, the former case may introduce race conditions and produce incorrect results because all requests to user space daemon are queued up by the FUSE driver, whereas requests to the extensions are not. Cached `lookup` replies can be invalidated in extensions for `unlink`, `rmdir`, and `rename` operations. Similarly, when attributes or permissions on a file change, cached `getattr` replies can be invalidated in `setattr` extension. Our design ensures race-free invalidation by executing the extensions before forwarding requests to user space daemon where the changes may be made.

Advantages over VFS caching. As previously mentioned, recent optimizations added to FUSE framework leverage VFS caches to reduce user-kernel context switching. For instance, by specifying non-zero `entry_valid` and `attr_valid` timeout values, dentries and inodes cached by the VFS from previous `lookup` operations could be utilized to serve subsequent `lookup` and `getattr` requests, respectively. However, the VFS offers no control to the user file system over the cached data. For example, if the file system is mounted without the `default_permissions` parameter, VFS caching of inodes introduces a security bug [21]. This is because the cached permissions are only checked for first accessing user. In contrast, with EXTFUSE, developers can define their own metadata caches and install custom code to manage them. For instance, extensions can perform `uid`-based access permission checks before serving requests from the caches to obviate the aforementioned security issue (Figure 10).

Additionally, unlike VFS caches that are only reactive, EXTFUSE enables proactive caching. For example, since a `readdir` request is expected after an `opendir` call, the user-space daemon could proactively cache directory entries in the

Metadata	Map Key	Map Value	Caching Operations	Serving Extensions	Invalidation Operations
Inode	<nodeID, name>	fuse_entry_param	`lookup, create, mkdir, mknod`	*`lookup`*	`unlink, rmdir, rename`
Attrs	<nodeID>	fuse_attr_out	`getattr, lookup`	*`getattr`*	`setattr, unlink, rmdir`
Symlink	<nodeID>	link path	`symlink, readlink`	*`readlink`*	`unlink`
Dentry	<nodeID>	fuse_dirent	`opendir, readdir`	*`readdir`*	`releasedir, unlink, rmdir, rename`
XAttrs	<nodeID, label>	xattr value	`open, getxattr, listxattr`	*`getattr`*, *`listxattr`*	`close, setxattr, removexattr`

Table 4: Metadata can be cached in the kernel using eBPF maps by the user-space daemon and served by kernel extensions.

kernel by inserting them in a BPF map while serving `opendir` requests to reduce transitions to user space. Alternatively, similar to read-ahead optimization, proactive caching of subsequent directory entries could be performed during the first `readdir` call to the user-space daemon. Memory occupied by cached entries could then be freed by the `releasedir` handler in user space that deletes them from the map. Similarly, security labels on a file could be cached during the `open` call to user space and served in the kernel by `getxattr` extensions. Nonetheless, since eBPF maps consume kernel memory, developers must carefully manage caches and limit the number of map entries to keep memory usage under check.

5.2 Passthrough I/O for stacking functionality

Many user file systems are stackable with a thin layer of functionality that does not require complex processing in the user-space. For example, LoggedFS [16] filters requests that must be logged, logs them as needed, and then simply forwards them to the lower file system. User-space union file systems, such as MergerFS [20] determine the backend host file in `open` and redirects I/O requests to it. BindFS [35] mirrors another mount point with custom permissions checks. Android sdcard daemon performs access permission checks and emulates the case-insensitive behavior of FAT only in metadata operations (e.g., `lookup`, `open`, etc.), but forwards data I/O requests directly to the lower file system. For such simple cases, the FUSE API proves to be too low-level and incurs unnecessarily high overhead due to context switching.

With EXTFUSE, `read/write` I/O requests can take the fast path and directly be forwarded to the lower (host) file system without incurring any context-switching if the complex slow-path user-space logic is not needed. Figure 4 shows how the user-space daemon can install the lower file descriptor in `InodeMap` while handling `open()` system call for notifying the EXTFUSE driver to store a reference to the lower inode kernel object. With the `custom_filtering_logic(path)` condition, this can be done selectively; for example, if access permission checks pass in Android sdcard daemon. Similarly, BindFS and MergerFS can adopt EXTFUSE to avail passthrough optimization. The `read/write` kernel extensions can check in `InodeMap` to detect whether the target file is setup for passthrough access. If found, EXTFUSE driver can be instructed with a special return code to directly forward the I/O request to the lower file system with the corresponding lower inode object as parameter. Figure 5 shows a template `read` extension. Kernel extensions can include additional logic or checks before returning. For instance, LoggedFS `read/write` extensions can filter and log operations, as needed §6.2.

```
1  void handle_open(fuse_req_t req, fuse_ino_t ino,
2          const struct fuse_open_in *in) {
3      /* file represented by @ino inode num */
4      struct fuse_open_out out; char path[PATH_MAX];
5      int len, fd = open_file(ino, in->flags, path, &out);
6      if (fd > 0 && custom_filtering_logic(path)) {
7  +       /* install fd in inode map for pasthru */
8  +       imap_key_t key = out->fh;
9  +       imap_val_t val = fd; /* lower fd */
10 +       extfuse_insert_imap(&key, &val);
11 }   }
```

Figure 4: FUSE daemon `open` handler in user space. With EXTFUSE, lines 7-9 (+) enable passthrough access on the file.

```
1  int read_extension(extfuse_req_t req, fuse_ino_t ino,
2          const struct fuse_read_in *in) {
3      /* lookup in inode map, passthrough if exists */
4      imap_key_t key = in->fh;
5      if (!extfuse_lookup_imap(&key)) return UPCALL;
6      /* EXAMPLE: LoggedFS log operation */
7      log_op(req, ino, FUSE_READ, in, sizeof(*in));
8      return PASSTHRU; /* forward req to lower FS */
9  }
```

Figure 5: The EXTFUSE `read` kernel extension returns `PASSTHRU` to forward request directly to the lower file system. Custom thin functionality could further be pushed in the kernel; LoggedFS logging function is shown as an example (see Figure 11).

6 Evaluation

To evaluate EXTFUSE, we answer the following questions:

- **Baseline Performance.** How does an EXTFUSE implementation of a file system perform when compared to its in-kernel and FUSE implementations? (§6.1)
- **Use cases.** What kind of existing FUSE file systems can benefit from EXTFUSE and what performance improvements can they expect? (§6.2)

6.1 Performance

To measure the baseline performance of EXTFUSE, we adopted the simple no-ops (null) stackable FUSE file system called Stackfs [50]. This user-space daemon serves all requests by forwarding them to the host (lower) file system. It includes all recent FUSE optimizations (Table 5). We evaluate Stackfs under all possible EXTFUSE configs listed in Table 5. Each config represents a particular level of performance that could potentially be achieved, for example, by caching metadata in the kernel or directly passing `read/write` requests through the host file system for stacking functionality. To put our results in context, we compare our results with EXT4 and

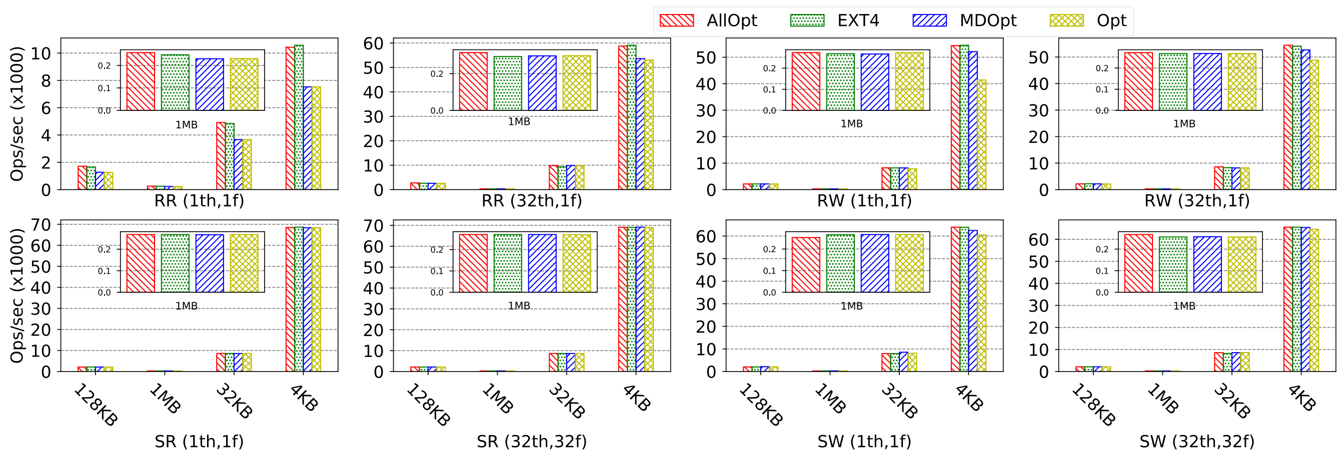

Figure 6: Throughput(ops/sec) for EXT4 and FUSE/ExtFUSE Stackfs (w/ xattr) file systems under different configs (Table 5) as measured by Random Read(RR)/Write(RW), Sequential Read(SR)/Write(SW) Filebench [48] data micro-workloads with IO Sizes between 4KB-1MB and settings *N*th: *N* threads, *N*f: *N* files. We use the same workloads as in [50].

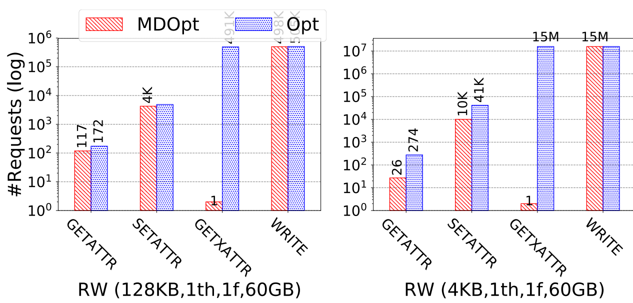

Figure 7: Number of file system request received by the daemon in FUSE/ExtFUSE Stackfs (w/ xattr) under workloads in Figure 6. Only a few relevant request types are shown.

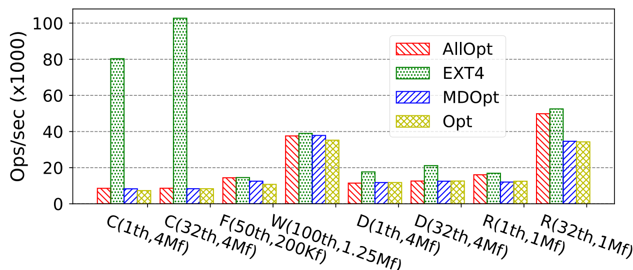

Figure 8: Throughput(Ops/sec) for EXT4 and FUSE/ExtFUSE Stackfs (w/ xattr) under different configs (Table 5) as measured by Filebench [48] Creation(C), Deletion(D), Reading(R) metadata micro-workloads on 4KB files and FileServer(F), WebServer(W) macro-workloads with settings *N*th:*N* threads, *N*f:*N* files.

the optimized FUSE implementation of Stackfs (`Opt`).

Testbed. We use the same experiments and settings as in [50]. Specifically, we used EXT4 because of its popularity as the host file system and ran benchmarks to evaluate. However, since FUSE performance problems were reported to be more prominent with a faster storage medium, we only carry out our experiments with SSDs. We used a Samsung 850 EVO 250GB SSD installed on an Asus machine with Intel Quad-Core i5-3550 3.3 GHz and 16GB RAM, running Ubuntu 16.04.3. Further, to minimize any variability, we formatted the SSD before each experiment and disabled EXT4 lazy inode initialization. To evaluate file systems that implement `xattr` operations for handling security labels (e.g., in Android), our implementation of `Opt` supports xattrs, and thus differs from the implementation in [50].

Config	File System	Optimizations
`Opt` [50]	FUSE	128K Writes, Splice, WBCache, MltThrd
`MDOpt`	ExtFUSE	`Opt` + Caches `lookup`, `attrs`, `xattrs`
`AllOpt`	ExtFUSE	`MDOpt` + Pass `R/W` reqs through host FS

Table 5: Different Stackfs configs evaluated.

Workloads. Our workload consists of Filebench [48] micro and synthetic macro benchmarks to test each config with metadata- and data-heavy operations across a wide range of I/O sizes and parallelism settings. We measure the low-level throughput (ops/sec). Our macro-benchmarks consist of a synthetic file server and web server.

Micro Results. Figure 6 shows the results of micro workload under different configs listed in Table 5.

Reads. Due to the default 128KB read-ahead feature of FUSE, the sequential read throughput on a single file with a single thread for all I/O sizes and under all Stackfs configs remained the same. Multi-threading improved for the sequential read benchmark with 32 threads and 32 files. Only one request was generated per thread for `lookup` and `getattr` operations. Hence, metadata caching in `MDOpt` was not effective. Since FUSE `Opt` performance is already at par with EXT4, the passthrough feature in `AllOpt` was not utilized.

Unlike sequential reads, small random reads could not take advantage of the read-ahead feature of FUSE. Additionally, 4KB reads are not spliced and incur data copying across user-kernel boundary. With 32 threads operating on a single file, the throughput improves due to multi-threading in `Opt`. However, degradation is observed with 4KB reads. `AllOpt` passes all reads through EXT4, and hence offers near-native throughput. In some cases, the performance was slightly better than

EXT4. We believe that this minor improvement is due to double caching at the VFS layer. Due to a single request per thread for metadata operations, no improvement was seen with EXTFUSE metadata caching.

Writes. During sequential writes, the 128K big writes and writeback caching in `Opt` allow the FUSE driver to batch small writes (up to 128KB) together in the page cache to offer a higher throughput. However, random writes are not batched. As a result, more `write` requests are delivered to user space, which negatively affects the throughput. Multiple threads on a single file perform better for requests bigger than 4KB as they are spliced. With EXTFUSE `AllOpt`, all writes are passed through the EXT4 file system to offer improved performance.

Write throughput degrades severely for FUSE file systems that support extended attributes because the VFS issues a `getxattr` request before every `write`. Small I/O requests perform worse as they require more `write`, which generate more `getxattr` requests. `Opt` random writes generated 30x fewer `getxattr` requests for 128KB compared to 4KB writes, resulting in a 23% decrease in the throughput of 4KB writes.

In contrast, `MDOpt` caches the `getxattr` reply in the kernel upon the first call, and serves subsequent `getxattr` requests without incurring further transitions to user space. Figure 7 compares the number of requests received by the user-space daemon in `Opt` and `MDOpt`. Caching replies reduced the overhead for 4KB workload to less than 5%. Similar behavior was observed with both sequential writes and random writes.

Macro Results. Figure 8 shows the results of macro-workloads and synthetic server workloads emulated using Filebench under various configs. Neither of the EXTFUSE configs offer improvements over FUSE `Opt` under creation and deletion workloads as these metadata-heavy workloads created and deleted a number of files, respectively. This is because no metadata caching could be utilized by `MDOpt`. Similarly, no passthrough writes were utilized with `AllOpt` since 4KB files were created and closed in user space. In contrast, the File and Web server workloads under EXTFUSE utilized both metadata caching and passthrough access features and improved performance. We saw a 47%, 89%, and 100% drop in `lookup`, `getattr`, and `getattr` requests to user space under `MDOpt`, respectively, when configured to cache up to 64K for each type of request. `AllOpt` further enabled passthrough `read/write` requests to offer near native throughput for both macro reads and server workloads.

Real Workload We also evaluated EXTFUSE with two real workloads, namely kernel decompression and compilation of 4.18.0 Linux kernel. We created three separate caches for hosting `lookup`, `getattr`, and `getxattr` replies. Each cache could host up to 64K entries, resulting in allocation of up to a total of 50MB memory when fully populated.

The kernel compilation `make tinyconfig; make -j4` experiment on our test machine (see §6) reported a 5.2% drop in compilation time, from 39.74 secs under FUSE `Opt` to 37.68 secs with EXTFUSE `MDOpt`, compared to 30.91 secs with EXT4. This was due to over 75%, 99%, and 100% decrease in `lookup`, `getattr`, and `getxattr` requests to user space, respectively (Figure 9). `getxattr` replies were proactively cached while handling `open` requests; thus, no transitions to user space were observed for serving xattr requests. With EXTFUSE `AllOpt`, the compilation time further dropped to 33.64 secs because of 100% reduction in `read` and `write` requests to user space.

In contrast, the kernel decompression `tar xf` experiment reported a 6.35% drop in the completion time, from 11.02 secs under FUSE `Opt` to 10.32 secs with EXTFUSE `MDOpt`, compared to 5.27 secs with EXT4. With EXTFUSE `AllOpt`, the decompression time further dropped to 8.67 secs due to 100% reduction in `read` and `write` requests to user space, as shown in Figure 9. Nevertheless, reducing the number of cached entries for metadata requests to 4K resulted in a decompression time of 10.87 secs (25.3% increase) due to 3,555 more `getattr` requests to user space. This suggests that developers must efficiently manage caches.

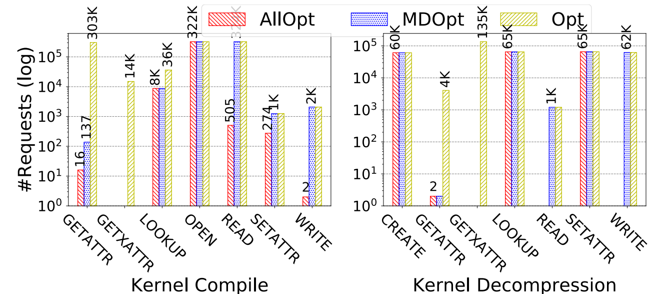

Figure 9: Linux kernel 4.18.0 untar (decompress) and compilation time taken with StackFS under FUSE and EXTFUSE settings. Number of metadata and I/O requests are reduced with EXTFUSE.

6.2 Use cases

We ported four real-world stackable FUSE file systems, namely LoggedFS, Android sdcard daemon, MergerFS, and BindFS to EXTFUSE and enabled both metadata caching §5.1 and passthrough I/O §5.2 optimizations.

File System	Functionality	Ext Loc
StackFS [50]	No-ops File System	664
BindFS [35]	Mirroring File System	792
Android sdcard [24]	Perm checks & FAT Emu	928
MergerFS [20]	Union File System	686
LoggedFS [16]	Logging File System	748

Table 6: Lines of code (Loc) of kernel extensions required to adopt EXTFUSE for existing FUSE file systems. We added support for metadata caching as well as R/W passthrough.

As EXTFUSE allows file systems to retain their existing FUSE daemon code as the default slow path, adopting EXTFUSE for real-world file systems is easy. On average, we made less than 100 lines of changes to the existing FUSE code to invoke EXTFUSE helper library functions for manipulating kernel extensions, including maps. We added ker-

nel extensions to support metadata caching as well as I/O passthrough. Overall, it required fewer than 1000 lines of new code in the kernel Table 6. We now present detailed evaluation of Android sdcard daemon and LoggedFS to present an idea on expected performance improvements.

Android sdcard daemon. Starting version 3.0, Android introduced the support for FUSE to allow a large part of internal storage (e.g., `/data/media`) to be mounted as external FUSE-managed storage (called `/sdcard`). Being large in size, `/sdcard` hosts user data, such as videos and photos as well as any auxiliary Opaque Binary Blobs (OBB) needed by Android apps. The FUSE daemon enforces permission checks in metadata operations (e.g.,`lookup`, etc.) on files under `/sdcard` to enable multi-user support and emulates case-insensitive FAT functionality on the host (e.g., EXT4) file system. OBB files are compressed archives and typically used by games to host multiple small binaries (e.g. shade rs, textures) and multimedia objects (e.g. images, etc.).

However, FUSE incurs high runtime performance overhead. For instance, accessing OBB archive content through the FUSE layer leads to high launch latency and CPU utilization for gaming apps. Therefore, Android version 7.0 replaced sdcard daemon with with an in-kernel file system called `SDCardFS` [24] to manage external storage. It is a wrapper (thin) stackable file system based on WrapFS [54] that enforces permission checks and performs FAT emulation in the kernel. As such, it imposes little to no overhead compared to its user-space implementation. Nevertheless, it introduces security risks and maintenance costs [12].

We ported Android sdcard FUSE daemon to EXTFUSE framework. First, we leverage eBPF kernel helper functions to push metadata checks into the kernel. For example, we embed access permission check (Figure 10) in `lookup` kernel extension to validate access before serving `lookup` replies from the cache (Figure 3). Similar permission checks are performed in the kernel to validate accesses to files under `/sdcard` before serving cached `getattr` requests . We also enabled passthrough on `read/write` using `InodeMap`.

We evaluated its performance on a 1GB RAM HiKey620 board [1] with two popular game apps containing OBB files of different sizes. Our results show that under `AllOpt` passthrough mode the app launch latency and the corresponding peak CPU consumption reduces by over 90% and 80%, respectively. Furthermore, we found that the larger the OBB file, the more penalty is incurred by FUSE due to many more small files in the OBB archive.

LoggedFS is a FUSE-based stackable user-space file system. It logs every file system operation for monitoring purposes. By default it writes to syslog buffer and logs all operations (e.g., open, read, etc.). However, it can be configured to write to a file or log selectively. Despite being a simple file system, it has a very important use case. Unlike existing monitoring mechanisms (e.g., Inotify [31]) that suffer from a host of limitations [10], LoggedFS can reliably post all file system events. Various apps, such as file system indexers, backup tools, Cloud storage clients such as Dropbox, integrity checkers, and antivirus software subscribe to file system events for efficiently tracking modifications to files.

App Stats		CPU (%)		Latency (ms)	
Name	**OBB Size**	**D**	**P**	**D**	**P**
Disney Palace Pets 5.1	374MB	20	2.9	2235	1766
Dead Effect 4	1.1GB	20.5	3.2	8895	4579

Table 7: App launch latency and peak CPU consumption of `sdcard` daemon under default (D), and passthrough (P) settings on Android for two popular games. In passthrough mode, the FUSE driver never forwards `read/write` requests to user space, but always passes them through the host (EXT4) file system. See Table 5 for config details.

```
1  bool check_caller_access_to_name(int64_t key, const char *name) {
2      /* define a shmap for hosting permissions */
3      int *val = extfuse_lookup_shmap(&key);
4      /* Always block security-sensitive files at root */
5      if (!val || *val == PERM_ROOT) return false;
6      /* special reserved files */
7      if (!strncasecmp(name, "autorun.inf", 11) ||
8          !strncasecmp(name, ".android_secure", 15) ||
9          !strncasecmp(name, "android_secure", 14))
10         return false;
11     return true;
12 }
```

Figure 10: Android `sdcard` permission checks EXTFUSE code.

We ported LoggedFS to EXTFUSE framework. Figure 11 shows the common logging code that is called from various extensions, which serve requests in the kernel (e.g., `read` extension Figure 5). To evaluate its performance, we ran the FileServer macro benchmark with synthetic a workload of 200,000 files and 50 threads from Filebench suite. We found over 9% improvement in throughput under `MDOpt` compared to FUSE `Opt` due to 53%, 99%, and 100% fewer `lookup`, `getattr`, and `getxattr` requests to user space, respectively. Figure 12 shows the results. `AllOpt` reported an additional 20% improvement by directly forwarding all `read/write` requests to the host file system, offering near-native throughput.

```
1  void log_op(extfuse_req_t req, fuse_ino_t ino,
2          int op, const void *arg, int arglen) {
3      struct data { /* log record */
4          u32 op; u32 pid; u64 ts; u64 ino; char data[MAXLEN];};
5      /* example filter: only whitelisted UIDs in map */
6      u16 uid = bpf_get_current_uid_gid();
7      if (!extfuse_lookup_shmap(uid_wlist, &uid)) return;
8      /* log opcode, timestamp(ns) and requesting process */
9      data.opcode = op; data.ts  = bpf_ktime_get_ns();
10     data.pid = bpf_get_current_pid_tgid(); data.ino = ino;
11     memcpy(data.data, arg, arglen);
12     /* submit to per-cpu mmap'd ring buffer */
13     u32 key = bpf_get_smp_processor_id();
14     bpf_perf_event_output(req, &buf, &key, &data, sizeof(data));
15 }
```

Figure 11: LoggedFS kernel extension that logs requests.

7 Discussion

Future use cases. Given negligible overhead of EXTFUSE and direct passthrough access to the host file system for stacking incremental functionality, multiple app-defined "thin" file system functions (e.g., security checks, logging, etc.) can be

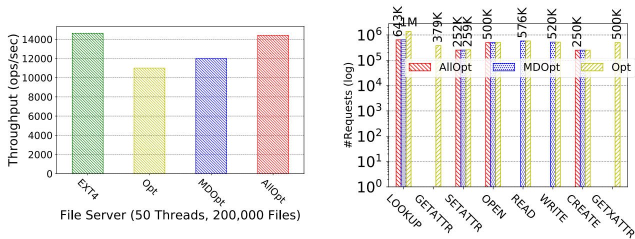

Figure 12: LoggedFS performance measured by Filebench FileServer benchmark under EXT4, FUSE, and EXTFUSE. Fewer metadata and I/O requests were delivered to user space with EXTFUSE.

stacked with low overhead, which otherwise would have been very expensive in user space with FUSE.

Safety. EXTFUSE sandboxes untrusted user extensions to guarantee safety. For example, the eBPF runtime allows access to only a few, simple non-blocking kernel helper functions. Map data structures are of fixed size. Extensions are not allowed to allocate memory or directly perform any I/O operations. Even so, EXTFUSE offers significant performance boost across a number of use cases §6.2 by offloading simple logic in the kernel. Nevertheless, with EXTFUSE, user file systems can retain their existing slow-path logic for performing complex operations, such as encryption in user space. Future work can extend the EXTFUSE framework to take advantage of existing generic in-kernel services such as VFS encryption and compression APIs to even serve requests that require such complex operations entirely in the kernel.

8 Related Work

Here, we compare our work with related existing research.

User File System Frameworks. There exists a number of frameworks to develop user file systems. A number of user file systems have been implemented using NFS loopback servers [19]. UserFS [14] exports generic VFS-like file system requests to the user space through a file descriptor. Arla [53] is an AFS client system that lets apps implement a file system by sending messages through a device file interface `/dev/xfs0`. Coda file system [42] exported a similar interface through `/dev/cfs0`. NetBSD provides Pass-to-Userspace Framework FileSystem (PUFFS). Mazières et al. proposed a C++ toolkit that exposes a NFS-like interface for allowing file systems to be implemented in user space [33]. UFO [3] is a global file system implemented in user space by introducing a specialized layer between the apps and the OS that intercepts file system calls.

Extensible Systems. Past works have explored the idea of letting apps extend system services at runtime to meet their performance and functionality needs. SPIN [6] and VINO [43] allow apps to safely insert kernel extensions. SPIN uses a type-safe language runtime, whereas VINO uses software fault isolation to provide safety. ExoKernel [13] is another OS design that lets apps define their functionality. Systems such as ASHs [17, 51] and Plexus [15] introduced the concept of network stack extension handlers inserted into the kernel. SLIC [18] extends services in monolithic OS using interposition to enable incremental functionality and composition. SLIC assumes that extensions are trusted. EXTFUSE is a framework that allows user file systems to add "thin" extensions in the kernel that serve as specialized interposition layers to support both in-kernel and user space processing to co-exist in monolithic OSes.

eBPF. EXTFUSE is not the first system to use eBPF for safe extensibility. eXpress DataPath (XDP) [27] allows apps to insert eBPF hooks in the kernel for faster packet processing and filtering. Amit et al. proposed Hyperupcalls [4] as eBPF helper functions for guest VMs that are executed by the hypervisor. More recently, SandFS [7] uses eBPF to provide an extensible file system sandboxing framework. Like EXTFUSE, it also allows unprivileged apps to insert custom security checks into the kernel.

FUSE. File System Translator (FiST) [55] is a tool for simplifying the development of stackable file system. It provides *boilerplate* template code and allows developers to only implement the core functionality of the file system. FiST does not offer safety and reliability as offered by user space file system implementation. Additionally, it requires learning a slightly simplified file system language that describes the operation of the stackable file system. Furthermore, it only applies to stackable file systems.

Narayan et al. [34] combined in-kernel stackable FiST driver with FUSE to offload data from I/O requests to user space to apply complex functionality logic and pass processed results to the lower file system. Their approach is only applicable to stackable file systems. They further rely on static per-file policies based on extended attributes labels to enable or disable certain functionality. In contrast, EXTFUSE downloads and safely executes thin extensions from user file systems in the kernel that encapsulate their rich and specialized logic to serve requests in the kernel and skip unnecessary user-kernel switching.

9 Conclusion

We propose the idea of extensible user file systems and present the design and architecture of EXTFUSE, an extension framework for FUSE file system. EXTFUSE allows FUSE file systems to define "thin" extensions along with auxiliary data structures for specialized handling of low-level requests in the kernel while retaining their existing complex logic in user space. EXTFUSE provides familiar FUSE-like APIs and abstractions for easy adoption. We demonstrate its practical usefulness, suitability for adoption, and performance benefits by porting and evaluating existing FUSE implementations.

FlexGroup Volumes: A Distributed WAFL File System

Ram Kesavan,[*] Jason Hennessey, Richard Jernigan, Peter Macko,

Keith A. Smith, Daniel Tennant, and Bharadwaj V. R., *NetApp, Inc.*

Abstract

The rapid growth of customer applications and datasets has led to demand for storage that can scale with the needs of modern workloads. We have developed FlexGroup volumes to meet this need. FlexGroups combine local WAFL® file systems in a distributed storage cluster to provide a single namespace that seamlessly scales across the aggregate resources of the cluster (CPU, storage, etc.) while preserving the features and robustness of the WAFL file system.

In this paper we present the FlexGroup design, which includes a new *remote access layer* that supports distributed transactions and the novel heuristics used to balance load and capacity across a storage cluster. We evaluate FlexGroup performance and efficacy through lab tests and field data from over 1,000 customer FlexGroups.

1 Introduction

With each new generation of hardware, computers become faster and more powerful. CPUs have more cores, memory is cheaper, networks are faster, and storage devices hold more data. Despite these advances, however, many modern applications require far more resources than a single machine can provide, leading to an explosion in the use of distributed applications and systems.

Network-attached storage solutions have evolved similarly from single-node to distributed systems. NetApp® Write Anywhere File Layout (WAFL) [11] was launched more than 20 years ago as a single-node, single-volume file system. Over time, we increased WAFL flexibility and scale by allowing many file systems per node [7], and by scaling performance with increasing core counts [5]. Today we have hundreds of thousands of storage controllers at customers' sites. But like other file systems, our single-node scale and performance have been limited by the resources (storage, memory, CPU, network) of a single machine.

This paper describes *FlexGroups*, a new feature that *automatically* balances capacity and load across the nodes of our storage cluster. A FlexGroup combines volumes from multiple nodes of a cluster into a single client-visible namespace and allows any directory entry to point to any inode on any of the member volumes. The FlexGroup selects a location for each new file or directory using heuristics that attempt to balance capacity and load. The result is a single file system that scales across the resources of an entire storage cluster.

Within a storage cluster, FlexGroups use a new *Remote Access Layer* (RAL) to perform transactional updates across multiple member volumes (for example, a directory entry on one node and the target inode on a different node). Because operations that span multiple FlexVols® necessarily introduce overhead, the FlexGroup heuristics dynamically adjust the levels of remote inode placement to minimize that overhead while still achieving a balanced system.

FlexGroups impose performance overhead on metadata operations that create or traverse cross-node links in the namespace. But the more costly of these operations, such as `MKDIR`, are relatively rare, and the overheads are modest compared to the larger latencies of I/O to SSDs or HDDs. On large mixed workloads, a FlexGroup performs comparably to a similarly sized group of individual volumes while providing the benefits of automatic scaling and balancing of the data and load across nodes.

This paper makes several contributions. We present a scalable distributed file system architecture that builds on an underlying single-node file system while preserving all of its features. We describe low-cost heuristics that dynamically balance load and capacity with little performance overhead. Finally, we analyze more than 1,000 customer FlexGroup deployments to evaluate our load balancing heuristics, understand challenging use cases, and identify improvements to FlexGroup heuristics.

2 The Building Blocks

A FlexGroup is a distributed file system built from a cluster of nodes running our storage operating system, NetApp Data ONTAP®, which includes WAFL [11], our proprietary copy-on-write (COW) file system. A FlexGroup is com-

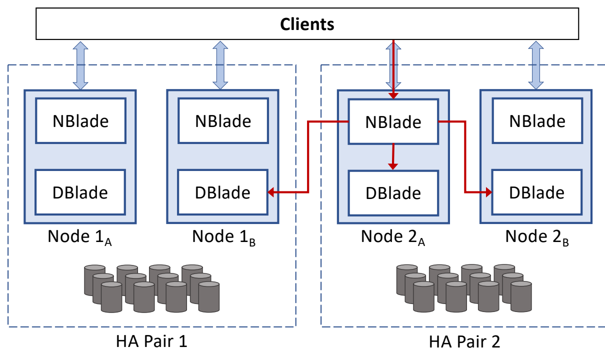

Figure 1: Arrows indicate some possible routing paths for operations. The NBlade in node 2_A may route a request to the DBlade on the same node, on the HA partner node (2_B), or to another node in the cluster (1_B).

posed of multiple single-node file systems called FlexVols; a FlexVol [7] is an exportable WAFL file system. As in other COW file systems [24, 30], every modified block of data or metadata in WAFL is written to a new location; only the superblock is ever written in place. The file system supports many enterprise features, such as snapshots [18, 19], replication [29], storage efficiency (compression, deduplication, etc.), and encryption.

A cluster of ONTAP [25] nodes is organized as multiple high-availability (HA) pairs of nodes. Each pool of storage is accessible by a different HA pair. A node is composed primarily of two software modules [8]: an *NBlade* and a *DBlade*. The NBlade is composed of the networking and protocol stacks (NFS, SMB, iSCSI, NVMe, etc.) that communicate with clients. The DBlade is composed of the WAFL file system, RAID [2, 9] module, and storage drivers to interact with the storage media. The storage pool dedicated to an HA pair is partitioned into *aggregates*, each of which can house hundreds of FlexVols. The storage devices in an aggregate are collected into RAID groups to protect against device failures [28]. Each aggregate is managed in an active-passive manner by the nodes of its HA pair. Thus the DBlade on each node serves requests for one or more aggregates while also acting as a standby to take over the HA partner's aggregates if the partner fails.

ONTAP exports file system namespaces over virtual interfaces (VIFs) that are mapped to nodes in the cluster. A client accesses the namespace within a FlexVol over NFS or SMB by connecting to a node via the corresponding VIF [8]. As illustrated in Fig. 1, each request is routed from the receiving node's NBlade to the DBlade of the node owning the FlexVol that contains the requested data. The NBlades consult a consistent, replicated database of volume information, which maps volume IDs to DBlades. Responses are routed back from a DBlade to the client via the NBlade that is connected to the client. Any operation that is routed to a different node pays a small latency penalty compared to one that is routed to the same node [8].

WAFL accelerates performance by placing a write-ahead log in NVRAM [11, 33] and provides a fast failover capability by mirroring this log to its HA partner's NVRAM. If a node (1_A) fails, the HA partner (1_B) takes ownership of its network interfaces and storage, replays its NVRAM log (aka NVLog), and starts servicing operations to those FlexVols almost instantly, thereby minimizing client outage. Even in the rare event that NVLog is lost—for example, if one node "panics" and the NVRAM devices on both nodes of the HA-pair are damaged—the COW nature of updates guarantees the consistency of the persistent file systems on the failed node [11, 24, 30]; only state from operations logged in the last few seconds is lost. In other words, no (fsck-style) repair of the file system is needed in such cases.

3 FlexGroup Volumes

ONTAP with FlexVols had been commercially successful with a wide customer deployment for several years before we tackled the problem of building a distributed namespace that seamlessly scales across the storage pools and compute resources of all nodes in a cluster. ONTAP already allowed the administrator to manually *junction* together multiple FlexVols in a cluster to export a namespace that spanned multiple nodes, but it was impossible to build an efficient junctioned namespace because avoiding conditions of imbalance—storage capacity or load—required a priori knowledge of future behavior of the applications. Customer deployments need directory namespaces to autonomously consume capacity and compute resources from nodes in the cluster with minimal administrator involvement.

Customers have high requirements of an enterprise-grade distributed file system: resiliency, availability, ease of administration, and other "standard" features, such as snapshots, replication, cloning, compression, deduplication, and encryption. Adding this comprehensive list of features into an existing open-source file system or creating a new feature-rich distributed file system would have been prohibitively expensive in terms of engineering resources and time.

Because these features had been baked into FlexVols over decades, building FlexGroups out of a collection of FlexVols was the obvious and prudent approach. It greatly simplified several aspects of our design. For example, the ability to nondisruptively move FlexVols between nodes is particularly useful for coarse-grained rebalancing without embedding any forward pointers in the file system; for more on this topic, see Sec. 3.3. Moreover, the NVLog, together with the transactional semantics of FlexVols [2, 7, 9, 17, 20, 29] provides the atomicity and reliability for maintaining metadata necessary for the distributed namespace.

More importantly, this choice simplified existing customers' workflows—a FlexGroup looks much like a FlexVol to the administrator and NFS or SMB clients—which was

key to its rapid adoption. FlexGroups also allow "upgrading" an existing FlexVol to a FlexGroup, on-the-fly addition of member FlexVols, presentation of a FlexGroup as a single volume for all administrative tasks, and other management features. Such details are outside of the scope of this paper.

3.1 Design Considerations

Data distribution comes at a cost. Typically, spreading data across nodes requires either a metadata server or internal pointers to redirect from one location to another. Maintaining this metadata costs additional CPU, network, and storage. Coarse-grained distribution of large directory subtrees minimizes metadata costs, but makes it harder to achieve balance between nodes. A distributed system can achieve better balance with a finer-grained distribution, but that comes with the additional cost of more pointers.

Because both fine- and coarse-grained distribution have drawbacks, a promising approach would be to offer a mechanism that can adaptively change distribution granularities based on need—using fine-grained distribution when necessary to ensure the use of all resources, while reverting to coarse-grained distribution when possible for higher overall performance.

An alternative approach to achieve fine-grained distribution without metadata overhead is to use hash-based algorithms to place each file on a pseudo-random node. We ruled this approach out for two reasons. First, hash-based placement causes a large fraction, $(n-1)/n$, of requests to pay the cost of a network hop (NBlade to DBlade) in an n-node system. More intelligent placement of files can reduce hops; for example, files within a directory could be colocated in the common case. Hash-based placement also prevents dynamic placement decisions based on current conditions; for example, avoiding new file creation on a node that is experiencing high load.

Ideally, a system should be capable of reacting to imbalance in load and storage space availability. Retroactive data movement has two serious challenges—picking the content to be moved and doing it in a *nondisruptive* fashion to the clients (i.e., no remounts). The latter requires inserting remote pointers in the file system to avoid invalidating file handles that were previously issued to clients.[1] However, the proliferation of these pointers over time creates an ever-increasing drag on overall system performance. Additionally, although centralizing metadata in one server simplifies some aspects, it leads to obvious performance bottlenecks.

We explored two less-successful designs before FlexGroups. In our first design, all data files were striped (based on file offset and range) across member FlexVols. Subsequently, metadata (directories and inode tables) were also striped and decentralized. A distributed ticketing mechanism was used to maintain cross-FlexVol consistency. However, the resultant fine-grained synchronization generated a high performance tax. In addition, increase in CPU core count in nodes and scaling improvements to the WAFL parallelism model [5] enabled concurrent execution of dozens of read and write operations to a single file, which obviated the need to stripe "hot" files.

The second design stored an inode indirection layer in a master FlexVol, which pointed to data files that were placed in other FlexVols based on simple round-robin policies. The design traded the extra FlexVol hop paid by each operation to consult and follow the indirection for the ease of moving data and metadata across the member FlexVols in response to imbalance in load or storage capacity. However, the design was unable to prevent the master FlexVol (hosting the indirection layer) from becoming a performance bottleneck.

To demonstrate the overhead of this indirection-based scheme, we benchmarked it against FlexGroups, which, as explained later in this section, have several important differences. FlexGroups use pointers rather than indirection to locate remote files and try to place each file in the same node as its parent directory so that most operations avoid an extra NBlade-to-DBlade hop. Finally, FlexGroup members are symmetric; no node or FlexVol necessarily handles more (or less) data, metadata, or traffic than its peers.

We ran SPEC SFS 2014 SWBUILD [35] on both a FlexGroup and the indirection-based approach using a mid-range HA pair.[2] The operational throughput (ops/s) of FlexGroups was more than 4 times that of the indirection approach. At low load points, both were easily able to handle the workload, but the average request latency of the indirection approach was 1.9 times higher than that of FlexGroups, reflecting the extra network hop required by every request.

This pattern continued at higher load points until the master FlexVol became a bottleneck in the indirection-based system. Queue lengths grew rapidly with increasing load, until a 20-fold increase in time spent to resolve indirection which caused the operational throughput to collapse in spite of the fact that almost half of the available CPU cores remained idle. In contrast, FlexGroup performance continued to scale until the cores on both nodes were almost fully utilized. Note that this test was performed on a 2-node cluster. The indirection bottleneck is more acute in a larger cluster.

3.2 Fusing FlexVols via Remote Hardlinks

FlexGroups distribute both data and metadata across multiple FlexVols by allowing directory entries to be *remote hardlinks* to inodes on other member FlexVols, as illustrated in Fig. 2. A client can connect to any node in the cluster, and the NBlade routes its requests to the appropriate FlexVol and DBlade.

FlexGroups perform most data distribution during *ingest*: an intelligent, immediate, and permanent placement decision

[1] NFS requires long-lived file handles.

[2] Each node had 16 cores and 96 GiB of DRAM.

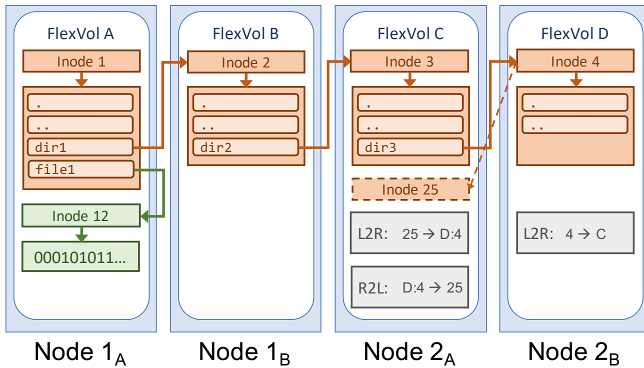

Figure 2: An example of a FlexGroup (DBlades only) that consists of member FlexVols in four nodes, along with hardlinks following `/dir1/dir2/dir3`. L2R and R2L are local-to-remote and remote-to-local databases. FlexVol C contains inode 25, which is a cached version of inode 4 from FlexVol D.

is taken when creating a new file or directory, thereby assigning the new object to one of the FlexVol members of the FlexGroup. FlexGroups adjust the granularity of distribution from the directory level down to individual files as necessary.

As explained in Sec. 3.1, striping individual files was not necessary to achieve our performance goals. Therefore, FlexGroups do not stripe individual files or directories across member FlexVols; each object lives entirely in one FlexVol. This greatly simplifies the design and allows all *data* operations (reads and writes) to be executed with the *same latency and throughput*. In other words, remote hardlinks are not traversed when servicing such operations; an additional network hop is incurred only if the NBlade connected to the client and DBlade in which the data resides are on different nodes. Only *metadata* operations that resolve or modify remote hardlinks incur additional latency for the extra internode communication.

The FlexVol identifier and the inode identifier are encoded within the opaque file handle that WAFL returns to operations such as `LOOKUP` and `OPEN`. An NFS client resolves `/dir1/dir2/foo` by starting at the root located in FlexVol A. Suppose that the client connects to Node 1_A and sends a `LOOKUP` operation for `dir1` to that NBlade. This operation is directed to the same node's DBlade, which contains the root directory, and the remote hardlink for `dir1` is located. The NFS handle returned to the client has B:2 encoded within it. The client then sends a `LOOKUP` for `dir2` using this opaque handle, which the NBlade forwards to FlexVol B (Node 1_B). The NFS handle returned to the client now embeds C:3. A `LOOKUP` for file `foo` returns a file handle that encodes the FlexVol (which could even be A) and the inode for that file. All subsequent reads and writes on that file get routed by the NBlade of Node 1_A directly to the correct DBlade with no further access of the remote hardlinks. Thus, as mentioned earlier, every data operation costs the same and is independent of the number of remote hardlinks that led to it.

Unlike NFS, the SMB client sends the entire pathname, starting from the root. For example, an SMB client may `OPEN /dir1/dir2/foo`, whereas an NFS client sends a series of `LOOKUP` operations that walk down to `foo`. NBlades accelerate these SMB operations by maintaining in-memory pathname-to-FlexVol tables that can be used to resolve an entire pathname to a FlexVol, similar to Sprite prefix tables [41]. Depending on the state of the table, the `OPEN` operation may avoid resolving some or all remote hardlinks in the pathname when it gets routed to a FlexVol. The resolved hardlinks are added to this table. Much as with NFS, once `OPEN`ed all subsequent reads and writes to that file are routed directly to the correct DBlade.

3.3 Load Balancing

Based on experience with prior designs and customer workloads we realized that remote hardlinks with ingest-based placement yield a close-to-optimal trade-off by reducing the necessary synchronization overhead even while reducing the likelihood of imbalances in storage capacity and load across member FlexVols. Sec. 3.5 explains how placement heuristics are based on both the recent IOPS load imbalance and the capacity imbalance across member FlexVols. Obviously, these heuristics cannot predictably avoid load imbalances in the future. For example, it is possible that data written aptly at ingest time to one (or a few) member FlexVols becomes "hot" several hours or days later due to some application workflow. As explained earlier, nondisruptive, retroactive, and fine-grained data redistribution requires creating permanent remote markers that will regress the overall file system performance over time. Instead, such a pathologically imbalanced FlexGroup is fixed efficiently and expeditiously by coarse-grained movement of "hot" member FlexVols to nodes that are sustaining less IOPS load. This is done by leveraging the *Volume Move* feature [26], which leaves no residual remote markers in the file system namespace of the FlexGroup.[3]

3.4 The Remote Access Layer

FlexGroup volumes work by having one member FlexVol take responsibility for executing an entire operation, updating its own state, and coordinating the state changes with the other members. Each time an operation needs to create, delete, or access a remote hardlink, control passes to the *Remote Access Layer (RAL)*. The RAL is responsible for managing and updating remote hardlinks in a transactional

[3]Movement is accomplished by taking periodic snapshots of the FlexVol and incrementally transferring all changes to the destination node. The frequency of these transfers increases as the movement catches up with the most recent version of the FlexVol at which point the volume information database consulted by the NBlades is atomically updated.

manner and allowing the existing file system code to operate on remote metadata as if it were local. The RAL is also responsible for recovering hardlink state after crashes and for dealing with network slowness and outages between nodes.

Conceptually, the RAL is a delegation service. When an operation accesses a remote hardlink, the RAL requests the corresponding metadata from the remote FlexVol and places it in a metadata cache where it can be accessed by the local operation. This caching represents a delegation from an *origin* FlexVol to the *caching* FlexVol. A delegation may be released proactively by the caching FlexVol or revoked by the origin FlexVol. Because the objects being cached are files or directories, each cache entry is conveniently stored in an inode at the caching FlexVol; the inode is freed when the caching relationship (and delegation) cease to exist.

The RAL persists its cached metadata to ensure that it is not lost in the event of a node failure. As described in Sec. 2, when a node fails, its HA partner takes over all of its FlexVols, replays logged operations, and resumes service of those FlexVols almost immediately. The RAL metadata caches benefit from this same high availability by persisting their state to metadata files in the FlexVols. This makes delegations fault tolerant and therefore simplifies the RAL design.

There are other approaches for tracking and maintaining distributed state, such as remote hardlinks. Porting and leveraging well-known services, such as ZooKeeper [15] or etcd [4], to maintain this state was tempting for reasons such as speed of implementation. However, building the RAL transactional mechanisms within our file system provided two major advantages: (1) low transactional overhead, because RAL bookkeeping occurs in the context of the client operation; and (2) resilient transaction tracking, because RAL bookkeeping leverages the enterprise-quality transactional semantics provided by WAFL.

The next three subsections explain the transactional infrastructure for creating and managing remote hardlinks.

3.4.1 RAL Caches

As summarized above, the RAL is a write-back metadata cache of remote inodes. The caching FlexVol creates (if necessary) and uses delegations cached in local inodes from one or more origin FlexVols to execute file system operations. These inodes may contain read-only (RO) or read-write (RW) caches. In other words, for any given object, its origin FlexVol can grant at most one exclusive RW cache to another FlexVol or multiple RO caches to multiple FlexVols.

The cached inodes are stored persistently in the regular inode table and are used by local file system operations much like regular inodes. Because they are stored in the local file system, updates to cached inodes are protected by the NVLog. This ensures that the delegations represented by cache entries are not lost in the event of node failures.

The combination of HA pairs with the mirrored NVLog, as described in Sec. 2, ensures that node failures appear, at worst, as transient delays to the RAL. When a node fails, its partner quickly takes over, replaying operations from the NVLog to recreate the RAL metadata state that had not yet been persisted to storage.

The caches are managed using *local-to-remote* (L2R) and *remote-to-local* (R2L) maps, which are implemented as B+ trees and stored in each FlexVol as hidden files. The L2R maps store two kinds of information: (1) the map from locally cached inodes to the corresponding remote inode number and origin FlexVol ID; and (2) the map of local inodes that are cached by other FlexVols. The R2L maps store the reverse mapping of the first type of L2R map data. For example, in Fig. 2, inode 25 on FlexVol C is a cached version of inode 4 on FlexVol D.

RAL caches are not intended as long-term storage, and are primarily used as (1) a temporary measure to complete metadata operations that choose to locate newly created content in a remote member; and (2) a mechanism for providing crash-consistent transactional semantics.

Caches can be evicted proactively by the caching FlexVol or revoked by the origin FlexVol. A background *scrub* process periodically walks and reclaims all caches, because caches are only needed temporarily. In fact, to improve performance, most read-write caches are aggressively evicted after their use, so that they don't have to be evicted when a later operation needs to create a cache of the inode in a different FlexVol. The scrub also reclaims all wasteful or stale outstanding references. The origin FlexVol can evict read-write caches of its inodes by examining its L2R map to find the set of caching FlexVols, sending them `REMOTE_WRITEBACK` messages to write back the dirty data, and then evicting the entries.

3.4.2 Example

We use an NFS `MKDIR` request—a sufficiently complex operation—to illustrate how RAL is used. Suppose that subdirectory `dir3` is created under `dir2`, that `dir2` is stored on FlexVol C, and that the placement logic decides to store the contents of `dir3` on FlexVol D. Fig. 2 illustrates this example.

1. FlexVol C suspends local processing of the `MKDIR` operation when it determines that it needs a remote hardlink.
2. FlexVol C sends a `RAL_RETRIEVE` message to FlexVol D, asking for the creation of a new inode and a copy of it for read-write caching.
3. FlexVol D allocates the new inode (4 in the figure), tags it as being cached elsewhere in the RW manner, and creates the corresponding L2R entry.
4. FlexVol D responds to FlexVol C by sending a `RAL_STORE` message to store the cached copy of this inode in FlexVol C.

5. FlexVol C processes the RAL_STORE message by allocating a local inode (25 in the figure), tags it as a RW cache, creates the appropriate L2R and R2L entries, and adds it to the pool of cached inodes for FlexVol D.
6. FlexVol C restarts the local MKDIR operation.

The MKDIR operation finds the cached inode in the pool and proceeds to completion using it as the proxy for dir3[4]. The MKDIR operation now creates the remote hardlink directory entry in dir2 pointing to dir3, converts the inode C:25 into a directory type, populates the . and .. entries in it, and marks the RW cache entry as "dirty."

If the client now sends a CREATE command to create a new file in dir3, that request gets routed to FlexVol D. When the operation executes, it notices the tag on dir3's inode that marks it as being in an RW cache elsewhere. The FlexVol suspends the operation, consults the L2R map to determine that it is cached in FlexVol C, and starts the eviction process. FlexVol C writes back the dirty RW cache to FlexVol D, removes it from the cache, and FlexVol D then marks the inode as a valid subdirectory with no RW caches. The CREATE operation is then resumed in FlexVol D.

As the MKDIR example illustrates, the DBlade of the caching FlexVol takes ownership of executing the client operation atomically, but only after it has created local RW caches from an origin FlexVol. We now briefly describe an example RENAME operation, which is more complex and may involve two origin FlexVols. A RENAME mv dirA/foo dirB/bar operation is routed to the DBlade that hosts dirB. Suppose that dirA is in FlexVol A, dirB is in FlexVol B, and foo is a hardlink from dirA to inodeC in FlexVol C. FlexVol B first acquires two RW caches[5]—one from FlexVol A for dirA and one from FlexVol C for inodeC—and then executes the RENAME as a regular WAFL operation that uses the two RW caches. The execution of the RENAME deletes bar if one already exists, creates a new local bar that hardlinks to inodeC, and deletes foo in the RW cache for dirA. The persistent RW cache entries are left in a "dirty" state; the origin FlexVols are modified when these cache entries are eventually flushed back.

Some operations require read-only (RO) caches; for example, an SMB OPEN operation creates RO caches for any traversed remote inodes while resolving a file pathname.

3.4.3 Consistency and Recovery

The FlexGroup consistency model builds on the transactional semantics of the underlying COW WAFL file system with its NVLog. A client operation is acknowledged only after it has been recorded in the NVLog of both the node and its HA partner. All RAL operations are similarly recorded to NVLog before they are acknowledged. After a node failure, NVLog replay returns the affected member FlexVols to a state representing a valid phase of any ongoing RAL transaction. It must be noted that the ONTAP HA-pair model (together with our RAID and WAFL software) is specifically engineered to be highly reliable[6], which informs the rest of this section.

For example, in the case of the MKDIR example, the node containing FlexVol D processes the RAL_RETRIEVE message, records the message and result in its NVLog, and responds to FlexVol C. If FlexVol D's node fails before the corresponding updates are persisted to the local file system, its HA partner replays the RAL_RETRIEVE message, recreating the inode.

If the node that hosts FlexVol C fails during the RAL_STORE phase, its HA partner may choose a different location for creating dir3 when it replays MKDIR. FlexVols D and C may be left with stale or unused cache entries or temporary inodes. This is the only allowed form of inconsistency after a node failure; it is eventually resolved by the background scrub process, which periodically walks and reclaims all caches, including all wasteful or stale outstanding references[7]. The continued existence of these stale references is safe and does not compromise the consistency of the file system.

Any dirty state left in the cache inode (25 in the MKDIR example) is recreated by replaying MKDIR if C fails after MKDIR is logged but before the subsequent file system transaction completes. Although a formal proof is not provided for lack of space, we conclude that *RAL usage for FlexGroup is crash consistent*.

Sec. 2 explains that no fsck-style repair is required if a node fails or even in the rare case that NVLog in both nodes of an HA pair is lost. When a member node in a FlexGroup fails, its HA partner replays its NVLog and recreates the file system state, including the RAL state. However, the loss of NVLog of one member FlexVol may result in inconsistencies between it and other members. Additional mechanisms were built to accomplish automatic on-the-fly repair when such an inconsistency is detected by an operation. In brief, the operation is suspended while a high-priority WAFL message investigates the inconsistency, fixes it, syslogs it, and restarts the original operation. For example, suppose that a LOOKUP consults a directory entry foo, which is a remote hardlink to an inode in FlexVol B that does not exist because FlexVol B suffered a failure followed by a loss of its NVLog. On-the-fly repair would be kicked off once the RAL_RETRIEVE fails,

[4] In theory, the MKDIR operation could find a RW cache entry in that pool on its first execution. That RW cache entry might have been created due to a RAL_RETRIEVE operation to member D initiated by a different operation. In that case, on resumption that operation kicks off yet another RAL_RETRIEVE operation to populate the pool.

[5] Each cache is acquired using the RAL_RETRIEVE and RAL_STORE handshake.

[6] The availability of our customers' systems is routinely measured at 5 to 6 nines; that is, annual system downtime between 3 and 30 seconds.

[7] The WAFL file system includes a time-tested background *scanner* infrastructure used to walk and operate on various file system metadata. The infrastructure paces itself based on current system load, thereby ensuring negligible (less than 2%) impact to client operations. There are about 20 different *scan* types, and the FlexGroup scrub is one of them.

which would eventually delete the entry `foo`. The restarted `LOOKUP` now finds no corresponding entry. A detailed discussion of on-the-fly repair techniques is beyond the scope of this paper.

3.5 Ingest Heuristics

As mentioned earlier, all placement decisions are made during ingest before the new inode is allocated. The heuristics balance two competing goals: distributing load (IOPS) and capacity among member FlexVols versus reducing the operational overhead associated with remote hardlinks.

Creating a remote hardlink to an idle member almost immediately brings traffic to it, which shifts some traffic to idle members and increases overall performance. Additionally, creating a remote hardlink to an underutilized FlexVol almost certainly causes it to fill up a little more, which helps bring its usage in line with that of its peers. This is more important when the member volumes are closer to full, and remote hardlinks can help get to every last byte of storage. Therefore, as the FlexVols become more and more full, the FlexGroup should employ more remote hardlinks.

On the other hand, every time the FlexGroup creates a new remote hardlink, there is a small performance penalty, both at the time of creation and in the future when accessing the remote hardlink. The penalties accumulated across too many remote hardlinks increase average request latency and reduce overall performance. However, too few remote hardlinks may mean a failure to use all available resources. Thus, the primary goal of ingest heuristics is to achieve the right balance while using as few remote hardlinks as possible.

3.5.1 Input to Heuristics

To minimize the overhead of heuristics, each node makes independent allocation decisions based on the following information about each member FlexVol:

- *Block usage:* The ratio of consumed to total storage space of the FlexVol.
- *Inode usage:* The ratio of the number of locally allocated inodes to the maximum number of inodes allowed for the FlexVol.
- *Recent ingest load:* The recent frequency with which it has created new files and directories (maintained by using a sliding window average across several seconds)[8].

The member FlexVols periodically exchange this information by using an asynchronous and lightweight viral *refresh process* provided by ONTAP. Each node propagates information about its local member FlexVols as well as information received from other nodes. Each node sends out a message to each peer every second and uses timestamps to decide the staleness of the received information. An asynchronous model suffices because the heuristics are reacting to trends in load and storage consumption rather than making instantaneously optimal decisions.

3.5.2 Heuristic Probability Tables

Each node consults a set of probability tables during inode allocation. The tables are recomputed approximately every second, using any new information that is received from the refresh process. The table in each FlexVol consists of two arrays:

- $RP[c]$: An array of *remote preference*—a value between 0 and 1 indicating the probability of remote allocation for objects of various categories, such as files and subdirectories at various depths from the root directory.
- $AT[m]$: An array of remote *allocation target* probability values for member FlexVol m; the sum of values across the array is 1.

When making an inode allocation decision, the FlexVol generates a random number between 0 and 1 and compares it to the corresponding value in RP for that category. If the randomly generated number is larger, it processes the allocation locally; otherwise it uses a weighted round-robin scheme to determine the FlexVol for remote allocation: Each remote member is assigned a target percentage based on its AT value, and each allocation selects the remote FlexVol that is furthest behind its target percentage compared to its peers.

3.5.3 Computing Heuristic Probability Tables

The probability tables are recomputed by comparing the properties of all member FlexVols and looking for trends and problem conditions. As mentioned earlier, each node computes these tables independently based on the information from the most recent refresh process. First, two intermediate values—*Urgency* and *Tolerance*—are computed.

Urgency biases the heuristics to react to imbalance in the FlexGroup. It is computed as a linear interpolation of each member's usage and each node's ingest load within their respective high and low thresholds, which are precomputed based on the FlexGroup configuration. An *Urgency* of 1 indicates that at least one member volume is critically low on one of these resources. Values between 0 and 1 indicate escalating degrees of concern.

Tolerance indicates how much disparity in load or usage among member volumes is acceptable. A low value tells the heuristics to react more strongly to disparities between member FlexVols. A FlexGroup that is empty with no load will have maximum *Tolerance*. As a FlexGroup gets closer to full capacity, *Tolerance* goes down, and the heuristics allow less disparity among the members.

[8] Sec. 3.3 explains the handling of unpredictable future imbalance in load across the member FlexVols.

Computing Remote Allocation Target (AT) Probabilities: First a hypothetical usage goal is computed—somewhere between the highest current capacity usage (combining both blocks and inodes) on any member and the maximum capacity of any member. The heuristics assign each member an allocation target based on the difference between that member's usage goal and its current usage. In essence, the heuristics select targets such that if all allocations were remote and all new files were exactly the same size, the remote members would then fill up at exactly the rates needed to reach their usage goals at the same time.

A non-zero *Urgency* affects this calculation significantly. A member that contributes to the non-zero *Urgency* is given a much lower target. For example, a member with the maximum *Urgency* value of 1 is assigned only 1% of its target. Once target values are assigned to each member, the values are normalized into $AT[m]$ as probabilities summing to 1.

Computing Remote Preference (RP) Probabilities: The heuristics iterate over each allocation category for a member FlexVol. Some categories are easily computed. For example, allocating a new subdirectory in the root directory is always a remote allocation to ensure that this new branch of content lands on the member with the least capacity usage or load. But for most categories, the calculation is more complex and uses the recent ingest load data from all members.

First, the heuristics compare the recent request load for an allocation category to the target load specified by the volume's allocation target (AT). If the recent load is below the target, then $RP[c]$ is set to 0, indicating a desire for the FlexVol to satisfy new allocations locally. However, if the recent load is above the target then $RP[c]$ is computed as the proportion of the load that is in excess of the target. For example, if a member with a target of 8% has recently received 10% of the overall allocations in a category, then that category is assigned a *RP* of 0.2 so it can attain its target. As an optimization, *RP* is reduced for members that have exceeded their target by less than the current *Tolerance* value, optimistically allowing them to keep a higher percentage of local traffic for local placement.

Again, a non-zero *Urgency* value for a member increases its *RP* values. As a member FlexVol or node runs low on resources, the allocations are more likely to happen on remote peers.

4 Topics in Practice

Building a scale-out file system required meeting customer expectations of the features, performance, and robustness that they were accustomed to with FlexVols. This section touches on a few selected topics related to satisfying those expectations.

Snapshots: Several features of ONTAP depend on the ability to efficiently create consistent snapshots. A FlexGroup snapshot is a collection of snapshots, one per member FlexVol, that are created in a coordinated fashion. First, each member FlexVol fences all new client operations and evicts all RW caches. Then each member FlexVol independently creates a snapshot and drops its fence. Because very few RW caches are outstanding at any point in time, this fencing creates no noticeable disruption to client performance (both latency and throughput of client operations). The design choice to evict all RW caches was made to avoid extra implementation work in various internal file system operations to understand, handle, and traverse RAL information when accessing snapshots. Eviction is not really necessary because the L2R and R2L metadata is consistently captured in each member FlexVol snapshot, and could be used to service reads of the FlexGroup snapshot image. The metadata can also be reactivated in the case of a restore of the entire FlexGroup to that coordinated image.

Quotas: Tracking and enforcement of user, directory, and group quotas must treat the entire FlexGroup as a single entity. Any incoming operation must fail when a quota rule is violated. Caches created by the RAL infrastructure count toward quota consumption. Quota credits are pro-actively distributed across member FlexVols to allow efficient, independent, and per-operation granular enforcement of the rules. In the worst case, an operation may be suspended while the FlexVol communicates with other members to borrow credits; the design makes such scenarios extremely rare.

Unreachable Member FlexVols: One or more members may become temporarily unreachable; for example, due to network problems. All client and RAL operations directed to those FlexVols will time out and get retried. Meanwhile, access to data in other FlexVols continues as usual. ONTAP clustering services indicate whether the FlexVols still exist, whether the outage is temporary, and whether retries will eventually succeed. If the problem is not transient or if clustering services indicate that FlexVols have been destroyed, either the FlexGroup can be restored to its most recent coordinated snapshot[9] or on-the-fly repair will eventually fix RAL metadata that point to the lost FlexVols. Both approaches recover file system consistency but result in data loss. The former is typically preferred because the loss is recent and predictable; all mutations after the snapshot are lost.

Testing: Enterprise-grade quality implies continuous validation; 102 different test suites are executed, totaling 160 hours of runtime daily. These tests use both NFS and SMB clients to specifically stress cross-member code paths that use RAL. Many of the suites also inject errors, such as dropping RAL operations, forcing node panics to trigger HA events, discarding NVLog during HA-events, and artificially creating memory pressure. There are also suites that explicitly create inconsistencies in the persisted RAL metadata to test on-the-fly repair mechanisms that correct them.

[9]Snapshots can be replicated to and restored from remote nodes by using NetApp SnapMirror® [29].

5 Evaluation

This section shows that the load-balancing automation of FlexGroups compares well to an ideal FlexVol in three areas: overhead, scale, and balance. It is not practical to formulate an apples-to-apples comparison of FlexGroup to other well-known distributed file systems, due to the difference in configurations, sizes, and associated feature sets. Instead, this section compares FlexGroup performance to ideal and worst-case scenarios that are manually configured (as explained below). Experiments to measure FlexGroup overhead (Sec. 5.1) and scale (Sec. 5.2) were completed using a cluster of up to 8 nodes, each with two 6-core Intel Broadwell DE processors, 64 GiB of DRAM, and a shelf of 24 SSDs. Capacity balancing was validated with data collected from customer deployments (Sec. 5.3).

5.1 Overhead

Automatic redirection of files and directories between FlexVols in a manner that is consistent in the face of faults adds two major sources of overhead: RAL (Sec. 3.4) introduces additional overhead for metadata operations, and some operations incur an additional network communication cost when the client sends a request to an NBlade that cannot be satisfied by the local DBlade. We measure these overheads by comparing the performance of FlexGroups to two manually created configurations with FlexVols, neither of which incur the overhead of RAL: (1) **FlexVol-Local** is an ideal configuration in which operations are routed by each NBlade to the DBlade on the same node. (2) **FlexVol-Remote** is a configuration in which operations are always routed by each NBlade to a DBlade on a different node.

Even though we used a single HA pair in these experiments, the results in these two cases are independent of the number of nodes: Either none (FlexVol-Local) or all (FlexVol-Remote) operations involve inter-node processing, and this does not change with the number of nodes. In the case of FlexGroups, the remote-to-local ratio might increase with the number of nodes, but no other are latencies added.

5.1.1 Overhead of NFS Operations

We measured overhead by generating a metadata load using `mdtest` [14] to a single HA pair. We used a single mdtest client connected by using NFSv3 to one of the nodes, with no other load on the system. We report the latencies of the individual metadata operations, measured on the storage systems. We configured mdtest to create approximately 2 million directories and 2 million 256KB files; the maximum NFS transfer size was set to 64KB.

Fig. 3 shows the normalized results. We observe that in the FlexGroup case, data is spread approximately evenly across the two DBlades. Read-only metadata operations that use NFS file handles, namely `ACCESS` and `GETATTR`, exhibit performance that is almost exactly halfway between the local and remote cases because there is no RAL overhead. Satisfying the request incurs additional communication across the cluster interconnect approximately 50% of the time. The `LOOKUP` operation incurs additional latency when resolving a name in a directory that happens to be a remote hardlink, because it creates a RO cache of the looked-up inode on the same node as its parent directory[10]. Metadata update operations, such as `CREATE`, `MKDIR`, `REMOVE`, and `RMDIR`, show the overhead of RAL and of communicating over the cluster interconnect, each occurring roughly 50% of the time.

Even though many of these metadata operations incur an overhead, they are relatively infrequent compared to data operations. Read operations exhibit performance that is approximately halfway between the local and remote cases. Write operations perform comparably worse than read operations because they require updating file inodes; for example, to extend the file lengths and to update `mtime`. As shown later in this section, the overall impact on performance is minimal when looking at the operations in aggregate.

5.1.2 Application and Data Benchmarks

Fig. 4 shows the performance of our application benchmarks, expressed as normalized operations per second. (Higher is better.) The figure presents two sets of results: random and sequential read and write benchmarks, and selected SPEC SFS 2014 benchmarks [35], which evaluate a realistic mixture of file system operations.

We generated the random and sequential results for reads and writes by using an internal benchmark that increases the load to find the maximum throughput possible while placing data in accordance with the configuration (FlexVol-Local, FlexVol-Remote, or FlexGroup). Unlike in the mdtest experiment, in which only one NBlade and one DBlade were active at any given time, in the FlexVol-Local case, we used several clients to saturate both nodes with requests. The results indicate that throughput for FlexGroups achieves a balance somewhere between the best (FlexVol-Local) and worst (FlexVol-Remote) cases.

SFS [35] is a standard file system workload generation tool that comes with profiles generated from real-world examples. We use three SFS profiles representing different mixes of metadata requests and data throughput [37]: **SWBUILD,** heavy metadata similar to Linux kernel builds; **EDA,** a balance of metadata and data throughput representative of electronic design automation applications; and **VDA,** streaming writes and few metadata operations, similar to a video recording system. Our goal in these benchmarks is to determine peak operations/second, not to produce compliant SFS numbers as defined by SPEC [36].

[10] The performance of `LOOKUP` is independent of the path length because NFSv3 resolves each pathname component separately.

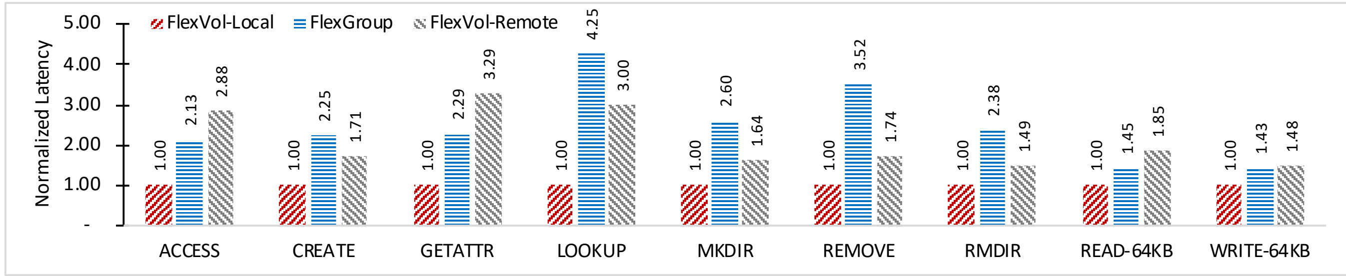

Figure 3: Server-side latency for select NFS operations generated by a single mdtest client, reported relative to FlexVol-Local latencies. Lower scores indicate better performance.

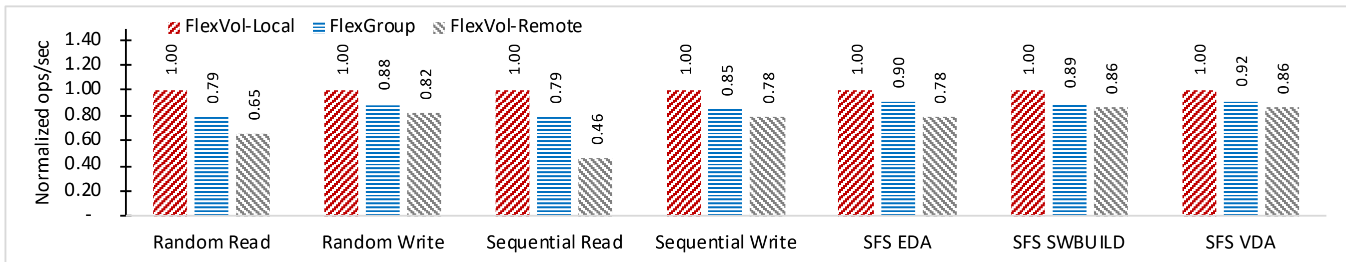

Figure 4: Operations per second for application and data benchmarksrelative to FlexVol-Local. Higher scores indicate better performance.

For the EDA and VDA workloads, FlexGroup performance fell almost exactly between FlexVol-Local and FlexVol-Remote, showing that the load-balancing heuristics achieved a balanced distribution of files across the two test nodes and that there was negligible overhead from RAL. In the SWBUILD test, FlexGroup performance was again between the extremes but closer to FlexVol-Remote. In this test, 87% of requests are metadata operations, increasing overhead due to more frequent RAL processing.

We also determined via profiling that the recomputation of the heuristic probability tables every second by each node adds a negligible amount of CPU cycles (less than 0.001%), even for large customer deployments.

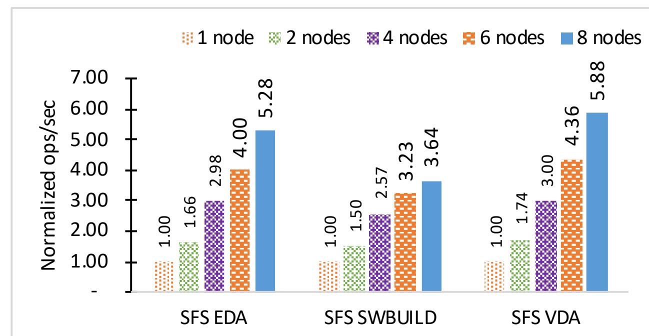

Figure 5: Scalability of FlexGroups. The max achieved operations/second for three SFS profiles, run against 1, 2, 4, 6, and 8 nodes. Each metric is reported relative to a 1-node cluster. Higher scores indicate better performance.

5.2 Workload Scaling

To examine the FlexGroup scalability under different workloads, we ran the three SFS profiles against 1-, 2-, 4-, 6-, and 8-node clusters (as described at the beginning of Sec. 5). Fig. 5 shows the scaled results. Workloads with lower metadata intensity (VDA) scale better than workloads with more metadata operations, as expected due to the added transaction overhead associated with RAL, discussed in Sec. 3.4.

5.3 Customer Experience

FlexGroups became available to customers in early 2017. In this section, we share information about how customers have used FlexGroups and about improvements made to our heuristics based on that experience. The storage systems can "phone home" to report customer configuration and event data [23]. This functionality is optional, but a large fraction of our customers enable it. Because our customers typically configure multiple FlexGroups and other FlexVols on the same nodes of a cluster, run dozens of applications on any given node of the cluster at various times, and ONTAP does not fully gather IOPS statistics on a per-FlexVol basis, it is not possible to compute or to clearly show whether the IOPS load stays balanced across member FlexVols over a long period of time. On the other hand, per-FlexVol capacity consumption is tracked for imbalance, and it also serves as a good proxy for imbalance in load.

This data shows a steady rise in FlexGroup adoption in

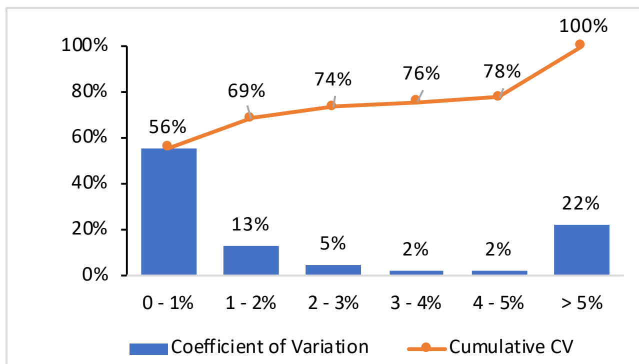

Figure 6: Do the placement algorithms balance data in the real world? This histogram shows the dispersion of FlexVol usage in customer-deployed FlexGroups using the coefficient of variation (CV). CV is the standard deviation normalized by dividing by the mean (σ/μ).A smaller CV indicates lower dispersion. Only FlexGroups greater than 10TB in size and more than 5% utilized were included.

the 2 years since its release. As of August 2018, hundreds of customers have deployed thousands of FlexGroups to manage hundreds of petabytes of storage. Roughly half of these FlexGroups are small (< 10TB), and we surmise that they are being used for testing and evaluation. 25% of these FlexGroups are larger than 100TB, and 5% are larger than 1PB. A handful of FlexGroups are larger than 5PB. Of the FlexGroups that are 10TB or larger, most (70%) have between 8 and 32 member FlexVols. 5% are larger, with the largest containing over 150 members.

Customer data also provides insight into the effectiveness of our ingest heuristics at balancing capacity across the members of a FlexGroup. Standard deviation (stdev or σ) measures dispersion. However, because different FlexGroups contain different amounts of data, the standard deviations are not directly comparable. For example, a stdev of 10^5 bytes would be interpreted differently for a 1TB FlexGroup than for a 100TB one. To normalize these numbers for comparison, we divide the stdev by the mean (μ), producing a coefficient of variation (CV), or σ/μ, that gives the stdev as a percentage of the mean.[11] A FlexGroup with a CV of 1% suggests that each FlexVol has a 95% probability of being $\pm 0.02\mu$; a CV of 3% indicates a 95% probability of being $\pm 0.06\mu$.

The data indicate that the FlexGroup placement algorithms are working in most customer use cases, as shown in Fig. 6. Over half (56%) of FlexGroups had a CV less than 1%, 78% of FlexGroups had a CV less than 5%, and 85% were below 10%. Only FlexGroups larger than 10TB and more than 5% utilized were included in this analysis. For the 15% of FlexGroups that had a CV greater than 10%, we found three patterns that account for most of the cases.

[11] CV is also known as relative standard deviation.

First there is a group of FlexGroups that have a bi-modal usage pattern—one set of members with similar high usage and another set with similar, but lower, usage. These appear to be FlexGroups that customers have expanded by adding a set of new member FlexVols, and the newer members show lower usage than the older ones.

The second pattern includes FlexGroups that hold a small number of very large files. An example would be a 200 TB FlexGroup with a small number of backup archives averaging 100 GB each. In these cases there aren't enough files to average out the effects of our ingest decisions, and the impact of allocating (extremely large) outlier file sizes can increase the CV of the FlexGroup.

Finally, there is a small number of FlexGroups that are well balanced except for a single volume with much higher usage. We believe that these cases are caused by oddities in customer workloads: an output archive file that encompasses an enormous amount of workload data, or a directory of log files that were co-located when they were created, but have grown very large over time.

It should be noted that such examples of capacity imbalance do not necessarily imply imbalance in IOPS load across the member FlexVols. In the second pattern, backup files experience sequential appends and infrequent sequential reads. In the third pattern, output archive files experience infrequent bursts of append operations. The WAFL file system is well tuned to absorb a spike in reads and writes to a single FlexVol. And as mentioned earlier, in the worst case a Volume Move operation can relocate such a FlexVol from a node that happens to be overloaded.

Based on specific customer experiences, we have improved the ingest heuristics over the four releases since FlexGroups were introduced. Early on, an interesting customer case motivated the addition of the inode usage property to the refresh process. Without accounting for inode usage, the heuristics had kept several million small files in a few members to balance out some extremely large files in the others. The per-FlexVol limit on the number of inodes was hit, causing out-of-space errors. Another customer experience resulted in converting the ingest load into a sliding window average to accommodate spikes. Other tweaks were made to various constants used while recomputing the probability tables to prevent the heuristics from over-reacting to changes.

5.4 Applicability Beyond WAFL

The FlexGroup design builds on years of engineering investment in our WAFL file system, but could these concepts be applied to other file systems? FlexGroups required modest changes to WAFL, and we believe that similar enhancements are possible to other file systems: remote hardlinks and the ability to traverse, create, and delete them. The inputs to ingest heuristics are simple and should be easy to implement.

The biggest challenges may be availability and fault tol-

erance. A robust file system like WAFL can persist RAL metadata locally with its reliable native consistency semantics. Other file systems may require more expensive distributed consensus techniques, like two-phase commit [22] or Paxos [21], to ensure fault tolerant updates to remote hardlinks.

6 Related Work

Many distributed file systems have been developed by the research, commercial, and open source communities. To discuss FlexGroups in the context of this large body of prior work, we focus on file systems that share our design goals and implementation choices. Thus we emphasize systems in which storage devices are controlled by a single node (or two nodes for fault tolerance) and in which nodes manage data at the granularity of files or objects. We will not discuss shared disk file systems such as GPFS [32] or Frangipani [38].

Distributed file systems use a variety of strategies for assigning files and directories to nodes. The simplest approach is a static partitioning, whereby an administrator assigns namespace subtrees to different servers. This strategy is exemplified by systems like NFS [31], AFS [13], and Sprite [27]. It was also the approach that ONTAP supported prior to the introduction of FlexGroups [8].

The disadvantage of static namespace partitioning is uneven load and capacity balancing. Dynamic distribution addresses this challenge by selecting or updating file locations on the fly. Slice [1] compared two heuristics for dynamic partitioning. *Name hashing* maximizes balancing by assigning every new file and directory to a random node chosen by hashing its name. *Mkdir switching* maintains namespace locality by assigning a configurable fraction of new directories to a different node than their parent and allocating all other files and directories on the same node as their parent.

The name hashing strategy has also been used in other distributed file systems including Vesta [3] and GlusterFS [12]. Like mkdir switching, FlexGroups aim to maintain namespace locality by rarely using remote links. But FlexGroups also uses current load and capacity in deciding when to split the namespace.

Unlike FlexGroups, many distributed file systems separate namespace management from data storage. These designs have nodes that store objects and a metadata service that maps filenames to objects. For scalability, some systems have multiple metadata servers, introducing the same tradeoff between load balancing and namespace locality that we address in FlexGroups. Ceph [39] is a widely-used system of this type. Unlike FlexGroups, Ceph repartitions the namespace in response to observed load. This is facilitated by Ceph's use of separate metadata servers; migrating a namespace subtree does not require moving the corresponding data objects. Policies for migrating subtrees is an area of ongoing research [34]. Ceph manages data placement using a hash-based algorithm to select object storage devices [40].

PanFS [42] represents another point in the design space. It statically partitions its namespace across metadata managers and randomly places files on different object servers (blades). Like FlexGroups it adjusts its allocation probabilities to reflect disparities in free space across the object servers. PanFS can also actively balance capacity by relocating data objects. Unlike FlexGroups, PanFS does not take load into account during data placement.

Farsite [6] takes a unique approach to metadata partitioning. It spreads files across servers based on file identifiers. But instead of using a hash, it uses a tree-structured system of file identifiers. This supports the colocation of related files, while avoiding the problem of directory renames forcing data migration between servers.

Chunkfs [10] is a single-node file system with dynamic namespace partitioning, but with different goals and implementation. Chunkfs improves fault isolation and recovery by dividing the file system into multiple *chunks*, each containing one or more namespace subtrees that can be checked independently. Chunkfs uses *continuation inodes* to connect subtrees across chunks, similar to remote hardlinks in FlexGroups, except that they are restricted to a single node.

Like Chunkfs, SpanFS [16] stitches together multiple local file systems, called *domains*, into a single volume. SpanFS provides better MP scaling because locks and other resources are local to a single domain, allowing threads in different domains to execute without contention.

7 Conclusion

In this paper, we presented FlexGroup volumes, a distributed version of NetApp FlexVol volumes. FlexGroups achieve seamless scaling across the storage cluster even while simplifying the job of the storage administrator. FlexGroups leverage the maturity, stability, and feature richness of FlexVols. We described the core elements of the design: the infrastructure for remote hardlinks and the ingest heuristics that distribute newly created content. We evaluated FlexGroup performance using both benchmarks and archived customer usage data. The success of FlexGroups has been further validated by rapid customer adoption.

Acknowledgements: We thank the many WAFL engineers who contributed to these designs over the years; they are too many to list. We thank the anonymous reviewers and our the shepherd, Michael Factor, for their helpful comments and advice. We also thank Mike Montour and Robert Franz for their help with performance experiments, and we thank Jessie Wood for copy editing this paper.

EROFS: A Compression-friendly Readonly File System for Resource-scarce Devices

Xiang Gao[1], Mingkai Dong[2], Xie Miao[1], Wei Du[1], Chao Yu[1], and Haibo Chen[2,1]

[1]Huawei Technologies Co., Ltd.
[2]Shanghai Jiao Tong University

Abstract

Smartphones usually have limited storage and runtime memory. Compressed read-only file systems can dramatically decrease the storage used by read-only system resources. However, existing compressed read-only file systems use fixed-sized input compression, which causes significant I/O amplification and unnecessary computation. They also consume excessive runtime memory during decompression and deteriorate the performance when the runtime memory is scarce. In this paper, we describe EROFS[1], a new compression-friendly read-only file system that leverages fixed-sized output compression and memory-efficient decompression to achieve high performance with little extra memory overhead. We also report our experience of deploying EROFS on tens of millions of smartphones. Evaluation results show that EROFS outperforms existing compressed read-only file systems with various micro-benchmarks and reduces the boot time of real-world applications by up to 22.9% while nearly *halving* the storage usage.

1 Introduction

Low-end smartphones with relatively low price are still prevalent in the market [18, 25], especially in developing countries. At a price, such devices are usually equipped with limited resources in both capacity and performance. For example, a low-end Android smartphone may have 1-2GB runtime memory and 8-16GB slow eMMC storage [19, 21, 22]. Even worse, the Android operating system itself can consume more than 3GB in storage, leaving scarce storage space available to users [46]. Even for high-end smartphones, the increasing storage and runtime memory consumption of popular or resident apps usually render a device resource-scarce for both user-initiated and system-initiated operations.

File systems with compression support, or compressed file systems, can be used to release more space to the users by transparently compressing/decompressing file data upon accesses. However, such file systems usually consume more resources and yield notably worse performance during compression/decompression. Thus they are not suitable for resource-limited devices, especially smartphones, on which user experience has the top priority.

Fortunately, for partitions with read-only data, such as the */system*, */vendor* and */odm* partitions of Android, the file system can be made read-only to boost the performance by simplifying the structures and designs for file changes. However, existing compressed read-only file systems, such as Squashfs [10, 11], usually cause notable degradation on access performance and incur extra memory usage during decompression. One key issue is that such file systems use fixed-sized input compression, in which file data is divided into fixed-sized chunks (e.g., 128KB) and each chunk is compressed individually. The fixed-sized input compression incurs significant read amplification and excessively unnecessary computations (§2.2). Even worse, they usually require a huge amount of runtime memory, which is scarce on low-end smartphones or heavily-used high-end smartphones (§2.2).

To save the storage space and retain high performance with low memory overhead, we design and implement EROFS, an enhanced read-only file system with compression support. EROFS introduces the fixed-sized output compression, which compresses file data to multiple fixed-sized blocks, to significantly mitigate the read amplification problem and reduce unnecessary computations as much as possible. By exploiting the characteristics of compression algorithms (such as LZ4), EROFS designs different memory-efficient decompression schemes to reduce extra memory usage during the decompression. EROFS also adopts a set of optimizations that carefully ensure guaranteed user experience.

The main contributions of this paper include:

- A study of existing compressed file systems which reveals the performance issues on resource-hungry devices (§2).
- A fixed-sized output compression scheme that signifi-

[1]Short for Enhanced Read-Only File System. It has been upstreamed to Linux 4.19 as a major feature and integrated into Huawei's Smartphone Operating System (called EMUI) as a top feature (https://consumer.huawei.com/en/emui/) of version 9.1.

cantly mitigates the read amplification issue (§3.1).

- A set of novel decompression schemes for both memory-efficiency and high performance (§3.3).
- An evaluation of EROFS against other file systems to validate the effectiveness of EROFS (§5) and a study on the deployment experience of EROFS on tens of millions of smartphones (§6).

2 Background and Motivation

2.1 Low user-perceived storage space

Smartphones are usually resource-scarce due to the cost constraint. Meanwhile, the space occupied by the Android operating system is constantly increasing. Fig. 1 shows the */system* partition size in stock Android factory images [6] for different Android versions. The sparse image strips off all zero blocks and thus only contains all effective data; while the raw image is the actual space consumed once stored into the devices. From the figure, we can see the data size of the */system* partition increases from 184MB in Android 2.3.6 to 1.9GB in Android 9.0.0. Besides the trend of increasing the effective data size, we can also see a large number of zero blocks in Android 7 and 8, which also consume large space. For Android 9, the zero blocks are significantly less, which is due to the support of data block deduplication [20] in the ext4 file system. Besides the */system* partition shown in Fig. 1, there are other space-consuming partitions for Android such as */vendor*, */oem* and */odm* [8]. As reported in previous work [46], the space used by the whole Android system itself is increasing and far larger than what we show here. For example, Android 6.0.0 consumes 3.17GB storage after a factory-reset [46].

Meanwhile, the storage consumption of Android applications also keeps growing. As reported by Google Play, by early 2017, the average app size has quintupled compared with that at the time Google starts its Android application marketplace [45]. As a result, the storage capacity of low-end smartphones available for users is rather small. Further, many top apps for smartphones tend to consume a huge amount of memory, leaving only a small amount of memory for system-initiated operations even on a high-end smartphone.

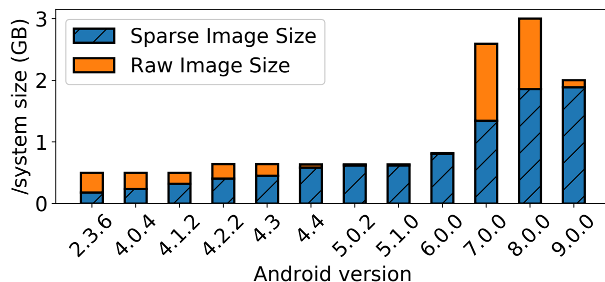

Fig. 1: Android /system partition sizes

Compressed file systems. One intuitive approach to unleashing more spaces for users is adopting compressed file systems, which exposes standard file interfaces to the applications but transparently compress and decompress file data during file writes and reads.

Btrfs [2] is a modern B-tree file system with compression support. When compression is enabled, the file data is divided into multiple 128KB chunks and compressed separately. Each of the compressed chunks will be stored in an extent, which is a run of contiguous blocks that store data sequentially. The locations of these extents are recorded as indexes in the B-tree structures. To read the file data, the corresponding extents are read from the storage and the whole chunks are decompressed. To update a file, the new data is compressed and written to new extents, and then the indexes are updated. To read the file data, Btrfs reads the corresponding extents from the storage and decompresses the whole chunks. To update a file, Btrfs compresses the new data, writes it to new extents, and updates the indexes.

Btrfs is a general-purpose file system, so its internal structures must consider efficient data modifications and cannot be aggressively optimized for compression. Furthermore, compression is not the only metric. The memory consumption during decompression should also be constrained.

For devices like smartphones, performance and responsiveness are important key metrics that cannot be compromised. Hence, with the burden of efficient data modification, Btrfs can hardly satisfy the requirements of both performance and compression efficiency, as we will show later in the evaluation (§5).

Compressed read-only file systems. Considering the access patterns of partitions in Android, we find that system resources are rarely modified once the Android operating system is installed. We can thus use compressed read-only file systems on read-only partitions to reduce the space consumption for system resources while retaining the performance. Unlike compressed read-write file systems which are complicated by data modifications, compressed read-only file systems exclude data updates by design, which exposes more opportunities for higher compression ratio and faster data reads.

Squashfs [11] is a widely-used compressed read-only file system in Linux with many features and moderate performance. It supports several compression algorithms, and the chunk (i.e., compression input) size can be chosen from 4KB to 1MB. In Squashfs, metadata can be compressed, and inodes and directories are stored more compactly. File data is compressed chunk by chunk, and the compressed data blocks are stored sequentially. The compressed sizes of each original data chunk are stored in a list within the inode. These sizes are used to locate the position of compressed blocks during decompression.

2.2 Deficiency of existing readonly file systems

Compressed read-only file systems are designed to minimize storage usage. However, applying existing compressed read-

only file systems on resource-scarce smartphones can induce significant overhead on both performance and memory consumption. For example, we first tried to use Squashfs for the read-only partitions on Android. While the system boots successfully with Squashfs, booting the camera application requires tens of seconds even with light background workloads.

Why is there such a huge performance slowdown? We conducted a detailed study of Squashfs with default configuration using microbenchmarks and uncover that the performance degradation mainly originates from two parts. The first one is I/O amplification. We used FIO [23] to evaluate the basic performance of Squashfs. When Android sequentially reads 16MB from the 1GB enwik9 [40] file stored in Squashfs, the actually issued I/O is 7.25MB. While the number looks decent regarding compression, Squashfs issues 165.27MB I/O reads when Android reads 16MB randomly. Moreover, when Android reads the first 4KB of every 128KB, reading 16M file data issued as much as 203.91MB I/O read. The difference suggests that when Squashfs reads some data that is not decompressed and cached before, the size of data requested is significantly amplified.

The second reason is extra memory consumption. The total memory consumption after sequentially reading the 1GB enwik9 file on Squashfs is about 1.35GB, which suggests that decompression in Squashfs requires a significant amount of temporary memory compared to the size of the original data needed. This causes high pressure to Android since memory is a key factor for user experience given that Android and its apps already consume a large amount of memory. On one hand, allocating memory during decompression may trigger memory swapping, which involves victim selections and I/Os with high cost. On the other hand, consuming much extra memory during decompression affects other components or applications by dropping their cached data or swapping out useful memory pages.

We further analyzed the design and implementation of Squashfs and found the following two defects.

Fixed-sized input compression. Existing file systems compress original data in a fixed-sized chunk, generating variable-sized compressed data. As shown in Fig. 2(a), Squashfs takes a fixed-sized data (e.g., a 128KB chunk) as the input of a single invocation of the compression algorithm. The compression algorithm then generates the compressed data whose size depends on the content of the input data. The compressed data of one file is usually compacted in the original data order, to reduce wasted space in the first and the last blocks of each compressed chunk.

Such a compression approach appears decent but has a notable deficiency due to amplified I/O and wasted computation. For example, in Fig. 2(b), the application wants to get the first byte of the 128KB chunk. To satisfy the application's request, the Squashfs has to read all compressed data from block 1 to block 7. Considering the minimal requested block size of the underlying storage devices is 4KB, the I/O is amplified 7 times! This is because the file system must read *all* related compressed blocks, even if the number of compressed blocks is very large. Even worse, even if not all data stored in the first block and the last block are useful for the decompression, they must be read from the storage altogether. In the example, the shadowed parts of block 1 and block 7 in Fig. 2(b) contribute nothing to the decompression but have to be read from the storage. Besides, the decompression process for useless data also causes huge CPU wastes that lead to high performance interference of other running apps (such as the Camera mentioned before).

One possible mitigation would be reducing the input chunk size to 4KB in Squashfs. While this might alleviate the I/O amplification, this non-trivially reduces the compression ratio and incurs higher CPU utilization, as we will show in section 5.

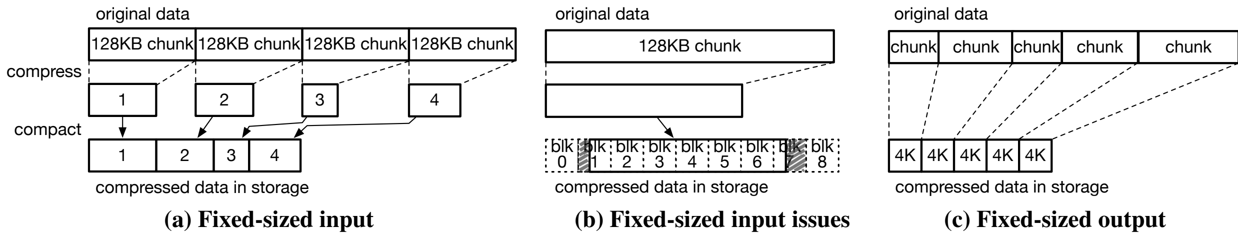
Massive memory consumption and data movements. The other defect we found is that Squashfs requires massive temporary memory during the decompression. Upon file read requests, Squashfs will first look up the metadata to get the number of related compressed blocks. It then allocates memory (e.g., the *buffer_head* structure) for each of the compressed blocks, and issues I/O reads to fetch the compressed blocks from the storage to the allocated *buffer_head*s. Since the buffers in *buffer_head*s of adjacent compressed blocks might not have continuous virtual addresses, Squashfs has to copy data in the *buffer_head*s of all compressed blocks to a single continuous buffer. Then, the compression algorithm decompresses all original data and puts them in a temporary output buffer. Finally, Squashfs copies the original data from the temporary output buffer to the corresponding page cache pages.

From the above routine, two pre-allocated temporary buffers are used and an array of *buffer_head*s are dynamically allocated for the decompression. The number of *buffer_head* needs to be large enough to store all compressed blocks. However, allocating such a large amount of memory can cause severe performance degradation under a low-memory situation.

In addition to extra memory allocation, there are two data movements during decompression: from the *buffer_head*s to the temporary input buffer, and from the temporary output buffer to the page cache. These two data movements also cause performance overhead since, most of the time, the compression/decompression algorithm is bottlenecked by memory accesses.

The above two defects in Squashfs reveal two challenges when designing a compressed read-only file system for resource-scarce smartphones.

- How to reduce I/O amplification during the decompression without sacrificing the compression ratio?
- How to reduce memory consumption during the decompression to prevent performance degradation?



(a) Fixed-sized input **(b) Fixed-sized input issues** **(c) Fixed-sized output**

Fig. 2: Compression approaches

3 EROFS:Enhanced Compressed File System

This section presents the design of EROFS, a compression-friendly readonly file system which overcomes the deficiency of prior systems. The key design of EROFS includes fixed-sized output compression, cached I/O and in-place I/O, and memory-efficient decompression.

3.1 Fixed-sized output compression

To overcome the read amplification incurred by the fixed-sized input compression, EROFS adopts a different compression approach: fixed-sized output compression.

To generate fixed-sized output, EROFS compresses the file data using a sliding window, whose size is a fixed value and can be configured during image generation. The compression algorithm is invoked multiple times until all file data is compressed. For example, with a 1MB sliding window, EROFS feeds the compression algorithm with 1MB original data at a time. The algorithm then compresses the original data as much as possible until all 1MB data is consumed or the consumed data can generate exactly 4KB compressed data. The remaining original data is combined with more data, forming another 1MB original data for the next invocation of compression. Fig. 2(c) depicts the fixed-sized output compression, in which variable-sized original data is compressed to 4KB blocks.

There are several benefits of using fixed-sized output compression compared to the fixed-sized input one. First, as what we will show in the evaluation (§5.3), it has better compression ratio under the same compression unit size. This is reasonable since the fixed-sized output compression can compress data as much as possible until the output limit is reached, while the fixed-sized input compression can only compress a fixed size of data at a time. Second, during the decompression, only the compressed blocks that contain the requested data will be read and processed. In the previous example where a single original block is requested, at most two compressed blocks will be read and decompressed. Third, as we will show later in §3.3, the fixed-sized output compression makes it possible to do in-place decompression, which further reduces the memory consumption in EROFS.

3.2 Cached I/O and in-place I/O

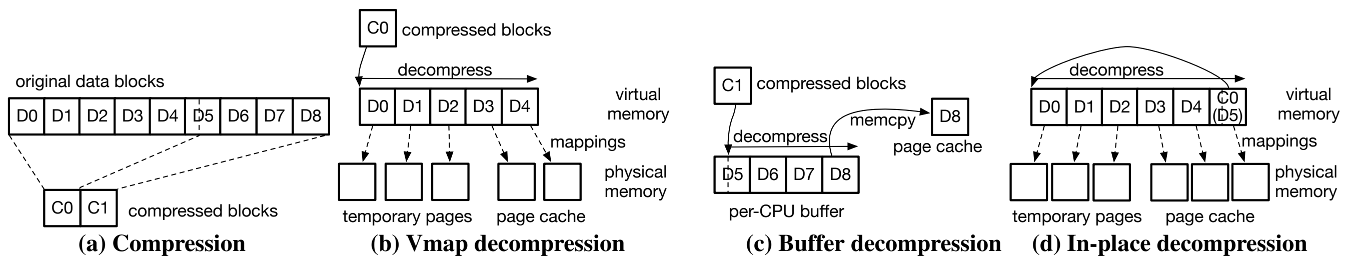
Before the actual decompression, EROFS needs space to store the compressed data retrieved from the storage. While this is costly for fixed-sized input compression due to excessive memory allocation and even page swapping, fixed-sized output compression would incur much less cost since EROFS clearly knows that each compression only retrieves up to two compressed blocks. There are two strategies for EROFS: cached I/O and in-place I/O. EROFS uses cached I/O for compressed blocks that will be partially decompressed. EROFS manages a special inode whose page cache stores compressed blocks indexed by the physical block number. Thus, for cached I/O, EROFS will allocate a page in the special inode's page cache to initiate the I/O request, so that the compressed data will be directly fetched to the allocated page by the storage driver.

For compressed blocks that will be completely decompressed, EROFS uses in-place I/O. On each file read, VFS will allocate pages in the page cache for the file system to put file data. For any one of these pages that contains no meaningful data before the decompression, we call it a *reusable page*. For in-place I/O, EROFS uses the last *reusable page* to initialize the I/O request.

Both I/O strategies are necessary. For cached I/O, partially decompressed blocks are cached in the special page cache, so that subsequent reads to the uncompressed part can use these blocks without invoking additional I/O requests. For blocks that are fully decompressed, they are unlikely to be used later since all decompressed data is stored in the page cache, which can serve subsequent reads without decompression. Thus, cached I/O vainly increases the memory spike due to page allocations for fully compressed blocks, while not contributing to subsequent file reads. In such cases, in-place I/O avoids unnecessary memory allocation, which relieves the memory pressure especially when there are many in-flight file read requests on different compressed blocks. Note that although it is possible to put the compressed block on the stack, it is not recommended to do so since the stack size is limited to be 16KB [14] and it is not easy to know how many bytes of the stack are still available.

3.3 Decompression

After loading compressed data into memory, we illustrate how EROFS decompresses data both fast and memory-efficiently. Examples in this section are based on Fig. 3(a) where the first five blocks (D0 to D4) and part of the block D5 are compressed to block C0, and the rest blocks are compressed to block C1. In this subsection, we only introduce



(a) Compression **(b) Vmap decompression** **(c) Buffer decompression** **(d) In-place decompression**

Fig. 3: Decompression

how a single compressed block is decompressed since, for read requests containing data in multiple compressed blocks, the compressed blocks are decompressed one by one similarly. For example, to read blocks D4 to D6 in Fig. 3(a), C0 is firstly decompressed to get D4 and the first part of D5; then C1 is decompressed to get the rest of D5 and D6.

Vmap decompression To get the data in block D3 and D4, EROFS first reads the compressed block C0 from the storage and stores it in the memory. Then EROFS will decompress it in following steps.

1. Find the largest needed block number that is stored in the compressed block (C0), which is the fifth block (D4) in the example. As an advantage, EROFS only needs to decompress the first five blocks (D0 to D4), rather than decompressing all original data blocks.
2. For each of the data blocks that need to be decompressed, find memory space to store them. In the example shown in Fig. 3(b), EROFS allocates three temporary physical pages to store D0, D1, and D2. For the requested two blocks, D3 and D4, EROFS reuses the two physical pages that have been allocated by VFS in the page cache.
3. Since the decompression algorithm requires continuous memory as the destination of decompression, EROFS maps physical pages prepared in the previous step into a continuous virtual memory area via the `vmap` interface.
4. If it's in-place I/O, in which case the compressed block (C0) is stored in the page cache page, EROFS also needs to copy the compressed data (C0) to a temporary per-CPU page so that the decompressed data won't overwrite the compressed data during the decompression.
5. Finally, the decompression algorithm is invoked, and data in the compressed block is extracted to the continuous memory area. After the compression, the three temporal physical pages and the virtual memory area can be reclaimed, and the requested data has already been written to the corresponding page cache pages.

Per-CPU buffer decompression The above decompression approach causes two problems. The first one is that it is still required to dynamically allocate physical memory pages, which increases the memory pressure on memory-constrained devices. The second problem is that using `vmap` and `vunmap` on each decompression is inefficient.

EROFS leverages per-CPU buffers to mitigate the problems when the decompressed data is less the four pages. As shown in Fig. 3(c), a four-page memory buffer is preallocated for each CPU as the per-CPU buffer. For decompression that extracts no more than four blocks of data, EROFS decompresses the data to the per-CPU buffer and then copy the requested data to the page cache pages. In the example demonstrated in Fig. 3(c), data in block D8 is requested. The compressed data in C1 is directly decompressed to the per-CPU buffer, and the content of D8 is copied to the page cache page via `memcpy`.

The length of the per-CPU buffer is empirically decided, but it can effectively eliminate memory allocations since the per-CPU buffer can be reused across different decompressions. The per-CPU buffer decompression is a cost-effective trade-off which mitigates issues in the vmap decompression while introducing extra memory copies.

Rolling decompression To avoid the overhead of `vmap` and `vunmap` and eliminate other dynamic page allocations, EROFS allocates a large virtual memory area[2] and 16 physical pages for each CPU.

Before each compression, EROFS uses the 16 physical pages, along with the physical pages of the page cache to fill in the VM area, so that step 2 and step 3 of the vmap decompression can be skipped.

EROFS uses LZ4 as the compression algorithm, which needs to look backward at no more than 64KB of the decompressed data [7]. Thus, for a compression that extracts more than 16 pages, EROFS can reuse the physical page mapped 16 virtual pages (i.e., 64KB) before. For example, in Fig. 4, the virtual addresses to store blocks D0 to D15 are backed by the 16 physical pages. The virtual page of D16 can be backed by the same physical page with D0 since each virtual address in D16 is 64KB away from the corresponding address in D0. D17 is backed in the same way by the physical page used by D1. D18, which is requested by the file read, uses the physical page of the page cache.

As a result, 16 physical pages are sufficient for any decompression cases by using such a rolling decompression.

[2] A virtual memory of 256 pages is sufficient for all the workloads we have met.

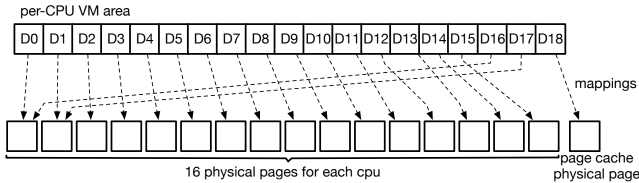


Fig. 4: An example of rolling decompression

In-place decompression In step 4 of the vmap decompression approach, the compressed data is moved to a temporary per-CPU page to avoid data not yet compressed from being overwritten by the compressed data (Fig. 5).

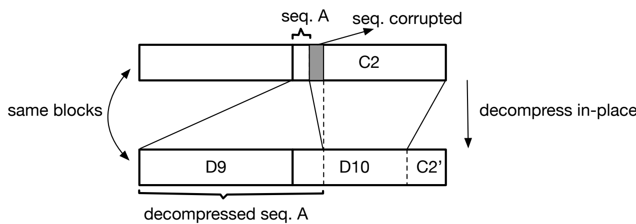

Fig. 5: An example compressed block (C0) that cannot be decompressed in-place. The decompressed data of sequence A corrupts the next sequence (the shadow part) which has not been decompressed.

However, if such a situation will never happen for a compressed block, we can decompress it in-place to avoid the extra memory allocation and memory copies. EROFS simulates the decompression during *mkfs* and marks whether a compressed block can be decompressed in-place in the block index. During the decompression of a block that can be decompressed in-place, step 4 is skipped. In our tested workload enwik9 in §5, 99.6% compressed blocks can be decompressed in-place; thus, most blocks can benefit from the in-place decompression as long as they are retrieved by in-place I/O.

4 Implementation

We have implemented EROFS as a Linux file system and upstreamed the common part of EROFS to Linux kernel[3].

In the current implementation, we use 4KB as the fixed output size since it is the minimal unit of page management and storage data transfers, and thus I/O amplification can be minimized. We support LZ4 (v1.8.3) as the compression algorithm since it has the fastest decompression speed and good compression ratio in our case. Other compression algorithms, such as LZO, can be supported once they are modified to provide fixed-sized output compression interfaces. Only the file data is compressed in EROFS; metadata such as inode and directory entries is stored without compression.

Currently, EROFS is still under active development and new features are constantly shipped into the smartphones after a rigorous commercial testing process. Hence, we introduce two versions of EROFS: 1) the latest version with all features and optimizations presented in this paper; 2) the commercially-deployed version, which has all features and optimizations except the rolling decompression and the in-place decompression. The two versions are also different in decompression policies which we will illustrate in §4.2.

4.1 EROFS image layout

Fig. 6 shows the layout of an EROFS image. As in other file systems, a super block is located at the beginning of the image. Following the super block, metadata and data may be stored in a mixed style without constraints on the order.

In the current implementation, metadata and data of a file are stored together for better locality. For each file, as shown in Fig. 6, an inode is stored at the beginning, followed by blocks containing the extended attributes (i.e., xattrs) and the block index. Blocks for compressed or uncompressed file data (encoded blocks) are stored at the end of each file.

Since an inode can be placed anywhere in the image, the inode number is calculated from the position of an inode, so that the inode can be quickly located. Blocks for xattrs and the block index are omitted if a file contains no xattrs or is uncompressed. Further, xattrs, the block index and file data can also be inlined within an inode if possible, which reduces storage overhead and decreases the number of I/O requests since the inlined data/metadata is read along with the inode.

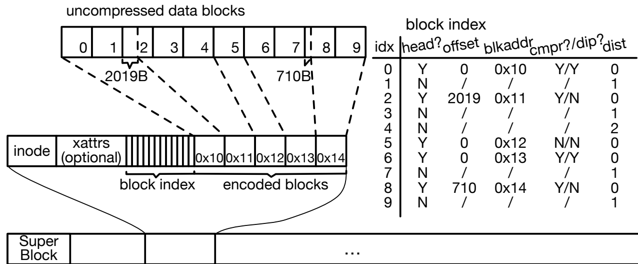
The block index is used to quickly locate the corresponding encoded block for read requests. Fig. 6 shows an example block index for a regular file containing ten blocks before compression. The block index is an array of 8B-length entries, each of which corresponds to a data block before compression. Each entry indicates whether the corresponding data block is the head block (the boolean `head` field in Fig. 6), which starts a new encoded block. If so, the encoded block address (`blkaddr`), the offset of the first byte in the new encoded block (`offset`), whether the encoded block is compressed (`cmpr`), and whether the block can be decompressed in-place (`dip`) are also stored. If not, there must be a head block before the uncompressed block, and the block number difference to the head block is recorded in `dist`.

For a read request to an uncompressed data block, EROFS gets the block index entry according to the requested block number. For a head block, EROFS decompresses data from the block at `blkaddr`, and if the `offset` is non-zero, EROFS may also need to decompress from the nearest encode block stored before the `blkaddr`. For a non-head block, EROFS calculates the location of the corresponding head block according to the stored `dist`, and starts to decompress until the requested block data is decompressed.

Some data blocks (e.g., block 5 in Fig. 6), which are larger after compression, are not compressed and directly stored as encoded blocks. For these cases, the corresponding `cmpr` fields are set to false (i.e., "N" in the figure).

[3]Since some optimizations are not yet upstreamed, we also make the latest version of the code available at https://github.com/erofs/atc19-erofs and https://github.com/erofs/atc19-mkfs.

Directories are stored similarly as the regular files, except that there is no block index, and the encoded blocks are used to store uncompressed directory entries. For better locality of random accesses in directories, EROFS puts all dirent headers (e.g., inode number, file type, and name length) at the beginning of directory entries part, and places filenames after those headers.



idx	head?	offset	blkaddr	cmpr?/dip?	dist
0	Y	0	0x10	Y/Y	0
1	N	/	/	/	1
2	Y	2019	0x11	Y/N	0
3	N	/	/	/	1
4	N	/	/	/	2
5	Y	0	0x12	N/N	0
6	Y	0	0x13	Y/Y	0
7	N	/	/	/	1
8	Y	710	0x14	Y/N	0
9	N	/	/	/	1

Fig. 6: EROFS image layout and the block index

4.2 Decompression policy

Two versions of EROFS have different decompression policies. The commercially-deployed EROFS uses the per-CPU buffer decompression if less than four original data blocks are to be extracted; otherwise, the vmap decompression is used.

In the latest EROFS, all four decompression approaches are implemented. If there is no more than one data block to be extracted, the per-CPU buffer decompression is chosen. Otherwise, if a compressed block is retrieved using in-place I/O and can be decompressed in-place, EROFS employs the in-place decompression approach which avoids unnecessary memory allocations and memory copies. For other cases where the decompressed blocks can fit in the pre-allocated VM area, EROFS uses the rolling decompression since it beats the vmap decompression with less memory allocation overheads. For any other cases, the vmap decompression approach is adopted.

4.3 Optimizations

Index memory optimization It is possible that EROFS compresses hundreds of pages of original data into a single compressed block. In such a case, EROFS needs hundreds of pointers to keep track of where each page of the original data should be stored. These pointers can consume a large amount of memory. To address such a problem, EROFS tries to store the information with the help of *reusable pages*. If there are more than one VFS allocated pages are *reusable*, EROFS uses the last page to store the compressed data, and the other pages to store some of these pointers during the I/O. Before the actual decompression, these pointers are moved onto the stack, so that the *reusable pages* are free to store the decompressed data.

Scheduling optimization Decompression requires a relatively long time. Thus it is not suitable to be done within the interrupt context. In some file systems, such as Btrfs [2], when compressed data has been fetched to memory, a dedicated thread will be woken up to decompress the data. When the decompression is finished, the reader thread which issues the I/O will be woken up to get the decompressed data from the page cache. To reduce scheduling overhead, EROFS decompresses data in the reader thread, without dedicated threads for decompression. Thus once the compressed data has been fetched to memory, the reader thread will be directly woken up and start decompressing the data.

Cohort decompression Several requests can be in-flight simultaneously. If an original data block is requested on thread A and the corresponding compressed block is being decompressed by another thread named thread B, rather than decompressing the data by itself, thread A can wait for thread B to finish the decompression, and then directly read the decompressed data from the page cache. Such cooperation reuses the decompressed data and prevents a single data being decompressed multiple times.

Image patching Although EROFS is a compressed read-only file system, there are cases such as system upgrade or security patching where the data stored in EROFS needs to be updated. EROFS provides a feature called image patching, which supports partial data updates. Usually, modifying a single bit in the original file data might cause a huge amount of scattered modifications in the compressed data. Instead of modification in-place, image patching places updated data at the end of the EROFS image, and when the corresponding file data blocks are requested, the origin data blocks are firstly decompressed and then the updated data is applied to overwrite the decompressed data in memory. In this way, image patching prevents scattering of changes and supports partial data updates without re-compressing the while file system.

5 Evaluation

We have conducted a set of experiments to answer the following questions:

- How does compression affect the performance of file system read accesses?
- How much memory does EROFS consume during decompression?
- How does EROFS affect the boot time on real-world applications?

5.1 Evaluation setup

By default, we conduct experiments on an ARM development board, HiKey 960, running Android 9 Pie with Linux kernel 4.14. The board is equipped with Kirin 960 (four Cortex-A73 big cores and four Cortex-A53 little cores), 3GB Hynix LPDDR4 memory and 32GB Samsung UFS storage. We also evaluate on two kinds of smartphones in some experiments. The low-end smartphones are equipped with MT6765 (eight Cortex-A53 cores), 2GB memory and 32GB

eMMC storage. High-end smartphones run with Kirin 980 (four Cortex-A76 cores and four Cortex-A55 cores), 6GB memory and 64GB UFS storage.

For micro-benchmarks, we run FIO [23], a flexible I/O tester, on various file systems including EROFS, Squashfs, Btrfs, Ext4, and F2FS. We use the latest version of EROFS for micro-benchmark evaluation. Among these file systems, EROFS and Squashfs are designed to be compressed read-only file systems; Btrfs is a file system with compression support, but it is not a file system designed for read-only data; Ext4 is the default file system used by Android; F2FS is a file system designed for mobiles and is widely used in some smartphones.

EROFS is configured to use 4KB-sized output compression with LZ4. Squashfs is configured to use LZ4 with 4KB, 8KB, 16KB, and 128KB compression chunk sizes, indicated by Squashfs-4K, Squashfs-8K, Squashfs-16K, and Squashfs-128K, respectively. Btrfs is configured to run in read-only mode without data integrity checks for a fair comparison. The compression algorithm used by Btrfs is LZO, since Btrfs does not support LZ4. Both Ext4 and F2FS are used without compression in the experiments since they do not support it.

For real-world applications, we compare EROFS with Ext4, since Ext4 is now the default file system used by Android [17]. We use the commercial version for real-world evaluation since it takes time to ship the latest version to smartphones. We also tried to use Squashfs on Android. However, it costed too much CPU and memory resources, and when trying to run a camera application, the phone froze for tens of seconds before it finally failed.

5.2 Micro-benchmarks

We use FIO to show the basic I/O efficiency of different file systems. In this experiment, we use enwik9 [40] as the workload, which is the first 10^9 bytes of the English Wikipedia dump. We store the file in different file systems and read the file to test the file system read throughput. Each read is a 4KB buffered read. We test the throughput under three scenarios: sequential read, random read, and stride read. For the sequential read, we read the file 4KB by 4KB sequentially; thus the following reads are highly likely to hit in cache since the data is already loaded in the memory by previous decompression or prefetching (i.e., readahead). For the random read, we randomly read the whole file; thus the reads can hit in the cache if the data is already decompressed by previous reads. The last scenario is the stride read, in which we only read the first 4KB in every 128KB data. Since the largest compression chunk is 128KB, stride reads will not hit in cache[4]. We test stride reads to illustrate the worst-case performance for compressed file systems.

Before each test, the page cache is dropped to reduce interference. All tests are done at least ten times, and the average throughputs are reported. The max relative standard deviation is 17.3% for stride reads on A53 cores and 5.1% for the rest results. Fig. 7 shows the following results we observed.

Btrfs performs worst in all tests compared with EROFS and Squashfs-128K, since it is designed neither for compression nor for read-only data. On one hand, Btrfs does not take advantage of the read-only property and has to consider updates; thus it is outperformed by the compressed read-only file systems EROFS and Squashfs-128K. On the other hand, decompression in Btrfs incurs notable performance overhead compared to Ext4 and F2FS which do not need to decompress data during reads. This is reasonable since Btrfs is not designed to be a compressed read-only file system.

Btrfs performs better than other configurations of Squashfs for sequential reads, which is caused by its larger compression chunk (128KB). The advantages shrink in random reads where prefetching does not work; the advantage disappears in stride reads where decompressing more data than requested becomes the burden.

Overall, this result shows the inefficiency of using general file systems with compression support for read-only data and emphasizes the necessity of designing compressed read-only file systems.

As the size of compression input increases, the performance of Squashfs increases for random reads and sequential reads, but decreases for stride reads. The main reason for this phenomenon is the locality and cache. Since file systems have enough memory to cache file data in this experiment, all decompressed data will be cached and possibly be read in the future. Thus for random reads and sequential reads, the larger-sized data is decompressed, more future reads will hit the cache. That is basically the reason why the Squashfs throughputs grow as the compression chunk size increases.

Since both sequential and random reads will read the whole file, there is only a little performance difference, which is caused by the good locality and prefetching.

For stride reads, however, FIO only reads the first 4KB data for each 128KB data, which eradicates the benefits of memory cache since all the data decompressed but not requested will never be used in the future. Thus the more irrelevant data is read and decompressed, the more time and resource are wasted, yielding worse performance. That explains why the throughput drops with the increase of the compression chunk size for Squashfs.

EROFS performs best in most of the tests among file systems with compression support and sometimes outperforms file systems that do not compress data. For sequential reads, EROFS exhibits the best performance among compressed file systems. Most wins come from the design of fixed-sized output compression and the elimination of unnecessary memory allocations and data movements compared with Squashfs. For random reads, EROFS is outperformed by Squashfs-128K since the latter can decompress and cache the whole file during the test, while EROFS only benefits from cached

[4] In enwik9 and silesia.tar, no more than 128KB data is compressed to a single block in EROFS.

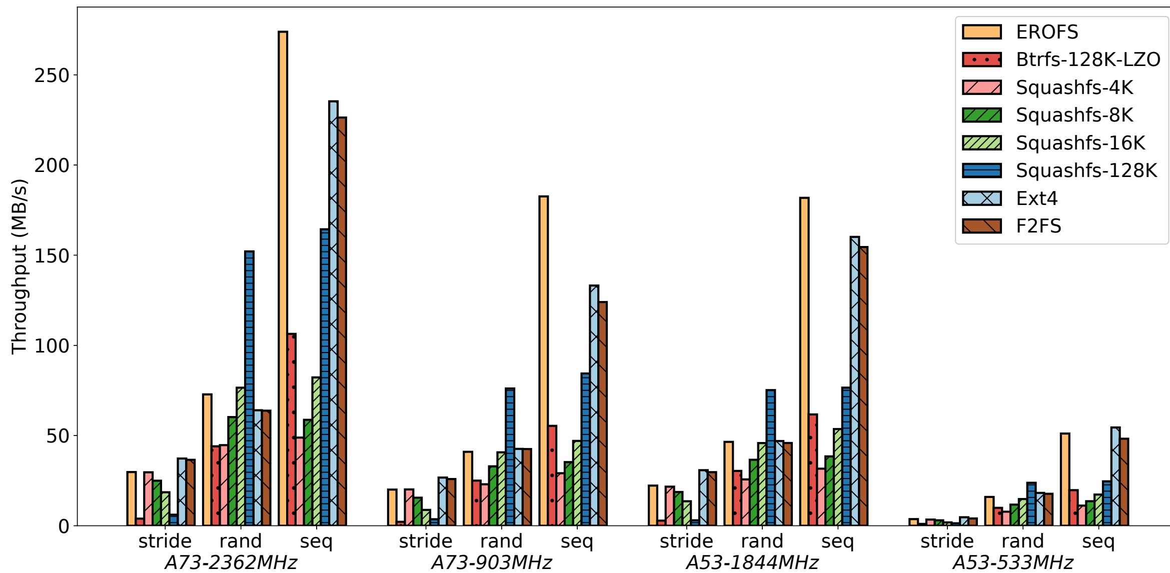


Fig. 7: FIO micro-benchmark results under three read patterns at four CPU frequencies

I/Os. However, EROFS still performs better than other compressed file systems. For stride reads, since the prefetching is barely useful, EROFS still yields the best throughput among compressed file systems, but the win is limited.

Compared with Ext4 and F2FS without compression support, EROFS always performs comparably with and even outperforms them (e.g., the sequential reads on A73 cores). The reason is that even if EROFS needs to decompress data, it reads much less data from the storage thanks to compression.

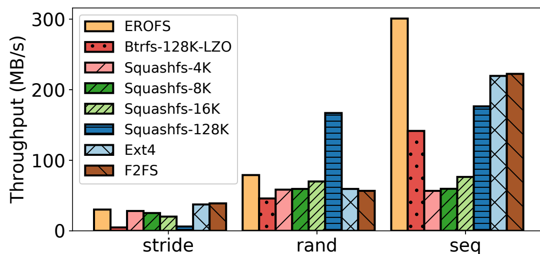

Fig. 8: FIO micro-benchmark results for silesia.tar

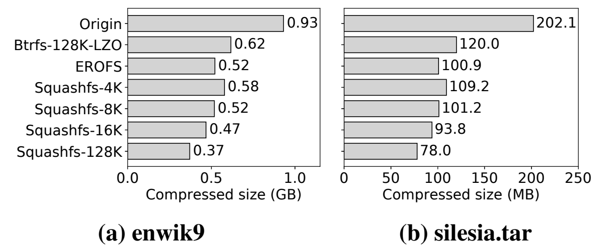
We also use the workload, *silesia.tar* [9], to conduct the same experiment. Silesia.tar is a tarball of the silesia compression corpus, which covers typical data types used nowadays. The results show the same trends as enwik9, so we only present the result for A73 cores at 2362MHz in Fig. 8.

5.3 Compression ratio and memory usage

We also evaluated the compression ratio and memory consumption during the decompression of each file system. We use both enwik9 and silesia.tar to present the compression ratio of different file systems. Fig. 9(a) and Fig. 9(b) show the number of bytes used on each file system for enwik9 and silesia.tar. The *origin* line in both figures represents the size of the uncompressed workload file, which is 953.67MB for enwik9 and 202.1MB for silesia.tar. Currently, EROFS only supports 4KB-sized output compression, but compared with Squashfs-4K, the compressed size is 10% and 9% smaller for the two workloads. The figure also matches the facts that the larger the compression unit, the better the compression ratio.



(a) enwik9 **(b) silesia.tar**

Fig. 9: Compressed size

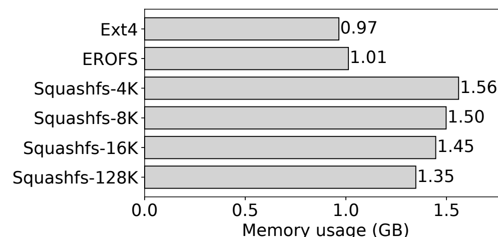


Fig. 10: Decompression memory usage

Fig. 10 shows the memory used after decompressing the enwik9 file. The test is conducted as follows: boot the machine, mount the file system, read the file stored in the file system, check the memory used, and then reboot.

Since the file is roughly 1GB, the remainders are either used by other parts of the operating system or temporarily

Table 1: I/O amount under different read patterns

I/O (MB)	seq-read	rand-read	stride-read
Requested	16.00	16.00	16.00
Squashfs-4K	10.65	26.19	26.23
Squashfs-8K	9.82	33.52	34.08
Squashfs-16K	9.05	46.42	48.32
Squashfs-128K	7.25	165.27	203.91
EROFS	10.14	26.12	25.93

Table 2: I/O patterns

I/O size	=4K	<=8K	<=16K	<128K	=128K	>128K
%	19.0	23.9	30.4	78.9	19.9	1.2

used by the file system. Besides EROFS and Squashfs, we also tested Ext4 as the baseline. From the figure, we can see that compared to Ext4, the memory overhead for four configurations of Squashfs ranges from 39.6% to 61.6%. However, memory used by EROFS is only slightly higher than the Ext4 (about 4.9%). The result shows that EROFS has much lower memory spikes than Squashfs and proves the effectiveness of memory-friendly decompression of EROFS.

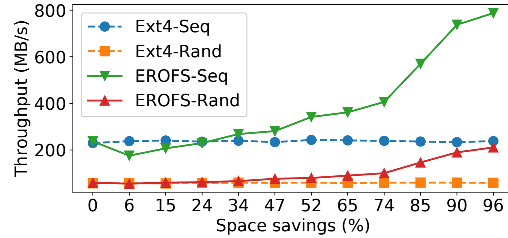
In the test, there is only one file to be decompressed, and we allocate abundant memory to ensure that no memory reclamation or swapping will happen during the decompression. However, in a real-world scenario where more files will be decompressed simultaneously, more memory will be needed by the decompression of Squashfs. Once the available memory is scarce, memory reclamation or swapping may happen, which is very expansive and affects not only the file systems, but also other components or applications in the whole system. Thus in real-world scenarios, the advantages of EROFS, which uses as little as memory during the decompression, will be more remarkable.

5.4 I/O amplification and I/O patterns

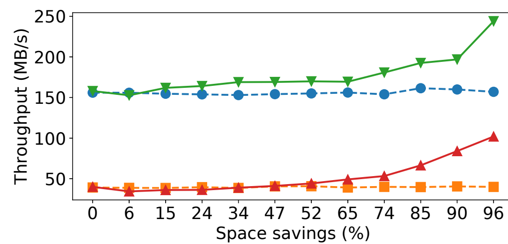
We reran tests mentioned in §2.2 on EROFS and different Squashfs configurations. Table 1 lists the actual I/O issued when reading 16MB file data under three read patterns. EROFS issued the least I/O for random reads and stride reads. Yet, since Squashfs-8K, Squashfs-16K and Squashfs-128K have a better compression ratio, they read less data than EROFS for sequential reads. In summary, EROFS reduces the I/O amplification for most cases compared with Squashfs, especially for random reads and stride reads.

We further identified the I/O pattern in a simulated real-world environment to illustrate how I/O amplification will affect real-world applications. We installed 100 apps and ran the Monkey tool [13] to randomly tap the screen once per second for 3 hours. We collected the I/O sizes passed to the `readpage` and `readpages` interfaces and show the proportion of different I/O sizes in Table 2. The result shows that there are quite a lot of I/Os (30.4%) with sizes no more than 16K, which we consider as random I/Os. The amount of random I/Os is reasonable since as the system keeps running for a long time, some pages in the applications' page cache are reclaimed due to memory shortage. The insignificant amount of random I/Os emphasizes the importance of EROFS's effort of reducing the I/O amplification.

5.5 Throughput and space savings



(a) Throughput on A73 cores 2362MHz



(b) Throughput on A73 cores 903MHz

Fig. 11: Throughput under different space savings

Fig. 11 depicts the throughput of EROFS and Ext4 under different space savings. The space savings is the value of space reduced by the compression divided by the size of original data; thus, a larger space savings indicates more space saved. For simplicity, we only show the results for big cores, since similar trends are presented on little cores.

For the test, we collected blocks in our compressed partitions and check their space savings. When we found a block that matches our expected space savings, the original data was decompressed and duplicated multiple times to form a roughly 512MB file. Then we stored the file in EROFS and read it to get the read throughput under its space savings. We also stored the file in Ext4 and got the corresponding read throughput for comparison.

Generally, the throughput of Ext4 remains stable during the test and the performance of EROFS increases together with space savings. EROFS achieves much better throughput than Ext4 when the space savings is high enough. In such cases, a single compressed block can be decompressed to dozens of blocks. Thus, the number of I/O requests is notably reduced, leading to higher performance. While when the space savings is low, the performance of EROFS is similar to Ext4 for random reads and worse than Ext4 for sequential reads. This is the result of the conjunction of I/O costs and decompression computation costs. For random reads, the I/O is more expensive than the decompression computation. While for sequential reads, due to prefetching, I/O is less costly and the computation cost dominates when the space

savings is low.

5.6 Different decompression approaches and optimization

To illustrate the effect of different decompression approaches, we ran FIO sequential reads on the Kirin 980 smartphone with A76 cores at 2600MHz. The vmap decompression approach serves file reads at 726.5MB/s while the per-CPU buffer decompression yields throughput of 736.5MB/s. File data is read at 769.7MB/s in the latest EROFS with the rolling decompression and the in-place decompression added.

We also evaluated the effect of scheduling optimization in §4.3 with the same configuration. In the random read workload, the average throughput of EROFS without the scheduling optimization is 64.49MB/s, while with the optimization, the performance improves 9.5% to be 70.61MB/s.

5.7 Real-world applications

For real-world applications, we ran modified Android 9 Pie on both low-end smartphones and high-end smartphones, whose hardware configurations are listed in §5.1. Android system partitions such as */system*, */vendor*, and */odm* are compressed with EROFS, and the space savings ranges from 30% to 35%. We tested the boot time of thirteen popular applications required by the production team. We compared application boot time on EROFS to those on Ext4 and present relative boot time in Table 3. On average, EROFS reduces the boot time by 5.0% for low-end smartphones and 2.3% for high-end smartphones compared with Ext4.

We also conducted the same test while running FIO as the background workload to simulate real-world scenarios. In the FIO workloads, four threads randomly read and write individual files with rate limited at 256KB/s for both reads and writes. The last two rows in Table 3 show the boot time with FIO workloads, where the reduction of boot time is 3.2% and 10.9% for low-end and high-end smartphones, respectively.

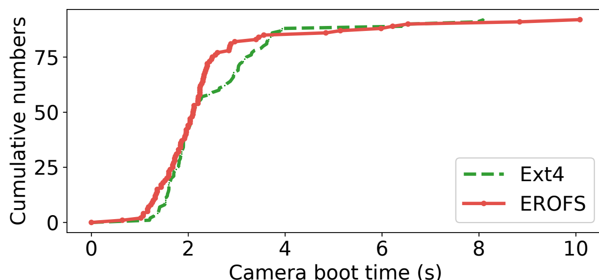


Fig. 12: Camera boot time

Other than the boot time of various applications, we also tested the boot time distribution of the camera application on the aforementioned high-end smartphones. To simulate the situation where memory is scarce, we ran a program in the background which continuously allocates memory and fills in garbage data. We waited until the program consumed all zram in the system before starting the experiment, and kept it running during the evaluation. In the experiment, we booted several applications in turn and recorded the boot time when it's the camera's turn to boot. We collected each time of 92 camera boots for both EROFS and Ext4, and present the cumulative distribution in Fig. 12. The camera application running on EROFS boots faster than on Ext4 for more than 90% of the boots, while the longest boot time on EROFS is worse than that on Ext4. We think the result is acceptable since EROFS saves the storage space while reduces the boot time in most of the cases.

6 Experience over deployment

EROFS has been deployed to tens of millions of smartphones. Here, we report some experiences during the deployment.

Optimizing for all cases, not only common cases. Deploying a new file system to replace an existing one is much harder than we first imagine. The reason is that a commercial product like a smartphone needs to retain the benefit and features of an existing file system. Hence, we need to carefully optimize EROFS for all cases instead of common cases to avoid performance degradation even in some rare cases.

For example, the performance of reading some files on EROFS is slightly worse than on Ext4. To optimize, we leave files with low compression ratio uncompressed for better performance. Further, we collect access frequencies of file blocks from anonymous beta users and store them in dedicated files. According to the frequency information, we pre-decompress the most frequently requested parts of compressed files and pin them in the memory to balance the storage consumption and the performance. As a result, the performance of EROFS can be as good as, and sometimes better than Ext4, while the storage consumption is significantly reduced.

Incomplete implementation leads to performance abnormalities and failures in real-world scenarios. We tested EROFS after the main functionalities have been implemented. However, several kinds of malfunctions happened during real-world tests.

One example is that after the smartphone runs on EROFS for days, several applications become extremely slow at times. Eventually, we found that the root cause is the missing implementation of page migration in EROFS. Page migration is invoked by the memory management subsystem to ask file systems to move their data somewhere else. Most of the time, the page migration will not be triggered and thus leaving it unimplemented is benign. However, when the memory is fragmented, which is the case when the bug happens, the functionality of page migration is crucial to the success of allocating contiguous memory in the system. The issue was solved after we implemented the page migration in EROFS.

Bottlenecks shift on different platforms. We developed

Table 3: **Relative boot time of thirteen applications on low-end and high-end smartphones. Each number in the table is the average value of at least five boots. Negative numbers show the boot time reduction (in %) compared with Ext4, while positive numbers indicate the boot time is prolonged (in %). FIO workloads are running in the background for cases with 'w/ FIO' suffix.**

App. #	1	2	3	4	5	6	7	8	9	10	11	12	13
Low-end	**-16.4**	-3.5	+4.2	-4.0	-7.5	-1.4	-6.8	+6.3	-2.2	**-18.4**	-3.3	-7.6	-4.5
High-end	-1.8	-0.7	-2.1	-1.8	**-12.3**	-3.7	+1.2	-8.0	-2.8	+0.7	+2.0	-2.7	+1.9
Low-end w/ FIO	-2.8	**-12.9**	-5.4	+3.9	-7.6	+3.7	+4.4	-2.6	+9.9	+4.0	**-11.1**	**-10.3**	**-15.1**
High-end w/ FIO	-4.6	**-14.1**	**-10.7**	**-19.3**	-7.0	**-11.0**	**-15.0**	+0.8	**-22.9**	-5.0	**-18.9**	-0.7	**-13.2**

early versions of EROFS on high-end smartphones where resources are abundant, and tuned it to use as fewer resources as possible. However, when we adopt the tuned EROFS to low-end smartphones, the performance is lower than we expected. This is surprising since we have already considered the limited resources and EROFS should work well. At last, the trouble-maker turned out to be the scheduler. Scheduling on low-end smartphones is much more costly and becomes the bottleneck of EROFS's decompression, which motivated us to introduce the scheduling optimization described in §4.3. Different platforms not only reflect resource limitation directly on the amount of memory available or how fast processors can run, but they can also shift the bottleneck of software.

7 Related Work

Other compressed file systems. Several other file systems support compression. AXFS [24] is a compressed read-only file system. It is designed to enable execute-in-place (XIP), which is not supported by common smartphone storage like eMMC or UFS. CramFS [3] is another compressed read-only file system, which is designed to be simple and space-efficient. However, it also has several limitations such as limited file size. Cramfs was once obsoleted by Squashfs in the Linux kernel [4] and then revived for XIP [5], which is not supported by common smartphone storage like eMMC or UFS. LeCramFS [27] extends CramFS for better read performance and memory efficiency on flash memory. However, the compression ratio is reduced, and LeCramFS generates much larger images.

JFFS2 [15], and UBIFS [12] are two file systems designed for flash memory. Although they support compression, they have to manage the wear-leveling, address translation, and garbage collection for NAND flash. Because all such features are already provided by the eMMC and UFS firmware, EROFS is much simpler and faster than JFFS2 and UBIFS.

Bcachefs [1] is a file system with an emphasis on reliability and robustness. ZFS [16] is a full-fledged file system designed by Sun Microsystems for Solaris. Although they both support compression, they have to consider updates on compressed files, which has a similar issue with Btrfs.

File system and storage for smartphones. File system and storage for smartphones have long been a hot topic. For example, Kim et al. [33] illustrated that storage can affect application performance on smartphones and proposed several approaches to mitigating the performance impact. Jeong et al. [31] uncovered and mitigated the journaling of journal (JOJ) anomaly by overhauling file systems on smartphones, which has generated several follow-up efforts [36, 38, 44]. They further identified Quasi-Asynchronous I/O in smartphone file systems and boosted them for responsiveness [28]. SmartIO [41] reduces the application delay by prioritizing reads over writes. MobiFS [43] is a memory-centric design for smartphone data storage that improves response time and energy consumption.

There has also been much work [29, 30, 34, 35, 37] providing benchmarking frameworks to evaluate file systems and storage on smartphones. Due to the emergence of non-volatile memory (NVM), recent researchers [26, 32, 39, 42, 47] also investigated how NVM can be used on smartphones.

8 Conclusion and Future Work

We introduce EROFS, a new compressed read-only file system designed for smartphones with limited resources. EROFS provides a comparable compression ratio while having much higher performance and less extra memory overhead compared to Squashfs. With fixed-sized output compression and fast and memory-efficient decompression, EROFS can store system code and resources with less storage usage and sometimes even better performance compared with file systems without compression support. Evaluation shows that apps on a system installed on EROFS can boot comparably or even faster compared with on Ext4. EROFS has been merged to the mainline Linux and has been deployed and used in tens of millions of smartphones. Currently, EROFS is still under active development, and we are continuously adding new features, such as deduplication, extended file statistics, fiemap, and EROFS-fuse in future versions of EROFS.

Abstract

Data compression can not only provide space efficiency with lower Total Cost of Ownership (TCO) but also enhance I/O performance because of the reduced read/write operations. However, lossless compression algorithms with high compression ratio (e.g. gzip) inevitably incur high CPU resource consumption. Prior studies mainly leveraged general-purpose hardware accelerators such as GPU and FPGA to offload costly (de)compression operations for application workloads. This paper investigates ASIC-accelerated compression in file system to transparently benefit all applications running on it and provide high-performance and cost-efficient data storage. Based on Intel® QAT ASIC, we propose QZFS that integrates QAT into ZFS file system to achieve efficient gzip (de)compression offloading at the file system layer. A compression service engine is introduced in QZFS to serve as an algorithm selector and implement compressibility-dependent offloading and selective offloading by source data size. More importantly, a QAT offloading module is designed to leverage the vectored I/O model to reconstruct data blocks, making them able to be used by QAT hardware without incurring extra memory copy. The comprehensive evaluation validates that QZFS can achieve up to 5x write throughput improvement for FIO micro-benchmark and more than 6x cost-efficiency enhancement for genomic data post-processing over the software-implemented alternative.

1 Introduction

Data compression has reached proliferation in systems involving storage, high-performance computing (HPC) or big data analysis, such as EMC CLARiiON [14], IBM zEDC [7] and RedHat VDO [18]. A significant benefit of data compression is the reduced storage space requirement for data volumes, along with the less power consumption for cooling per unit of logical storage [12, 51]. Furthermore, if the input data to Hadoop [3], Spark [4] or stream processing job [40] is compressed, the data processing performance can be effectively enhanced as the compression not only saves bandwidth but also decreases the number of read/write operations from/to storage systems.

It is widely recognized that the benefits of data compression come at the expense of computational cost [1, 9], especially for lossless compression algorithms with high compression ratio [41]. In a number of fields (e.g., scientific big data or satellite data), lossless compression is the preferred choice due to the requirement for data precision and information availability [12, 43]. Prior studies mainly leveraged general-purpose hardware accelerators such as GPU and FPGA to alleviate the computational cost incurred by (de)compression operations [15, 38, 41, 45, 52]. For example, Ozsoy *et al.* [38] presented a pipelined parallel LZSS compression algorithm for GUGPU and Fowers *et al.* [15] detailed a scalable fully pipelined FPGA accelerator that performs LZ77 compression. Recently, the emerging AISC (Application Specific Integrated Circuit) compression accelerators, such as Intel® QuickAssist Technology (QAT) [24], Cavium NITROX [34] and AHA378 [2], are attracting attentions because of their advantages on performance and energy-efficiency [32].

Data compression can be integrated into different system layers, including the application layer (most common), the file system layer (e.g., ZFS [48] and BTRFS [42]) and the block layer (e.g., ZBD [27] and RedHat VDO [18]). Professional storage products such as IBM Storwize V7000 [46] and HPE 3PAR StoreServ [19] may contain competitive compression feature as well. If compression is performed at the file system or lower layer, all applications, especially big data processing workloads, running in the system can transparently benefit from the enhanced storage efficiency and reduced storage I/O cost per data unit. This feature also implies that only lossless compression is acceptable to avoid influences on applications. To the best of our knowledge, there is no practical solution at present that provides hardware-accelerated data compression at the layer of local or distributed file systems.

In this paper, we propose QZFS (QAT accelerated ZFS) that

*Co-equal First Author

integrates Intel® QAT accelerator into the ZFS file system to achieve efficient data compression offloading at the file system layer so as to provide application-agnostic and cost-efficient data storage. QAT [24] is a modern ASIC-based acceleration solution for both cryptography and compression. ZFS [6, 48] is an advanced file system that combines the roles of file system and volume manager and provides a number of features, such as data integrity, RAID-Z, copy-on-write, encryption and compression.

In consideration of the goal of cost-efficiency, QZFS selects to offload the costly gzip [1] algorithm to achieve high space efficiency (i.e., high compression ratio) and low CPU resource consumption at the same time. QZFS disassembles the (de)compression procedures of ZFS to add two new modules for integrating QAT acceleration. First, a compression service engine module is introduced to serve as a selector of diverse compression algorithms, including QAT-accelerated gzip and a number of software-implemented compression algorithms. It implements compressibility-dependent offloading (i.e., compression/non-compression switch) and selective offloading by source data size (i.e., hardware/software switch) to optimize system performance. Second, a QAT offloading module is designed to efficiently offload compression and decompression operations to the QAT accelerator. It leverages the vectored I/O model, along with address translation and memory mapping, to reconstruct data blocks prepared by ZFS, making them able to be accessed by QAT hardware through DMA operations. This kind of data reconstruction avoids expensive memory copy to achieve efficient offloading. Besides, considering QAT characteristics, this module further provides buffer overflow avoidance, load balancing and fail recovery.

In the evaluation, we deploy QZFS as the back-end file system of Lustre [44] in clusters with varying nodes, and measure the performance with FIO micro-benchmark and practical genomic data post-processing. For FIO micro-benchmark, QZFS with QAT-accelerated gzip can achieve up to 5x average write throughput with a similar compression ratio (3.6) and about 80% reduction of CPU resource consumption (from more than 95% CPU utilization to less than 20% CPU utilization), compared to the software-implemented alternative. For practical genomic data post-processing workloads, benefiting from QAT acceleration, QZFS provides 65.83% reduction of average execution time and 75.58% reduction of CPU resource consumption over the software gzip implementation. Moreover, as compression acceleration is performed at the file system layer, QZFS also significantly outperforms the traditional simple gzip acceleration for applications while conducting genomic data post-processing.

2 Background and Motivation

This section presents data compression benefits and the motivation of hardware-assisted compression.

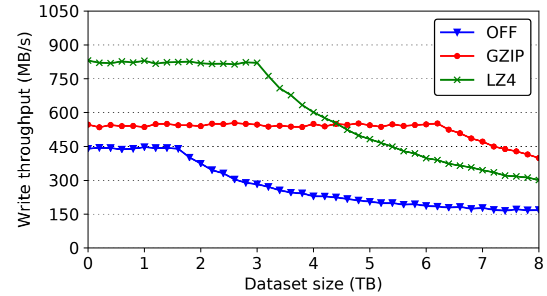

Figure 1: Write throughput on hybrid storage of one 1.6TB NVMe SSD and backup HDDs. Gzip and LZ4 achieve a compression ratio of about 3.8 and 1.9 respectively.

2.1 Data Compression on Storage Devices

As high-performance storage devices, NVMe SSDs can remarkably improve the read/write speed with low energy consumption [25, 49]. Nonetheless, the limited capacity and high price significantly discourage their widespread use and storage devices have accounted for a large proportion of Total Cost of Ownership (TCO) [50]. In the Mistral Climate Simulation System, storage devices occupy more than 20% of the TCO for the entire system [28]. Many studies have investigated data compression on storage devices to improve I/O performance and reduce system TCO simultaneously [31, 36].

To show the benefits of data compression, we evaluated the performance of a compression-enabled file system (i.e., ZFS) by the FIO tool [5] on a hybrid storage system, including one 1.6TB NVMe SSD (Intel® P3700 series) and backup HDDs. Two representative lossless compression algorithms, gzip [16] and LZ4 [35], were used in ZFS to compare with the compression OFF configuration. As shown in Figure 1, the write throughput with data compression (for both gzip and LZ4) outperforms the case of OFF because compression can effectively reduce the total data size written into the storage [33,53]. If the dataset size is larger than the capacity of the 1.6TB NVMe SSD, the excessive data are written into backup HDDs. Due to the poor read/write performance of HDD, the OFF configuration incurs throughput degradation rapidly once the dataset size exceeds 1.6TB. The gzip algorithm achieves a compression ratio of about 3.8 in this evaluation and the write throughput degrades after the dataset size exceeds 6.1TB. Since LZ4 is a fast compression algorithm (i.e. CPU time for compression is largely reduced), it can bring a higher write throughput than the gzip case although the compression ratio is lower, with a value of about 1.9. However, the performance of the LZ4 configuration begin to degrade after the dataset size exceeds 3TB and has no advantage over the gzip algorithm for a dataset size large than 4.5TB. In conclusion, data compression improves space efficiency and allows more data to benefit from the high-performance storage devices.

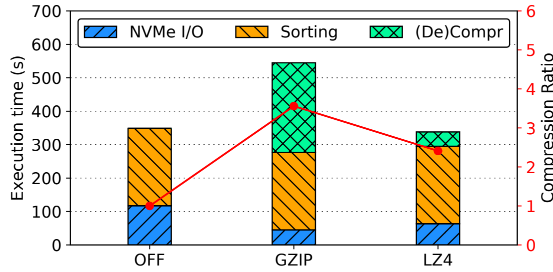

Figure 2: The execution time of genomic data sorting under different compression algorithms

2.2 The Selection of Compression Algorithms

Compression-enabled file systems leverage lossless data compression algorithms to transparently serve upper applications. An algorithm with both high compression ratio and low CPU resource consumption is an optimal choice yet these two aspects are actually hard to achieve at the same time. We conducted an experiment with scientific big data workloads running on ZFS to compare two representative lossless algorithm: gzip and LZ4. SAMtools [30], a popular set of utilities for sequence analysis, was used to manipulate 150GB genomic data stored on a NVMe SSD and perform the sorting operation, which needs to create temporary files and conduct a series of complex data reading and writing actions.

Figure 2 illustrates the breakdown of the total execution time under different compression algorithms, including *NVMe SSD I/O time* (T_{io}), *sorting time* (T_s) and *(de)compression time* (T_c). The execution time for the compression OFF configuration only comprises of T_{io} (117.21s) and T_s (231.77s). The gzip and LZ4 algorithms have a similar T_s value because of the same sorting processing while T_{io} is reduced to 35.02s and 48.45s respectively due to the different compression ratios: 3.56 for gzip and 2.41 for LZ4. However, the high compression ratio of gzip leads to a high T_c value of 278.02s, compared to the 24.77s for the LZ4 configuration. This high CPU resource consumption of gzip may further cause resource competition and impact other tasks. Intuitively, if (de)compression operations can be offloaded to hardware accelerators to eliminate T_c for CPU, gzip could be an ideal compression algorithm as it can achieve the highest space efficiency. This motivates the design of a hardware-assisted compression-enabled file system for high-performance and cost-efficient data storage.

2.3 Hardware-Assisted Data Compression

Nowadays, diverse hardware accelerators are continuously emerging in cloud infrastructures and datacenters [10, 31, 32]. ASIC accelerators are increasingly attracting attentions due to their advantages on performance and energy-efficiency over general-purpose CPU, GPU and FPGA [1, 8, 32]. This paper selects Intel® QAT, a purpose-built ASIC for cryptography and compression, to offload (de)compression tasks and free up CPU resources. The latest high-performance QAT device has been directly integrated into chipsets and is becoming increasingly cheaper [22].

In essence, the offloading of a (de)compression task is to replace the compression-related function call with an I/O call to interact with the underlying QAT accelerator. However, the way the QAT hardware treats data (e.g., physical address and DMA operation) is different from that in the case of software-implemented compression (i.e., using CPU). Runtime translation and optimizations are necessary and important to achieve an efficient offloading. Moreover, considering the offload overhead (e.g., preparation/consumption of QAT requests/responses and PCIe transactions) and the needed preallocated system resources for QAT offloading, not all (de)compression tasks are worth being offloaded into QAT hardware. A well-designed heterogeneous data compression system should investigate the necessity of software/hardware switch or even compression/non-compression switch.

3 System Design

In this paper, based on ZFS file system and Intel® QAT compression accelerator, we propose QZFS (QAT-accelerated ZFS), which can serve as either a local file system or the back-end file system of Lustre (a type of parallel distributed file system). The overall QZFS architecture, including the I/O path of storage and the QAT acceleration subsystem, is illustrated in Figure 3. The modification starts with the ZIO Module of ZFS. The ZIO Module is a centralized I/O process module where all I/O requests are abstracted as ZIOs and forwarded to other modules for further processing, such as data compression and checksum verification. Among the subsequent modules, the ZIO_Compress Module is responsible for data (de)compression. To enable QAT offloading of (de)compression operations, QZFS introduces two new modules: the *Compression Service Engine* and the *QAT Offloading Module*.

To explain the functions of these QZFS modules, the compression workflow is depicted in Figure 3. **(1)-(2)**: The ZIO Module forwards ZIO requests to the ZIO_Compress Module which registers compression algorithms and delivers configuration information to the Compression Service Engine. **(3)**: The Compression Service Engine selects the compression algorithm among one (gzip) accelerated by QAT and others from software compression libraries. **(4)-(5)**: The QAT Offloading Module sends compression requests to the QAT accelerator and consumes QAT responses to fetch compressed result data. **(6)-(8)**: The compressed result data is returned and goes through the upper modules one by one. The data decompression workflow is similar to this compression workflow but does not involve the selection of decompression algorithm.

The main function of the Compression Service Engine is to serve as a selector of diverse compression algorithms. The

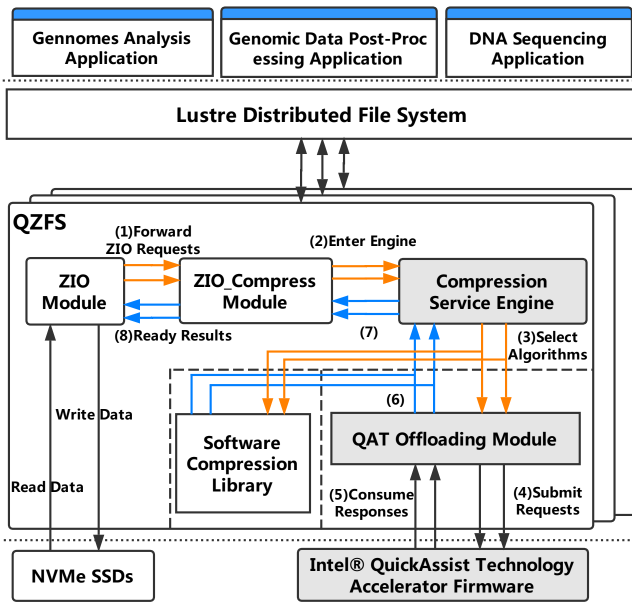

Figure 3: The overall architecture of QZFS

QAT-accelerated gzip is the default algorithm and another four software-implemented compression algorithms, including gzip, LZ4, ZLE and LZJB, are provided. The engine currently selects the compression algorithm according to the configuration set by users. Besides, the Compression Service Engine provides a uniform interface to the upper module. This kind of decoupling makes it able to be easily extended to support other hardware accelerators. Developers only need to focus on the detailed implementation of a new compression scheme and add it to this engine.

The QAT Offloading Module is responsible for offloading data (de)compression operations to the QAT accelerator. The existing source data prepared by the ZIO_Compress Module are suitable for software-based compression schemes. However, they cannot be directly used in the (de)compression requests to the QAT accelerator as data may be mapped into discontiguous physical memory and cannot be accessed through DMA operations of the QAT accelerator. To address this problem, a vectored (a.k.a. scatter/gather) I/O model is introduced to avoid memory copy and ensure that the QAT accelerator can sequentially read source data from multiple flat (i.e., physically contiguous) buffers and organize them to a single data stream for (de)compression, or read (de)compressed result data from a single data stream and organize them to multiple flat buffers.

4 Implementation & Optimization

The implementation of QZFS prototype relies on QAT development APIs and Linux environment (CentOS with Linux Kernel 3.10) and it has been integrated into ZFS official releases [37]. This section introduces detailed features and recent bug fixes of QZFS, especially regarding performance optimizations, to demonstrate the accomplishment of effective compression offloading in QZFS.

4.1 Compression Service Engine

The detailed architecture of the Compression Service Engine is illustrated in Figure 4, which contains a *compressibility checker* and an *algorithm selector*.

4.1.1 Compressibility Dependent Offloading

Compressibility is a performance factor that is determined by data compression ratio to reduce unnecessary offloading operations. Low compressibility means that data are not worth being stored in a compressed format because, in that case, the compressed data will not save much storage space but only incur extra resource consumption for later decompression. Even with the QAT acceleration, the decrease of unnecessary offloading operations is beneficial as QAT resources can be spared for useful (i.e., high compression ratio) tasks, especially in peak hours.

The *compressibility checker* in QZFS uses an auto-rejection method to determine whether to store the data in a compressed format or not. When the checker receives a ZIO request, it has the knowledge of the source data size, denoted by S_{src}, and presets the result data size, denoted by S_{res}, for placing the returned compressed data. Conventionally, S_{res} may be set to the same size as S_{src} when executing compression tasks. In QZFS, the *compressibility checker* uses a default $S_{res} = 0.9 * S_{src}$ for QAT-accelerated gzip algorithm to indicate a compressibility threshold of 10%. If the compressed result data overflows the buffer of S_{res}, it is automatically rejected and the uncompressed source data is returned to the ZIO_Comress Module as the result. Compared to the original compressibility threshold (i.e., 12.5%) in ZFS, QZFS actually relaxes the restriction as the decompression operation can be performed more efficiently by the QAT accelerator. Users can further adjust this compressibility threshold to maximize space efficiency, depending on the characteristics of workloads and hardware conditions. For data decompression, the compressibility checking is not necessary and the S_{res} is set to the size of original uncompressed data, which is recorded by QZFS during compression processing.

4.1.2 Selective Offloading by Source Data Size

The source data size (i.e., S_{src}) is an important factor that may have an influence on system performance. ZFS has a parameter named *record size* which defines the maximum size of a block that may be compressed and written by ZFS. A storage I/O operation with data size smaller than the record size may be packed into one ZIO request for processing. That's to say,

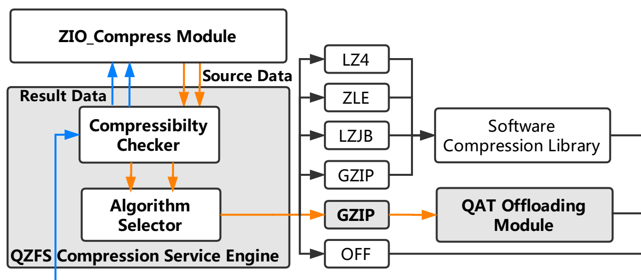

Figure 4: Architecture of compression service engine

S_{src} is variable within the upper limit defined by the record size. ZFS uses a default record size value of 128KB, which achieves a good performance in most cases, and users may modify this parameter to obtain better performance in their own scenarios.

QZFS selectively offloads ZIO requests with S_{src} from 4KB to 1MB and uses software alternatives to process other ZIO requests. For small source data (i.e., $S_{src} < 4\text{KB}$), the offload overhead, including preparation/consumption of QAT requests/responses and PCIe communication, offsets most of the benefit of QAT accelerating, so the software-based compression is a better choice. The QAT support for big source data (i.e., $S_{src} > 1\text{MB}$) requires a large kernel memory preallocated to work as intermediate buffers. This memory size is several times the product of the maximum S_{src} and the number of allocated (typically tens of) QAT instances. Moreover, for a fixed number of worker threads in ZFS that synchronously offload (de)compression operations to QAT, the use of bigger source data cannot give obviously higher performance. Therefore, QZFS only preallocates a kernel memory region that can support a maximum S_{src} of 1MB to achieve both good performance and acceptable consumption of kennel memory resources.

4.1.3 Applicability and Availability

The *algorithm selector* is implemented as a centralized scheduler of data compression algorithms. Algorithms are organized in a scalable algorithm vector that can easily be extended to incorporate other algorithms, either software-based or hardware-assisted ones. Developers only need to focus on the detailed implementation of a new compression scheme, add it to this the algorithm vector and update the configuration as needed. When runtime error occurs in some hardware accelerator, the algorithm selector can seamlessly switch to other software alternatives to provide fault tolerance and high availability.

Currently, the selection of compression algorithm mainly relies the the configuration, which defines the priorities of different algorithms, with the QAT-accelerated gzip as the default one. If in future, a number of hardware-assisted compression algorithms with their own features are incorporated into the Compression Service Engine, an intelligent selection (e.g., use the hints from upper layers) is a good optimization to reap the strengths of different compression schemes.

4.2 QAT Offloading Module

4.2.1 Vectored I/O Model

The QAT accelerator accesses data blocks through DMA operations, which require the data to be stored in contiguous physical memory. The original source and result data of a ZIO request are stored using virtual memory pointed by two pointers P_{src} and P_{res}. The vectored I/O model can effectively bunch together the discontinuous memory to form I/O transactions for DMA operations. As illustrated in the left part of Figure 5, we employ two buffer structures, *flat buffer* and *scatter/gather buffer list* (SGL), to implement the vectored I/O model.

The flat buffer consists of two parts: a data buffer length, denoted by *DataLenInByte* and a pointer, *pData*, to the data buffer owning contiguous physical memory. SGL is introduced to organize multiple flat buffers in a vector manner and consists of four parts: (1)*numBuffers*, the number of flat buffers in this list; (2)*pBuffers*, a pointer to an unbounded array containing multiple flat buffers; (3) *pUserData*, an opaque field; (4)*pPrivateMetaData*, private representation of this buffer list. In summary, SGL describes a collection of flat buffers, each of which is physically contiguous. The QAT accelerator can parse the SGL structure to obtain the beginning physical address of each flat buffer and sequentially access each data block through DMA operations.

4.2.2 Data Reconstruction and Memory Zero Copy

A simple approach for data reconstruction is to allocate enough contiguous physical memory and copy data from/to this memory. Specifically, before the (de)compression offloading, a region of contiguous physical memory is allocated to store data copied from P_{src} and delivered in the request to QAT. Also, another region of contiguous physical memory is allocated to store the response (i.e., result data) from QAT. After the completion of (de)compression offloading, the result data is copied from the contiguous physical memory to P_{res} prepared by ZIO.

Although the allocated contiguous physical memory can be reused by multiple ZIO requests, this approach inevitably introduces the overhead of memory copy, which likely become a bottleneck in today's high speed I/O. Therefore, we introduce the vectored I/O model, along with virtual address translation and memory mapping, to achieve memory zero copy. As shown in Figure 5, the QAT Offloading Module translates the virtual addresses of the source data prepared by ZIO into physical addresses and organizes the physical contiguous data blocks into the Input SGL structure.

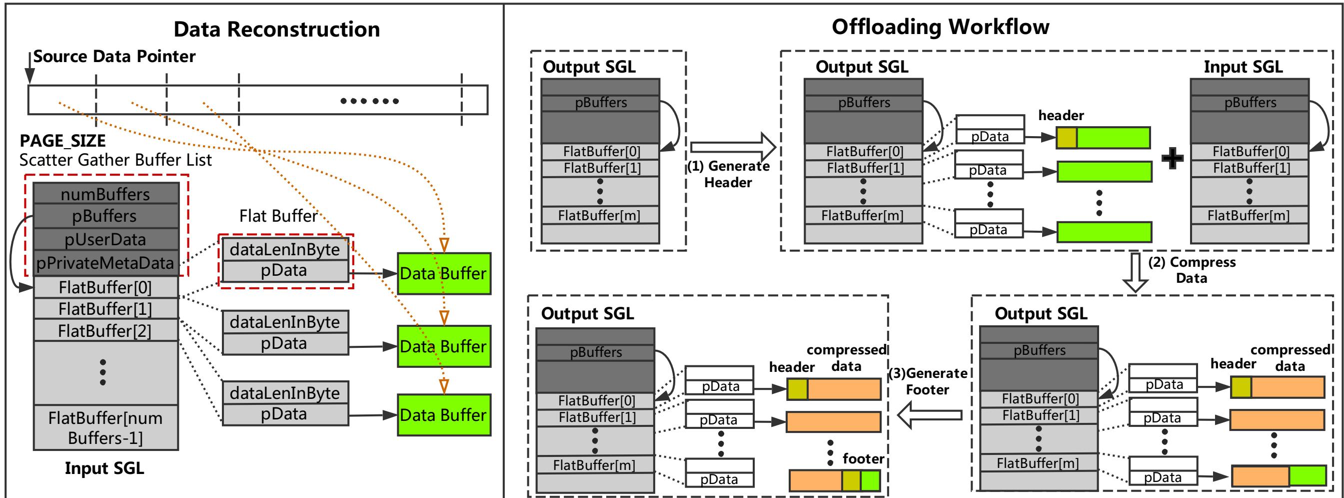

Figure 5: Data reconstruction and QAT offloading workflow in the QAT Offloading Module

A physical page (a.k.a. page frame) is the smallest fixed-length contiguous block of physical memory into which virtual pages are mapped by the operating system. The source data represented by contiguous virtual addresses could be divided into physical contiguous data blocks in terms of physical pages. The QAT Offloading Module directly maps these physical pages to serve as the data of the flat buffers and each flat buffer maps at most one *PAGE_SIZE* data. Note that the start and end virtual addresses of the source data may not be page-aligned, which has an influence on the number of involved physical pages. For example, in the case of 4KB PAGE_SIZE, a 11KB source data may correspond to four physical pages (2KB+4KB+4KB+1KB), instead of three ones. This information is important for the creation of the data structures of Input/Output SGLs. The memory allocation for the Input SGL data structure is performed according to the maximum possible number of flat buffers: $numBuffers = (S_{src} >> \text{PAGE_SHIFT}) + 2$.

The details of the data reconstruction for source data (i.e., building Input SGL) are as follows and the process for the result data buffer to build Output SGL is similar. At first, the virtual address indicated by the P_{src} pointer (pointing to the start address of the source data initially) is translated to obtain the corresponding physical page structure. Note that the virtual address may come from different kernel memory zones, including the *vmalloc region* or the *direct memory region*. The QAT Offloading Module checks whether the a virtual address belongs to the vmalloc region by invoking the *is_vmalloc_addr* function. If so, the *vmalloc_to_page* function is used to get the corresponding physical page structure; otherwise, the *virt_to_page* function is used to obtain the right page. Next, the QAT Offloading Module employs the *kmap* function to establish a long-lasting mapping from kernel's address space to the obtained physical page. The *pData* field of the first flat buffer points to the returned mapped address, plus the same page offset as the P_{src} value. The *dataLenInBytes* field is accordingly set by considering the page offset. Finally, the P_{src} pointer moves to the beginning of the remaining untreated source data and the above steps are repeated to fill subsequent flat buffers. For the last piece of the source data that may correspond to only part of a physical page, the *dataLenInBytes* field is set to the actual size of this last piece. After the completion of an offloading task, the *kunmap* function needs to be invoked to release long-lasting mappings.

4.2.3 QAT Offloading Organization

Overflow avoidance and load balancing: When QZFS boots up, the QAT Offloading Module initializes the QAT logical instances to set up communication channels for requests/responses to/from the QAT accelerator. Thus, a region of contiguous physical memory needs to be allocated for the QAT instance which includes an *intermediate buffer* to place run-time process data (e.g., dynamic Huffman encoding) of the QAT accelerator. The size of the intermediate buffer should be enough for the maximally allowed source data (i.e., 1MB). Data compression is supposed to reduce data size but compression algorithms may cause data expansion at some moment during compression. To avoid the buffer overflow, its size is enlarged to be double of the maximally allowed data size. Besides, when too many data compression tasks are offloaded, the module may not obtain the QAT logical instances because there are not enough QAT computing resources. Therefore, the module will balance the system's computational resources by sending the task to software alternatives and employing the CPU to finish it.

Fail recovery: A QAT compression session describes the compression parameters to be applied across a number of requests. After the initialization of logical instances and source/result data reconstruction, the module sets up the com-

munication with the QAT accelerator by QAT compression sessions. Occasionally, the error may occur in these compression sessions, such as a driver process crash where a wrong DMA address passed to the accelerator. If a failure on the QAT accelerator cannot be handled correctly, the QAT device may be restarted for recovery. In this situation, the QAT Offloading Module cleans all sessions and sets an availability flag as FALSE to disable all QAT offloading actions until the completion of re-initialization. The related internal data structures, QAT logical instances and intermediate buffers will be reset as well.

Offloading workflow: The data compression offloading operations are organized as three steps shown in the right part of Fig. 5. **First**, a header generator API function is called to produce the gzip style header[1], which requires the output SGL as the parameter. The header is added to the front of the output SGL, and the *pData* of the flat buffer is moved to the corresponding offset of the gzip header. **Second**, the data compression API function submits input and output SGLs to the QAT accelerator that consumes the source data from the input SGL and generates processed result data to the output SGL. Note that the QAT accelerator uses the interrupt mode for response processing which requires the module to use the *wait_for_completion_interruptible_timeout* function to wait the completion of the tasks. **Third**, a gzip compliant footer[2] is produced by the footer generator API function. More details of the header and footer formats are given in RFC 1952 [13], which are supported by the QAT accelerator. The difference with data decompression is that it invokes the data decompression API function for three steps.

5 Evaluation

In this section, we first describe the evaluation platform and testing methodology. Then we use FIO micro-benchmark and scientific big data processing workloads to evaluate our implemented QZFS prototype on cluster servers.

5.1 Evaluation Methodology

Experimental testbed: We established an experimental testbed with four physical servers, each of which was equipped with two 22-core Intel® Xeon® E5-2699 v4 processors, 128GB RAM, one NVMe SSD array and one Intel® DH8950 PCIe QAT card [21]. The NVMe SSD array was comprised of three 1.6TB Intel® P3700 Series NVNe SSDs. In each server, a separate SATA SSD was used for housing the operating system (CentOS 7.2) with Linux Kernel 3.10 and QZFS. All these servers were connected via Intel® XL710 40GbE NICs and a 100GbE switch. The detailed topology is illustrated in Figure 6.

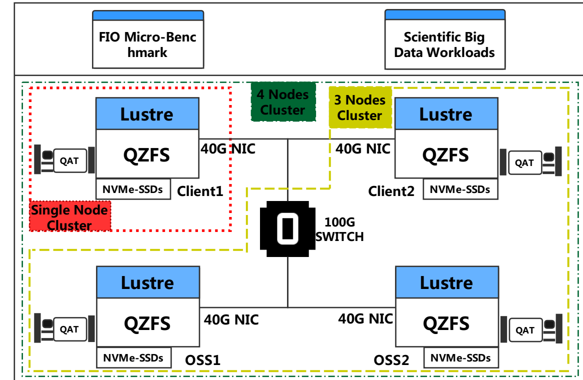

Figure 6: Topology of experimental testbed

Cluster: QZFS was deployed as the back-end file system of Lustre distributed file system. To evaluate different Lustre scenarios, three types of cluster settings were used: (1) all-in-one *single-node cluster*, i.e., a single physical server as both the client and the Object Storage Server (OSS); (2) *three-node cluster* with one physical server as the client and the other two physical servers as OSSes; (3) *four-node cluster* with one more physical server as a client (on the basis of the three-node cluster). All the servers in a cluster shared the same Lustre distributed file system. The client server ran benchmark workloads locally and read/wrote data from/to one or two OSSes.

Note that Lustre inherently provides the ability to support a large number of clients. In our in-lab evaluation, the number of available clients was limited. As a workaround, we leveraged high-performance physical servers along with high-speed NICs to work as *heavy* clients and produce enough stress. In the following experiments, we will show that the total stress is equivalent to tens to hundreds of ordinary clients. The I/O stress from an ordinary client depends on a lot of factors, including workload characteristics, client hardware limits (e.g., NIC limit), the interconnection between Luster clients and OSSes, etc. We assume that each ordinary client generates an I/O stress between 100Mbps and 1Gbps.

Performance metrics: We mainly compared three configurations: (1) *OFF*: QZFS without data compression; (2) *GZIP*: QZFS with software-implemented gzip algorithm enabled; (3) *QAT*: QZFS with QAT-accelerated gzip algorithm enabled. Other algorithms in the software compression library including LZ4, ZLE and LZJB may also be measured for comparison. The following important metrics were collected as performance indicators: read/write *throughput* of micro-benchmarks, average *execution time* of completing big data analytic tasks, *compression ratio* for indicating space efficiency and *CPU utilization* (collected using Intel® Performance Analysis Tool [23]) for indicating computing resource

[1] a gzip header indicates metadata including compression ID, file flags, timestamp, compression flags and operating system ID.

[2] a gzip footer containing a CRC-32 checksum and the length information of the original uncompressed data.

consumption.

Particularly, we define a new comprehensive metric to measure the *cost-efficiency* of the entire system, which equals compression ratio divided by CPU utilization (i.e., computing resource consumption):

$$\frac{compression_ratio}{cpu_utilization}$$

CPU and high-performance storage devices account for a large proportion of TCO. This metric reflects a combined benefit of saved storage space and saved CPU resources, and a higher value means more cost-efficiency gains. Note that we do not consider QAT cost in this metric because QAT device is becoming increasingly cheaper. The latest high-performance QAT, directly integrated into chipsets, only costs about $32 (comparing $132 for C625 chipset with QAT and $100 for C624 chipset without QAT) [22], which is negligible in comparison to CPU price.

5.2 Evaluation Benchmark

Micro-benchmark workloads: FIO (Flexible I/O tester) [5] is a productive tool in Linux that can simulate all kinds of I/O workloads and accurately measure I/O performance. We used FIO to spawn several threads or processes for measuring read/write throughput. The default FIO setting for random data generation and management were employed. More specifically, a buffer of random data (actually pseudo-random) was created at the beginning and it was used continuously during the test to reduce overhead. To comprehensively evaluate QZFS, we conducted the FIO experiments with different I/O patterns, block sizes (i.e, the size of chunks for issuing read/write I/O) and compression algorithms.

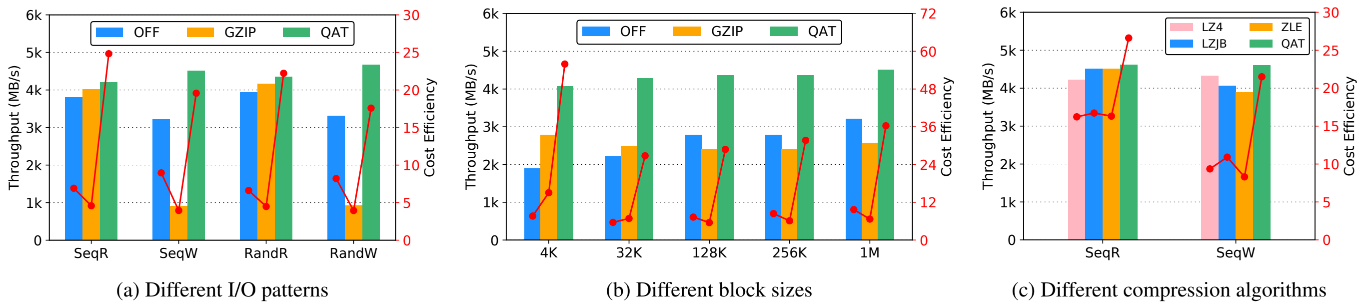
Scientific big data workloads: Genomic data post-processing is a representative workload of scientific big data. The original 3TB genomic dataset used in this experiment are available in European Nucleotide Archive [29] and International Genome Sample Resource [11]. These data are stored as specific formats, such as FastQ, BAM and SAM, which are widely used in both industry and academia. For each client, two genomic data post-processing tools, SAMTools (v1.3.1) with htslib (1.3.2) [30] and Biobambam2 (v2.0.82) with libmaus (2 2.0.435) [47], were used to work as computing workloads. Specifically, we selected five representative operations from these two tools to evaluate the advantage of QZFS. *Converting* is to convert one kind of genomic data to other kind (e.g. FastQ format converted to BAM format in this evaluation), which involves heavy CPU-bound tasks. *Viewing* is to print all alignments information in the specified input file to standard output in SAM format (with no header). *Sorting* is to sort these data by leftmost coordinates and create temporary BAM files as needed when the entire alignment data cannot fit into memory. *Merging* is to merge multiple sorted files, producing a single sorted output file that contains all the input records and maintains the existing sorting order. *Indexing* is to index a coordinate-sorted BAM or CRAM file for fast random access.

5.3 FIO Micro-benchmark

The experiments were conducted in the four-node cluster where 16 FIO threads were created in each Lustre client to read/write job files independently from/to the two Lustre OSSes. The total size of file I/O for each FIO thread is 2GB. The read/write throughput stated in the evaluation is the sum value collected from two clients and the CPU utilization is the average value collected from Lustre OSSes.

Figure 7a shows experimental results for diverse I/O patterns with a fixed 128KB FIO block size, including sequential read/write (SeqR/SeqW) and random read/write (RandR/RandW). In the compression OFF configuration, the average read throughput (i.e., the average value of SeqR and RandR) is 18% higher than the average write throughput, and RandR achieves up to 3937 MB/s throughput, which is the highest. These results are in accordance with the hardware characteristics of NVMe SSDs [17]. The average read throughput in the GZIP configuration outperforms the average write throughput by about 4.5x because the gzip algorithm has an asymmetric compression/decompression speed, with the former lagging much behind the latter [1]. After enabling the QAT accelerator, the average read throughput is similar with the average write throughput. In general, the QAT configuration has the highest read/write throughput and cost-efficiency. The GZIP configuration has a similar compression ratio with the QAT configuration (3.78:3.65), but its high CPU resource consumption (i.e., long compression time) causes not only low write throughput but also low cost-efficiency. The QAT offloading for gzip compression operations achieves about 5x improvement on average write throughput and enhances the cost-efficiency by a factor of more than four. In comparison to the OFF configuration, the QAT configuration also provides a throughput improvement (10% for read and 28% for write) as the compressed data reduces storage I/O cost. Meanwhile, the cost-efficiency is enhanced by a factor of more than three due to the high compression ratio (3.65).

Figure 7b shows the I/O throughput and cost-efficiency with the same amount of sequential read and write operations (SeqR:SeqW = 1:1) while varying the FIO block size in each I/O request from 4KB to 1MB. Note that the record size (128KB by default) in ZFS only defines the maximum size of a block that may be compressed and written by ZFS. As a result, a FIO block may be directly compressed/written by ZFS or multiple FIO blocks may be combined into a whole block for processing. For the compression OFF configuration which can directly benefit from the high-performance NVMe SSDs, the I/O throughput gradually grows from 1899MB/s to 3213MB/s (about 70% improvement) as the increase of FIO block size. For the GZIP and QAT configurations, the



(a) Different I/O patterns (b) Different block sizes (c) Different compression algorithms

Figure 7: The read/write throughput and cost-efficiency on FIO micro-benchmark

varying of FIO block size does not show obvious influence on I/O throughput. Still, the QAT configuration always has the highest I/O throughput and cost-efficiency. A notable phenomenon is that for the case of 4KB FIO block size with software or QAT-accelerated gzip in ZFS, the cost efficiency (actually compression ratio) is obviously higher than other cases with bigger FIO block sizes. This may be a joint result of the record size mechanism in ZFS and the reuse of random data in FIO. Specifically, multiple small (i.e., 4KB) FIO blocks may have a higher probability of being combined into a whole block in ZFS for compression. Then, the possible reuse of random data across these FIO blocks leads to a high compression ratio for the whole block.

Figure 7c compares the QAT-accelerated gzip with other software-implemented fast compression algorithms including LZE, LZJB and ZLE. The QAT configuration gains an average of 12.71% throughput improvement with SeqW and an average of 4.83% throughput improvement with SeqR, compared to these software-implemented algorithms. Also, QAT-accelerated gzip in ZFS provides an average of 2.25x and 1.62x cost-efficiency for SeqW and SeqR respectively. This performance advantage comes from the high compression ratio of the gzip algorithm and the offloading of gzip (de)compression operations. In addition, we can see that SeqR operations show an obviously higher cost-efficiency than SeqW operations. This is because decompression typically costs less computing resources in comparison to compression.

Finally, we give a calculation about how many ordinary clients the total stress in FIO experiments is equivalent to. As shown in Figure 7, the average stress from the two heavy client servers is more than 4000MB/s in the QAT configuration, which equals the stress from 32 to 320 ordinary clients (100Mbps to 1Gbps each).

5.4 Scientific Big Data Evaluation

The scientific workloads running on Luster clients interact with the Luster OSSes to access the stored scientific data. We used two different deployment modes for evaluation: shared

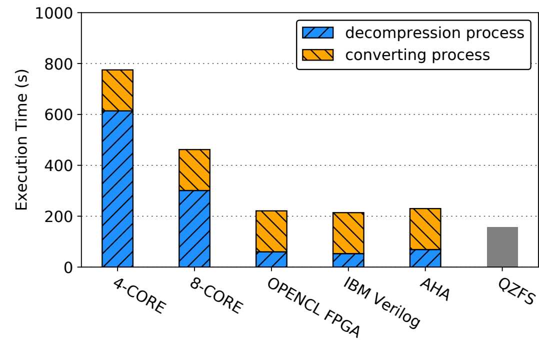


Figure 8: Execution time of a complete converting operation under different data compression schemes

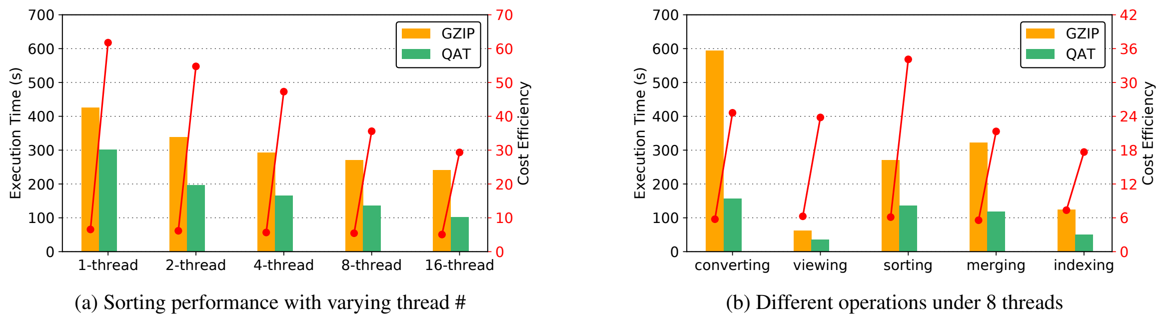
deployment mode (i.e., single-node cluster) and separate deployment mode (including three-node and four-node clusters).

5.4.1 Shared Deployment Mode

Eight scientific workload processes ran in parallel in the shared server. Each workload process was set to read/write 9.5GB data and a total of 76GB data may be processed simultaneously in memory.

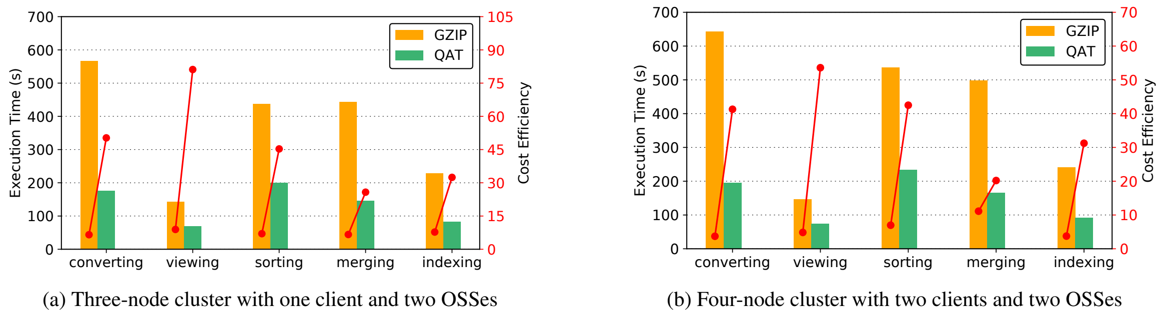
We first validated the benefits of QAT-accelerated gzip compression at the file system layer over *simple* gzip use at the application layer (i.e., the compressed big data needs to be first decompressed into storage and then read again for processing). The experiment results are shown in Figure 8. For the first five configurations, the execution time of a complete converting operation consists of two parts: (1) decompression process time with given computing resources (e.g., 4 cores or AHA accelerator), which includes the time for reading the compressed data from storage, the time for decompression and the time for writing the uncompressed data into storage; (2) converting process time using eight scientific workload processes, which includes the time for reading uncompressed data from storage (76GB totally), the time for converting operations and the time for writing new format data back to storage.



(a) Sorting performance with varying thread #

(b) Different operations under 8 threads

Figure 9: The execution time and cost-efficiency on shared mode deployment (single-node cluster)



(a) Three-node cluster with one client and two OSSes

(b) Four-node cluster with two clients and two OSSes

Figure 10: The execution time and cost-efficiency on separate mode deployment

The first five configurations share a same converting process time of 161.12s. The decompression process time of OpenCL FPGA, IBM Verilog and AHA is calculated according to the performance results reported in [1]. These accelerators show an obvious advantage on decompression compared to the 4 or 8 CPU cores. QZFS keeps data compression transparent to scientific workloads and obtains the shortest execution time (156.71s). This value is even smaller than the above pure converting process time without (de)compression (161.12s) because QZFS directly reads compressed data from storage, performs decompression and converting simultaneously and then writes compressed data back to storage. Since the reading/writing of compressed data largely reduces storage I/O cost and (de)compression is offloaded to QAT accelerator, a higher performance (i.e., shorter execution time) is achieved.

It is true that an application may integrate (de)compression module that can efficiently process compressed big data (e.g., small block based (de)compression and multiple threads), along with the enabling of QAT acceleration, to achieve similar performance to QZFS. However, this likely involves heavy modifications for each new application. In comparison, one-time modification to the file system (i.e., the proposed QZFS) can transparently benefit all applications running on it.

Figure 9a shows the execution time and cost-efficiency with varying number of threads in each scientific workload process performing sorting operations. When there is only one thread in each workload process, the software gzip configuration gives an execution time of 426s and a cost-efficiency value of 6.6. The QAT configuration provides a 30% reduction of execution time and enhances the cost-efficiency by a factor of nearly 10 due to the faster (de)compression and largely reduced CPU resource consumption. As the thread number increases from 1 to 16, the execution time decreases gradually for both GZIP and QAT configurations. In the case of 16 threads in each workload process, the performance advantage of QAT-accelerated gzip grows from 30% to 60% as more threads produce more parallel I/O requests and increases the utilization of underlying QAT accelerators. This further leads to a growing of CPU utilization for sorting from 5.8% to 12.2% in the QAT configuration. In comparison, the CPU utilization in the GZIP configuration grows from 64% to 83%.

Figure 9b evaluates the post-processing scientific workloads performing different operations with a fixed eight threads in each workload process. All the five types of operations need to read the genomic data from storage and the operations excluding viewing further needs to write the newly-generated data (smaller or bigger) back to storage. We can see that the QAT configuration achieves 73% and 63% reduction of execution time for the converting and merging operations respectively over the GZIP configuration. For other opera-

tions, the QAT-accelerated gzip in ZFS can provide about 2x performance enhancement. On average, the QAT configuration brings a 3.91x cost-efficiency improvement over the software-implemented gzip. Especially, the cost-efficiency enhancement is up to 5.57x for the sorting operation because it is a complicated operation that creates many intermediate data files and repeatedly involves reading (decompression) and writing (compression) actions.

The total stress from the one heavy client (eight threads in each workload process) is up to 75GB/35s=2143MB/s (the viewing operation), which equals the stress from 17 to 171 ordinary clients (100Mbps to 1Gbps each).

5.4.2 Separate Deployment Mode

We first evaluated QZFS with one client that remotely accesses two OSSes and then increased the client number to two. In each client sever, eight scientific workload processes ran in parallel and each workload process with a fixed eight threads was set to read/write 9.5GB data.

In the three-node cluster with different operations, as shown in Figure 10a, the QAT configuration on average reduces 63.10% execution time and achieves more than 6x cost-efficiency compared with the QAT configuration. Like the shared deployment mode, the QAT-accelerated gzip in ZFS still shows a high performance enhancement (68.95% reduction of the execution time) for the converting operation. A notable phenomenon is that the biggest cost-efficiency enhancement (9.11x) is witnessed on the viewing operation because it does not need to write data back to the remote storage (i.e., reduced CPU resource consumption on the costly network stack).

For the case of four-node cluster with double stress from two heavy clients, as shown in Figure 10b, the overall performance results are similar to the case of three-node cluster. In comparison to the software-implemented gzip in ZFS, the QAT acceleration on average provides a 63.14% reduction of execution time and a 6.26x improvement of cost-efficiency. It demonstrates that QZFS has a good scalability to provide stable and effective compression services as the scaling of clients. The total stress from the two heavy clients is up to 150GB/75s=2000MB/s (the viewing operation), which equals the stress from 16 to 160 ordinary clients (100Mbps to 1Gbps each).

6 Bottleneck Analysis

This section analyzes the performance bottleneck in QZFS. We use the experiment result of RandW in Figure 7a for analysis, which shows the highest I/O throughput (4680MB/s) for the QAT configuration. In this case, the average CPU utilization in the two OSSes is 20.2%, which means CPU resources are still abundant. The compression ratio is 3.55 and the actual NVMe SSD I/O throughput is 4680/3.55 = 1318MB/s, which means the NVMe SSD is not the bottleneck as the compression OFF configuration can achieve a storage I/O throughput of 3314MB/s. The network throughput for each physical server is about 4680/2 = 2340MB/s = 18.72Gpbs, which is only half of the hardware limit of 40GbE NIC. The QAT compression throughput in each Lustre OSS is also about 18.72Gpbs, which reaches nearly 80% of the hardware limit (24Gpbs [21]) of a DH8950 QAT card. In summary, the I/O throughput (4680MB/s) does not achieve the hardware limit of the testbed system while this throughput cannot be further enhanced even if we launch more FIO threads in clients to generate more RandW jobs in parallel.

Actually, the main performance bottleneck may reside in the ZFS software stack. Although ZFS is designed to automatically leverage multi-core resources, the number of ZFS worker threads that can offload (de)compression operations to QAT is restricted by: the number of CPU cores and the number of available QAT instances. What's more, the worker thread interacts with QAT in a synchronous mode, which means the worker cannot submit the next (de)compression request until the completion and consumption of the first one. As a result, the use of more FIO threads at the application layer cannot give rise to more concurrent/parallel (de)compression requests sent to QAT.

An approach to overcome this bottleneck is to optimize the way the worker thread interacts with QAT to increase the utilization of the underlying QAT accelerator. QAT provides an inherently non-blocking interface with the request/response mechanism. If we can enable asynchronous offload mode in ZFS, a single worker thread then has the ability to concurrently offload multiple (de)compression operations to QAT and the QAT hardware limit can be easily reached with only several threads. However, the enabling of asynchronous offload mode is a hard work, involving the design of (1) asynchronous support in all layers of ZFS software stack to correctly handle an uncompleted (de)compression block and (2) efficient pause (context saving) and resumption (context restoring) of an offload job. One can refer to our previous work [20] on how to enable high-performance asynchronous crypto offload framework for TLS servers/terminators.

7 Related Work

Hardware-assisted data compression techniques has been well studied in the literature by using general-purpose accelerators. Patel *et al.* proposed a parallel algorithm and implemented a bzip2-like lossless data compression scheme on GPU architecture [39]. Their implementation enabled the GPU to become a co-processor of data compression, which lightened the computing burden of CPU by using idle GPU cycles. Ozsoy *et al.* [38] presented a pipelined parallel LZSS compression algorithm for GUGPU. Li *et al.* proposed an efficient, scalable GPU-accelerated OLAP system which tackled the bandwidth discrepancy using compression and an optimized

data transfer path [31]. Abdelfattah *et al.* utilized the Open Computing Language to implement high-speed gzip compression on an FPGA, which achieved higher throughput over standard compression benchmark, with equivalent compression ratio [1]. Kim *et al.* presented high throughput Xpress FPGA compressor to achieve CPU resource saving and high power efficiency [26]. Fowers *et al.* detailed a scalable fully pipelined FPGA accelerator that performs LZ77 compression and static Huffman encoding at rates up to 5.6 GB/s [15]. Pekhimenko *et al.* employed FPGA and GPU accelerators to implement Base-Delta encoding data compression algorithms in stream processing [40]. In comparison, our QZFS leverages the emerging ASIC accelerator for compression offloading and integrates it into the layer of file system to provide transparent, high-performance and cost-efficient compression service.

8 Conclusions

High storage I/O performance and low Total Cost of Ownership (TCO) are two important optimization objectives, which are hard to be obtained at the same time. Data compression is considered as an effective solution, but the compression tasks incur high computing resource consumption and likely impact the running of application workloads. Instead of directly accelerating compression tasks in applications, this paper investigated the data compression offloading at the file system level. QZFS (QAT accelerated ZFS) was proposed to integrate Intel® QAT accelerator into ZFS file system to provide application-agnostic and cost-efficient data storage. The evaluation has validated that QZFS can effectively save CPU resources and further enhance the performance of big data processing workloads in comparison with the software-implemented gzip in ZFS or traditional gzip acceleration for applications.

Abstract

Optimizing scheduling and communication of distributed data processing for resource and data characteristics is crucial for achieving high performance. Existing approaches to such optimizations largely fall into two categories. First, distributed runtimes provide low-level policy interfaces to apply the optimizations, but do not ensure the maintenance of correct application semantics and thus often require significant effort to use. Second, policy interfaces that extend a high-level application programming model ensure correctness, but do not provide sufficient fine control.

We describe Apache Nemo, an optimization framework for distributed dataflow processing that provides fine control for high performance, and also ensures correctness for ease of use. We combine several techniques to achieve this, including an intermediate representation, optimization passes, and runtime extensions. Our evaluation results show that Nemo enables composable and reusable optimizations that bring performance improvements on par with existing specialized runtimes tailored for a specific deployment scenario.

1 Introduction

It is becoming increasingly important to optimize scheduling and communication for different characteristics of resources and data in distributed data processing. Examples of such characteristics widely discussed in recent literature are geographically-distributed resources [19, 33, 44, 45], cheap transient resources [37, 38, 42, 47, 48], disk-based large data shuffle [35, 36, 51], and skewed data [22, 24, 25, 34]. Researchers have shown that the existing scheduling and communication methods, unaware of these characteristics, often suffer from substantial performance degradation.

Distributed runtimes such as Dryad [20], Tez [40], and the Spark runtime [4] provide low-level interfaces to plug in computation scheduler and data channel policies to optimize for such diverse deployment scenarios. These policy interfaces have direct access to control messages and data elements, and can apply optimizations such as placing computations on specific types of resources and performing in-memory data shuffle. Unfortunately, runtime policy developers must exercise care to ensure that the policies they build and apply maintain correct application semantics. The main reason is that runtime interfaces are designed to be general, and allow

*Corresponding author.

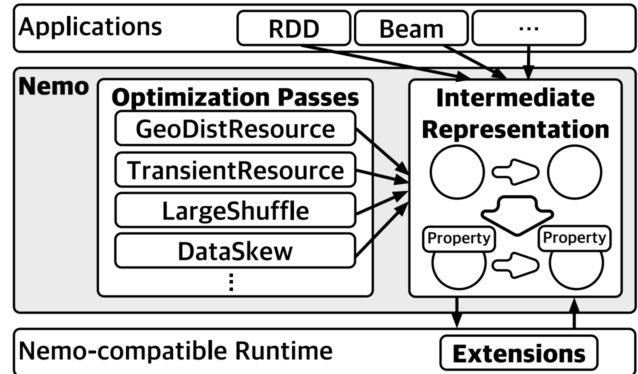

Figure 1: Nemo optimizes scheduling and communication of distributed data processing.

for arbitrary modifications to scheduling and communication methods.

On the other hand, policy interfaces integrated with a high-level application programming model offer indirect control over runtime execution. For example, Optimus [22] integrates with the DryadLINQ programming model to enable specifying alternative DryadLINQ subqueries. This ensures correct application semantics as long as the specified subqueries compute the same results, and thus reduces the effort required to build different optimization policies. However, such application-level interfaces do not provide sufficient fine control over distributed scheduling and communication, because application programming models are designed to hide distributed execution from application developers.

To overcome the limitations of existing interfaces, we believe it is critical to introduce a new policy interface that provides both fine control for high performance, and also ensures correct application semantics for ease of use. In this work we take a middle ground between the existing runtime and application-level interfaces. We design a policy interface that transforms an intermediate representation (IR) of applications to express indirect but fine-grained control over distributed scheduling and communication.

There are three main challenges to designing an optimization framework that embodies this middle ground approach. First, the framework should define the IR transformation methods that provide fine control and also ensure correctness. Second, the framework should enable the development of reusable and composable user-defined optimization policies

that transform the IR. Third, the framework should apply the transformations of the IR in the distributed execution of the application.

Figure 1 depicts our Nemo optimization framework that addresses the challenges. Specifically, its IR directed-acyclic graph (DAG), optimization passes, and runtime extensions address the three challenges, respectively. Nemo integrates with high-level application programming model libraries, and compatible distributed runtimes.

First, the Nemo IR DAG represents a data processing application with vertices representing logical operations and edges representing data dependencies. To ensure that the transformed IR DAG produces the same outputs as the original IR DAG, we provide two types of transformation methods: reshaping and annotation. Reshaping methods can insert a set of utility vertices whose semantics are known to Nemo, such as a vertex that samples data. Annotation methods set execution properties of each vertex and edge to configure fine-grained scheduling and communication, such as speculative cloning and data persistence strategies. Nemo ensures correctness using the information about the communication patterns (e.g., shuffle) of edges, and the information about the configured utility vertices and execution properties.

Second, the Nemo optimization pass abstraction enables expressing optimizations as a function that takes as input an IR DAG and calls its transformation methods. Because a pass is a simple function, different combinations of passes can be applied across different applications. We show that optimization techniques previously employed in specialized runtimes, such as Iridium [33] and Pado [48], can be expressed as optimization passes with concise lines of code.

Third, the Nemo runtime extensions integrate with the underlying runtime to apply the IR DAG transformations. Runtimes typically provide a runtime DAG abstraction to run computations on a cluster of machines [4, 20, 40]. Our scheduler extension applies various scheduling policies when scheduling the IR vertices of an IR DAG through a runtime DAG. It also rewrites the runtime DAG during job execution to apply run-time optimizations. Our data channel extension applies the optimized data communication within the runtime DAG.

We have implemented Nemo, and also a distributed runtime that is compatible with Nemo. At present, Nemo provides full support for Beam [1] applications and a subset of Spark RDD [50] applications. Our runtime integrates with REEF [46] to run on Hadoop YARN [2] and Mesos [18] clusters. We have evaluated Nemo in a cluster of Amazon EC2 instances using different optimization passes, datasets, and resource environments. Evaluation results show that each optimization pass brings performance improvements on par with existing specialized runtimes, and combinations of passes further improve performance for scenarios with a combination of different resource and data characteristics. Nemo is currently an Apache Incubator project [3].

```
class TreeAggregate implements ConnectionManager {
 void onUpstreamVertexEvent(event) {
  mapVertexGroups = analyzeLocationsAndSizes(event)
  aggregateVertices = newVertices(mapVertexGroups)
  connect(mapVertexGroups, aggregateVertices)
 }
}

class Repartition implements ConnectionManager {
 void onUpstreamVertexEvent(event) {
  desiredPartitions = analyzeDataStatistics(event)
  modifyPartitionVertices(desiredPartitions)
  modifyReduceVertices(desiredPartitions)
 }
}
```

Figure 2: Pseudocode of Dryad policies. The Dryad policy interface provides fine control over distributed scheduling and communication, but does not ensure correctness.

2 Background

We first discuss in detail the existing runtime policy interfaces and application-level policy interfaces using concrete code examples. Specifically we describe the interfaces of Dryad [20] and Optimus [22].

The Dryad policy interface allows for arbitrary modifications to its directed-acyclic graph (DAG) representation of applications. In a Dryad DAG, a vertex represents a unit of work performed on a machine and an edge represents a data transfer from a vertex to another. For example, a map-reduce application can be represented in Dryad as a number of map vertices fully connected with a number of reduce vertices. The Dryad runtime coordinates the scheduling and communication of the vertices on a cluster of machines.

Figure 2 shows the pseudocode of two example Dryad policies [5]. Here, `ConnectionManager` is a callback-based abstraction that listens to events from the configured upstream vertices. First, `TreeAggregate` builds an aggregation tree with a goal to use network bandwidth resources more efficiently. Suppose `TreeAggregate` listens to the map vertices in a map-reduce application, to obtain the information on the locations and sizes of map vertex outputs. Using the information, `TreeAggregate` groups map vertices, creates intermediate aggregation vertices, and then connects each map vertex group to an aggregation vertex. Second, `Repartition` dynamically distributes data with a goal to handle data skew. Suppose the map-reduce application additionally has bucketizer vertices that consume sample output data from the map vertices, and partition vertices that partition the original map vertex outputs prior to transferring the data to the reduce vertices. Then, `Repartition` can be used to monitor the bucketizer vertices, and modify the partition and reduce vertices with the goal to evenly distribute the map outputs.

```
// Application code
mulA = defineMatMulSubqueryA(matrixX, matrixY)
mulB = defineMatMulSubqueryB(matrixX, matrixY)

// Policy code
stats = collectDataStatistics(matrixX, matrixY)
rewriter.registerAlternatives(stats, mulA, mulB)
```

Figure 3: Pseudocode of an Optimus policy. The application-level Optimus policy interface ensures correctness, but provides coarse-grained control of substituting subqueries.

As shown by these examples, runtime policies can configure various scheduling and communication methods.

However, the flexibility of runtime interfaces comes at a cost: the policy developer must exercise care to ensure application correctness when developing, reusing, and composing different policies [4, 20, 22, 40]. First, the interface allows for a bug in `TreeAggregate` to miss connecting one of the map vertices to an intermediate aggregation vertex, making the optimized DAG produce partial results. Second, `Repartition` can break application semantics when applied on a random vertex in a different DAG that does not use bucketizer and partition vertices. Third, applying both `TreeAggregate` and `Repartition` on the same DAG can lead to conflicting executions that produce incorrect results. Manually building a combined policy can require a significant effort for complex policies, such as the `DrDynamicAggregateManager` in Dryad that consists of 1.3K lines of C++ code [5]. As a consequence, runtime policies have been mostly hard coded in runtimes and data processing application compilers such as the DryadLINQ compiler [22,49], and the Hive compiler [43]. The authors of Optimus also report that their system-level optimization policies are hard-coded in the DryadLINQ compiler, maintaining the DAG property and operator semantics for the pre-defined operators in DryadLINQ [22].

In contrast to runtime interfaces, Optimus provides an application-level policy interface that ensures correctness, by restricting the interface to substituting DryadLINQ subqueries. Figure 3 shows the pseudocode for optimizing a matrix multiplication application described in the original Optimus paper [22]. The code defines two alternative subqueries for multiplying two matrices, and a policy for selecting a subquery to use for the execution. Note that as long as the two subqueries produce the same results, changing the policy code does not alter the semantics of the application. However, as this example shows, such application-level policy interfaces lack fine-grained control over scheduling and communication like selecting the types of resources to run specific computations on. The main reason is that application programming models are designed to hide distributed execution from application developers.

3 System Design

The goal of the Nemo optimization framework is to support fine control over distributed execution of data processing applications, and at the same time maintain correct application semantics. Concretely, given a *DAG* representation of a data processing application with deterministic operations and a user-defined policy P where $DAG' = P(DAG)$, Nemo aims to provide the following properties.

- **Correctness**: Given the same inputs the optimized DAG' should produce the same outputs as the *DAG*, even when P is applied while the *DAG* is being executed. This ensures that the optimizations maintain correct application semantics.
- **Reusability**: The same P should be applicable to different *DAG*s. This enables reusing the same policy across different data processing applications, although the effects may differ between applications.
- **Composability**: If P and P' do not override optimizations specified by the other policy then enable composing different policies like $P'' = (P \circ P')$. If the policies do have a conflict, then automatically detect it for analysis. This enables distinct policies that each optimizes for a different resource or data characteristic to be incorporated into a single policy.

We show how Nemo combines an intermediate representation (IR) DAG, optimization passes, and runtime extensions to ensure these properties. First, the IR DAG provides reshaping and annotation methods for specifying optimizations (Section 3.1). Second, optimization passes define functions that operate on the IR DAG methods (Section 3.2). Third, runtime extensions apply the optimizations in the underlying runtime (Section 3.3).

3.1 Intermediate Representation

The Nemo IR DAG aims to provide the desired *DAG* representation of an application. The main challenge in designing the IR DAG is defining the methods for transforming it. For Nemo to ensure the desired properties, we make explicit both the intention and the effect of the optimization for each method invocation. For example, instead of providing a single method to insert arbitrary computations, we provide multiple higher-level methods such as those specifically for increasing parallelism, speculative cloning, and sampling. We describe the IR DAG reshaping and annotation methods that embody this approach, and in particular how those methods enable ensuring correctness. We then discuss the types of applications and runtimes supported by our IR DAG design.

IR DAG Reshaping: irdag.insert()	$Relay(f : x \to x), e$	:	$V \cup \{v\}, E \setminus \{e\} \cup \{e.comm(e.src \to v), oneToOne(v \to e.dst)\}$
	$Reshuffle(f : x \to x), e$	:	$V \cup \{v\}, E \setminus \{e\} \cup \{e.comm(e.src \to v), shuffle(v \to e.dst)\}$
	$Sampling(f : x \to sv.f(x)), sv, rate$	:	$V \cup \{v\}, E \cup \{e.comm(e.src \to v) \mid e \in E \wedge e.dst = sv\}$
	$Trigger(f : x \to udf(x)), udf, e$	:	$V \cup \{v\}, E \cup \{oneToOne(e.src \to v)\}$
	(V/E = original vertex/edge set, v = inserted vertex, f = function of v, $e.comm$ = oneToOne/shuffle/broadcast)		
IR Vertex Annotation: v.set()	$Parallelism/Integer$	:	sets the number of tasks for executing v
	$SpeculativeCloning/Thresholds$	:	sets the thresholds for determining and cloning straggler tasks
	$ResourceSite/Map(Index, Site)$	:	sets the geographical sites of the resources to place tasks on
	$ResourcePriority/Enum(Transient)$	:	sets the priority of the resources to place tasks on
IR Edge Annotation: e.set()	$DataFlow/Enum(Pull, Push)$	:	$e.dst$ is scheduled after $e.src$ finishes, or scheduled concurrently
	$DataStore/Enum(Memory, Disk)$	:	$e.src$ tasks store output data for e in memory, or disk
	$NumPartitions/Integer$	:	sets the number of partitions that $e.src$ tasks create for e
	$PartitionSets/List(Set(Index))$	:	sets the partitions that each $e.dst$ task fetches for e
	$Persistence/Enum(Keep, Discard)$	:	sets whether to keep or discard data after $e.dst$ processes e

Table 1: Example IR DAG transformation methods for optimizing scheduling and communication. Reshaping methods take as input a utility vertex and additional arguments. Annotation methods take as input a key/value execution property.

3.1.1 Transforming an IR DAG

The Nemo IR DAG represents a data processing application with vertices representing logical operations and edges representing data dependencies. When executed, an IR vertex is translated into parallel tasks that run on multiple nodes. An IR edge can be translated into key-partitioned data blocks that are produced by tasks. The initial IR DAG translated from an application, such as an RDD [50] and Beam [1] application, typically consists of vertices containing functions defined by the application, and edges with the information on communication patterns (one-to-one, shuffle, broadcast).

Table 1 shows example reshaping and annotation methods Nemo provides to transform the IR DAG. The reshaping methods specify a new utility vertex to insert into the IR DAG, and Nemo inserts new edges to connect the specified vertex with the existing vertices in the IR DAG. Table 1 specifies four utility vertices. `Relay` and `Reshuffle` simply apply an identity function to forward data from an upstream vertex to a downstream vertex, connecting with the downstream vertex with the one-to-one and the shuffle dependency, respectively. `Sampling` vertex applies the same function as an existing vertex, and consumes the same data that the existing vertex consumes. During the execution, Nemo schedules only a subset of `Sampling` tasks according to the given sampling rate. `Trigger` vertex applies a user-defined function on intermediate data. When a `Trigger` vertex executes and completes, Nemo collects the results of the user-defined function to generate a message. Nemo then halts the execution of the job, and uses the message to trigger a corresponding run-time optimization pass, which we describe in Section 3.2. The IR DAG also supports deleting the inserted utility vertices.

The annotation methods configure scheduling and communication of vertices and edges by annotating specified execution properties. Table 1 specifies nine execution properties. For scheduling, we have execution properties for deciding how, where, and when to schedule tasks. `Parallelism` and `SpeculativeCloning` configure how many tasks to schedule. `ResourceSite` and `ResourcePriority` specify where to schedule the tasks. `DataFlow` determines whether or not to schedule source and destination tasks concurrently. For communication, we enable configuring the medium to store intermediate data with `DataStore`, the persistence method with `Persistence`, and data partitioning strategies with `NumPartitions` and `PartitionSets`. Combinations of different execution properties can express optimizations that can require significant efforts to implement with runtime policy interfaces. For example, we can configure upfront task cloning with a persistent in-memory data shuffle that pushes data eagerly from transient resources to reserved resources, through simply annotating appropriate `SpeculativeCloning`, `ResourcePriority`, `Persistence`, `DataStore`, and `DataFlow` properties on two vertices and a shuffle edge that connects them. The IR DAG also supports looking up the execution properties annotated on vertices and edges.

3.1.2 Ensuring Correctness

The reshaping methods ensure correctness, because Nemo connects the newly inserted utility vertex with existing vertices correctly. As shown in Table 1, only the outputs of the `Relay` and `Reshuffle` vertices are consumed by existing vertices, and these outputs are equivalent to the data that the existing vertices originally consumed. The other utility vertices, on the other hand, do not reach data sinks and thus do not affect the final results that the IR DAG produces. When a utility vertex is specified to be deleted, Nemo reverts appropriate changes.

The annotation methods ensure correctness through enabling Nemo to examine the configured execution properties. For each vertex in the IR DAG, Nemo checks its execution

properties and the execution properties of its neighboring edges and vertices, while also examining the communication patterns of the edges. This ensure correctness because execution properties do not use and modify computation semantics [17, 21, 52] inside each vertex, and also do not have direct access to control messages and data elements in the runtime. For example, Nemo checks that the sets in the `PartitionSets` are disjoint and together contain all offsets for the `NumPartitions`, to read each partition exactly once. Nemo also checks that `PartitionSets` and `NumPartitions` are set on shuffle edges, and that vertices connected with an one-to-one edge have the same `Parallelism`. `Persistence`, for example, is not checked, because discarded intermediate data can always be recomputed from the source data when needed.

Our transformation methods ensure correctness even when invoked during the execution of the IR DAG. Because the IR DAG is decoupled from the underlying runtime, Nemo ensures correctness by controlling when to apply the transformations of the IR DAG in the runtime. Specifically, we define that a vertex is being executed when its tasks are being executed, and an edge is being executed when its source or destination vertex is being executed. First, if the transformed vertices and edges have not yet been executed, then we apply the changes immediately, such that the changes are used when they are executed. Second, if they are being executed, then we delay applying the changes until they finish execution to ensure correctness. Third, if they have already finished execution, then we apply the changes immediately, such that the changes are used when they are re-executed due to reasons such as faults.

3.1.3 Supported Applications and Runtimes

The current design of the IR DAG supports data processing applications that can be represented as a DAG of data-parallel and deterministic operators that process bounded data. Many real-world applications, such as Beam and RDD batch applications and also higher-level domain-specific applications like machine learning and SQL applications, meet this assumption. The current IR DAG would need to be extended to support other types of applications, such as those that have cyclic dependencies and process unbounded data [31].

The IR DAG assumes an underlying distributed runtime that supports configuring and applying utility vertices and execution properties. Existing runtimes can be enhanced to provide full support for the IR DAG optimizations through introducing additional features. For example, new data channels in addition to the existing ones (FIFO, File, TCP Pipe) can be introduced in Dryad [20] to provide support for various combinations of the `DataStore`, `DataFlow`, and `Persistence` execution properties. Similarly, a feature to dynamically add computations to a running application can be introduced in Tez [40] and the Spark runtime [4] to apply utility vertices inserted at run time.

3.2 Optimization Passes

Nemo optimization passes aim to provide the desired user-defined policy abstraction P. A pass is a function that receives an input IR DAG and produces a transformed IR DAG. We first describe how to develop and compose passes. We then describe how Nemo applies the given passes on the IR DAG.

3.2.1 Developing and Composing Passes

We describe the rationale and the algorithm for several example passes to demonstrate how to develop and compose new passes. We can write two types of passes: compile-time and run-time. Compile-time passes take as input only an IR DAG, and are run prior to job execution. Run-time passes additionally receive a message produced by a `Trigger` vertex during job execution.

Geo-distributed data analytics: We aim to cope with the low and variable capacity of WAN links when processing data that are geographically distributed [19, 33, 44, 45]. To reduce network bottlenecks, we formulate the problem of placing computations to geographically distributed sites as a linear program (LP), similar to specialized scheduler extensions like Iridium [33]. Here, we use bandwidth information and data size estimations. We also use an off-the-shelf linear solver library, since Nemo allows using external libraries when writing a pass. The pseudocode of this algorithm is as follows.

```
CompileTimePass GeoDistPass(irdag):
 solution = solveLP(bwInfo(), sizeEstimates(irdag))
 for v in irdag.vertices:
  v.set(newResourceSite(solution.get(v)))
```

Harnessing transient resources: We aim to reduce recomputation costs when using transient resources that are cheap but frequently evicted [37, 38, 42, 47, 48]. Based on the communication patterns, we identify operations that incur large recomputation costs and place them on reserved resources. We place the other operations on transient resources. We also quickly move intermediate data produced on transient to reserved resources. This applies key scheduling and communication optimizations employed in specialized runtimes like Pado [48]. The pseudocode of this algorithm is as follows.

```
CompileTimePass TransientResourcePass(irdag):
 for v in irdag.vertices.topologicallySorted():
  if (allOneToOneFromReserved(v.inEdges)
   || existsNonOneToOne(v.inEdges)):
   v.set(ResourcePriority.Reserved)
  else:
   v.set(ResourcePriority.Transient)
  for e in v.inEdges:
   if fromTransientToReserved(e.src, v):
    e.set(DataFlow.Push)
```

Large-scale data shuffle: We aim to reduce random disk read overheads that can grow quadratically with data size when shuffling data, similar to specialized shuffle systems

like Sailfish [35] and Riffle [51]. We insert a Relay vertex to specify shuffling data in memory as soon as produced and writing the data as-is to a local disk. We also ensure that the in-memory data are discarded once transferred, to avoid running into out of memory errors. Following computations sequentially read the data from the local disk, after the shuffle completes. The pseudocode of this algorithm is as follows.

```
CompileTimePass LargeShufflePass(irdag):
 for e in irdag.edges.filter(isShuffleEdge()):
  rv = newRelayVertex()
  irdag.insert(rv, e)
  rv.inEdge.set(DataFlow.Push, DataStore.Memory)
  rv.inEdge.set(Persistence.Discard)
  rv.outEdge.set(DataFlow.Pull, DataStore.Disk)
```

Mitigating data skew: We aim to assign the same amount of data across parallel computations to prevent stragglers. We first set the number of partitions for the data to be shuffled. We then insert a Trigger vertex with a function for obtaining the set of data partition sizes. We also ensure that the shuffle receiver is executed after the the shuffle sender and the Trigger vertex complete, at which point we will have obtained the statistics and optimized the execution of the shuffle receiver. The pseudocode of this algorithm is as follows.

```
CompileTimePass SkewCTPass(irdag):
 for e in irdag.edges.filter(isShuffleEdge()):
  e.set(newNumPartitions(e), DataFlow.Pull)
  irdag.insert(newOptVertex(), sizeFunction(), e)
```

At run time, when the Trigger vertex completes and makes available the set of size numbers, we partition the set into subsets such that the sum of the numbers in the subsets are as equal as possible. We then assign each subset to a distinct shuffle receiver task. The pseudocode of this algorithm is as follows.

```
RunTimePass SkewRTPass(irdag, message):
 subsets = partition(message)
 message.edge.set(newPartitionSets(subsets))
```

Finally, we can compose multiple passes to build an optimization policy like the following example. Registering a run-time pass requires specifying a compile-time pass that inserts Trigger vertices, which produce the same type of message the run-time pass uses.

```
policyBuilder.register(LargeShufflePass)
policyBuilder.register(SkewRTPass, SkewCTPass)
policy = policyBuilder.build()
```

3.2.2 Applying Passes

Given an IR DAG and a policy composed of passes, Nemo first applies the compile-time passes on the IR DAG in the same order as they were registered. The optimized IR DAG output by the last compile-time pass is executed. As the execution progresses, each Trigger vertex completes execution and produces a message. For each message, Nemo runs the corresponding run-time pass to transform the IR DAG. Nemo runs the passes for different messages serially.

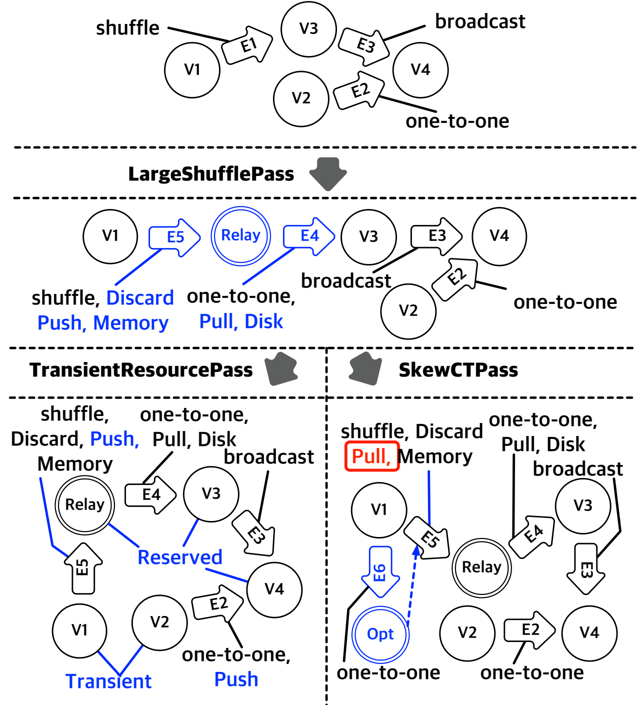

Figure 4: A policy composed of the LargeShufflePass and the TransientResourcePass, and another policy composed of the LargeShufflePass and the SkewCompileTimePass are applied on an input IR DAG.

After applying each pass, Nemo checks whether the IR DAG produced by the pass is correct as described in Section 3.1.2, and also whether the pass has encountered a conflict with a previous pass. A conflict occurs when a pass overwrites the value of an execution property set by a previous pass to a different value, or deletes a utility vertex inserted by a previous pass. Nemo throws an error and refuses to execute in case of a check failure after running a compile-time pass. Upon a check failure of a run-time pass, Nemo just ignores the IR DAG output by the pass and logs the failure, as stopping an already running application can be costly.

Figure 4 shows how Nemo runs two example policies. Both policies first apply the LargeShufflePass, which inserts a Relay vertex between V1 and V3, and annotates E5 and E4. The first policy then applies the TransientResourcePass, which performs annotations without any conflict with the previous pass. The second policy applies the SkewCTPass, which inserts a Trigger vertex, and tries to annotate E5 with the pull DataFlow. However, the SkewCTPass encounters a conflict as the push DataFlow has already been set for E5 by the previous LargeShufflePass.

Fundamentally, the conflict in the second policy occurs

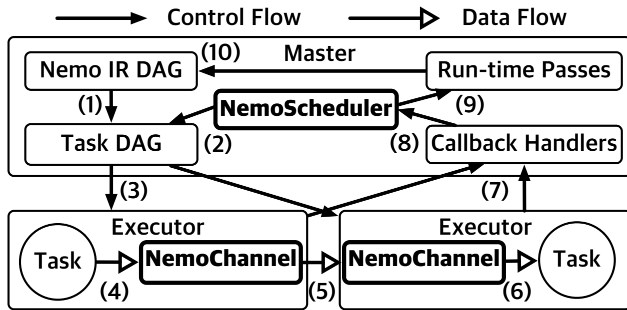

Figure 5: Nemo runtime extensions (bold) apply optimizations in a distributed runtime.

because the `LargeShufflePass` tries to shuffle data eagerly in memory, whereas the `SkewCTPass` tries to use the statistics of the data before the downstream computations start to consume the data. If undetected, this conflict results in a pull-based in-memory data shuffle, where the outputs of all `V1` tasks are stored in memory before the `Relay` tasks start fetching the data. Although this configuration avoids disk seek overheads and also handles data skew at the same time, it can cause out of memory errors for large input data.

Because Nemo detects such conflicts explicitly, we can quickly address the issue. In this case, we design a new `SkewSamplingPass` that avoids the conflict with the `LargeShufflePass`. This new compile-time pass clones the IR DAG using `Sampling` vertices, and first runs the clone to obtain the statistics of sampled data. Our third policy with the `LargeShufflePass` and the `SkewSamplingPass` can be applied together on the IR DAG to optimize for both large data shuffle and data skew. However, compared to the `SkewCTPass`, the `SkewSamplingPass` incurs the cost of executing additional vertices and using the statistics of sampled data rather than the entire data.

Next, we describe how these various transformations of the IR DAG are reflected in the distributed execution.

3.3 Runtime Extensions

We use a Nemo-compatible runtime depicted in Figure 5 to describe how the Nemo runtime extensions apply the IR DAG transformations in the distributed runtime. Upon job launch, the runtime starts a master process and executor processes on user-specified resources. In the master, the `NemoScheduler` extension operates on the task DAG abstraction that the runtime provides for scheduling tasks to executors. Executors spawn a thread to run each scheduled task, and uses the `NemoChannel` extension to communicate data between the tasks. In the rest of the section we describe how these extensions apply optimizations.

First, we set up the initial task DAG using the IR DAG optimized by compile-time passes (1). Here, we merge neighboring IR vertices into the same tasks as much as possible to minimize data communication overheads, while considering communication patterns of the IR edges and related execution properties such as the `Resource` properties and the `Parallelism` property. In case of a `Trigger` vertex, we also register a callback handler to collect the results produced by the corresponding tasks from executors as a message. Upon job start, we select candidate tasks for scheduling, which are the source tasks and their children tasks connected with the push `DataFlow` (2). For each candidate task, we select candidate executors by comparing the corresponding `Resource` properties of the task with the information on the executors. We then schedule the task to a candidate executor with the least number of running tasks (3).

When a task emits a data element, we write it to the corresponding `DataStore` implementation, creating a data block when all data elements for the channel are written (4). If the corresponding edge is shuffle, then the block is partitioned into `NumPartitions`. When a task reads input data elements, we look for the locations of the input data blocks, blocking the call when looking for blocks that are not yet available. We fetch the input data elements from the local and remote `DataStores`, while applying `PartitionSets` for shuffle edges (5-6). Once all of the downstream tasks successfully read a block, we decide to either keep or discard the block based on the `Persistence` property.

Upon learning about task progress and executor status, we schedule new tasks, restart tasks to recover from failures and evictions, and clone tasks based on the `SpeculativeCloning` property (7-8). When a message is produced for a `Trigger` vertex, we postpone scheduling new tasks, invoke the corresponding run-time pass (9), rewrite the task DAG based on the new IR DAG output by the run-time pass at the correct timing described in Section 3.1.2 (10), and resume scheduling.

4 Implementation

We have implemented Nemo and a distributed runtime that is compatible with Nemo in around 32K lines of Java code. Our Nemo implementation consists of the following three components similar to Musketeer [15] and LLVM [26]: frontend, optimizer, and backend.

The frontend translates applications such as Beam and RDD applications into an IR DAG (Section 3.1). At present, our frontend provides translation support for all Beam [1] operators, and a subset of `RDD` [50] operators such as `map`, `reduce`, `collect`, `broadcast`, and `cache`. The main reason for not fully supporting RDDs is that the current iterator implementation used in Nemo is not readily compatible with the various `RDD` implementations. In the future we plan to modify our iterator implementation to address this limitation. The optimizer applies optimization passes on the IR DAG (Section 3.2). The backend configures the underlying runtime

with the optimizer and the runtime extensions (Section 3.3).

Existing Beam applications can run on Nemo by modifying the line importing the Beam `PipelineRunner` implementation to our implementation of the runner. The frontend converts each Beam `PTransform` to an IR vertex, and `PCollection` to an IR edge. The frontend also obtains the information on communication patterns during the translation. For example, it specifies shuffle edges for the incoming `PCollections` of the `GroupByKey` `PTransforms`.

Similar to Beam, existing RDD applications can run on Nemo with simple modifications to the lines importing the implementations of `SparkSession` and `SparkContext` to our implementations of the classes. Each RDD becomes an IR edge, and each user-defined function that generates an RDD becomes an IR vertex. Our frontend also aims to respect all of the user-specified parameters on RDDs such as parallelism and data caching, by setting the execution properties on the translated IR DAG accordingly.

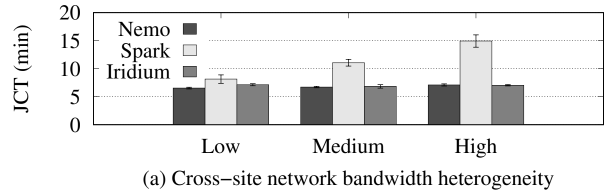
Our runtime implementation is built on top of REEF [46], and consists of master and executor processes similar to the Nemo-compatible runtime described in Section 3.3. A REEF job consists of the driver that obtains containers from a resource manager, and evaluators that provide runtime environments on containers. To take advantage of the abstractions provided by REEF, the runtime master runs as the REEF driver and the runtime executors run as the REEF evaluators. Through the integration with REEF [46], our runtime runs on resource managers such as Hadoop YARN [2] and Mesos [18].

5 Experimental Evaluation

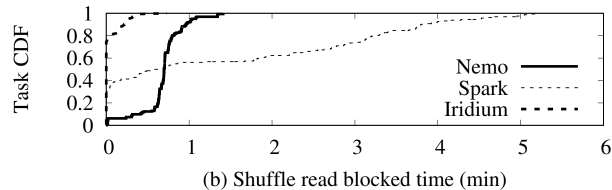
We evaluate Nemo on the following three dimensions. First, we evaluate how Nemo applies fine control under different resource and data characteristics. Second, we evaluate how different combinations of optimization passes optimize the same application. Third, we evaluate how the same Nemo policy optimizes different applications.

We run data processing applications with different combinations of following resource and data characteristics: geographically distributed resources, transient resources, large-shuffle data, and skewed data. We run each application five times, and we report the mean values with error bars showing standard deviations.

We use h1.4xlarge Amazon EC2 instances, each of which provides 16 vCPUs, 64 GiB memory, two 2 TB HDDs, and 10 Gbps network. We use different numbers of instances for different experiments. On each instance, one of the two disks is used by a Hadoop Distributed File System [2] cluster that we set up on the instances, and the other is used as a scratch disk for maintaining intermediate data. Input datasets are stored in HDFS, and fetched by the systems at the beginning of each job.



(a) Cross−site network bandwidth heterogeneity



(b) Shuffle read blocked time (min)

Figure 6: JCT for different cross-site network bandwidths, and CDF of shuffle read blocked time of tasks under the high cross-site network bandwidth heterogeneity.

5.1 Fine Control

In this experiment, we evaluate how Nemo applies fine control under different resource and data characteristics. For comparison we run Spark 2.3.0 [4], because it is an open-source, state-of-the-art system. We also run a specialized runtime for each deployment scenario. Specifically, we run Iridium [33] for geo-distributed resources, Pado [48] for transient resources, and Hurricane [12] for data skew. We examine the results of Beam applications on Nemo and Pado, Spark RDD applications on Spark and Iridium, and a Hurricane application on Hurricane.

We confirm that the baseline performance is comparable for Beam and basic RDD applications on Nemo. We also confirm that the baseline performance is comparable for Spark and Nemo with the `DefaultPass`, which configures pull-based on-disk data shuffle with locality-aware computation placement similar to Spark. We observe that the overhead of running the compile-time passes on Nemo is roughly 200ms. We also measure and report run-time overheads of the `Relay` vertex, `Trigger` vertex, and `SkewRTPass` in this section.

Geo-Distributed Resources: To set up geo-distributed resources and heterogeneous cross-site network bandwidths, we use Linux Traffic Control [6] to control the network speed between instances, as described in Iridium [33]. Each site is configured with 2Gbps uplink network speed, and a specific downlink network speed between 25Mbps and 2Gbps. We experiment with Low, Medium, and High bandwidth heterogeneity with the fastest downlink outperforming the slowest downlink by 10×, 41×, and 82×. With this, we use 20 EC2 instances as resources scattered across 20 sites. To evaluate data shuffle under heterogeneous network bandwidths, we use a workload that joins two partitions of 373GB Caida [8] network trace dataset and computes network packet flow statistics.

The job completion time (JCT) of Iridium, Spark, and

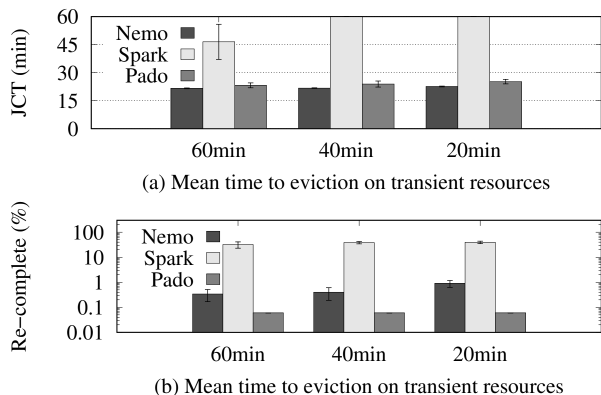


Figure 7: JCT and ratio of re-completed tasks to original tasks for different mean times to eviction on transient resources.

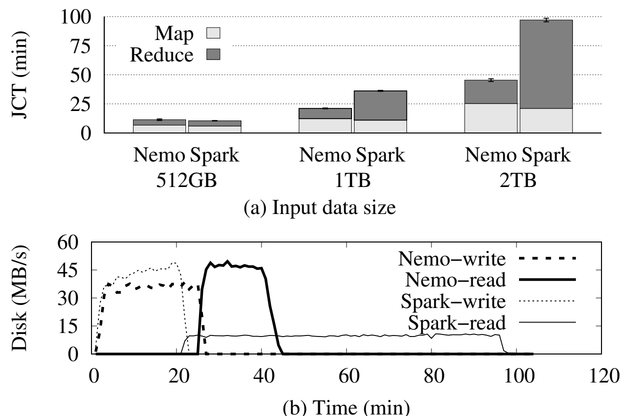

Figure 8: JCT for different input data sizes, and mean throughput of scratch disks for maintaining intermediate data when processing the 2TB input data.

Nemo optimized with the `GeoDistPass`, are shown on Figure 6 (a). Spark degrades significantly with larger bandwidth heterogeneity, since tasks that fetch data through slow network links become stragglers. In contrast, Iridium and Nemo are stable across different network speeds. Figure 6 (b) shows that the cumulative distributive function (CDF) of shuffle read time has a long tail for Spark compared to Iridium and Nemo. Iridium and Nemo show comparable performance with similar largest shuffle read blocked times, although Iridium shows overall better shuffle read blocked times using a more sophisticated linear programming model.

Transient Resources: Based on existing works [42,47,48], we classify resources that are safe from eviction as reserved resources and those prone to eviction as transient resources. We set up 10 EC2 instances for providing transient resources and 2 instances for reserved resources. When an executor running on transient resources is evicted, we allow the system to immediately re-launch a new executor using the transient resources to replace the evicted executor as described in Pado [48]. To evaluate handling long and complex DAGs with transient resources, we run an Alternating Least Squares [23] (ALS) workload, an iterative machine learning recommendation algorithm, on 10GB Yahoo! Music user ratings data [10] with over 717M ratings of 136K songs given by 1.8M users. We use 50 ranks and 15 iterations for the parameters. By varying the mean time to eviction for transient resources, we show how systems deal with the different eviction frequencies. The distribution of the time to eviction is approximated as an exponential distribution, similar to TR-Spark [47].

Figure 7 (a) shows the JCT of Pado, Spark and Nemo optimized with the `TransientResourcePass` for different mean times to eviction. With the 40-minute and 20-minute mean time to eviction, Spark is unable to complete the job even after running for an hour, at which point we stop the job. The main reason is heavy recomputation of intermediate data across multiple iterations of the ALS algorithm, which is repeatedly lost in recurring evictions. On the other hand, Nemo and Pado successfully finish the job in around 20 minutes, as both systems are optimized to retain a set of selected intermediate data on reserved resources. Figure 7 (b) shows the ratio of re-completed tasks to original tasks for different mean times to eviction. It shows that Nemo and Pado re-complete significantly fewer tasks compared to Spark, leading to a much shorter JCT. Nemo and Pado show comparable performance although Nemo re-completes more tasks, because the tasks that both systems re-complete are executed quickly and do not cause cascading recomputations of parent tasks.

Large-Shuffle Data: We evaluate how Nemo and Spark handle large shuffle operations using 512GB, 1TB, and 2TB data of the Wikimedia pageview statistics [7] from 2014 to 2016, as the datasets provide sufficiently large amount of real-world data. We use a Map-Reduce application that computes the sum of pageviews for each Wikimedia project. We choose the ratio of map to reduce tasks to 5:1, similar to the ratios used in Riffle [51] and Sailfish [35], and use 20 EC2 instances to run the workload.

The JCT of Spark and Nemo optimized with the `LargeShufflePass` are shown on Figure 8 (a). Both show comparable performance for the 512GB dataset, but Nemo outperforms Spark with larger datasets. To understand the difference, we measured the mean throughput of the disks used for intermediate data. Figure 8 (b) illustrates the mean disk throughput of scratch disks used for intermediate data when running the 2TB workload. Here, a spike in the write throughput is followed by a spike in the read throughput, which illustrates disk writes during the map stage followed by disk reads during the reduce stage while performing the shuffle operation. For Spark, the disk read throughput during the reduce stage is as low as about 10 MB/s, indicating severe disk seek overheads. In contrast, the throughput is as high as 45 MB/s for Nemo, as the `LargeShufflePass` enables sequential read of intermediate data by the following reduce

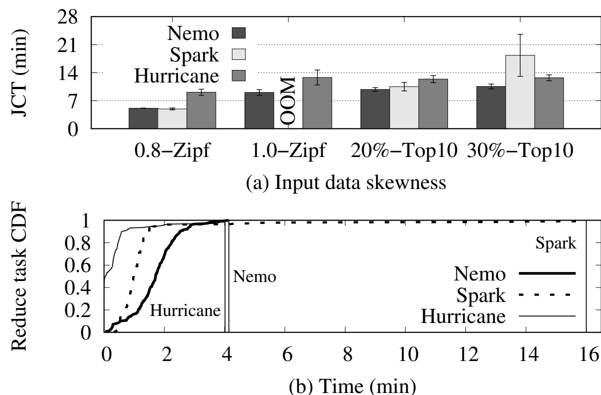

Figure 9: JCT for different input data skewness, and CDF of reduce task completion time when processing the 30%-Top10 skewed data. Each vertical line in the CDF graph denotes the completion time of the slowest reduce task.

tasks, which minimizes the disk seek overhead.

To measure the overhead of the `Relay` vertex inserted by the `LargeShufflePass` before the reduce operation, we have also run the 2TB workload on Nemo without the `LargeShufflePass`. The reduce operation begins 56 seconds earlier without the `LargeShufflePass` and the `Relay` vertex, where 56 seconds represent 2.05% of the JCT of Nemo with the `LargeShufflePass`.

Skewed Data: To experiment with different degrees of data skewness, we generate synthetic 200GB key-value datasets with two different key distributions: Zipf and Top10. For the Zipf distribution, we use parameters 0.8 and 1.0 with 1 million keys [12]. Datasets with Top10 distribution have heaviest 10 keys that represent 20% and 30% of the total data size. We run a Map-Reduce application that computes the median of the values per key on 10 EC2 instances. Because this application is non commutative-associative, for evaluating Hurricane we use an approximation algorithm similar to Remedian [39] to fully leverage its task cloning optimizations [12]. The Hurricane application also uses 4MB data chunks and uses its own storage to handle input and output data, similar to the available example application code.

Figure 9 (a) shows the JCT of Hurricane, Spark, and Nemo optimized with the `SkewCTPass` and the `SkewRTPass`. Performance of Spark degrades significantly with increasing skewness. Especially, Spark fails to complete the job with the 1.0 Zipf parameter, due to the load imbalance in reduce tasks with skewed keys which leads to out-of-memory errors. In contrast, both Nemo and Hurricane handle data skew gracefully. In particular, Nemo achieves high performance, and at the same computes medians correctly without using an approximation algorithm.

Figure 9 (b) shows the CDF of reduce task completion time when processing the 30%-Top10 dataset. The CDF for Spark shows that reduce tasks with popular keys take a significant amount of time to finish compared to other tasks. In contrast, the slowest task completes much quicker for Hurricane and Nemo. We have observed short-lived tasks alongside with longer tasks in Hurricane with its task cloning optimization, and longer tasks with balanced completion times for Nemo with its data repartitioning optimization.

Skewed data on Geo-distributed	Large Shuffle on Transient	Large Shuffle with Skewed
DP: OOM	DP: 100m	DP: OOM
GDP: OOM	TP: OOM	LSP: OOM
SKP: 27.2m	LSP: 100m	SSP: OOM
GDP + SKP: 14.9m	TP + LSP: 48.2m	LSP + SSP: 31.4m

Table 2: JCT when using different combinations of `DefaultPass` (DP), `GeoDistPass` (GDP), `SkewCTPass` (SKP), `TransientResourcePass` (TP), `LargeShufflePass` (LSP), and `SkewSamplingPass` (SSP).

To measure the overhead of the `Trigger` vertex inserted by the `SkewCTPass`, we also run the 30%-Top10 workload on Nemo without the `SkewCTPass` and the `SkewRTPass`. The reduce operation begins 35 seconds earlier without the `Trigger` vertex, where 35 seconds represent 5.52% of the JCT of Nemo configured with the `SkewCTPass` and the `SkewRTPass`.

These results for each deployment scenario show that each optimization pass on Nemo brings performance improvements on par with specialized runtimes tailored for the specific scenario.

5.2 Composability

We now evaluate combinations of different optimization passes. Table 2 summarizes the results.

Skewed Data on Geo-distributed Resources: In this experiment, we use the same 1.0-Zipf workload for the skew handling experiment in Section 5.1, because the workload showed the largest load imbalance. We use 10 EC2 instances representing geo-distributed sites with heterogeneous network speed in between 25Mbps to 2Gbps. Here, DP and GDP run into out-of-memory errors due to the reduce tasks with skewed keys that are requested to process excessively large portions of data. SKP and GDP+SKP both successfully complete the job with the skew handling technique in SKP, but GDP+SKP outperforms SKP by also benefiting from the scheduling optimizations in GDP.

Large Shuffle on Transient Resources: For this experiment, we use the same 1TB workload for the large shuffle experiment in Section 5.1, to use sufficiently large data that incurs disk seek overheads. In this case, we use 10 reserved instances and 10 transient instances with the 20-minute mean time to eviction setting.

Most notably, DP and LSP fail to complete even after 100

minutes, at which point we stop the job, and TP runs into out-of-memory errors. We have observed that heavy recomputation caused by frequent resource eviction significantly slows down the DP and LSP cases. We have also found out that the LSP optimization makes the application much more vulnerable to resource evictions compared to DP. The main reason is that with LSP, eviction of a single receiving task in the shuffle boundary leads to the entire recomputation of the sending tasks of the shuffle operation, to completely re-shuffle the intermediate data in memory. In contrast, DP does not need to recompute shuffle sending tasks whose output data are not evicted and stored in local disks. TP by itself also is not sufficient, as it leads to out-of-memory errors while pushing large shuffle data in memory from transient resources to reserved resources.

TP+LSP is the only case that successfully completes the job by leveraging both optimizations in TP and LSP. With TP+LSP, the job pushes the shuffle data from transient to reserved resources, and also streams them to local disks on reserved resources that are safe from evictions. This allows TP+LSP to handle frequent evictions on transient resources, and also to utilize disks for storing large shuffle data with minimum disk seek overheads. However, TP+LSP incurs the overhead of using only half of the resources (transient or reserved) for each end of the data shuffle. As a result, the JCT for TP+LSP with transient resources is around twice the JCT for LSP without using transient resources, which is displayed in Section 5.1. Nevertheless, we believe that this overhead is worthwhile, taking into account that transient resources are much cheaper than reserved resources from the perspective of datacenter utilization [38, 48].

Large Shuffle with Skewed Data: For this experiment, we generate a synthetic key-value dataset with a skewed key distribution that is around 1TB in size, as the datasets used in Section 5.1 for skew handling are not sufficiently large to incur disk seek overheads. This dataset has the distribution where heaviest 20 keys represent 30% of the total data size. Using this dataset, we run the same application that we have used for the skewed data experiment in Section 5.1 on 20 EC2 instances.

In this experiment, only SSP+LSP successfully completes the job, whereas all other cases run into out-of-memory errors. DP and LSP fails to complete the job, due to particular tasks assigned with excessively large portions of data, incurring out-of-memory errors. SSP by itself also runs into out-of-memory errors although it repartitions data across the receiving tasks of the shuffle boundary. We have observed that with large data size, the absolute size of the heaviest keys is significantly larger compared to smaller scale experiments with skewed data shown in Section 5.1. Without the LSP optimization, this problem is combined with random disk read overheads that degrade the running time of the shuffle receiving tasks, leading to out-of-memory errors. In contrast, SSP+LSP successfully completes the job by leveraging both of the optimizations from SSP and LSP.

These various results confirm that Nemo can apply combinations of distinct optimization passes to further improve performance for deployment scenarios with a combination of different resource and data characteristics.

5.3 Reusability

Finally, we evaluate how the same Nemo policy optimizes different applications. In addition to different applications used in prior experiments, we apply the policies on several ad-hoc BeamSQL [1] TPC-H [9] queries (Q) with different scale factors (SF), as they are widely used for benchmarking distributed data processing systems. Here, 1 SF is approximately 1GB of input data. We specifically use workloads that handle smaller input and intermediate data compared to the previous experiments, and thus are much less affected by the issues that occur in the specific scenarios like disk-seek overheads and resource evictions.

First, using 20 nodes with the `LargeShufflePass`, we observe 20.8 minute JCT for SF1000 Q3 that is 25% smaller than the JCT without the optimization, but no significant performance improvements for SF1000 Q14. We also observe 41.1 minute JCT for SF3000 Q12 that brings 22% performance improvements. Second, we do not observe meaningful performance improvements for SF100 Q4 and Q13 with the `SkewCTPass` on 10 nodes, as the dataset is not skewed. Finally, using 8 transient nodes with the 10-minute expected eviction rate and 2 reserved resources, we apply the combination of the `TransientResourcePass` and the `LargeShufflePass` on SF100 Q4 and Q14. For the respective queries, we observe JCTs of 8.2 minutes and 3.4 minutes, which are smaller than when not applying the optimizations by 9% and 15%.

These results as well as the results of different workloads in previous experiments confirm that the same optimization passes on Nemo can speed up different workloads instantly, with varying degrees of effectiveness.

6 Related Work

Nemo builds on many years of research in dataflow processing, relational database, and compiler optimizations. Nevertheless, we believe the set of trade-offs we have chosen to design the IR DAG, optimization passes, and runtime extensions for optimizing distributed dataflow processing makes Nemo a unique system.

Dataflow processing: Nemo differentiates itself from the existing application-level [22] and runtime-level [4, 20, 22, 40] approaches to dataflow scheduling and communication optimizations by taking a middle ground approach. Nemo provides a policy interface that transforms an intermediate representation (IR) of applications to express indirect but fine control over distributed scheduling and communication.

Our decoupled system design and our DAG-based IR are similar to Musketeer [15]. However, our work is complementary to Musketeer, as we focus on providing fine control over physical scheduling and communication in our IR, whereas Musketeer focuses on dynamically mapping its IR to a range of different execution runtimes.

The SparkSQL Catalyst optimizer [11] takes as input a SparkSQL application and outputs a Spark RDD application, which Nemo can take as input. Compared to Nemo, Catalyst has more information about application semantics (e.g., 'Add' '1' and '2'), but has less fine control over scheduling and communication (e.g., speculative task cloning).

Recently proposed dynamic query optimizers [28, 29] for distributed dataflow processing runtimes operate on high-level logical plans for SQL queries. Leveraging the semantics of SQL queries and the runtime information, these optimizers focus on choosing an optimal logical plan, for example by finding an optimal join order. Nemo operates on a lower-level IR DAG that supports general dataflow processing applications, and provides the methods to configure scheduling and communication methods of each data-parallel operation in the applications.

Weld [32] takes as input code that composes imperative libraries such as Pandas [30] and Numpy [41], creates a combined Weld IR program, and outputs optimized assembly code using LLVM. Weld can reduce data movement overheads across such imperative libraries, but it is not designed to optimize distributed scheduling and communication like Nemo.

Relational databases: Many of the optimizations in Nemo, such as parallelization and distributed scheduling optimizations, can be traced to research in parallel databases [14, 16]. Nemo enables expressing and composing various types of such optimizations for distributed dataflow processing applications, by introducing a policy interface that provides fine control and at the same time ensures correctness.

Our idea of annotating operators with execution properties is similar to using query hints in relational databases to influence the optimizer [13]. Nevertheless, these works focus on restricting the search space of SQL query execution plans, whereas Nemo focuses on tuning the scheduling and communication of dataflow processing applications.

Compilers: Our approach of expressing optimizations as passes that transform an IR is similar to LLVM [26]. However, in contrast to the LLVM IR that represents assembly code, the Nemo IR explicitly captures the dependencies and the communication patterns of coarse-grained, data-parallel operations. This enables passes on Nemo to express various distributed scheduling and communication optimizations.

Verified compilers, such as CompCert [27], aim to ensure the correctness of optimized assembly code using formal verification methods. Nemo aims to ensure the correctness of optimized distributed execution of dataflow processing applications, by introducing utility vertices and execution properties that make it simple to ensure correctness.

7 Discussion

Nemo provides a programming interface for building correct, reusable, and composable optimization policies. We discuss several directions to extend the interface and further facilitate the development of new policies.

Ensuring resource constraints: Although Nemo provides execution properties to specify where to place computations and data, Nemo relies on the runtime to determine the actual resources to acquire. To ensure that the resource constraints are met in the execution, we can incorporate the information into the IR DAG on the resource availability and acquisition.

Declaring optimizations ahead of time: To enable compile-time analysis of run-time pass conflicts and optimizations, we can provide the option to declare intended optimizations ahead of time. For example, we can receive more explicit information on the predicates (e.g., is a shuffle edge) and actions (e.g., store in memory) that a run-time pass intends to use.

Leveraging historical information: We can enable passes to use information on previous executions of the same application, and employ more sophisticated techniques such as machine learning to determine how to transform the IR DAG. To facilitate this, we can maintain a database that stores the information of the executed IR DAGs and their performance metrics, and provide an interface for passes to access the information in the database.

8 Conclusion

We presented Nemo, an optimization framework that provides fine control over distributed scheduling and communication of data processing applications, and at the same time ensures correct application semantics. We hope Nemo serves as a platform for dataflow optimization research and development. Nemo is available at https://nemo.apache.org.

Tangram: Bridging Immutable and Mutable Abstractions for Distributed Data Analytics

Yuzhen Huang*, Xiao Yan*, Guanxian Jiang, Tatiana Jin, James Cheng, An Xu, Zhanhan Liu, Shuo Tu
The Chinese University of Hong Kong

Abstract

Data analytics frameworks that adopt immutable data abstraction usually provide better support for failure recovery and straggler mitigation, while those that adopt mutable data abstraction are more efficient for iterative workloads thanks to their support for in-place state updates and asynchronous execution. Most existing frameworks adopt either one of the two data abstractions and do not enjoy the benefits of the other. In this paper, we propose a novel programming model named *MapUpdate*, which can determine whether a distributed dataset is mutable or immutable in an application. We show that MapUpdate not only offers good expressiveness, but also allows us to enjoy the benefits of both mutable and immutable abstractions. MapUpdate naturally supports iterative and asynchronous execution, and can use different recovery strategies adaptively according to failure scenarios. We implemented MapUpdate in a system, called Tangram, with novel system designs such as lightweight local task management, partition-based progress control, and context-aware failure recovery. Extensive experiments verified the benefits of Tangram on a variety of workloads including bulk processing, graph analytics, and iterative machine learning.

1 Introduction

Existing offline data analytics frameworks can be roughly classified into two categories according to their data abstractions: **immutable** or **mutable**. The choice of data mutability results in two sets of fundamentally different system features and complex trade-offs between *efficiency* and *robustness* [1].

MapReduce [17] and Spark [70] are representative systems that adopt immutable data abstractions, where data accesses are bulk data movements. MapReduce and Spark provide effective *straggler mitigation* (by speculative execution) and efficient *failure recovery* (by recomputing only the lost partitions), which are critical for large-scale production deployment. As their immutable data abstractions imply a *bulk synchronous parallel* (*BSP*) execution model and lack support for in-place update, MapReduce and Spark do not perform well for workloads that benefit from fine-grained state access and asynchronous execution [2], e.g., sparse logistic regression and single source shortest path (SSSP).

There are also many systems that adopt mutable data abstractions to accelerate iterative workloads, such as vertex-centric graph systems (e.g., Pregel [36], GraphLab [34, 35], PowerGraph [21]) and machine learning systems based on the parameter server architecture (e.g., Parameter Server [31], Petuum [60], TensorFlow [1]). Mutable abstractions enable features such as fine-grained state access and asynchronous execution, which result in enhanced performance for iterative graph analytics and machine learning workloads. However, mutable abstractions make failure recovery and straggler mitigation more challenging. In these systems, failure recovery usually relies on a full restart from the latest checkpoint, and straggler mitigation with speculative execution is not supported as the backup tasks will conduct repetitive updates.

In general, immutable data abstraction leads to efficient failure recovery and effective straggler mitigation, while mutable data abstraction supports a richer set of features at the expense of weaker robustness. We discuss in greater details the interplay among data abstractions, system features and robustness in Section 2. In summary, a clear distinction in existing systems is that they support either mutable or immutable data abstraction, and lack a mechanism to choose which abstraction to use according to a given workload. Our analysis on the trade-offs between the two data abstractions leads to the following questions: *Can we model both mutable and immutable data abstractions under a unified framework? Can the system determine which abstraction to use according to the workloads? Is it possible to provide efficient failure recovery and straggler mitigation under mutable abstraction?*

*Co-first-authors ordered alphabetically.

[1] We refer robustness to efficient failure recovery and straggler mitigation.

[2] Compared with BSP, asynchronous execution by *stale synchronous parallel* (*SSP*) [24, 60] or *asynchronous parallel* (*ASP*) [49, 58] allows the machines/objects to have different progresses in iterative applications. The progress differences among the machines are bounded in SSP but unbounded in ASP.

We propose a distributed data analytics system, called **Tangram**, to bridge the gap between mutable and immutable data abstractions. Tangram adopts a new programming model, **MapUpdate**, which is used in the form ***A.map(B).update(C)***, where *A*, *B* and *C* are distributed data collections. Similar to MapReduce, the map tasks in MapUpdate are coarse-grained and side-effect-free, which allows speculative execution for straggler mitigation and failure recovery by only recomputing the lost partitions. However, the side-input (i.e., collection *B*) is read on a per-record basis and the update tasks conduct in-place update on states (i.e., collection *C*) to make recent updates visible to the map tasks. On this basis, MapUpdate also inherently supports iterative and asynchronous execution.

MapUpdate provides a simple rule to determine whether a collection should be mutable (Section 3), thus enabling the system to use mutable or immutable data abstraction for each collection adaptively according to a given workload. With this adaptability, Tangram provides elegant implementations for workloads including *bulk processing*, *vertex-centric graph analytics* and *iterative machine learning* (Section 4). In addition to good expressiveness, the ability to determine data mutability also enables the system to apply different failure recovery strategies for immutable and mutable collections, providing similar robustness as immutable systems (Section 5).

Tangram translates a MapUpdate plan (i.e., an invocation of "*A.map(B).update(C)*") into a number of *map* and *update* tasks. To reduce the overhead of centralized scheduling, Tangram uses a lightweight local task management strategy to schedule the execution of the tasks and to resolve access conflicts on each machine. A partition-based progress control mechanism is introduced to support iterations and asynchronous execution (Section 5). To achieve high efficiency, Tangram also incorporates optimizations such as delay combiner, process cache, and local zero-copy communication.

Our experiments show that Tangram provides efficient failure recovery and effective straggler mitigation. We also implemented a variety of workloads (e.g., bulk processing, machine learning, graph analytics, distributed crawler) on Tangram and compared their performance with specialized systems and highly optimized low-level MPI implementations. We found that Tangram can concisely express these workloads in an intuitive manner and the experiments show that Tangram's performance is comparable with that of specialized systems. Tangram's expressiveness and efficiency are especially useful for pipelined workloads consisting of multiple types of tasks as it eliminates context switch overheads.

Our main contributions can be summarized as follows:

- An in-depth analysis of the interplay among data abstraction, system features and robustness in existing systems. (Section 2)
- A novel programming model that can determine data mutability and can model both mutable and immutable data abstractions, resulting in good expressiveness. (Sections 3 and 4)
- A set of novel designs (e.g., partition-based progress control) and optimizations (e.g., delay combiner) that support different workloads efficiently on a common runtime. (Section 5)
- A comprehensive evaluation of Tangram's performance on a variety of workloads. (Section 6)

2 Immutable and Mutable Abstractions

We review related systems and analyze the complex interplay among their data abstractions, key features, failure recovery and straggler mitigation strategies. For convenience of discussion, we refer to systems that adopt an immutable/mutable data abstraction as **immutable/mutable systems**. We give a summary in Table 1 and discuss the details below.

Data-parallel analytics frameworks such as MapReduce [17], DryadLINQ [68] and Spark [70] are typical examples of immutable systems. They use functional dataflow graphs to model the dependency among datasets and break a job into multiple stages with dependency. The parallel tasks in each stage are independent and the stages are executed in a synchronous manner in which a stage can only start after its predecessors finish. This execution model enables straggler mitigation with speculative execution, which has been widely adopted and optimized in practice [3–5, 17, 71].

Immutable systems also provide efficient lineage-based failure recovery, for which only the lost data partitions are reconstructed from their parent partitions in the lineage graph. Compared with checkpoint-based recovery, lineage-based recovery can distinguish failure scenarios and does not need to roll back to the latest checkpoint upon every failure. For example, in K-means, if a machine holding a part of the training samples fails (i.e., narrow dependency), Spark only needs to reload the lost samples in parallel and recompute their updates to the centers. Only in cases such as PageRank, when the rank values of some vertices are lost (i.e., wide dependency), a full re-computation from the latest checkpoint is required. Moreover, Spark only checkpoints/reloads datasets that have a long lineage graph containing wide dependency (e.g., the rank RDD in the above example), which is more efficient than checkpointing all RDDs involved in computation.

Immutable systems are inherently stateless and only support BSP. However, many iterative workloads have intuitive stateful representations (e.g., the rank values in PageRank, and the model parameters in sparse logistics regression) and can benefit from asynchronous execution. For example, machine learning algorithms such as stochastic gradient descent (SGD) converge faster under SSP and ASP [24, 49, 69], and it has also been proven that a number of asynchronous graph algorithms have faster convergence compared to their synchronous counterparts [49, 73]. Therefore, many specialized mutable systems such as vertex-centric graph systems [21, 35, 36] and parameter-server-based machine learning systems [31, 60] support in-place state updates and asynchronous execution.

Table 1: The data abstractions and key features of some representative systems

Category	Systems	Usability	Abstraction		System Support		
		Programming Model	State Representation	Access Pattern (Shuffle)	Execution Model	Straggler Handling	Failure Recovery
Stateless Dataflow	MapReduce [17], DryadLINQ [68], Spark [70]	functional	immutable	coarse-grained	BSP	speculative execution	lineage and checkpoint
Distr. Shared Mem.	Piccolo [46]	push/pull	mutable kv table	fine-grained	BSP	task stealing	checkpoint
Parameter Server based	Parameter Server [31]	push/pull	mutable kv table	fine-grained	BSP/SSP/ASP	N/A	replication
	Petuum [60]	push/pull	mutable kv table	fine-grained	BSP/SSP/ASP	N/A	checkpoint
Distributed Graph	Pregel [36]	vertex-program	mutable state	coarse-grained	BSP	N/A	checkpoint or message replay
	GraphLab [34, 35], PowerGraph [21]	vertex-program	mutable state	fine-grained	BSP/ASP	N/A	checkpoint
	Tangram	functional map in-place update	immutable/mutable	partition-based	BSP/SSP/ASP	partition migration	lineage and checkpoint

Asynchronous execution also makes mutable systems more robust to micro stragglers [3] as fewer barriers are enforced. In contrast, immutable systems are prone to micro stragglers as their BSP execution model enforces a synchronization barrier in every iteration.

However, mutable systems only provide sub-optimal system-level solutions to straggler mitigation and failure recovery. Most of the mutable systems in Table 1 rely on the nature of the applications for straggler mitigation and do not provide a system-level support. For example, graph systems such as Pregel [36] and PowerGraph [21] rely on graph partitioning to ensure a balanced workload distribution among workers. Parameter Server [31], Petuum [60], GRACE [58] and Maiter [73] utilize the asynchronous nature of the application algorithms to mitigate micro stragglers. Mutable systems do not support speculative execution as updates are conducted in a fine-grained manner and it is costly to keep track of the committed writes in order to avoid repetitive updates. Instead, mutable systems typically use task stealing to handle stragglers [23, 46].

For fault tolerance, mutable systems usually require a full restart from the latest checkpoint (e.g., Petuum, Pregel), or use expensive replication when recovery time is critical (e.g., Parameter Server). Contrary to immutable systems, mutable systems often recompute everything from the latest checkpoint. In addition, any failure would cause these systems to discard and reload all data. The key problem is that these systems do not distinguish the mutable and immutable parts in an application. Although existing mutable systems can be modified individually to support more efficient fault tolerance, we offer a unified mechanism to solve this problem, which is especially useful for pipelined workloads where datasets can change between mutable and immutable status (e.g., the TF-IDF vectors in the pipelined workload in Section 6.2).

[3] *Micro stragglers* are transiently stalling workers and may be caused by packet loss, system cron jobs, etc. *Macro stragglers* are slow due to more persistent reasons, such as workload imbalance and resource contention.

3 Programming Model

In this section, we introduce our MapUpdate programming model and discuss its differences from MapReduce and stream processing frameworks.

3.1 MapUpdate

The basic data abstraction in our MapUpdate programming model is *collection*, which contains a set of objects (or records) and is usually kept in memory. A collection is divided into partitions and partitions are distributed across machines in the cluster (with hash partitioner by default, but configurable by users). The **MapUpdate** programming model is typically used in the form of

A.map(B, map_func).update(C, update_func),

in which A, B, and C are *map collection*, *side-input collection*, and *update collection*, respectively. The *map_func* has a signature $(T, [S, \ldots]) => seq(K, V)$, which takes in an object of type T in the map collection and (optionally) handler(s) S to the side-input collection(s), and generates some key/value (K/V) pairs. The *update_func* has a signature $(U*, V) => nil$, which takes in a pointer $U*$ to an object in the update collection and an update value V, and returns nothing.

To execute a MapUpdate command (also called a *plan*), a machine launches parallel map tasks on its local partitions of the map collection, where each map task performs *map_func* on the objects in one partition of A to generate intermediate results. The *map_func* may use the information (parameters) provided in the side-input collection B. The intermediate results (of a map task) are then shuffled according to their keys and committed to the corresponding objects in update collection C with the *update_func*. By default, the retrieval of the objects in the side-input collection is fine-grained (i.e., on a per-key basis), while the shuffle of intermediate results and modification to the update collection are conducted on a per-partition basis. MapUpdate associates progress with each partition and allows different partitions to have differ-

ent progresses, and state access is also progress dependent (Section 5.2). This *partition-based state access pattern* of MapUpdate is different from the *coarse-grained state access pattern* in dataflow systems (e.g., Spark), in which all partitions have the same progress (i.e., BSP). Task execution in the Tangram system is also partition-based, i.e., a partition is the granularity of task execution.

MapUpdate has an explicit side-input collection. In contrast, without the side-input, existing systems (e.g., Spark) may use broadcast for state sharing, which is inefficient for large and sparse states (e.g., sparse logistic regression). Some other systems (e.g., Google Dataflow [2]) also support the side-input collection but require it to be small and immutable. MapUpdate does not have such constraints, enabling it to succinctly and efficiently express workloads that have intuitive stateful representations (see examples of machine learning and graph analytics applications in Section 4). MapUpdate also does not require A, B and C to be different collections. When $A = C$ or $B = C$, by default, MapUpdate does not make a copy of C for read. Instead, MapUpdate reads and writes the same collection, which enables the map tasks to see the latest (maybe inconsistent) updates. As we will show in Section 4, this is important for the asynchronous execution of workloads such as distributed crawler as they can tolerate inconsistent states and benefit from fewer synchronization barriers.

MapUpdate ensures consistency [4] if a plan (e.g., word count) does not write/read the same collection. For plans that write/read the same collection, consistency is not guaranteed. This is not problematic because applications such as SGD can trade consistency for efficiency without sacrificing correctness, and many specialized systems deliberately incorporate designs to benefit from that. When strict consistency is required, users can create another copy of the read collection for write as in Spark and Piccolo. MapUpdate does not enforce any order when committing the updates of the map tasks, and the results of a plan may not be deterministic for some applications (e.g., SGD based logistic regression). In the face of failure, MapUpdate ensures that each update is committed exactly once.

In general, the map collection A contains the input data, such as samples in machine learning and documents in word count, while the side-input collection B provides information needed in computation, such as model parameters in machine learning. The update collection C holds the computation results, e.g., the final count values in word count. The side-input collection can be omitted, for example, a user can write *docs.map(map_func).update(count, update_func)* for word count. Instead of a single collection and function, users can provide multiple side-input collections, update collections, and update functions. Users can easily specify how a plan is executed using the configurations in Table 2, for example, *A.map(B).update(C).setIter(100).setStaleness(2)* will

[4] At iteration t, a read on data sees all updates from iteration smaller than t but not updates from iteration equal or larger than t.

Table 2: Configurations in MapUpdate

Configuration	Description
setIter(*int n*)	Run for *n* iterations
setStaleness(*int s*)	Set staleness to *s*
setCombine(*func*)	Register combiner
setCheckpointInterval(*int n*)	Set checkpoint interval

conduct the MapUpdate plan for 100 iterations using SSP with $staleness = 2$. Additionally, *setCombine(func)* provides a function to combine the map outputs before shuffling for communication reduction, and *setChecktpointInterval(n)* configures the checkpoint interval in an iterative application. We will show how these flexibilities of MapUpdate translate into good expressiveness in Section 4.

3.2 Comparison with Existing Frameworks

We highlight the main differences between MapUpdate and MapReduce [17], Flink [10] and Spark Structured Streaming [6] in this section.

MapReduce. MapUpdate differs from MapReduce in several important aspects. First, while *map* in MapUpdate is functional (similar to *map* in MapReduce), *update* allows for asynchronous in-place modification to the stateful collection. Second, MapUpdate allows the side-input collections to be specified explicitly and access to the side-input collections is fine-grained, which improves efficiency in many applications such as machine learning and graph analytics. Third, with designs to be introduced in Section 5, MapUpdate provides support for iteration and consistency protocols including BSP, SSP and ASP (configurable by *setStaleness*). Although there are attempts to support key-value-style update (IndexedRDD [26]) and iteration (HaLoop [9], iterative MapReduce [18], Map-Reduce-Update [8]) under the MapReduce framework, MapUpdate is fundamentally different as these systems do not support in-place updates and asynchronous execution due to their data immutability.

The most important contribution of MapUpdate, however, is that it provides a simple mechanism for the system to determine whether a collection is mutable in a plan from the API call: *the update collection is mutable, and other collections, if different from the update collection, are considered immutable*. For example, a MapUpdate plan training a logistic regression model may be expressed as *samples.map(param).update(param)*, and the system can infer that collection *param* (storing the parameters) is mutable and collection *samples* (storing data samples) is immutable. The ability to determine data mutability allows the system to distinguish failure scenarios and provides efficient failure recovery strategies accordingly as in immutable systems. For example, when a machine fails, the system can determine whether the failed machine holds partitions of *param*. If not, only the lost partitions of *samples* need to be reloaded. Otherwise, the system rolls back to the latest checkpoint for *param*, but the partitions of *samples* on the healthy machines do not

need to be reloaded.

To support speculative execution, MapUpdate restricts updates to be conducted on a per-partition basis, in which updates from a map partition are committed together. This per-partition update strategy enables Tangram to record which partition has already committed update and is crucial for speculative execution.

Stream Processing Frameworks. Modern stream processing systems such as Flink and Spark Structured Streaming also support both mutable and immutable abstractions but with restricted applicability. We discuss how MapUpdate is different from them here.

First, states in MapUpdate are shared and can be accessed globally, which allows Tangram to support workloads such as machine learning and graph analytics more efficiently. In contrast, states in Flink are bounded with operators and states in Spark Structured Streaming are restricted to key groups. In fact, states in Flink and Spark Structured Streaming are mainly designed for maintaining states across streaming records (e.g., for session tracking). Thus, they are not efficient for read/write in machine learning and graph analytics workloads, which introduce loops in the computation graph. Specifically, using loops in Flink requires to limit the input rate of the input stream to avoid deadlocks caused by cyclic backpressure [20], while Spark Structured Streaming does not allow loops in the dataflow graph, which is necessary when using the stateful operators for iterative workloads. In contrast, MapUpdate naturally supports iteration and in-place update.

Second, checkpointing in Flink and Spark Structured Streaming is more complicated (as they are designed for stream processing), while Tangram is designed for batch processing and only checkpoints mutable collections. Spark Structured Streaming uses checkpointing and write-ahead logs for fault tolerance. Flink also needs to restart from the latest checkpoint for any failure.

4 Applications

Programming with MapUpdate to construct data-parallel applications is simple: users define the collections, construct the MapUpdate plan by providing the *map/update* functions and specify the plan configurations. Low-level system issues such as parallelism and fault tolerance are hidden from users. In this section, we demonstrate how MapUpdate can be used to implement a wide range of applications.

4.1 Bulk Processing

MapUpdate can easily implement the bulk processing workloads targeted by MapReduce, which are usually stateless, non-iterative and involve only bulk data movement. We illustrate by the word count example, which is similar to the one in Spark: the map function generates (word, count) pairs when scanning local documents, while the update function aggregates the (word, count) pairs for final counts. Note that in the plan of word count, there is no side-input collection.

```
// Doc: (word1, word2...): (string, string...)
// WordCount: (word, count): (string, int)
// docs: collection<Doc>
// wordcount: collection<WordCount>
docs.map(doc => (w, 1) for each word w in doc)
    .update(wordcount, (wc, c) => wc.count += c)
```

4.2 Iterative Machine Learning

Iterative machine learning algorithms repeatedly refine a set of model parameters with updates computed from the training samples. These algorithms (e.g., SGD) are usually robust to asynchronous execution, in which update is calculated using outdated or inconsistent model parameters. Parameter-sever-based systems (e.g., Parameter Server [31], Petuum Bösen [60]) are widely used for distributed machine learning and support SSP and ASP to benefit from asynchronous execution. Tangram can model parameter server by using the model parameters as both the side-input collection and update collection. We show an example of training logistic regression using SGD with SSP ($s = 2$). The map function calculates the stochastic gradient of local samples using the model parameters, while the update function commits the gradient updates to the model parameters. Iteration and asynchronous execution can be configured using the *setIter* and *setStalenss* commands in Table 2. Note that when *setStalenss* is not configured, Tangram uses BSP by default.

```
// Sample: (label,(k,v)..): (int, (int,float)..)
// Param: (k,v): (int, float)
// data: collection<Sample>
// params: collection<Param>
map_func(Sample sample, Params params, Output o):
  grad = CalcGrad(sample, params)
  o <- grad  // grad: ((k,v)...)

update_func(Param param, float update):
  param.val -= learning_rate * update

data.map(params, map_func)
    .update(params, update_func)
    .setIter(100).setStalenss(2)
```

4.3 Vertex-Centric Graph Analytics

Vertex-centric graph analytics systems (e.g., Pregel [36], PowerGraph [21]) usually update vertex states iteratively according to the states of neighboring vertexes. Tangram can model vertex-centric graph processing by using the vertex state collection as both map collection and update collection [5]. We use PageRank as an example. The map function calculates the contribution of a vertex's PageRank value to its out-neighbors, while the update function merges the contributions from the in-neighbors. The ranks and the links collection are

[5]Using vertex state as side-input and update collection is also feasible.

co-partitioned (by using the same partitioner) to reduce communication overhead. Similarly, Tangram can also implement the edge-centric model [51].

```
// Rank: (id, pr): (int, float)
// Link: (id, nb1, nb2...): (int, int, int...)
map_func(Rank r, Links links, Output o):
  for each neighbor nb in links[r.id]:
    o <- (nb.id, 0.85 * r.pr/len(links[r.id]))

update_func(Rank r, float contrib):
  r.pr += contrib

ranks.map(links, map_func)
     .update(ranks, update_func)
     .setIter(30)
```

4.4 Distributed Crawler

Tangram supports crawler by using urls as both the map collection and update collection. The map function downloads the web page pointed by the current url and extracts new urls, while the update function inserts the new urls into the urls collection and marks the processed urls as visited. Note that there is no side-input collection. *setIter(-1)* keeps executing the iteration (i.e., keep crawling), while *setStaleness(-1)* means using ASP.

```
// Url: (url, status): (string, ToFetch/Done)
map_func(Url url, Output o):
  if url.status is ToFetch:
    new_urls = DownloadAndExtractNewUrls(url)
    for each new_url in new_urls:
      o <- (new_url, ToFetch)
    o <- (url, Done)

update_func(Url url, Status s):
  if url.status is not Done:
    url.status = s

urls.map(map_func)
    .update(urls, update_func)
    .setIter(-1).setStaleness(-1)
```

In the above applications, we use different combinations of the three collections (A,B,C) to achieve different computation patterns. Tangram also supports many other applications (e.g., Nomad [69] and graph matching [12]) that are hard to be implemented in existing systems.

4.5 Pipelined Workloads

MapUpdate is especially useful for pipelined workloads. In fact, the Tangram project was motivated by production data analytics workloads that are common in companies such as Alibaba, which consist of pipelines involving different types of tasks. Typical pipelines begin with MapReduce-style data processing, then conduct various advanced analytics (e.g., parameter-server-style model training), and end with testing and verification. We briefly describe a *user classification* pipeline and a *fraud detection* pipeline as examples.

In a user classification pipeline, users are divided into groups according to their purchase records to generate labels. The basic information (e.g., age, gender and location), search history and activity patterns (e.g., log-in frequency, active time period) are gathered from multiple tables using MapReduce-style join to produce features. Then, various machine learning models (e.g., logistic regression, SVM) are trained using a parameter-server-based framework to classify users into different purchase pattern groups. Lastly, the models are tested on a held-out dataset to select the best-performing one for use. We remark that user classification is only a component of the much larger item recommendation pipeline, which involves a more diverse set of workloads such as graph analytics and matrix factorization.

In a fraud detection pipeline, the goal is to find malicious sellers who use fake transactions to bump up their scales records [47]. The static relationship among users (i.e., buyers or sellers) and the dynamic payment activities are first processed, and a graph is extracted from the pre-processed data to model the buyer-seller interaction. Then, graph matching is applied to find interaction patterns that match some predefined templates corresponding to fraud patterns. Finally, these interactions are verified by further analysis and the results are used to update the fraud template library. The verification process typically involves MapReduce (e.g., joins to obtain details of suspected users) and graph analytics such as computing the distances from suspected users to blacklisted users.

As we will show in the experiments, processing different tasks in a pipeline with respective specialized systems introduces expensive context switch overheads for dumping/loading output/input data by the systems. Using many systems for a single pipeline also hurts robustness because different systems provide different fault tolerance semantics and require engineers to learn/tune all the systems. With the expressive API of MapUpdate, unified fault tolerance semantics and high efficiency, Tangram (our system that implements MapUpdate) can handle the entire pipeline in a unified framework and thus completely remove the context switch overheads. Moreover, the unified MapUpdate API also significantly reduces development costs without users' need to learn many systems.

5 System Design

Designing a system to support the MapUpdate API is challenging in the following aspects: (1) As tasks in MapUpdate have complicated interactions and dependencies (e.g., read/write conflicts, requiring remote data transfer), a low-overhead task management and scheduling strategy is crucial for efficiency. (2) MapUpdate supports iterative plans and flexible consistency control, which requires a distributed progress control protocol that enables various execution models (i.e., BSP, SSP and ASP) under a unified framework. (3) To achieve efficient failure recovery, effective mechanisms are needed to distinguish failure scenarios and apply different recovery

strategies accordingly as analyzed in Section 2.

Tangram adopts a master-worker architecture. The master is responsible for DAG scheduling (coordinating the workers to execute runnable plans), progress tracking (managing progress and collecting execution statistics from workers for fault tolerance and straggler mitigation), and partition management (keeping track of the location of the partitions by maintaining the master copy of the partition map). The workers serve as the distributed in-memory storage for the partitions and each worker uses a local controller to manage local task execution. For scheduling, the master only issues control commands (start, update progress, migrate, recover, etc.) to workers and the local controller is responsible for scheduling its own tasks. The local controller also synchronizes the local copy of the partition map and the execution progress with the master. This design reduces centralized scheduling overhead and is crucial for scaling to large clusters.

5.1 Local Task Management

The local controller in each machine manages three kinds of tasks, i.e., map task, respond task, and update task. A map task runs the user-defined map function for every object in a local map partition, combines the intermediate results locally if a combine function is provided, serializes the (combined) results and adds the results to the sender, which will send them to remote machines (according to the partition map) for update. A map task invokes a fetcher if it needs to fetch some records (e.g., parameters in machine learning) in the side-input collection. The requested records are indexed by keys and the fetcher splits these keys into multiple subsets, each corresponding to a partition of the side-input collection. Then the fetcher sends out the fetch requests to the remote controllers holding the records and blocks the map task. The fetch request will invoke a respond task in the remote controller and the map task will be unblocked when all the responses are received. An update task updates a local partition with the received intermediate results (from a map task) using the update function, while a respond task answers a fetch request using a local partition of the side-input collection.

Different from the pull-based shuffle mechanism in MapReduce-like systems (where reducers pull intermediate results from mappers), a push-based shuffle mechanism is used in Tangram, in which updates are pushed to the update partitions on a per-partition basis. Push-based shuffle can overlap network communication with the computation of map tasks, but the system needs to handle more complex read/write conflicts between tasks. To resolve the read/write conflicts for a partition, the controller enforces a simple access control strategy. It assumes that map and respond tasks read a partition, while update tasks write a partition. The controller ensures that writes to a partition are exclusive while reads are not. If there is an ongoing update task on a partition, then map tasks, respond tasks and other update tasks on the same partition will be blocked. If there is an ongoing map or respond task on a partition, then other map and respond tasks on this partition can still run but update tasks will be blocked.

The execution of a plan starts when the global scheduler instructs the local controller to push a number of map tasks to the map thread pool. When the controller receives a fetch/update request, it invokes a respond/update task. The respond/update task is pushed to the thread pool for execution if it satisfies the access control policy; otherwise, it will be inserted into a pending buffer. Once a task finishes, the controller will be notified and it will check the pending buffer to find tasks satisfying the access control policy and push them to the thread pool for execution. The local controller is implemented as a single-thread event loop and manages the pending buffer and all control-related data structures. The event-loop simplifies the implementation logic by avoiding complex locking.

5.2 Partition-Based Progress Control

As a partition is the granularity of task execution in Tangram, each partition can have its own progress. Therefore, Tangram uses a partition-based progress control mechanism to support the BSP, SSP and ASP execution models. Different from parameter-server-based systems, in which progress is associated with a worker, Tangram associates progress with a partition. The local controller records the map progresses of the local map partitions and the update progresses of the local update partitions. Note that when the map collection and the update collection are the same (e.g., in PageRank), a partition has both map progress and update progress. We will show that partition-based progress control also ensures correctness upon failure and improves recovery efficiency in Section 5.3.

At the start of a plan, the map progresses and the update progresses are initialized as zero. When a map task finishes, the map progress of the corresponding partition is incremented by one, and the update requests generated by this map task also carry the map progress (before increment). For an update partition, the local controller uses a bitmap (for each map progress) to record the map partitions for which update has already been committed. The controller sets the update progress of a partition as the minimum progress for which there are still missing updates. The controller assumes that a map partition will generate update for all partitions in the update collection and can confirm that all update requests are committed using the bitmap.

The controller sets its local progress as the minimum update progress of its partitions and reports it to the global scheduler. The global scheduler regards the minimum progress among workers as the global progress and broadcasts it to all workers upon changes. If the staleness is k and the global progress is m, the local controller will only schedule map tasks for its partitions with a progress no larger than $m+k$. An example of progress control is provided in Figure 1. Partition P1 in worker 0 has an update progress of 2 as it has not received

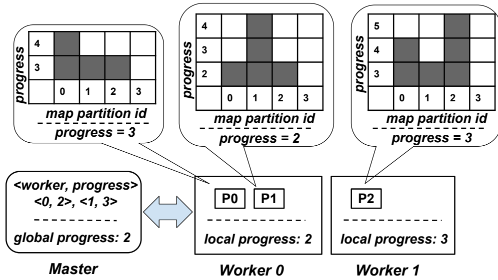

Figure 1: Example of progress management. Dark squares denote the received updates for each update collection.

the update with progress 2 from map partition 3. The local progress of worker 0 is 2 as the update progress of P0 and P1 are 3 and 2, respectively. Collecting the local progresses from worker 0 and worker 1, the master sets the global progress as 2. Once the update with progress 2 from map partition 3 is committed to P1, both the local progress of worker 0 and the global progress will be updated to 3.

Assume that there are M map partitions in total and a machine hosts n update partitions, the machine needs $O(MnT)$ memory to store the bitmap for a plan, where T is the number of active iterations (iterations for which there are uncommitted updates) and is usually small. We reduce the memory consumption of the bitmaps by deleting the bitmap for which all update requests have been committed and creating a bitmap only when receiving a new map progress. As the number of partitions is usually not large, the cost of progress control is acceptable as we will show in our experiments.

5.3 Context-Aware Failure Recovery

Tangram distinguishes two failure scenarios, i.e., *local failure* and *global failure*, and applies different recovery strategies.

Local failure is the case that the failed machines do not hold update partitions. Local failure does not directly affect the task execution on the healthy machines and is similar to losing RDDs with narrow dependency in Spark. In this case, Tangram only reloads the lost partitions on the healthy machines in parallel and sets their progresses as the current global progress. Some of the updates from the lost partitions may have been committed to the update collection and setting their progresses as the global progress may result in repetitive map tasks. Tangram rejects the repetitive updates generated by these map tasks using the bitmap.

Global failure happens when the failed machines contain partitions of the update collection. Examples include losing machines holding the model parameters in logistic regression or the rank values in PageRank. Global failure directly affects the computation on all machines and is similar to losing RDDs with wide dependency in Spark. In this case, Tangram reloads the lost mutable collection from the latest checkpoint and resets the global progress and the progresses of all partitions to the latest checkpoint. But for immutable collections, such as the graph links in PageRank, Tangram only reloads the lost partitions. The master assigns the tasks of loading the lost partitions to the healthy machines in a balanced manner so that the machines can recover from failure in parallel. Moreover, Tangram also respects the co-partitioning relation of the collections in failure recovery.

Tangram infers which collection is mutable and checkpoints only the mutable collections. Checkpointing is conducted in an asynchronous manner and on a per-partition basis, so that the execution of the entire plan does not need to be stopped. When the progress of an update partition reaches the checkpoint iteration, write access is blocked and a copy is written to disk along with the bitmap. Note that this checkpoint may be inconsistent, as the partition may have seen updated from iterations larger than the checkpoint iteration (under ASP or SSP). The bitmap is used to reject repetitive updates from these iterations during recovery. For pipelines that involve multiple plans, Tangram also checkpoints the mutable collections once a plan finishes so that failure recovery can be conducted inside a plan. Tangram only handles worker failures, while the master failure can be handled by a standby master (similar to the standby master in Spark [55]) but is not implemented in the current version.

5.4 Straggler Mitigation

Tangram uses partition migration for straggler handling. As update tasks and respond tasks are relatively lightweight, Tangram focuses on balancing the workload of map tasks by migrating map partitions. For non-iterative workloads (e.g., word count), the master monitors the number of ongoing and pending map tasks on each machine. If some machines do not have map tasks to run, the master migrates some of the map partitions from the heavily loaded machines to them. We allow the system to migrate map partitions with ongoing map tasks, which resembles speculative execution in Spark. Migration does not necessarily require data transfer from slow machines, as will be discussed later.

For iterative workloads, Tangram only handles macro stragglers, while micro stragglers can often be handled by asynchronous execution. By default (tunable by users), Tangram considers a machine as a macro straggler if its per-iteration time is more than 1.1 times of the median (of all machines) in three consecutive iterations or more than 1.5 times of the median in one iteration. Tangram also respects the co-partitioning relation among the collections to avoid high communication overhead after migration.

Tangram adopts different migration strategies for immutable and mutable partitions. For immutable partitions, the destination machines just load them from a shared storage system like HDFS rather than asking the source machine for transfer, since the source machine is already overloaded. For mutable partitions, Tangram uses a migration procedure similar to the two-stage migration in Piccolo [46].

The load of the system may be unbalanced due to skewed partition size (e.g., due to improper hash function). Currently, Tangram does not support online re-partitioning for workload redistribution. Similar to other systems, skewed partitions can be addressed by either fine-grained sharding (setting the number of partitions to be much larger than the number of machines) or providing a tailored partitioning function.

5.5 Communication Optimizations

Delay Combiner. In Tangram, combining the updates from many map tasks leads to higher compression ratio, but sending out the updates immediately reduces latency. We provide a delay combiner, in which users can specify the granularity of combining with a *combine_timeout*. Setting *combine_timeout* to 0 sends out the updates immediately, while setting *combine_timeout* to *kMaxCombineTimeout* combines all local map outputs in an iteration.

Process Cache. The process cache in Tangram is similar to the one in Petuum. Previously fetched records of the side-input collection and their versions are kept in the cache. A new fetch request will not be sent if the records with the required version are already in the cache.

Local Zero-Copy Communication. Tangram utilizes local zero-copy communication whenever possible: if an update request is to be sent to a local partition, it will be moved to the local controller and can be directly accessed by the update task. Similarly, zero-copy communication is also used for fetching local objects.

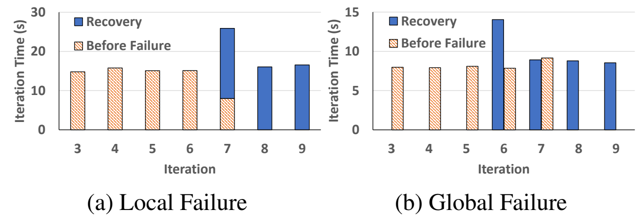
6 Experiments

We implemented Tangram in about 16K lines of C++ code. The communication module was built using ZeroMQ [72] and libhdfs3 [32] was used to exchange data with HDFS without the JNI overhead. Source code for the system and the applications in Section 4 can be found at https://github.com/Yuzhen11/tangram/. We evaluated Tangram on a cluster of 20 machines connected with 1 Gbps Ethernet. Each machine is equipped with two 2.0GHz E5-2620 Intel(R) Xeon(R) CPU (12 physical cores in total), 48GB RAM, a 450GB SATA disk (6Gb/s, 10k rpm, 64MB cache), running on 64-bit CentOS release 7.2. We optimized the number of partitions for both Tangram and the systems we compared in the experiments.

6.1 Failure Recovery & Straggler Mitigation

Failure recovery and straggler mitigation are critical for data analytics in production. In this set of experiments, we show that Tangram achieves efficient failure recovery and effective straggler mitigation, even for workloads with mutable states, by distinguishing immutable and mutable collections.

Failure Recovery. We used two experiments to simulate different failure scenarios. In the first experiment, we unplugged



(a) Local Failure (b) Global Failure

Figure 2: Performance of failure recovery

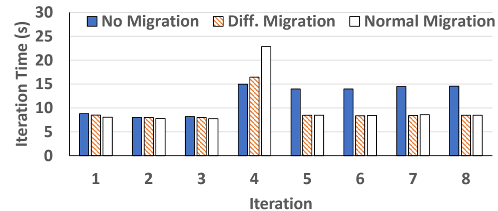


Figure 3: Performance of straggler handling

one machine holding the training data for K-means, which is a *local failure* according to Section 5.3. The second experiment unplugged one machine for PageRank, which corresponds to *global failure*.

We report the failure recovery performance under the two scenarios in Figure 2. For clearer presentation, we only plot the performance of Tangram, while we report the performance of Spark in text as a baseline. For local failure, Tangram took 17.8 seconds to reload the lost training data (∼6 GB) and finish the 7th iteration, while Spark took around 40 seconds to recover. Both Tangram and Spark did not restart the job from the latest checkpoint, but performed re-computation only on the lost partitions. In contrast, most of the mutable systems such as Petuum, PowerGraph and Naiad, would have to roll back to the latest checkpoint in case of any failure.

For the global failure (occurred at the 7th iteration), Tangram rolled back to the latest checkpoint (taken at the 5th iteration) and continued by re-executing the 6th iteration. The roll-back is necessary because some partitions of the (mutable) rank collection are lost. The longer recovery bar at the 6th iteration in Figure 2b includes the normal execution time for the iteration and another 5.2 seconds to reload the mutable collection (∼50 MB) and the lost immutable partitions (∼1 GB). In total, Tangram took 29 seconds to finish the 7th iteration, while Spark took 47 seconds. We note that Spark also requires a full re-computation from checkpoint in this case (i.e., long lineage with wide dependency [70]).

To provide a better picture of Tangram's failure recovery performance, we also implemented the baseline strategies (e.g., full reload, full checkpoint) in Tangram for a fair comparison. A full reload (as used in existing mutable systems) needs to load 121GB and 23GB data, and took 56.8 and 15.7 seconds (vs. Tangram's 17.8 and 5.2 seconds) for K-means and PageRank, respectively. In addition, distinguishing the immutable and mutable parts also results in more efficient checkpointing for PageRank, as checkpointing only the ranks

(∼1GB) took 5 seconds, while a full checkpoint (∼23GB) took 127 seconds. Tangram also supports asynchronous background checkpointing, which makes a copy of the mutable collection and writes the checkpoint in the background. Without background checkpointing, each checkpoint would take an extra 5 seconds for PageRank.

Straggler Mitigation. To test the performance of straggler mitigation, we used *cpulimit* tool to restrict one Tangram worker to have only 600% of the total 2400% cpu shares in the PageRank job at the 4th iteration, and the per-iteration time is reported in Figure 3. *Diff. migration* asks the straggler only for mutable partitions, while *Normal migration* asks the straggler for both mutable and immutable partitions. Both strategies were implemented in Tangram. The result shows that partition migration effectively reduces per-iteration time as an iteration took about 14.5 seconds without migration, but only 8.4 seconds with migration. In addition, distinguishing immutable and mutable collections also speeds up the migration. *Diff. migration* only requires the straggler to transfer the mutable partitions (ranks: ∼50MB) and reloads the immutable partitions (links: ∼ 1GB) from HDFS, which improves migration speed by approximately 38% (10 seconds vs. 16 seconds) compared with *Normal migration*.

6.2 Expressiveness and Efficiency

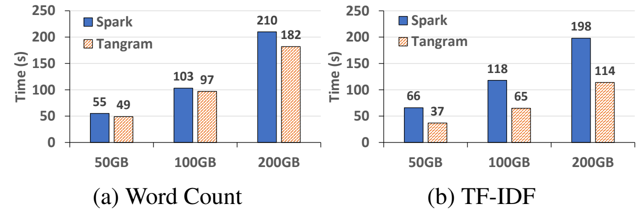
We have shown that the MapUpdate API is flexible and can express a wide variety of workloads in Section 4. In this set of experiments, we show that Tangram achieves comparable performance as specialized systems.

Bulk Processing. For non-iterative bulk processing workloads, e.g., MapReduce-style workloads, we tested word count and TF-IDF[6], and compared with Spark [70] (version 2.2.0). We replicated the Wikipedia corpus [19] to test the scalability of the systems and report the running time in Figure 4.

Tangram achieved slightly better performance compared with Spark for word count, but is 2x faster for TF-IDF. For fair comparison, we ensured that Spark does not write intermediate results to disk before shuffle. Both Tangram and Spark have high CPU utilization (over 80% for all cores overtime) and low disk utilization (less than 20% at most) for the two applications, similar to the results reported in [44]. We also tested the systems on a faster 10-Gbps network and on a single machine, and Tangram's performance advantage over Spark on TF-IDF is consistent in both settings, which shows that network communication is not the key factor that affects the performance of the systems on TF-IDF. We believe the language (C++ vs. Scala) and other system overheads are the main reasons for the performance difference. Tangram also achieves almost linear scaling when increasing dataset size.

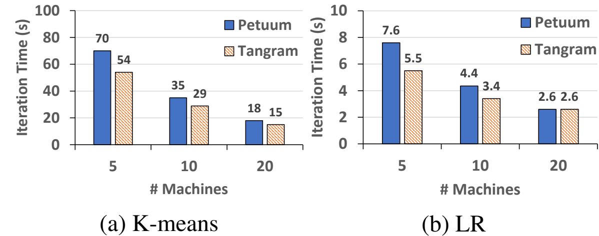
Iterative Machine Learning. For iterative machine learning workloads, we tested K-means [54] and SGD based logistic regression (LR). We used a dense dataset (mnist8m [33]) for

[6] https://en.wikipedia.org/wiki/Tf-idf



(a) Word Count (b) TF-IDF

Figure 4: Running time for word count and TF-IDF



(a) K-means (b) LR

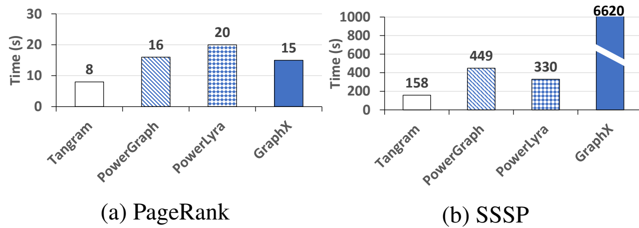
Figure 5: Per-iteration time for K-means and LR

K-means and a sparse dataset (webspam [59] with a sparsity of 2.24×10^{-4}) for LR, in order to test Tangram's performance under different data sparsity. We replicated the datasets 10 times for better scalability tests. BSP was used for K-means, while SSP ($s = 2$) was used for LR. We compared Tangram with the state-of-the-art parameter server system, Petuum Bösen [60]. We did not compare with Spark as it has been shown to be inefficient for iterative machine learning workloads compared with Petuum [29, 62].

Figure 5 reports the per-iteration time obtained by averaging 20 iterations, while varying the numbers of machines. Tangram's performance is very competitive compared with Petuum, as Tangram also supports optimizations generally used in parameter server based systems, such as process cache and message combining (Section 5.5). The scaling performance of Tangram and Petuum is better for K-means than for LR since K-means is CPU-bound, while LR is network-bound due to the large model.

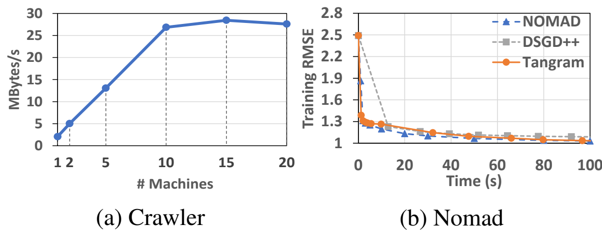
Graph Analytics. For graph analytics workloads, we compared with GraphX [22], PowerGraph [21] and PowerLyra [13]. GraphX is built on Spark and adopts immutable data abstraction, while PowerGraph and PowerLyra use mutable abstraction and support fine-grained state access. We tested PageRank and single source shortest path (SSSP), in BSP mode. We used the webuk graph [7], which has 133M vertices and 5.5B edges.

We report the per-iteration time for PageRank and the total running time for SSSP in Figure 6. Tangram achieves better performance than even the specialized systems. We found that this is because both PageRank and SSSP are network-bound, and message combining in Tangram (edge-cut + delay combiner) is more effective in reducing communication than other systems (vertex/hybrid-cut + combiner). GraphX outperforms PowerGraph and PowerLyra on PageRank as the workload is heavy and balanced in each iteration. In contrast, the access



(a) PageRank (b) SSSP

Figure 6: Comparison on PageRank and SSSP



(a) Crawler (b) Nomad

Figure 7: Performance of distributed crawler and Nomad

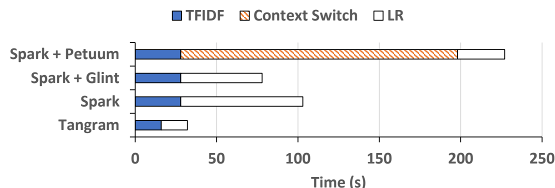


Figure 8: Completion time of the pipelined workload

pattern of SSSP is more sparse, and thus the lack of support for in-place updates renders GraphX inefficient.

Other Workloads. We also evaluated the performance of Tangram on a wider variety of computation patterns using distributed crawler and Nomad [69].

Figure 7a reports the download speed of Tangram-based crawler. The download speed of the crawler scales almost linearly with the number of machines and quickly consumes the download bandwidth of the whole cluster and reaches a plateau, which is similar to Piccolo-based crawler [46].

Nomad is an efficient SGD-based asynchronous algorithm for matrix factorization (MF) and has a complex computation pattern that migrates item latent factors among machines. We used the Yahoo! Music dataset [63] and compared Tangram-based Nomad with MPI-based Nomad [69] and DSGD++ [56] (another state-of-the-art MF algorithm). Figure 7b reports their training root mean square errors (RMSE). Tangram performs slightly worse than MPI-based Nomad initially but catches up later. Compared with MPI-based DSGD++, Tangram has better performance most of the time. Although the MPI-based implementations are efficient, Tangram offers very competitive performance and more user-friendly API.

Pipelined Workload. We implemented a simple pipelined workload that computes TF-IDF vectors with 2^{18} features from the 50GB English Wikipedia dataset and trains an LR model using gradient descent for 30 iterations. We compared

Table 3: Overhead of Task Management & Progress Control

App	Controller CPU %	Bitmap size
WordCount	1.12%	636KB
PageRank	0.99%	638KB
LR	0.29%	341KB
K-means	0.02%	4KB
Nomad	3.38%	153KB

Tangram with Spark, Spark + Glint [28], and Spark + Petuum. Glint is a built-in parameter server for Spark, and thus Spark + Glint uses Spark for TF-IDF and Glint for LR. Spark + Petuum uses Petuum for LR. Other systems (e.g., Naiad [39]) can also handle such a pipeline, but they mainly target at streaming workloads and have more expensive fault tolerance mechanisms. This experiment was conducted using a faster 10-Gbps network but the relative performance of the systems is consistent when running on a 1-Gbps network.

We report the execution time of the pipeline in Figure 8. Tangram used much less time than Spark mainly because Spark is not efficient for machine learning workloads [29, 62]. However, Spark + Petuum took even longer time, even though Petuum was much faster than Spark (29 seconds vs. 75 seconds) for LR. This is because there is a costly context switch overhead when moving from Spark to Petuum (around 170 seconds for dumping and loading the 45GB TF-IDF vectors) [7]. Spark + Glint removes the context-switch overhead and the performance is slightly better than Spark. However, adding dependencies (e.g., Glint) in Spark violates Spark's unified abstraction and breaks Spark's fault tolerance semantics.

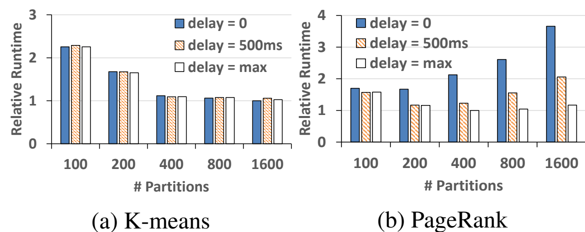
We also tested Flink [10], but LR was an order of magnitude slower on Flink compared with Spark [8]. Thus, we do not report the details of Flink's results. In comparison to these popular systems, the performance of Tangram in Figure 8 demonstrates its benefits as a general and efficient system for processing pipelined workloads.

6.3 Evaluation of System Designs

This set of experiments evaluates the effects of the system designs on the performance of Tangram. We first examine the average CPU consumption of the local controller on each worker and the total size of the bitmap used for progress control. Table 3 shows that the CPU consumption of the local controller is consistently low and the bitmap has a small memory footprint for all workloads. Nomad has the highest controller overhead as the algorithm needs to handle the frequent migration of item latent vectors. K-means has the smallest bitmap size because a single partition is used for the centers. In general, both controller CPU consumption and bitmap size increase with the number of partitions. Empirically, setting the number of partitions to 1-3 times the number

[7] Although in-memory caching systems like RAMCloud [41] or optimized distributed file systems like Tachyon [30] may reduce the context switch cost, the cost of dumping and loading the datasets is still non-negligible.

[8] The per-iteration time of LR using Flink Machine Learning library and using Flink DataSet API is 97x and 21x of that of Spark, respectively.



(a) K-means (b) PageRank

Figure 9: Effects of partitioning and delay combiner

of cores achieves good performance. Thus, the cost of local task control and progress management is acceptable.

Next we examine the effect of the number of partitions. Figure 9 shows that the per-iteration time (as a ratio to the optimal setting) of K-means first decreases and is then stabilized as the number of partitions increases. This is because increasing the number of partitions improves the parallelism, until the cores are fully occupied (the cluster has 480 virtual cores). Beyond that point, using more partitions does not improve performance. For PageRank, the per-iteration time first slightly decreases and then increases with the number of partitions. This is because PageRank is network-bound and thus using more partitions results in more communication. The delay combiner in Section 5.5 can be used to reduce the communication overhead by merging the map outputs from multiple local partitions. By setting the combine timeout to maximum, the per-iteration time of PageRank stays almost constant when increasing the number of partitions beyond 400. For K-means, as it is CPU-bound due to a small number of parameters, using the delay combiner has almost no effect.

7 Related Work

Programming Model. MapReduce [17] has inspired the development of many data-parallel analytics frameworks with two coarse-grained high-order functions, *map* and *reduce*. Map-Reduce-Merge [67] extended MapReduce with a Merge phase to support the join of multiple heterogeneous datasets. HaLoop [9], Twister [18] and Map-Reduce-Update [8] adapted MapReduce for iterative computation. Other frameworks, e.g., Dryad [27], FlumeJava [11], Spark [70], Tez [52], etc., generalized the coarse-grained functional model by introducing dataflow graph, which enables easy construction of pipelines involving multiple stages. CIEL [40] and Ray [38] further support dynamic task graph. Flink [10] and Naiad [39] support the dataflow model on top of their streaming execution engines. Tensorflow [1] adopts dataflow graph to represent machine learning pipelines.

Some systems adopt the distributed shared memory (DSM) model. Piccolo [46] allows user-defined kernels to read and update distributed key-value tables in parallel. Parameter server systems, e.g., DistBelief [16], Project Adam [14], Parameter Server [31], Petuum [60,62], FlexPS [25], incorporate machine learning specialized optimizations such as bounded delay execution. DSM is flexible but the push/pull API is considered more low-level than the functional API in the dataflow model. Husky [66] adopts an object-oriented API to model different computational frameworks. GraphLab [34, 35] uses a data graph to represent computational structure and data dependencies for some machine learning problems. Graph processing frameworks [12, 15, 21, 22, 34, 36, 50, 51, 61, 64, 65, 74] usually expose vertex/edge/subgraph-centric programming models and incorporate graph specific optimizations.

Execution Model. Popular dataflow systems, e.g., Tez [52], DryadLINQ [68], and Spark [70], adopt a BSP execution model, in which a stage waits for its predecessors to finish. Specialized systems often adopt execution models tailored for their target workloads. GraphLab [34, 35] allows asynchronous vertex execution and uses distributed locking to resolve access conflict. Parameter server systems, e.g., Parameter Server [31], Petuum [60], adopt a bounded delay model (SSP) in which the progress differences among workers are bounded by a user-defined threshold. Maiter [73] and PowerGraph [21] support asynchronous execution optimized for graph workloads. In comparison, Tangram supports BSP, SSP and ASP, enabling it to efficiently process various types of workloads such as graph analytics, machine learning, etc.

Scheduling Model. Recent work [37, 43, 45, 53] observed that centralized scheduling is the bottleneck for scaling out when there are a large number of short-lived tasks. To reduce the control plane overhead, Drizzle [57] and Nimbus [37] cache the scheduling decision, while MonoSpark [42] and Canary [48] use local/distributed scheduler. Tangram avoids the centralized scheduling overhead by relying on the local controllers to schedule their own tasks. The global scheduler only launches plans and manages progress.

8 Conclusions

We proposed a programming model called MapUpdate to determine data mutability according to workloads, which not only brings good expressiveness but also enables a rich set of system features (e.g., asynchronous execution) and provides strong fault tolerance. We developed Tangram to support MapUpdate with novel designs such as partition-based progress control and context-aware failure recovery. We also incorporate optimization techniques such as process cache and partition migration. Our experiments show that Tangram is expressive and efficient, and achieves comparable performance with specialized systems for a wide variety of workloads. Our work demonstrates that we do not have to choose either mutable or immutable abstraction, but can embrace both of them in one unified framework to enjoy the best of both worlds.

Abstract

It is a daunting task for a data scientist to convert sequential code for a Machine Learning (ML) model, published by an ML researcher, to a distributed framework that runs on a cluster and operates on massive datasets. The process of fitting the sequential code to an appropriate programming model and data abstractions determined by the framework of choice requires significant engineering and cognitive effort. Furthermore, inherent constraints of frameworks sometimes lead to inefficient implementations, delivering suboptimal performance.

We show that it is possible to achieve *automatic* and *efficient* distributed parallelization of *familiar* sequential ML code by making a few mechanical changes to it while hiding the details of concurrency control, data partitioning, task parallelization, and fault-tolerance. To this end, we design and implement a new distributed ML framework, STRADS-Automatic Parallelization (AP), and demonstrate that it simplifies distributed ML programming significantly, while outperforming a popular data-parallel framework with a *non-familiar* programming model, and achieving performance comparable to an ML-specialized framework.

1 Introduction

The systems community has made significant progress on simplifying distributed parallel programming, producing many high-level frameworks such as MapReduce [13], Spark [54], Pregel [34], PowerGraph [19], GraphX [20], PyTorch [40], and TensorFlow [2]. To automatically parallelize computation while achieving essential requirements such as fault tolerance and load balancing, these frameworks offer constrained programming models and limited data abstractions. For example, Spark offers Resilient Distributed Datasets (RDDs) without fine-grained write access; Spark and MapReduce ask programmers to specify a program using a handful of operators such as *map* and *reduce* while GraphLab requires adopting a rarely used *vertex-centric* programming model.

The programming models of these frameworks are different from a sequential programming model that is widely taught and easily understood [27]. Therefore, it is not surprising that rewriting sequential ML code using the data abstractions and programming models provided by the frameworks incurs significant effort. Furthermore, the simplicity of the mechanisms provided can often result in suboptimal use of cluster resources. These frameworks abstract away data placement, task mapping, and communication, which comes at the cost of limited access to hardware resources, and challenge in implementing ML algorithms efficiently. Studies show that a single threaded [35] or an MPI implementation [50] of popular ML algorithms is up to two orders of magnitude faster than the corresponding implementations on popular frameworks. In summary, a high-level framework often requires data scientists to switch to a **different mental programming model** with its own peculiarities, and it can end up delivering **suboptimal performance**. We believe that the complexity surrounding distributed ML programming as well as the inefficiency in execution are *incidental* and not *inherent*. That is, many sequential ML code can be automatically parallelized to make near optimal use of cluster resources. To prove our point, we present STRADS-AP, a novel distributed ML framework that provides an API requiring minimally-invasive, mechanical changes to sequential ML program code, and a runtime that automatically parallelizes the code on an arbitrary-sized cluster while delivering the performance of hand-tuned distributed ML programs.

STRADS-AP is an evolution of STRADS [26] that provides a framework for parallelizing the execution of ML programs according to user-specified scheduling plan. The plan usually avoids data conflicts, thereby improving statistical progress per iteration. The challenge with STRADS is that the user needs to understand the code and manually come up with a scheduling plan. STRADS-AP addresses this challenge by automatically generating data conflict-free scheduling plan.

STRADS-AP's API frees data scientists from the challenge of molding sequential ML code to a framework's programming model. To achieve this, the STRADS-AP API offers Distributed Data Structures (DDSs), such as *vector* and *map*, that allow fine-grained read/write access to elements, as well as two familiar loop operators. During runtime, these loop operators parallelize loop bodies over a cluster following two popular ML parallelization strategies: asynchronous parallel execution, and synchronous parallel execution, with strong or relaxed consistency.

STRADS-AP's workflow, shown in Figure 1, starts with a data scientist making mechanical changes to sequential code (Figure 1(a, b).) The code is then preprocessed by STRADS-AP's preprocessor and complied into binary code by a C++ compiler (Figure 1(c).) Next, STRADS-AP's runtime executes the binary on nodes of a cluster while hiding details of distributed programming (Figure 1(d).) The runtime system is responsible for (1) transparently partitioning DDSs that store training data and model parameters, (2) parallelizing slices of ML computations across a cluster, (3) fault-tolerance, and (4) enforcing strong consistency on shared data if required, or synchronizing partial outputs with relaxed consistency.

To fill the gap of debugging tools for distributed ML pro-

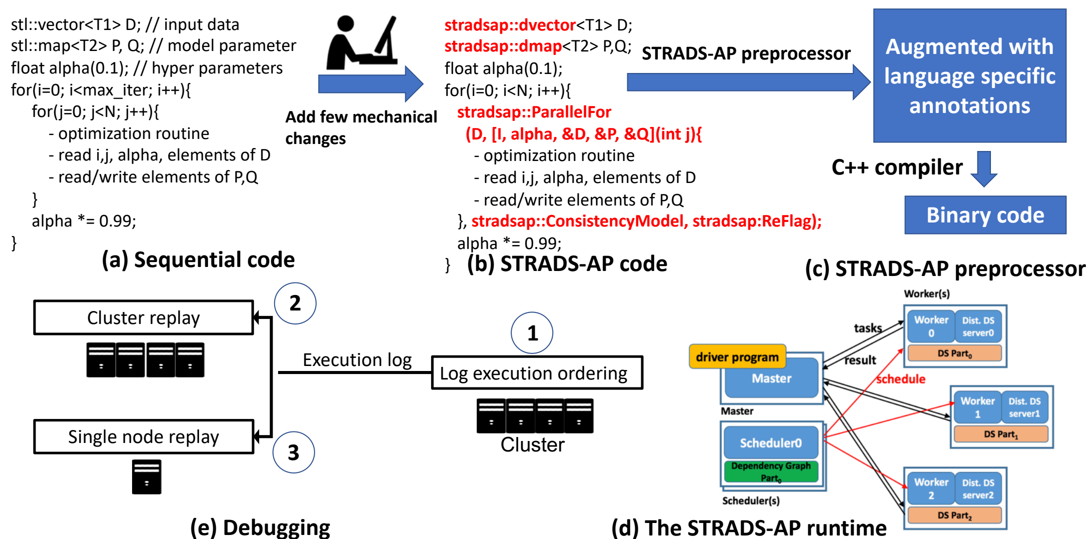

Figure 1: STRADS-AP workflow: (a) Data scientist implements an ML algorithm in sequential code; (b) Derives STRADS-AP parallel code with mechanical changes; (c) STRADS-AP preprocessor adds more annotation to address language-specific constraints, and the source code is compiled by a native compiler; (d) The STRADS-AP runtime runs the binary in parallel on a cluster; (e) Debugging features of STRADS-AP: Logging parallel execution order, and replaying it on a cluster ② for deterministic re-execution, or on a single node ③ for easy debugging.

grams, STRADS-AP offers two debugging modes—*cluster replay* and *single-node replay*—as shown in Figure 1(e). In *cluster replay* mode, the parallel execution log from the previous parallel run is replayed by obeying the same lock grant ordering and message ordering (② in Figure 1(e)), allowing deterministic re-execution. In *single-node replay* mode, the parallel execution log is replayed on a single node (③ in Figure 1(e)) allowing easier inspection of program state with a debugger.

TensorFlow and PyTorch simplify programming Deep Neural Networks (DNN) models, which is just one of the plethora of ML models. Implementing or researching non-DNN models and algorithms in these frameworks, however, often requires adding new kernel operators for parallelization, taking significant effort (Section 6.1). STRADS-AP, on the other hand, provides automatic parallelization of a wide range of non-DNN algorithms by requiring few mechanical changes to a serial implementation.

We implement STRADS-AP as a C++ library in about 16,000 lines of code.[1] STRADS-AP is largely rewritten from scratch, reusing some components of STRADS. We evaluate its performance on a moderate-sized cluster with four widely-used ML applications, using real data sets. To evaluate the increase in user productivity, we ask a group of students to convert a serial ML application to a distributed one using STRADS-AP, and we report our findings. The key contributions of our work are:

- The STRADS-AP API, a familiar C++ STL-like data structures and loop operators, requiring minimal changes when converting sequential ML code to STRADS-AP parallel code.
- The STRADS-AP runtime that achieves low latency DDS access, fault-tolerance, and concurrency control.
- Two debugging modes that simplify debugging and verification of distributed ML programs.
- Performance and productivity evaluation with four well-established ML applications implemented on STRADS-AP.

In the rest of this paper, we first make the case for STRADS-AP by presenting the complications imposed by high-level frameworks on users (Section 2), as well as the performance bottlenecks caused by their simple mechanisms, giving specific examples. We then present the STRADS-AP API (Section 3), and runtime implementation details (Section 4). Next, we give an overview of STRADS-AP's debugging features (Figure 5), followed by an extensive performance and productivity evaluation (Section 6). Finally, we cover the related work (Section 7) and conclude (Section 8).

2 The Cost of Using a Framework

In this section, we demonstrate that converting sequential ML code into high-level framework code requires substantial programming effort and leads to suboptimal performance

Algorithm 1 Pseudocode for SGDMF

1: A: a set of ratings. Each rating contains (i:user id, j:item id, r: rating)
2: W:$M \times K$ matrix; initialize W randomly
3: H:$N \times K$ matrix; initialize H randomly
4: for each rating r in A
5: err = r.r - W[r.i]$*H$[r.j]
6: $\Delta W = \gamma *$(err$*H$[r.j] -$\lambda * W$[r.i])
7: $\Delta H = \gamma *$(err$*W$[r.i] -$\lambda * H$[r.j])
8: W[r.i] += ΔW
9: H[r.j] += ΔH

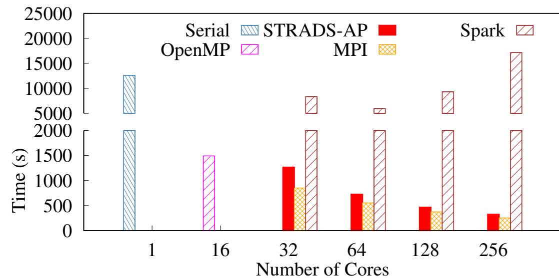
[1] Reported by CLOC [1] tool, skipping blanks and comments.

```
struct rate{int i, int j, float r};
typedef rate T1;
typedef array<float, K> T2;
vector<T1> A = LoadRatings(Datafile_Path);
vector<T2> W(M); RandomInit(W);
vector<T2> H(N); RandomInit(H);
float gamma(.01f), lambda(.1f);
for(int i=0;i<maxiter;i++){
 for(int j=0; j<A.size(); j++){
   const T1 &r = A[j];
   T2 err = r.r - W[r.i]*H[r.j];
   T2 Wd = gamma*(err*W[r.i]-lambda*H[r.j]);
   T2 Hd = gamma*(err*H[r.j]-lambda*W[r.i]);
   W[r.i] += Wd;
   H[r.j] += Hd;
 }
}
```

(a) Sequential SGDMF code

```
struct rate{int i, int j, float r};
typedef rate T1;
typedef array<float, K> T2;
float gamma(.01f), lambda(.1f);
vector<mutex> WLock(M), HLock(N);
for(auto i(0);i<maxiter;i++){
  #pragma omp parallel for
  for(int j=0; j<A.size(); j++){
    const T1 &r = A[j];
    WLock(r.i).lock() // locks to avoid data race
    HLock(r.j).lock()// on shared W,H matrices
    T2 err = r.r - W[r.i]*H[r.j];
    T2 Wd = gamma*(err*W[r.i]-lambda*H[r.j]);
    T2 Hd = gamma*(err*H[r.j]-lambda*W[r.i]);
    W[r.i] += Wd;
    H[r.j] += Hd;
    HLock(r.j).unlock()
    WLock(r.i).unlock()
    // Note that locks are released in reverse
    // ordering of obtaining to avoid deadlock
  }
}
```

(b) Code in (a) parallelized with OpenMP



(e) Time for 60 iterations with Netflix dataset [24], rank = 1000.

```
struct rate{int i, int j, float r};
typedef rate T1;
typedef array<float, K> T2;
dvector<T1> &A = ReadFromFile(Datafile_Path, parser);
dvector<T2> &W = MakeDVector(M, RandomInit);
dvector<T2> &H = MakeDVector(N, RandomInit);
float gamma(.01f), lambda(.1f);
for(int  i=0;i<maxiter;i++){
 AsyncFor(0, A.size()-1, [gamma, lambda, &A,&W,&H](int j){
   const T1 rate &r = A[j];
   T2 err = r.r - W[r.i]*H[r.j];
   T2 Wd = gamma*(err*W[r.i]-lambda*H[r.j]);
   T2 Hd = gamma*(err*H[r.j]-lambda*W[r.i]);
   W[r.i] += Wd;
   H[r.j] += Hd;
 });
}
```

(c) Code in (a) parallellized with STRADS-AP API

```
1  val P = K  // number of executors
2  val ratings = sc.textFile(rfile, P).map(parser)
3  val blks=sc.parallelize(0 until P, P).persist()
4  val W = blks.map(a->Create_WpSubmatrix(a))
5  var H = blks.map(a->Create_HpSubmatrix(a))
6  var AW = ratings.join(W,P)
7  var AWH = AW.join(H,P).mapPartitions(a->ComputeFunc(a,0))
8  float gamma(.01f), lambda(.1f);
9  for(auto i(0);i<maxiter;i++){
10   for(auto sub(0);sub<P;sub++){ // subiteration
11     val idx = i*P + sub;
12     if(idx > 0){
13       AWH = AW(idx).join(H,P).
14         mapPartitions(a->ComputeFunc(a,subepoch))
15     }
16     AW = AWH(idx).mapPartitions(x->separateAW_Func(x))
17     H = AWH.map(x->separateH_and_Shift_Func(x))
18   }
19 }
20 def ComputeFunc(it:Iterator to AWH){
21   val tmp = ArrayBuffer[type of AWH]
22   for(e <- it){
23     val Ap = e.Ap
24     var Wp = e.Wp
25     var Hp = e.Hp
26     for(auto r: Ap){
27       if(r.2 not belong to Hp)
28         continue //skip if not in Hp item indices
29       val err = r.3 - Wp[r.1]*Hp[r.2]
30       val Wd = gamma*(err*Wp[r.1]-lambda*Hp[r.2])
31       val Hd = gamma*(err*Hp[r.2]-lambda*Wp[r.1])
32       Wp[r.i] += Wd
33       Hp[r.j] += Hd
34     } // end of for(auto r ..
35     tmp += Tuple2(e.key, ((Ap, Wp), Hp));
36   } // end of for(e ..
37   val ret = tmp.toArray
38   ret.iterator
39 } // end of def update_Func
```

(d) Algorithm 1 reimplemented with Spark

Figure 2: SGDMF (Algorithm 1) implemented as sequential code (a), and parallelized using OpenMP (b), STRADS-AP (c) and Spark (d). The code snippets show only the core training routine, and do not include data loading and parsing code. STRADS-AP code requires fewer changes to the sequential code compared to OpenMP code, while achieving efficient distributed parallelism in addition to shared-memory parallelism. Spark, on the other hand, requires a complete reimplementation using its abstractions. STRADS-AP outperforms Spark by more than an order of magnitude (e) and continues to scale up to 256 cores, while Spark stops scaling at 64 cores. Hand-tuned MPI code is faster than STRADS-AP by 22% on 256 cores at the cost of a significantly longer programming and debugging effort.

that is orders of magnitude slower than a STRADS-AP implementation, or a hand-tuned implementation.

As a concrete example, we choose Spark as the framework, and Matrix Factorization (MF) as the algorithm—a popular recommender systems algorithm. First, we write sequential code that solves MF using Stochastic Gradient Descent (SGD), denoted as SGDMF in Algorithm 1. Then, we convert the sequential code into three different parallel implementations—shared-memory, STRADS-AP, and Spark—and compare their performance.

2.1 Programming Effort

MF learns user's preferences over all items from an incomplete rating dataset represented as a sparse matrix $A \in \mathbb{R}^{M \times N}$ where M and N are the number of users and items, respectively. MF factorizes the incomplete matrix A into two low-rank matrices, $W \in \mathbb{R}^{M \times K}$ and $H \in \mathbb{R}^{N \times K}$, such that $W \cdot H^T$ approximates A.

Algorithm 1 iterates through the ratings in the matrix A and for each rating $r_{i,j}$, it calculates gradients $\Delta W[i]$, $\Delta H[j]$ and adds the gradients to $W[i]$, $H[j]$, respectively. The computed parameter values for the rating $r_{i,j}$ are immediately visible when computing the next rating, which is an example of asynchronous computation.

2.1.1 Sequential SGDMF code

Sequential implementation of Algorithm 1 is a direct translation of the pseudocode as shown in Figure 2(a).

2.1.2 OpenMP Parallel SGDMF

We parallelize the sequential code in Figure 2(a) using OpenMP [12] to form a single-node baseline. We make two modifications to the sequential code as shown in Figure 2 (b): annotate the loop with parallel-for pragma to let the OpenMP runtime know what to parallelize, and add mutexes to avoid data race on shared matrices W and H. OpenMP parallelizes the inner loop over loop indices using fork-join model where threads run the loop body with different loop indices and join at the completion.

2.1.3 STRADS-AP Distributed SGDMF

Parallelizing the same sequential code using STRADS-AP is done almost mechanically by (1) replacing serial data structures with STRADS-AP's distributed data structures, and (2) replacing the inner loop with STRADS-AP's AsyncFor loop operator, as shown in Figure 2(c).

Unlike OpenMP code, STRADS-AP code has no explicit locking. The runtime is responsible for addressing data conflicts on matrices W and H while executing the loop body in a distributed setting, relieving users from writing error-prone locking code. With little effort, STRADS-AP achieves efficient distributed parallelism, in addition to shared-memory parallelism.

2.1.4 Spark Distributed SGDMF

Unlike with STRADS-AP, parallelizing the sequential code in Figure 2 (a) with Spark requires significant programming effort as detailed below.

Concurrency Control: Spark lacks concurrency control primitives. Since the inner loop of SGDMF leads to data dependencies when parallelized, we need to implement a scheduling plan for correct execution. Reasoning about concurrency control is application-specific and often requires a significant design effort. For SGDMF, we use the Strata scheduling algorithm by Gemulla [18]. The scheduling code shown in Figure 2(d) (lines 9-19) and the training code (lines 20-40) were abridged to fit the page.

Molding SGDMF to Spark API: Even after handling concurrency, implementing SGDMF in Spark requires substantial programming effort for the following reasons.

First, Spark operators, such as *map*, operate on a single RDD object, while the inner loop body in Figure 2(a) accesses multiple objects: the input data A, and the parameter matrices W and H. To parallelize the inner loop with *map* we need to merge A, W, and H into a single RDD, requiring multiple *join* operations involving costly data shuffling.

Second, merging via *join* operator requires changes to data structures. Since *join* operator works only on RDD[Key,Value] type, we have to replace the vectors A, W, H, in Figure 2(a), with RDD[K,V] where V might be also key-value pair type.

Finally, data movement for concurrency control requires extra *join* and *map* operations. At the end of every subiteration, the Strata scheduling algorithm moves H partitions among nodes, which requires two extra operations for every subiteration: (1) a *map* operation that separates H from the merged RDD and modifies the key field of H, (2) a *join* operation that remerges H and AW into AWH for the next subiteration, as shown in Figure 2(d) (lines 9-19.)

In summary, engineering the Spark implementation of SGDMF algorithm involves a large amount of *incidental* complexity that stems from the limitations of Spark API and its data abstractions. As we show next, in addition to the loss in productivity, there is also a loss in efficiency.

2.2 Performance Cost

As a baseline for the distributed implementations, we implement SGDMF using MPI [16] and OpenMP, which are efficient at the cost of larger programming effort. MPI SGDMF uses the same Strata scheduling algorithm and point-to-point communication to circulate H partitions among nodes. All SGDMF implementations achieve proper concurrency control, making similar statistical progress per iteration. Therefore, our performance comparison focuses only on elapsed time for running 60 iterations, after which all implementations converge. We run experiments with Netflix dataset using up to 256 cores on 16 machines that are connected via 40Gbps Ethernet.

As Figure 2(e) shows, Spark is about 68$\times$ slower than MPI on 256 cores. In the same setting, STRADS-AP is slower than

	Requires Changing Programming Model	Programming Language	Application-Level Concurrency Control	Hides Details of Distributed Programming	Fault Tolerance	Debuggability for Distributed ML
STRADS-AP	No	C++	Yes	Yes	Yes (Fast re-execution)	Yes

TensorFlow [2]	Yes (data-flow)	Multi	No	Yes	Yes (Checkpoint)	Yes
Parameter Server [31]	Yes (key-value)	C++	No	Partly (parameter comm)	Yes (Replication)	No
MPI [16]	Yes (message-passing)	C	No	Partly (communication)	No	No
UPC [14]	Yes (PGAS)	C	Partly (lock APIs)	Yes	No	No

Table 1: Summary of features of frameworks used in distributed ML programming. For detailed comparison, refer to Section 2.3 and Section 7. For efficiency comparison, see Section 6

MPI by only 22%, whereas it is over 50× faster than Spark. The suboptimal performance of Spark implementation is due to the aforementioned factors (Section 2.1.4). STRADS-AP is 38.8 and 4.6 times faster than sequential and OpenMP, respectively.

2.3 Other High-Level Frameworks

Our findings of incidental complexity and suboptimal performance are not limited to the example of Spark and SGDMF. For example, PowerGraph provides concurrency control mechanisms, but its *vertex-centric* programming model requires users to redesign data structures to fit to a graph representation and express computations using GAS (Gather, Apply, Scatter) routines. TensorFlow provides a very high-level programming model taking a loss function and automates the gradient update process but does not support serializable asynchronous computation well. Parameter Servers (PS) [3,11,31,48] abstract away the details of parameter communication through the key-value store interface but many other details of distributed parallel programming, such as data partitioning, parallelization of tasks, and application-level concurrency control, are left to the user; that is, PS does not provide an illusion of sequential programming. UPC [14] extends the C programming language with Partitioned Global Address Space (PGAS) programming model that burdens the programmer with the job of doing careful performance tuning (i.e. affinity between threads and shared memory partitions, low-level data layout, use of collective functions such as gather, scatter, reduce.) As Table 1 shows, STRADS-AP and Orion [49] are the only frameworks that allow users to take their sequential code and automatically parallelize it to run on a cluster without sacrificing productivity or efficiency. STRADS-AP owes this flexibility to its familiar API and data structures that we describe next. The differences between STRADS-AP and Orion are described in detail in Section 7.

3 STRADS-AP Programming Interface

STRADS-AP targets ML applications with a common structural pattern consisting of two parts: (1) pretraining part that initializes the model and input data structures, and performs coarse-grained transformations; (2) training part that iteratively optimizes the objective function using nested loop(s) where inner loop(s) perform optimization computations.

To implement a STRADS-AP application, a user writes a simple *driver program* that declares hyper-parameters, invokes operators to create and transform DDSs (Figure 3 (a)), and then invokes STRADS-AP loop operators for optimization (Figure 3(b).) We describe each of these in the following subsections.

```
Create and initialize data structures D for input data
Create and initialize data structures P for model parameters
// run transformations on input data or parameter if necessary
Create and initialize hyper parameters V to control training
```

(a) Pretraining part

```
for(i=0; i<maxiter; i++){// outer loop
  for(j=0; j<N; j++){// inner loop
    // Computations for optimization happen here
    Read a part of input data D
    Read hyper parameters V and loop indices i,j
    Read/writes to a part of model paraemters P
  }
  change hyper parameters
  if(stop condition is true)
    break;
}
```

(b) Training part

Figure 3: ML applications targeted by STRADS-AP are divided into two parts: (a) pretraining part and (b) training part.

3.1 Distributed Data Structures (DDSs)

Table 2 shows a subset of STRADS-AP programming interface. DDS[T] is a mutable in-memory container that partitions a collection of elements of type T over a cluster. DDSs provide a global address space abstraction with fine-grained read/write access and uniform access model independent of whether the accessed element is stored in a local memory or in the memory of a remote node. STRADS-AP offers three types of containers: *dvector*, *dmap*, and *dmultimap*, with interfaces similar to their C++ STL counterparts. These DDSs allow all threads running on all nodes to read and write arbitrary elements while unaware of details such as data partitioning and placement.

Support for distributed and fine-grained read/write accesses gives STRADS-AP an important advantage over other frameworks. It allows reuse of data structures and routines from a sequential program by changing just the declaration of the data type. We describe the inner workings of DDSs in Section 4.3.

3.2 STRADS-AP Operators

The two parts of ML applications, pretraining and training (Figure 3), have different workload characteristics. Pretraining is data-intensive, non-iterative, and embarrassingly-parallel,

	Type	Description
Distributed Data Structures (DDSs)	dvector[T]	A distributed vector of type T elements with per-element read/write access
	dmap[K,V]	A distributed map of [K,V] element pairs of type K and V with per-element read/write access
	dmultimap[K,V]	A distributed multimap of [K,V] element pairs of type K and V with per-element read/write access
Loop Operators	AsyncFor(int64 **S**, int64 **E**, UDF **F**)	Parallelizes closure **F** over indices [**S**, **E**] in isolated manner—avoid ing data conflicts
	SyncFor(DDS[T] **&D**, int **M**, UDF **F**, SyncOpt **S**, bool **RE**)	Parallelizes closure **F** over minibatches of **D** each of size **M** using synchronization option **S** in data-parallel manner. **RE** indicates whether to perform Reconnaissance Execution(§ 4.2)

Table 2: A subset of STRADS-AP API—DDSs, and loop operators for ML training.

whereas training is compute-intensive and iterative, and the inner loop(s) may have data dependencies. STRADS-AP provides two sets of operators that allow natural expression of both types of computation.

3.2.1 Pretraining Operators

STRADS-AP provides *Map*, *Reduce*, *Join*, *Load*, and *Create* operators for loading, storing, and creating DDSs during pretraining. However, STRADS-AP puts no constraints on their usage for expressing training computations.

3.2.2 Loop Operators

STRADS-AP provides loop operators shown in Table 2 to replace the inner loop(s) in the training part of ML programs (Figure 3 (b)). The loop operators take a user-defined closure as the loop body. The closure is a C++ lambda expression that captures the specified DDSs and variables in the scope, and implements the loop body by reading from and writing to arbitrary elements of the captured DDSs. This allows users to mechanically change the loop body of a sequential ML program to STRADS-AP code that is automatically parallelized.

STRADS-AP supports four models of parallelizing ML computations: (1) serializable asynchronous [33], (2) synchronous (BSP [46]), (3) stale-synchronous (SSP [23]), and (4) lock-free asynchronous (Hogwild! [38]) within a node and synchronous across nodes, which we call Hybrid.

STRADS-AP offers two loop operators to support these models. A user can choose AsyncFor loop operator for serializable asynchronous model. For the remaining models a user can choose SyncFor operator and specify the desired model as an argument to the loop operator, as shown in Table 2. Other than choosing the appropriate loop operator, a user does not have to write any code for concurrency-control—the STRADS-AP runtime will enforce the chosen model as described next.

AsyncFor parallelizes the loop over loop indices and ensures isolated execution of the loop bodies even if loop bodies have shared data. In other words, it ensures serializability: the output of the parallel execution matches the ordering of some sequential execution.

AsyncFor takes three arguments: the start index S, the end index $S+N$, and a C++ lambda expression F. It executes $N+1$ lambda instances, $F(S), F(S+1), \ldots, F(S+N)$ concurrently. At runtime, STRADS-AP partitions the index range $S, \ldots, S+N$ into P chunks of size C, and schedules up to P nodes to concurrently execute F with different indices. A node schedules multiple threads to run C lambda instances allowing arbitrary reads and writes to DDSs.

If the lambda expression modifies a DDS, then data conflicts will happen. Although ML algorithms are error-tolerant [23], some algorithms, like Coordinate Descent Lasso [29, 45], LDA [5, 53], and SGDMF [18, 28] converge slowly in the presence of numerical errors due to data conflicts. Following previous work [26], STRADS-AP runtime improves statistical progress by avoiding data conflicts using data conflict-free scheduling for lambda executions. Figure 2(c) shows an example use of AsyncFor implementing SGDMF.

SyncFor parallelizes the loop over the input data. It splits input data into P chunks, where each chunk is processed by P nodes in parallel. Each node processes its data chunk, updating a local replica of model parameters.

SyncFor takes five arguments: the input data D of type DDS[T], the size of a mini-batch M, a C++ lambda expression F, a synchronization option (BSP, SSP, or Hybrid), and a flag indicating whether it should perform Reconnaissance Execution (Section 4.2). The runtime partitions the input data chunk of a node into L mini-batches of size M (typically L is much larger than the number of threads per node), and then schedules multiple threads to process mini-batches concurrently. A thread executes the lambda expression with a local copy of captured variables, and allows reads and writes only to the local copy while running F. At the end of processing a mini-batch, a separate per-node thread synchronizes the local copy of only those DDSs captured by reference across the nodes, and synchronizes local threads according to the sync option. Figure 4 shows an example use of SyncFor that reimplements Google's Word2vec model [22].

By default, SyncFor performs averaging aggregation of model parameters. Users can override this behavior by registering an application-specific aggregation function to a DDS through RegisterAggregationFunc() method.

4 Implementation

This section covers important details of STRADS-AP implementation: the driver program execution (Section 4.1), Reconnaissance Execution (Section 4.2), DDSs (Section 4.3), Concurrency Control (Section 4.4), and STRADS-AP preprocessor (Section 4.5).

4.1 Execution of Driver Program

In the STRADS-AP driver program, the statements are classified into three categories: sequential statements, STRADS-AP

```
typedef vector<word> T1;
typedef vector<array<float, vec_size>> T2;
dvector<T1> &inputD = ReadFromFile<T1>(path, parser);
dvector<T2> &Syn0 = MakeVector<T2>(vocsize, initrow1);
dvector<T2> &Syn1 = MakeVector<T2>(vocsize, initrow1);
float alpha = 0.025;
int W = 5, N = 10;
vector<int> &dtable = InitUnigramtable();
expTable &e = MakeExpTable();
for (int i = 0; i < maxiter; i++){
  SyncFor(inputD, mini-batchsize,
  [W, N, alpha, e, dtable, &Syn0, &Syn1]
  (const vector<T1> &m){
    for (auto &sentence: m){
      //for each window in setence, pick up W words
      //  for each word in the window
      //    run N negative sampling using dist. table
      //    r/w to N rows of Syn0 and Syn1 tables
    }
  }, Hybrid, false);
}
```

Figure 4: Reimplementing Google's Word2vec model using STRADS-AP API.

data processing statements, and STRADS-AP loop statements. The runtime maintains a state machine with one state per category to keep track of the type of code to execute. A driver node starts the driver program in sequential state, and performs sequential execution locally until the first invocation of a STRADS-AP operator. On a STRADS-AP operator invocation, the state machine switches to the corresponding state and the runtime parallelizes the operator over multiple nodes. At the completion of the STRADS-AP operator, the runtime switches back to sequential state and continues running the driver program locally.

The key challenges of the STRADS-AP runtime design are: (1) full automation of concurrency control when parallelizing loop operators, and (2) reducing the latency of accessing DDS elements located on remote nodes. To address these challenges, STRADS-AP implements Reconnaissance Execution.

4.2 Reconnaissance Execution

The runtime system keeps track of the number of invocations of all loop operators in the driver program. On the first invocation of a loop operator, the runtime starts Reconnaissance Execution (RE)—a *virtual execution* of the loop operator. RE is a read-only execution that performs all reads to DDSs, and discovers read/write sets for individual loop bodies. A read/write *access record* of a loop body is a list of tuples, each consisting of a DDS identifier and a list of read/write element indices.

The runtime uses a read/write set for two purposes: (1) performing dependency analysis and generating a data conflict-free scheduling plan for concurrent execution of loop bodies in the AsyncFor operator, and (2) prefetching and caching of DDS elements on remote nodes for low-latency access during the *real execution*.

For the SyncFor operator, when the parameter access is sparse (that is, a small portion of parameters are accessed when processing a mini-batch), the runtime reduces the amount of data transferred by referring to *access records* of RE. However, in applications with dense parameter access, (that is, most parameters are accessed when processing a mini-batch), RE does not help to improve the performance. Therefore, the SyncFor operator's boolean RE parameter (Table 2) allows users to skip RE and prefetch/cache all elements of DDSs captured by the corresponding lambda expression.

To reduce RE overhead, STRADS-AP runs it once per parallel loop operator in the driver program, and reuses read/write set for subsequent iterations. This optimization is based on two assumptions about ML workloads: (1) *iterativeness*—a loop operator is repeated many times until convergence, and (2) *static control flow*—read/write sets of loop bodies do not change over different iterations. That is, the control flow of the inner loop does not depend on model parameter values. Both assumptions are routinely accepted in ML algorithms [3–5, 8, 17, 24, 28, 30, 41, 45, 51–53, 55].

4.3 Distributed Data Structures

On the surface, a DDS is a C++ class template that provides index- or key-based uniform access operator. Under the hood, the elements of a DDS are stored in a distributed in-memory key-value store as key-value pairs. The key is uniquely composed of the table id plus the element index for *dvector*, and the table id plus the element key for *dmap/dmultimap*. Each node in a cluster runs a server of the distributed key-value store containing the elements of a DDS partitioned by the key hash. The implementation of DDS class template reduces the element access latency by prefetching and caching remote elements based on the access records generated by RE (Section 4.2).

The DDSs achieve fault-tolerance through checkpointing. At the completion of a STRADS-AP operator that runs on DDSs, the runtime takes snapshots of any DDSs that were modified or created by the operator. The checkpoint I/O time overhead is negligible because ML programs are compute-intensive, and the input data DDSs are not checkpointed (except once at creation), as they are read-only.

The traditional approach to checkpointing is to dump the whole program state onto storage during the checkpoint, and load the state from the last successful checkpoint during the recovery. Since an ML program may have an arbitrary number of non-DDS variables (like hyper-parameters), the traditional approach would require users to write boilerplate code for saving and restoring the state of these variables, reducing productivity and increasing opportunities for introducing bugs. Therefore, STRADS-AP takes a different approach to checkpointing that obviates the need for such boilerplate code.

Upon a node failure, STRADS-AP restarts the application program in *fast re-execution* mode. In this mode, when the runtime encounters a parallel operator *op* executing iteration i, it first checks to see whether a checkpoint for op_i exists. If yes, the runtime skips the execution of op_i and loads the DDS state from the checkpoint. Otherwise, it continues *normal execution*. Hence, the state of non-DDS variables are quickly and correctly restored without forcing the users to write extra code.

4.4 Concurrency Control

STRADS-AP implements two concurrency control engines: (1) *serializable engine* for the AsyncFor operator, and (2) *data-parallel engine* for the SyncFor operator. Both engines use the read/write set from Reconnaissance Execution (Section 4.2) for prefetching remote DDS elements, while the serializable engine also uses it for making data conflict-free execution plans.

4.4.1 Serializable Engine for AsyncFor

In the serializable engine, a task is defined as the loop body with a unique loop index value i, which ranges from S to E, where S and E are AsyncFor arguments (Table 2). The serializable engine implements a scheduler module that takes the read/write set from RE, analyzes data dependencies, generates a dependency graph, and generates a parallel execution plan that avoids data conflicts. To increase parallelism, the serializable engine may change the execution order of tasks assuming that any serial reordering of the loop body executions is acceptable. This assumption is also routinely accepted in ML computations [26, 33, 39].

The scheduler divides the loop bodies into N *task groups*, where N is much larger than the number of nodes in a cluster, using an algorithm that combines the ideas of static scheduling from STRADS [26] and connected component-based scheduling from Cyclades [39]. The algorithm allows dependencies within a task group but ensures no dependency across task groups. At runtime, the scheduler places task groups on nodes, where each node keeps a pool of task groups.

To balance the load, serializable engine runs a greedy algorithm that sorts task groups in the descending order of size, and assigns task groups to the node whose load is the smallest so far. Once task group placements are finalized, the runtime system starts the execution of the loop operator.

The execution begins by each node initializing DDSs to prefetch necessary elements from the key-value store into a per-node DDS cache. Then each node creates a user-specified number of threads, and dispatches task groups from the task pool to the threads. All threads on a node access the per-node DDS cache without locking, since each thread executes a task group sequentially, and the scheduling algorithm guarantees that there will be no data conflicts across the task groups. In the case of an excessively large task group, we split it among the threads and use locking to avoid data races, which leads to non-deterministic execution.

To reduce scheduling overhead, the serializable engine caches the scheduling plan and reuses it over multiple iterations based on the aforementioned assumptions (Section 4.2). Hence, the overhead of RE and computing a scheduling plan is amortized over multiple iterations.

4.4.2 Data-Parallel Engine for SyncFor

In the data-parallel engine, a task is defined as the loop body with a mini-batch of D with size M, where D and M are SyncFor arguments (Table 2). Hence, a single SyncFor call generates multiple tasks with different mini-batches. The engine places the tasks on nodes that hold the associated mini-batches, where nodes form a pool of assigned tasks.

Similar to the serializable engine, an execution begins by each node initializing DDSs to prefetch necessary elements from the key-value store into the per-node DDS cache, based on the read/write set from RE, and continues by creating a user-specified number of threads.

Unlike the serializable engine, the threads contain a per-thread cache, and are not allowed to access the per-node cache, since in this case there is no guarantee of data conflict-free access. When a node dispatches a task from the task pool to a thread, it copies the parameter values from the per-node cache to the per-thread cache.

Upon task completion, a thread returns the delta between the computed parameter values and the starting parameter values. The node dispatches a new task to the thread, accumulates deltas from all threads, and synchronizes per-node cache with the key-value store by sending the aggregate delta and pulling fresh parameter values.

The SyncFor operator allows users to choose among BSP, SSP, and Hybrid (Section 3.2.2) models of parallelizing ML computations. The BSP [46] and SSP [23] models are well-known, and our implementation follows previous work. Hybrid, on the other hand, is a lesser-known model [25]. It allows lock-free asynchronous update of parameters among threads within a node (Hogwild! [38]), but synchronizes across machines at fixed intervals. In the Hybrid model, a node creates a single DDS cache that is accessed by all threads without taking locks. When all of the threads complete a single task, which denotes a subiteration, the node synchronizes the DDS cache with the key-value store.

4.5 STRADS-AP Preprocessor

While there exist mature serialization libraries for C++, none of them support serializing lambda function objects. The lack of reflection capability in C++, and the fact that lambda functions are implemented as anonymous function objects [36], make serializing lambda challenging. We overcome this challenge by implementing a preprocessor that analyzes the source code using Clang AST Matcher library [10], identifies the types of STRADS-AP operator arguments, and generates RPC stub code and a uniquely-named function object for each lambda expression that is passed to STRADS-AP operators.

The preprocessor also analyzes the source code to see if it declares DDSs of user-defined types. While DDSs of built-in types are automatically serialized using Boost Serialization library [6], for user-defined types the library requires adding boilerplate code, which is automatically added by the preprocessor.

5 Debugging STRADS-AP Applications

STRADS-AP supports two debugging modes: (1) *cluster replay* mode, and (2) *single-node replay* mode. Currently, STRADS-AP debugging modes support only serializable parallel execution generated by AsyncFor operator whose

Dataset	Workload	Feature	Size	Application	Purpose
Netflix [24]	100M ratings	489K users, 17K movies, rank=1000	2.2 GB	SGDMF	Recommendations
1Billion [9]	1 billion words	Vocabulary size 308K, vector size=100	4.5 GB	Word2Vec	Word Embeddings
ImageNet [43]	285K images	1K classes, 21K features, preprocessed by LCC feature extraction [47]	21 GB	MLR	Multi-Class Classification
FreeBase-15K [7]	483K facts	14,951 entities, 1,345 relations, vector size=100	36 MB	TransE	Graph Embeddings

Table 3: Datasets used in benchmarks.

Application	Serial	OpenMP	MPI	STRADS-AP	TF	Spark
SGDMF	✓	✓	✓	✓		✓
MLR	✓	✓	✓	✓	✓	
Word2vec	✓	✓	✓	✓	✓	
TransE	✓			✓		

Table 4: ML programs used for benchmarking. Serial and OpenMP are single core and multi-core applications on a shared-memory machine, respectively, while the rest are distributed parallel applications. MPI applications use OpenMP for shared-memory parallelism within the nodes.

execution can be non-deterministic (Section 4.4.1). The support for SyncFor operator is in progress.

Cluster Replay: The AsyncFor operator allows non-deterministic execution for achieving high performance. Instead of predefined deterministic execution [32], STRADS-AP logs the execution order including lock grant ordering and message ordering, and allows users to replay the log. For this purpose, STRADS-AP implements record/replay modules. The record module records the ordering of lock grantings in every node, and the ordering of message arrivals in the DDS key-value store into persistent storage. To avoid coordination overhead and bottlenecking a single node, each node records partial ordering locally, without making a total ordering. When replaying the log, each node enforces the same partial order.

Single-node Replay: Debugging an ML program can be classified into two categories: (1) search for a traditional software bug, and (2) the inspection of the optimization path. Unfortunately, these debugging tasks are not easy to do in a distributed environment since step-by-step tracing of a distributed application is hard. To address this problem, STRADS-AP offers *single-node replay* mode for parallel ML applications. The *single-node replay* mode takes a parallel execution log, and replays the ordering in a single node setting, where users can trace the program execution using a debugger like GDB.

6 Evaluation

We evaluate STRADS-AP on (1) application performance, and (2) programmer productivity, using the following real world ML applications: SGDMF, Multinomial Logistic Regression (MLR), Word2vec, and TransE [7], summarized in Table 4.

For performance evaluation, as a baseline we implement these applications as (1) a sequential C++ application, (2) a single-node shared-memory parallel C++ application using OpenMP, and (3) a distributed- and shared-memory parallel C++ application using MPI and OpenMP. We then compare the iteration throughput (time per epoch) and the statistical accuracy of Spark, TensorFlow (TF), and STRADS-AP implementations of these applications to those of the baselines, while running them on real datasets shown in Table 3. For brevity, in the rest of the paper, when we mention that an application is implemented using MPI, we mean that it uses OpenMP on a single node and MPI among the nodes.

For productivity evaluation, we conduct two user studies on a group of students with Word2vec and TransE applications. As a measure of productivity, we count the lines of code produced, and measure the time it took students to convert a serial implementation of the algorithm into a STRADS-AP implementation.

All experiments were run on a cluster with 16 machines each with 64 GB of memory and 16-core Intel Xeon E5520 CPUs, running Ubuntu 16.04 Linux distribution, connected with 40 Gbps Ethernet network. The reported numbers are the averages of at least three runs. Error bars are not included due to low variance among the runs.

6.1 Word2Vec

Word2vec is a Natural Language Processing (NLP) model developed by Google that computes vector representations of words, called "word embeddings". These representations can be used for various NLP tasks, such as discovering semantic similarity. Word2vec can be implemented using two architectures: continuous bag-of-words (CBOW) or continuous skip-gram, the latter of which produces more accurate results for large datasets [22].

We implement the skip-gram architecture in STRADS-AP based on Google's open source multithreaded implementation [22] written in C. We make two changes to Google's implementation: (1) modify it to keep all the input data in memory to avoid I/O during training, and (2) replace POSIX threads with OpenMP. After our changes, we observe 6% increase in performance on 16 cores. We then run our improved implementation using a single thread for the serial baseline, and using 16 threads on 16 cores for the shared-memory parallel baseline.

Google recently released a highly-optimized multithreaded Word2vec [21] implementation on TensorFlow with two custom kernel operators written in C++. As of now, Google has not yet released a distributed version of Word2vec on TensorFlow. Therefore, we extend Google's implementation to run in a data-parallel distributed setting. To this end, we modify the kernel operators to work on partitions of input data, and synchronize parameters among nodes using MPI.

Performance Evaluation: Figure 5 shows the execution time

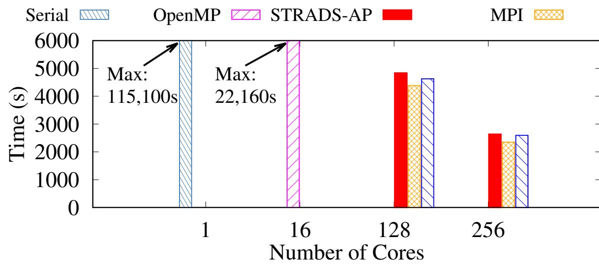

Figure 5: Time for 10 iterations of Word2Vec on 1 Billion word dataset [9] with vector size = 100, window = 5, negative sample count = 10.

Cores	Similarity			Analogy		
	STRADS-AP	MPI	TF	STRADS-AP	MPI	TF
128	0.601	0.601	0.602	0.566	0.564	0.568
256	0.603	0.597	0.601	0.562	0.557	0.561

	Similarity	Analogy
Serial	0.610	0.570
OpenMP	0.608	0.571

Table 5: The top table reports similarity test accuracy [15], and analogy test accuracy [37] for distributed Word2Vec implementations on 1 Billion word dataset, after 10 iterations. The bottom table shows respective values for the serial and OpenMP implementations.

of Word2vec for 10 iterations with a 1 billion word data set. On 256 cores (16 machines), MPI performs better than TensorFlow and STRADS-AP by 9.4% and 10.1%, respectively; that is, a STRADS-AP program obtained by mechanical changes to serial code matches the performance of a highly optimized TensorFlow program. The higher performance of an MPI program stems from the serialization overhead in TensorFlow and STRADS-AP. The MPI implementation stores parameters in arrays of built-in types, and uses in-place MPI_Allreduce call to operate on values directly. STRADS-AP outperforms serial and OpenMP implementations by 45× and 8.7×, respectively.

Table 5 shows the similarity test accuracy [15] and the analogy test [37] accuracy, after running 10 iterations. Using the accuracy of the serial algorithm as the baseline, we see that parallel implementations report slightly lower accuracy (within 1.1%) than the baseline due to the use of stale parameter values.

Productivity Evaluation: Table 6 shows the line counts of Word2vec implementations in the first column. The STRADS-AP implementation has 15% fewer lines than the serial implementation, which stems mainly from the coding style and the use of STRADS-AP's built-in text-parsing library. If we focus the comparison on the core of the program—the training routine—both implementations have around 100 lines, since STRADS-AP implementation takes the serial code and makes a few simple changes to it.

The TensorFlow implementation, however, has three times more lines in the training routine. The increase is due to (1) splitting the training into two kernel operators to fit the

Implementation	Word2vec	MLR	SGDMF
Serial	468	235	271
STRADS-AP	404	245	279
MPI	559	313	409
TensorFlow	646*	155 (Python)	N/A
Spark	N/A	N/A	249 (Scala)

Table 6: Line counts of model implementations using different frameworks. Unless specified next to the lines counts, the language is C++. *TensorFlow implementation of Word2vec has 282 lines in Python and 364 lines in C++.

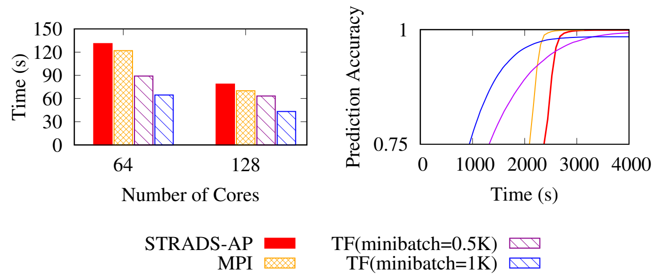

Figure 6: The left figure shows time for a single iteration. We run the TensorFlow implementation with a minibatch sizes of 500 and 1,000. STRADS-AP and MPI implementations do not use vector instructions, therefore, we run them with a minibatch size of 1. Serial and OpenMP implementations (omitted from the graph) also run with a minibatch size of 1, and take 3,380 and 467 seconds to complete, respectively. The right figure shows prediction accuracy as the training progresses. While each implementation runs for 60 iterations, the graph shows only the time until all of them converge to a stable value.

dataflow model, (2) converting tensors into C++ Eigen library matrices and back, and (3) lock management.

While TensorFlow enables users to write simple models easily, it requires a lot more effort and knowledge, which most data scientists lack, to produce high-performance distributed model implementations with custom kernel operators. On the other hand, STRADS-AP allows ordinary users to easily obtain performance on par with the code that was optimized by Google, by making trivial changes to a serial implementation.

6.2 Multinomial Logistic Regression

We implement a serial, OpenMP, MPI, TensorFlow, and STRADS-AP versions of MLR. Our distributed TensorFlow implementation uses TensorFlow parameter servers, and is based on the MNIST code in the TensorFlow repository. Similar to other implementations in our benchmark, our TensorFlow implementation preloads the dataset into memory before starting the training, and uses the Gradient Descent optimizer.

Performance Evaluation: Figure 6 shows single iteration time on 25% of the ImageNet dataset [43] on the left, and accuracy after 60 iterations on the right. TensorFlow makes heavy use of vector instructions, which explains the 30% decrease in runtime when increasing the minibatch size from 500 to 1,000, and almost two times shorter runtime than MPI and STRADS-

Subject	Major (Main PL)	C++ Skill Level	[T1]	[T2]	[T3]	[T4]	[T5]	Total	Challenges
Student 1	Data Mining (Python)	Low	0.25	0.1	0.25	0.1	1.7	2.4	Lack of C/C++ experience
Student 2	Data Mining (Java)	Low	0.3	0.2	0.1	0.2	1.4	2.2	Lack of C/C++ experience
Student 3	Machine Learning (Python)	Low	0.3	0.5	0.5	0.5	1	2.8	Lack of C/C++ experience
Student 4	Compilers (Java)	High	0.3	0.3	0.2	0.1	1.0	1.9	Lack of ML programming familiarity
Student 5	Systems (C++)	High	0.25	0.25	0.5	0.25	0.25	1.5	N/A

Table 7: The breakdown of times (in hours) of five students that converted the serial implementation of the TransE [7] graph embedding algorithm to a distributed STRADS-AP implementation. We split the conversion task into five subtasks: [T1] understand the algorithm, [T2] understand the reference serial code, [T3] review STRADS-AP API guide, [T4] review the provided serial MLR code and the corresponding STRADS-AP code, [T5] convert the serial implementation to STRADS-AP implementation.

AP implementations, which do not use vector instructions. On the other hand, as the right graph in Figure 6 shows, TensorFlow sacrifices accuracy for higher throughput. Unlike the MPI and STRADS-AP implementations that achieve 99.5% accuracy after about 2,800 seconds, the accuracy of TensorFlow remains under 98.4 even after 4,000 seconds. The difference in accuracy is due to STRADS-AP and MPI implementations running with a minibatch size of 1, given that they do not use vector instructions. A single iteration of TensorFlow with a minibatch size of 1 (for which it was not optimized) took about 6 hours, which we omitted from the graph.

Productivity Evaluation: Table 6 shows the line counts of MLR implementations in the second column. The TensorFlow implementation has 38% and 50% fewer lines than the STRADS-AP and MPI implementations, respectively, because while both of the latter implement large chunks of code to compute gradients and apply them to parameters, TensorFlow hides all of these under library function calls. On the other hand, most of the TensorFlow implementation consists of code for partitioning data and setting up the cluster and parameter server variables. This is counter-productive for users who do not want to deal with cluster setup and data partitioning, but want to change the algorithms.

6.3 Matrix Factorization

We already covered (Section 2.1) the implementation details and performance evaluation of solving Matrix Factorization algorithm using SGD optimization (SGDMF). Therefore, we continue with the productivity evaluation.

Productivity evaluation: Table 6 shows line counts of SGDMF implementations in the third column. SGDMF implementation in Scala, even after including the line count for Gemulla's Strata scheduling algorithm (Section 2.1.4), has about 15% fewer lines than STRADS-AP implementation. This is not surprising, given that functional languages like Scala tend to have more expressive power than imperative languages like C++. However, the difficulty of implementing the Strata scheduling algorithm is not captured well in the line count. Figuring out how to implement this algorithm using the limited Spark primitives, and tuning the performance so that the lineage graph would not consume all the memory on the cluster took us about a week, whereas deriving STRADS-AP implementation from the pseudocode took us about an hour.

The line count of MPI is higher than serial code due to Strata scheduling implementation and manual data partitioning.

6.4 User Study

To further evaluate the productivity gains of using STRADS-AP, we conducted two more user studies. In the first study, as a capstone project we assigned a graduate student to implement a distributed version of Word2vec using STRADS-AP and MPI, after studying Google's C implementation [22]. The student had C and C++ programming experience, and had just finished an introductory ML course. After studying the reference source code, the student spent about an hour studying the STRADS-AP API and experimenting with it. It then took him about two hours to deliver a working distributed Word2vec implemented with STRADS-AP API. On the other hand, it took the student two days to deliver a distributed Word2vec implemented with MPI. The MPI implementation was not able to match the STRADS-AP implementation in terms of accuracy and performance until the student had invested two weeks of performance optimizations.

In the second study, we conducted an experiment similar to a programming exam, with five graduate students. We provided the students with a two-page STRADS-AP API documentation, example serial MLR code, and the corresponding STRADS-AP code. We then gave the students a serial C++ program written by an external NLP research group that implemented the TransE [7] graph embedding algorithm, and asked them to produce a distributed version of the same program using STRADS-AP.

Table 7 shows the breakdown of times each student spent at different phases of the experiment, including the students' backgrounds, and the primary challenges they faced. While most students lacked proficiency in C++, they still managed to complete the conversion in a reasonable amount of time. Student 5, who was the most proficient in C++, finished the experiment in 1.5 hours, while Student 1 took 2.4 hours, most of which he spent in the last subtask debugging syntax errors, after breezing through the previous subtasks. Feedback from the participants indicated that (1) converting serial code into STRADS-AP code was straightforward because data structures, the control flow, and optimization functions in the serial program were reusable with a few changes, and (2) the lack of C++ familiarity was the main challenge. The list of reported

mistakes included C++ syntax errors, forgetting to resize local C++ STL vectors before populating them, and an attempt to create a nested DDS, which STRADS-AP does not currently support. We evaluated the students' implementations by running them on FreeBase-15K [7] dataset for 1000 iterations with vector size of 50. The students' implementations were about 22× faster than the serial implementation on 128 cores, averaging at 45.3% accuracy, compared to 46.1% accuracy achieved by the serial implementation.

6.5 Scope and Limitations of STRADS-AP

STRADS-AP facilitates converting serial ML programs into distributed ML programs with minimal changes. Our evaluation shows that the converted ML programs achieve performance comparable to hand-tuned distributed implementations, and to implementations written using ML-specialized frameworks. To achieve higher performance, STRADS-AP relies on two optimizations: reordering of loop indices to find more opportunities for parallelism, and reuse of RE output to amortize the overhead of running RE and making scheduling decision over multiple iterations. These optimizations require ML programs to meet three assumptions: serializability (4.4.1), iterativeness (4.2), and static control flow (4.2). Fortunately, these three assumptions are commonly found in a broad range of ML applications. However, STRADS-AP has some limitations on its expressiveness. For example, it does not support nested parallel loops and user defined data structures having nested DDSs.

7 Related Work

STRADS-AP's design elements rely on a body of previous work. The virtual iteration of IterStore parameter server [11] inspired Reconnaissance Execution (RE). IterStore uses the read/write set only for prefetching parameters into nodes from the parameter server. STRADS-AP, however, uses the read/write set for generating a data conflict-free execution schedule as well as prefetching.

Calvin [44] introduces reconnaissance queries for efficient distributed transactions with low locking overhead. However, Calvin cannot reuse the results of the query because DBMS workloads do not generally have the *iterativeness* and *static control flow* properties of ML workloads. STRADS-AP runtime runs RE on just the first invocation, and the output of RE is reused for every iteration until convergence, amortizing the cost of RE.

OpenMP [12] and Distributed R [42] are popular among ML programmers and provide parallel loop operators. However they lack the support of high-level abstractions to parallelize ML programs in which the ML training routine has data dependencies. For example, when loop bodies of a parallel loop have data dependencies on shared ML model parameters, OpenMP and Distributed R delegate concurrency control to the ML programmer. This requires ML programmers to write routines for aggregating shared parameters in the case of synchronous parallel execution, and handling data dependencies in the case of asynchronous execution. On the contrary, the STRADS-AP runtime hides parameter aggregation and concurrency control from ML programmers through Sync/Async loop operators.

GraphLab [19, 33], Cyclades [39], and STRADS [26, 29] present ML scheduling ideas that avoid executing updates with data conflicts to improve statistical progress per iteration. However, GraphLab expects users to express a serial ML algorithm using GAS (Gather, Apply, Scatter) primitives, Cyclades targets a single shared-memory machine, limiting scalability, and STRADS requires users to design and implement data conflict-free scheduling strategy. STRADS-AP addresses all of these limitations by (1) allowing users to convert a serial program into parallel program through mechanical changes, (2) scaling out to an arbitrary-sized cluster, and (3) automatically generating data conflict-free execution schedules.

More recently, Orion [49] proposed automatic parallelization using static analysis of matrix index access patterns. STRADS-AP and Orion [49] share the same goal of automating scheduling decision. However, while Orion targets ML programs written in Julia scripting language, STRADS-AP targets C++ ML programs because there are a large number of serial ML programs in written in C++. This difference in the choice of programming language leads us to explore substantially different design options, such as STL-like DDSs and dynamic analysis, instead of distributed matrix and static analysis. Specifically, Orion's static analysis requires that data dependencies are determined statically in the form of a linear combination of loop variables. This assumption does not hold frequently in real-world ML applications. On the contrary, STRADS-AP performs dynamic analysis that captures data accesses and dependencies at runtime without relying on such assumptions.

8 Conclusion

Despite the availability of a plethora of frameworks for distributed Machine Learning (ML) programming, we believe distributed ML programming is still unnecessarily complicated. Each framework comes with its own restricted programming model and abstractions, its inefficiencies, and peculiarities that add to the growing list of things that data scientists should master. We take a step back and ask: how can we take a serial imperative implementation of an ML model, and parallelize it over a cluster with minimal effort from the user.

Our answer is STRADS-AP—a distributed ML framework, which is a combination of a runtime and an API comprised of Distributed Data Structures (DDSs) and parallel loop operators. Using four real-world applications, we show that STRADS-AP allows data scientists to easily convert a serial implementation of an ML model to a distributed implementation that achieves performance comparable to hand-tuned MPI and TensorFlow implementations, while outperforming a Spark implementation by more than an order of magnitude.

Abstract

Reconfiguring NoSQL databases under changing workload patterns is crucial for maximizing database throughput. This is challenging because of the large configuration parameter search space with complex interdependencies among the parameters. While state-of-the-art systems can automatically identify close-to-optimal configurations for static workloads, they suffer for dynamic workloads as they overlook three fundamental challenges: (1) Estimating performance degradation during the reconfiguration process (such as due to database restart). (2) Predicting how transient the new workload pattern will be. (3) Respecting the application's availability requirements during reconfiguration. Our solution, SOPHIA, addresses all these shortcomings using an optimization technique that combines workload prediction with a cost-benefit analyzer. SOPHIA computes the relative cost and benefit of each reconfiguration step, and determines an optimal reconfiguration for a future time window. This plan specifies when to change configurations and to what, to achieve the best performance without degrading data availability. We demonstrate its effectiveness for three different workloads: a multi-tenant, global-scale metagenomics repository (*MG-RAST*), a bus-tracking application (*Tiramisu*), and an HPC data-analytics system, all with varying levels of workload complexity and demonstrating dynamic workload changes. We compare SOPHIA's performance in throughput and tail-latency over various baselines for two popular NoSQL databases, Cassandra and Redis.

1 Introduction

Automatically tuning database management systems (DBMS) is challenging due to their plethora of performance-related parameters and the complex interdependencies among subsets of these parameters [45, 64, 17]. For example, Cassandra has 56 performance tuning parameters and Redis has 46 such parameters. Several prior works like Rafiki [45], OtterTune [64], BestConfig [69], and others [17, 62, 61], have solved the problem of optimizing a DBMS when workload characteristics relevant to the data operations are relatively static. We call these "*static configuration tuners*". However, these solutions cannot decide on a set of configurations over a window of time in which the workloads are changing, i.e., what configuration to change to and when. Further, existing solutions cannot perform the reconfiguration of a cluster of database instances without degrading data availability.

Workload changes lead to new optimal configurations. However, it is not always desirable to switch to new configurations because the new workload pattern may be short-lived. Each reconfiguration action in clustered databases incurs costs because the server instance often needs to be restarted for the new configuration to take effect, causing a transient hit to performance during the reconfiguration period. In the case of dynamic workloads, the new workload may not last long enough for the reconfiguration cost to be recouped over a time window of interest to the system owner. Therefore, a proactive technique is required to estimate when executing a reconfiguration is going to be globally beneficial.

Fundamentally, this is where the drawback of all prior approaches to automatic performance tuning of DBMS lies—in the face of dynamic changes to the workload, they are either silent on when to reconfigure or perform a naïve reconfiguration whenever the workload changes. We show that a naïve reconfiguration, which is oblivious to the reconfiguration cost, actually *degrades* the performance for dynamic workloads relative to the default configurations and also relative to the best static configuration achieved using a static tuner with historical data from the system (Figure 3). For example, during periods of high dynamism in the read-write switches in a metagenomics workload in the largest metagenomics portal called MG-RAST [50], naïve reconfiguration degrades throughput by a substantial 61.8% over default.

Our Solution: We develop an online reconfiguration system—SOPHIA—for a NoSQL cluster comprising of multiple server instances, which is applicable to dynamic workloads with various rates of workload shifts. SOPHIA uses historical traces of the workload to train a workload predictor, which is used at runtime to predict future workload

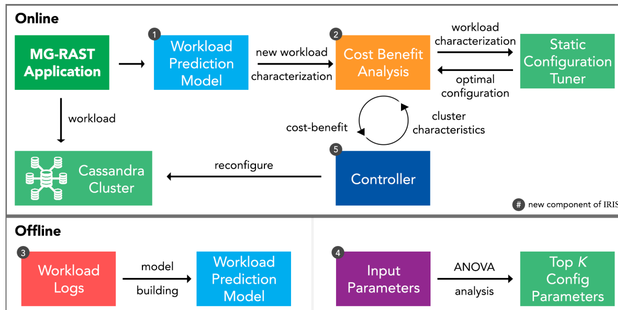

Figure 1: Workflow of SOPHIA *with offline model building and the online operation, plus the new components of our system. It also shows the interactions with the NoSQL cluster and a static configuration tuner, which comes from prior work.*

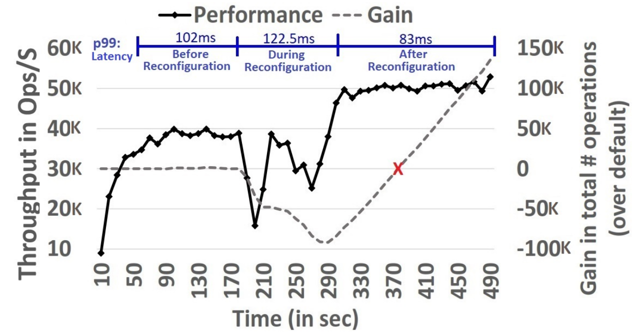

Figure 2: The effect of reconfiguration on the performance of the system. SOPHIA *uses the workload duration information to estimate the cost and benefit of each reconfiguration step and generates plans that are globally beneficial.*

patterns. Workload prediction is a challenging problem and has been studied in many prior works [43, 19, 51]. However, the workload predictor itself is not a contribution of SOPHIA, and it can operate with any workload predictor with sufficiently accurate and long-horizon predictions. SOPHIA searches the vast space of all possible reconfiguration plans, and hence determines the best plan through a novel Cost-Benefit-Analysis (CBA) scheme. For each shift in the predicted workload trace, SOPHIA interacts with any existing static configuration tuner (we use RAFIKI in our work because it is already engineered for NoSQL databases and is publicly available [15]), to quickly provide the optimal *point configurations* for the new workload and the estimated benefit from this new configuration. SOPHIA performs the CBA analysis, taking into account the predicted duration of the new workload and the estimated benefit from each reconfiguration step. Finally, for each reconfiguration step in the selected plan, SOPHIA initiates a distributed protocol to reconfigure the cluster without degrading data availability and maintaining the required data consistency requirement.

During its reconfiguration, SOPHIA can deal with different replication factors (RF) and consistency level (CL) requirements specified by the user. It ensures that the data remains continuously available through the reconfiguration process, with the required CL. This is done by controlling the number of server instances that are concurrently reconfigured. However, this is only possible when RF>CL. In cases where RF=CL, reconfiguring any node in the cluster will degrade data availability as every request will require a response from every replica before it is returned to the user. Therefore, we also implement an aggressive variant of our system (SOPHIA-AGGRESSIVE), which relaxes the data availability requirement in exchange for faster reconfiguration and hence better performance.

Evaluation Cases

We evaluate SOPHIA on two NoSQL databases, Cassandra [39] and Redis [7]. The first use case is based on real workload traces from the metagenomics analysis pipeline, MG-RAST [9, 49]. It is a global-scale metagenomics portal, the largest of its kind, which allows users to simultaneously upload their metagenomic data and use its computational pipeline. The workload does not have any discernible daily or weekly pattern, as the requests come from all across the globe and we find that the workload can change drastically over a few minutes. This presents a challenging use case as only 5 minutes or less of accurate lookahead is possible. The second use case is a bus-tracking application where read, scan, insert, and update operations are submitted to a backend database. The data has strong daily and weekly patterns to it. The third use case is a queue of data analytics jobs such as would be submitted to an HPC computing cluster. Here the workload can be predicted over long time horizons (order of an hour) by observing the jobs in the queue and leveraging the fact that a significant fraction of the job patterns are recurring. Thus, our three cases span the range of patterns and corresponding predictability of the workloads.

We compare our approach to existing solutions and show that SOPHIA increases throughput (and decreases tail-latency) under all dynamic workload patterns and for all types of queries, with no downtime. For example, SOPHIA achieves 24.5% higher throughput over default configurations and 21.5% higher throughput over a statically determined idealized optimal configuration in the bus-tracking workload. SOPHIA achieves 38% and 30% higher aggregate throughput over these two baselines in the HPC cluster workload. With SOPHIA's auto-tuning capability, Redis is able to operate through the entire range of workload sizes and read/write intensities, while the *vanilla Redis fails with large workloads*. The main contributions of SOPHIA are:

1. We show that state-of-the-art static tuners when applied to dynamic workloads degrade throughput below the state-of-practice of using the default parameter values and also degrade data availability.

2. SOPHIA performs cost-benefit analysis to achieve *long-horizon optimized performance for clustered NoSQL instances* in the face of dynamic workload changes, including unpredictable and fast changes to the workload.

3. SOPHIA executes a decentralized protocol to gracefully

switch over the cluster to the new configuration while respecting the data consistency guarantees and keeping data continuously available to users.
First, we show the improvement of using SOPHIA to tune a Cassandra cluster. Afterwards, we show how SOPHIA can be used to tune Redis and improve its performance. The rest of the paper is organized as follows. Section 2 provides an overview of our solution SOPHIA. We provide a background on Cassandra and its sensitivity to configuration parameters and on static configuration tuners in Section 3. We describe our solution in Section 4. We provide details of the workloads and our implementation in Section 5. We give the evaluation results in Section 6 and finally conclude.

2 Overview of SOPHIA

Here we give an overview of the workflow and the main components of SOPHIA. A schematic of the system is shown in Fig. 1. Details of each component are in Sec. 4.

SOPHIA runs as a separate entity outside the Cassandra cluster. It measures the workload by intercepting and observing received queries at the entry point(s) to Cassandra. Periodically, SOPHIA queries the **Workload Predictor** (box 1 in figure) to determine if any future workload changes exist that may merit a reconfiguration—no change also contributes information for the SOPHIA algorithm. Also, an event-driven trigger occurs when the predictor identifies a workload change. The prediction model is initially trained from representative workload traces from prior runs of the application and incrementally updated with additional data as SOPHIA operates. With the predicted workload, SOPHIA queries a static configuration tuner that provides the optimal configuration for a single point in time in the predicted workload. The static configuration tuner is initially trained on the same traces from the system as the workload predictor. Similarly, the static configuration tuner is also trained incrementally like the workload predictor.
The **Dynamic Configuration Optimizer** (box 2) generates a time-varying reconfiguration plan for a given look-ahead window using cost-benefit analysis (CBA). This plan gives both the time points when reconfiguration should be initiated *and* the new configuration parameters at each such time point. The CBA considers both the static, point solution information and the estimated, time-varying workload information. It is run every look-ahead time window apart or when the workload characteristics have changed significantly enough. The **Controller** (box 3) initiates a distributed protocol to gracefully switch the cluster to new configurations in the reconfiguration plan (Sec.4.5). This controller is conceptually centralized but replicated and distributed in implementation using off-the-shelf tools like ZooKeeper. SOPHIA decides how many instances to switch concurrently such that the cluster always satisfies the user's availability and consistency requirements. The Workload Predictor is located at a point where it can observe the aggregate workload such as at a gateway to the database cluster or by querying each database instance for its near past workload profile. The Dynamic Configuration Optimizer runs at a dedicated node close to the workload monitor. A distributed component runs on each node to apply the new reconfiguration plan.
Cost-Benefit Analysis in the Reconfiguration Plan
Each reconfiguration has a cost, due to changing parameters that require restarting or otherwise degrading the database services, e.g., by flushing the cache. The CBA in SOPHIA calculates the costs of implementing a reconfiguration plan by determining the number, duration, and magnitude of degradations. If a reconfiguration plan is found globally beneficial, the controller initiates the plan, else it is rejected. This insight, and the resulting protocol design to decide *whether* and *when* to reconfigure, are the fundamental contributions of SOPHIA.
Now we give a specific example of this cost-benefit trade-off from real MG-RAST workload traces. Consider the example in Fig. 2 where we apply SOPHIA's reconfiguration plan to a cluster of 2 servers with an availability requirement that at least 1 of 2 be online (i.e. CL=1). The Cassandra cluster starts with a read-heavy workload but with a configuration C_1 (Cassandra's default), which favors a write-heavy workload and is therefore suboptimal. With this configuration, the cluster provides a throughput of $\sim$40,000 ops/s and a tail latency of 102 ms (P99), but a better read-optimized configuration C_2 exists, providing $\sim$50,000 ops/s and a tail latency of 83 ms. The Cassandra cluster is reconfigured to the new C_2 configuration setting, using SOPHIA's controller, resulting in a temporary throughput loss due to the transient unavailability of the server instances as they undergo the reconfiguration, one instance at a time given the specified availability requirement. Also during the reconfiguration period, the tail latency increases to 122.5 ms on average. The two dips in throughput at 200 and 270 seconds correspond to the two server instances being reconfigured serially, in which two spikes in tail latency of 180 ms are observed. We plot, using the dashed line, the gain (benefit minus cost) over time in terms of the total # operations served relative to the default configuration. We see that there is a crossover point (the red X point) with the duration of the new workload pattern. If the predicted workload pattern lasts longer than this threshold (190 seconds from the beginning of reconfiguration in our example), then there is a gain from this step and SOPHIA would include it in the plan. Otherwise, the cost will outweigh the benefit, and any solution implemented without the CBA risks degrading the overall system performance. *Thus, a naïve solution (a simple extension of all existing static configuration tuners) that always reconfigures to the best configuration for the current workload will actually degrade performance for any reasonably fast-changing workload.* Therefore, a workload predictor and a cost-benefit analysis model are needed to develop a reconfiguration plan that achieves globally optimal performance over time.

3 Background

Overview of Apache Cassandra: Cassandra is one of the most popular NoSQL databases that is being used by many companies such as Apple, eBay, Netflix and many others [8]. This is because of its durability, scalability, and fault-tolerance, which are essential features for production deployments with large volumes of data. To be able to support a wide range of applications and access patterns, Cassandra (like many other DBMS) exposes many configuration parameters that control its internal behavior and affect its performance. This is intended to customize the DBMS for widely different applications. According to the Cassandra architecture, it caches writes in an in-memory Log-structured merge tree [58] called *Memtable* for a certain period of time. Afterwards, all Memtables get flushed to their corresponding persistent representation on disk called *SSTables*. The same flushing process can be triggered if the size of the Memtable exceeds a specific threshold. A Memtable is always flushed to a new SSTable, which is never updated after construction. Consequently, a single key can be stored accross many SSTables with different timestamps, and therefore a read request to that key will require Cassandra to scan through all existing SSTables and retrieve the one with the latest timestamp. To keep the number of SSTables manageable, Cassandra applies a compaction strategy, which combines a number of old SSTables into one while removing obsolete records. This achieves better performance for reads, but is also a heavy operation that consumes CPU and memory and can negatively impact the performance for writes during compaction.

Dynamic Workloads in Cassandra: Optimal values of these performance-sensitive parameters are dependent on the workload. For example, we find empirically that size-tiered compaction strategy achieves 44% better performance for write-heavy workloads than leveled compaction strategy, while leveled compaction strategy achieves 90% better performance for read-heavy workloads (Figure 3). When the workload changes, the optimal parameters for the new workload will likely change as well. An incremental approach is desired, rather than restarting all servers concurrently, which renders all the data unavailable during reconfiguration.

Workloads in our pipeline have shifts in the number of requests/s and also the relative ratio of the different operations on the database (i.e., transaction mixture). Therefore, SOPHIA needs to react in an agile manner to such shifts. For example, MG-RAST traces show 443 sharp (more than 80% change) shift/day on average, mostly from read-heavy to write-heavy workloads and vice-versa. For the bus-tracking application, a smaller, but still significant, value of 63 shift/-day is observed. The static tuners cannot handle such dynamism and cannot even pick a single parameter set that will on an average give the highest throughput aggregated over a window of time because of the lack of lookahead and also the lack of the Cost-Benefit analysis model.

4 Design of SOPHIA

SOPHIA seeks to answer the following two broad questions: When should the cluster be reconfigured? How should we apply the reconfiguration steps? The answer to the first question leads to what we call a *reconfiguration plan*. The answer to the second question is given by our distributed protocol that reconfigures the various server instances in rounds. Next, we describe SOPHIA's components.

4.1 Workload Modeling and Forecasting: In a generic sense, we can define the workload at a particular point in time as a vector of various time-varying features:

$$\boldsymbol{W}(t) = \{p_1(t), p_2(t), p_3(t), ..., p_n(t)\} \qquad (1)$$

where the workload at time t is $\boldsymbol{W}(t)$ and $p_i(t)$ is the time-varying i-th feature. These features may be directly measured from the database, such as the load (i.e., requests/s) and the occupancy level of the database, or they may come from the computing environment, such as the number of users or jobs in a batch queue. These features are application dependent and are identified by analyzing the application's historical traces. Details for time-varying features of each application are described in Section 5. For workload forecasting, we discretized time into sliced T_d durations ($= 30s$ in our model) to bound the memory and compute cost. We then predicted future workloads as:

$$\boldsymbol{W}(t_{k+1}) = f_{\text{pred}}(\boldsymbol{W}(t_k), \boldsymbol{W}(t_{k-1}), ..., \boldsymbol{W}(t_0)) \qquad (2)$$

where k is the current time index into T_d-wide steps. For ease of exposition for the rest of the paper, we drop the term T_d, assuming implicitly that this is one time unit. The function f_{pred} is any function that can make such a prediction, and in SOPHIA, we utilize a simple Markov-Chain model for MG-RAST and Bus-Tracking, while we use a deterministic, fully accurate output from a batch scheduler for the HPC data analytics workload, i.e., a perfect f_{pred}. However, more sophisticated estimators, such as neural networks [43, 31, 33], even with some degree of interpretability [32], have been used in other contexts and SOPHIA is modular enough to use any such predictor.

4.2 Adapting a Static Configuration Tuner for SOPHIA: SOPHIA uses a static configuration tuner (RAFIKI), designed to work with Cassandra, to output the best configuration for the workload at any given point in time. RAFIKI uses Analysis-of-variance (ANOVA) [55] in order to estimate the importance of each parameter. It selects the top-k parameters in its configuration optimization method, which is in turn determined by a significant drop-off in the importance score. The ability to adapt optimized "kernels" to build robust algorithms comes from our vision to accelerate the pipeline of creating efficient algorithms, conceptualized in Sarvavid [44]. The 7 highest performance-sensitive parameters for all three of our workloads are: (1) Compaction method, (2) # Memtable flush

writers, (3) Memory-table clean-up threshold, (4) Trickle fsync, (5) Row cache size, (6) Number of concurrent writers, and (7) Memory heap space. These parameters vary with respect to the reconfiguration cost that they entail. The change to the compaction method incurs the highest cost as it causes every Cassandra instance to read all its SSTables and re-write them to the disk in the new format. However, due to inter-dependability between these parameters, the compaction frequency is still being controlled by reconfiguring the second and third parameters with the cost of a server restart. Similarly, parameters 4, 6, 7 need a server restart for their new values to take effect and these cause the next highest level of cost. Finally, some parameters (parameter 5 in our set) can be reconfigured without needing a server restart and therefore have the least level of cost.

In general, the database system has a set of performance-impactful configuration parameters $\boldsymbol{C} = \{c_1, c_2, \cdots, c_n\}$ and the optimal configuration $\boldsymbol{C}_{opt}$ depends on the particular workload $\boldsymbol{W}(t)$ executing at that point in time. In order to optimize performance across time, SOPHIA needs the static tuner to provide an estimate of throughput for both the optimal and the current configuration for any workload:

$$H_{\text{sys}} = f_{\text{ops}}(\boldsymbol{W}(t), \boldsymbol{C}_{\text{sys}}) \tag{3}$$

where H_{sys} is the throughput of the cluster of servers with a configuration $\boldsymbol{C}_{\text{sys}}$ and $f_{\text{ops}}(\boldsymbol{W}(t), \boldsymbol{C}_{\text{sys}})$ provides the system-level throughput estimate. $\boldsymbol{C}_{\text{sys}}$ has $N_s \times |\boldsymbol{C}|$ dimensions for N_s servers and C different configurations. Cassandra by careful design achieves efficient load balancing across multiple instances whereby each contributes approximately equally to the overall system throughput [39, 20]. Thus, we define a single server average performance as $H_i = \frac{H_{\text{sys}}}{N_s}$.

From these models of throughput, optimal configurations can be selected for a given workload:

$$C_{\text{opt}}(\boldsymbol{W}(t)) = \arg\max_{\boldsymbol{C}_{\text{sys}}} H_{\text{sys}} = \arg\max_{\boldsymbol{C}_{\text{sys}}} f_{\text{ops}}(\boldsymbol{W}(t), \boldsymbol{C}_{\text{sys}}) \tag{4}$$

In general, $\boldsymbol{C}_{\text{opt}}$ can be unique for each server, but in SOPHIA, it is the same across all servers and thus has a dimension of $|\boldsymbol{C}|$ making the problem computationally easier. This is due to the fact that SOPHIA makes a design simplification—it performs the reconfiguration of the cluster as an atomic operation. Thus, it does not abort a reconfiguration action mid-stream and all servers must be reconfigured in round i prior to beginning any reconfiguration of round $i+1$. We also speed up the prediction system f_{ops} by constructing a cached version with the optimal configuration $\boldsymbol{C}_{opt}$ for a subset of $\boldsymbol{W}$ and using nearest-neighbor lookups whenever a near enough neighbor is available.

4.3 Dynamic Configuration Optimization:

SOPHIA's core goal is to maximize the total throughput for a database system when faced with dynamic workloads. This introduces time-domain components into the optimal configuration strategy $\boldsymbol{C}_{\text{opt}}^T = \boldsymbol{C}_{\text{opt}}(\boldsymbol{W}(t))$, for all points in (discretized) time till a lookahead T_L. Here, we describe the mechanism that SOPHIA uses for CBA modeling to construct the best reconfiguration plan (defined formally in Eq. 5) for evolving workloads.

In general, finding solutions for $\boldsymbol{C}_{\text{opt}}^T$ can become impractical since the possible parameter space for $\boldsymbol{C}$ is large and the search space increases linearly with T_L. To estimate the size of the configuration space, consider that in our experiments we assumed a lookahead $T_L = 30$ minutes and used 7 different parameters, some of which are continuous, e.g., `Memory-table clean-up threshold`. If we take an underestimate of each parameter being binary, then the size of the search space becomes $2^{7\times 30} = 1.6 \times 10^{63}$ points, an impossibly large number for exhaustive search. We define a compact representation of the reconfiguration points (Δ's) to easily represent the configuration changes. The maximum number of switches within T_L, say M, is bounded since each switch takes a finite amount of time. The search space for the dynamic configuration optimization is then $Combination(TL, M), M) \times |\boldsymbol{C}|$. This comes from the fact that we have to choose at most M points to switch out of all the T_L time points and at each point there are $|\boldsymbol{C}|$ possible configurations. We define the reconfiguration plan as:

$$\boldsymbol{C}_{\text{sys}}^{\Delta} = [\boldsymbol{T} = \{t_1, t_2, ..., t_M\}, \boldsymbol{C} = \{C_1, C_2, ..., C_M\}] \tag{5}$$

where t_k is a point in time and C_k is the configuration to use at t_k. Thus, the reconfiguration plan gives *when* to perform a reconfiguration and at each such point, *what* configuration to choose.

The objective for SOPHIA is to select the best reconfiguration plan $(\boldsymbol{C}_{\text{sys}}^{\Delta})^{\text{opt}}$ for the period of optimization, lookahead time T_L:

$$(\boldsymbol{C}_{\text{sys}}^{\Delta})^{\text{opt}} = \arg\max_{\boldsymbol{C}_{\text{sys}}^{\Delta}} B(\boldsymbol{C}_{\text{sys}}^{\Delta}, \boldsymbol{W}) - L(\boldsymbol{C}_{\text{sys}}^{\Delta}, \boldsymbol{W}) \tag{6}$$

where $\boldsymbol{C}_{\text{sys}}^{\Delta}$ is the reconfiguration plan, B is the benefit function, and L is the cost (or loss) function, and $\boldsymbol{W}$ is the time-varying workload description. Detailed derivation of functions B and L is shown in Supplemental Material (Section 9.1). When SOPHIA will extend to allow scale out, we will have to consider the data movement volume as another cost to minimize. The L function captures the opportunity cost of having each of N_s servers offline for T_r seconds for the new workload versus if the servers remained online with the old configuration. As the node downtime due to reconfiguration never exceeds Cassandra's threshold for declaring a node is dead (3 hours by default), data-placement tokens are not re-assigned due to reconfiguration. Therefore, we do not include cost of data movement in functions L. SOPHIA can work with any reconfiguration cost, including different costs for different parameters—these can be fed into the loss function L.

The objective is to maximize the time-integrated gain (benefit – cost) of the reconfiguration from Eq. (6). The three

unknowns in the optimal plan are M, $\boldsymbol{T}$, and $\boldsymbol{C}$, from Eq. (5). If only R servers can be reconfigured at a time (explained in Sec. 4.5 how R is calculated), at least $T_r \times \frac{N_s}{R}$ time must elapse between two reconfigurations. This puts a limit on M, the maximum number of reconfigurations that can occur in the lookahead period T_L.

A greedy solution for Eq. (6) that picks the first configuration change with a net-increase in benefit may produce suboptimal $\boldsymbol{C}^{\Delta}_{\text{sys}}$ over the horizon T_L because it does not consider the coupling between multiple successive workloads. For example, considering a pairwise sequence of workloads, the best configuration may not be optimal for either $\boldsymbol{W}(t_1)$ or $\boldsymbol{W}(t_2)$ but *is* optimal for the paired sequence of the two workloads. This could happen if the same configuration gives reasonable performance for $\boldsymbol{W}(t_1)$ or $\boldsymbol{W}(t_2)$ and has the advantage that it does not have to switch during this sequence of workloads. This argument can be naturally extended to longer sequences of workloads.

A T_L value that is too long will cause SOPHIA to include decision points with high prediction errors, and a value that is too short will cause SOPHIA to make almost greedy decisions. The appropriate lookahead period is selected by benchmarking the non-monotonic but convex throughput while varying the lookahead duration and selecting the point with maximum end-to-end throughput. We give our choices for our three applications when describing the first experiment with each application (Section 6).

4.4 Finding Optimal Reconfiguration Plan with Genetic Algorithms: We use a heuristic search technique, Genetic Algorithms or GA, to find the optimal reconfiguration plan. Although meta-heuristics like GA do not guarantee finding global optima, they have two desirable properties for SOPHIA. Our space is non-convex because many of the parameters impact the same resources such as CPU, RAM, and disk, and settings of one parameter impact the others.Therefore, greedy or gradient descent-based searches are prone to converge to a local optima. Also the GA's tunable completion is needed in our case for speedy decisions, as the optimizer executes in the critical path.
The representation of the GA solution incorporates two parts. First, the chromosome orientation, which is simply the reconfiguration plan (Eq. 5). The second part is the fitness function definition used to assess the quality of different reconfiguration plans. For this, we use the cost-benefit analysis as shown in Eq. 6 where fitness is the total number of operations (normalized for bus-tracking traces to account for different operations' scales) for the T_L window for the tested reconfiguration plan and given workload. We build a simulator to apply the individual solutions and to collect the corresponding fitness values, which are used to select the best solutions and to generate new solutions in the next generation. We utilize a Python library, `pyeasyga`, with 0.8 crossover fraction and population size of 200. We run 10 concurrent searches and pick the best configuration from those. The runtime of this algorithm is dependent on the length of the lookahead period and the number of decision points. For MG-RAST, the GA has 30 decision points in the lookahead period and results in execution time of 30-40 sec. For the HPC workload, the number of decision points is 180 as it has a longer lookahead period, resulting in a runtime of 60-70 sec. For the bus-tracking workload, the GA has 48 decision points and a runtime of 20-25 sec. The GA is typically re-run toward the end of the lookahead period to generate the reconfiguration plan for the next lookahead time window. Also, if the actual workload is different from the predicted workload, the GA is re-invoked. This last case is rate limited to prevent too frequent invocations of the GA during (transient) periods of non-deterministic behavior of the workload.

4.5 Distributed Protocol for Online Reconfiguration: Cassandra and other distributed databases maintain high availability through configurable redundancy parameters, consistency level (CL) and replication factor (RF). CL controls how many confirmations are necessary for an operation to be considered successful. RF controls how many replicas of a record exist throughout the cluster. Thus, a natural constraint for each record is RF $\geq$ CL. SOPHIA queries token assignment information (where a token represents a range of hash values of the primary keys which the node is responsible for) from the cluster, using tools that ship with all popular NoSQL distributions (like `nodetool ring` for Cassandra), and hence constructs what we call a *minimum availability subset* (N_{minCL} for short). We define this subset as the minimum subset of nodes that covers at least CL replicas of *all* keys. To meet CL requirements, SOPHIA insures that N_{minCL} nodes are operational at any point of time. Therefore, SOPHIA makes the design decision to configure up to $R = N_s - N_{minCL}$ servers at a time, where N_{minCL} depends on RF, CL, and token assignment. If we assume a single token per node (Cassandra's default with vnodes disabled), then a subset of $\lceil \frac{N_s}{RF} \rceil$ nodes covers all keys at least once. Consequently, N_{minCL} becomes CL $\times \lceil \frac{N_s}{RF} \rceil$ to cover all keys at least CL times. Thus, the number of reconfiguration steps $= \frac{N_s}{R} = \frac{RF}{RF-CL}$ becomes independent of the cluster size N_s.
In the case where RF = CL, N_{minCL} becomes equivalent to N_s and hence SOPHIA cannot reconfigure the system, without harming data availability, hence we use the SOPHIA-AGGRESSIVE variant in that case. However, we expect most systems with high consistency requirements to follow a read/write quorum with CL $= \lceil \frac{\text{RF}}{2} \rceil$ [23]. Note that SOPHIA reduces the number of available data replicas during the transient reconfiguration periods, and hence reduces the system's resilience to additional failures. However, one optional parameter in SOPHIA is how many failures during reconfiguration the user will want to tolerate (our experiments were run with zero). This is a high-level

parameter that is intuitive to set by the database admin. Also notice that data that existed on the offline servers prior to reconfiguration is not lost due to the drain step, but data written during the transient phase has lower redundancy until the reconfigured servers get back online. In order to reconfigure a Cassandra cluster, SOPHIA performs the following steps, R server instances at a time:

51. Drain: Before shutting down a Cassandra instance, we flush the entire Memtable to disk by using Cassandra's tool `nodetool drain` and this ensures that there are no pending commit logs to replay upon a restart.

1. **Drain**: Before shutting down a Cassandra instance, we flush the entire Memtable to disk by using Cassandra's tool `nodetool drain` and this ensures that there are no pending commit logs to replay upon a restart.
2. **Shutdown**: The Cassandra process is killed on the node.
3. **Configuration file**: Replace the configuration file with new values for all parameters that need changing.
4. **Restart**: Restart the Cassandra process on the same node.
5. **Sync**: SOPHIA waits for Cassandra's instance to completely rejoin the cluster by letting a coordinator know of where to locate the node and then synchronizing the missed updates during the node's downtime.

In Cassandra, writes for down nodes are cached by available nodes for some period and re-sent to the nodes when they rejoin the cluster. The time that it takes to complete all these steps for one server is denoted by T_r, and T_R for the whole cluster, where $T_R = T_r \times \frac{RF}{RF-CL}$. During all steps 1-5, additional load is placed on the non-reconfiguring servers as they must handle the additional write and read traffic. Step 5 is the most expensive and typically takes 60-70% of the total reconfiguration time, depending on the amount of cached writes. We minimize step 4 practically by installing binaries from the RAM and relying on draining rather than commit-log replaying in step 1, reducing pressure on the disk.

5 Datasets

MG-RAST Workload: We use real workload traces from MG-RAST, the leading metagenomics portal operated by the US Department of Energy. As the amount of data stored by MG-RAST has increased beyond the limits of traditional SQL stores (23 PB as of August 2018), it relies on a distributed NoSQL Cassandra database cluster. Users of MG-RAST are allowed to upload "jobs" to its pipeline, with metadata to annotate job descriptions. All jobs are submitted to a computational queue of the US Department of Energy private Magellan cloud. We analyzed 80 days of query trace from the MG-RAST system from April 19, 2017 till July 9, 2017. From this data, we make several observations: (i) Workloads' read ratio (RR) switches rapidly with over 26,000 switches in the analyzed period. (ii) A negative correlation of -0.72 is observed between the Workloads' read ratio and number of requests/s (i.e., load). That is due to the fact that most of the write operations are batched to improve network utilization. (iii) Majority (i.e., more than 80%) of the switches are abrupt, from RR=0 to RR=1 or vice versa. (iv) KRD (key reuse distance) is very large. (v) No daily or weekly workload pattern is discernible, as expected for a globally used cyberinfrastructure.

Bus Tracking Application Workload: Secondly, we use real workload traces from a bus-tracking mobile application called **Tiramisu** [43]. The system provides live tracking of the public transit bus system. It updates bus locations periodically and allows users to search for nearby bus stops. There are four types of queries—read, update, insert, and scan (retrieving all the records in the database that satisfy a given predicate, which is much heavier than the other operations). A sample of the traces is publicly available [42]. We trained our model using 40 days of query traces, while 18 days were used as testing data. We draw several observations from this data: (i) The traces show a daily pattern of workload switches. For example, the workload switches to scan-heavy in the night and switches to update-heavy in the early morning. (ii) The Workload is a mixture of Update, Scan, Insert, and Read operations in the ratio of 42.2%, 54.8%, 2.82%, and 0.18% respectively. (iii) KRD is very small. From these observations, we notice that the workload is very distinct from MG-RAST and thus provides a suitable point for comparison.

Simulated Analytics Workload: For long-horizon reconfiguration plans, we simulate synthetic workloads representative of batch data analytics jobs, submitted to a shared HPC queue. We integrate SOPHIA with a job scheduler (like PBS [27]), that examines jobs while they wait in a queue prior to execution. Thus, the scheduler can profile the jobs waiting in the queue, and hence forecast the aggregate workload over a lookahead horizon, which is equal to the length of the queue. We model the jobs on data analytics jobs submitted to a Microsoft Cosmos cluster [21] and as in that paper, we achieve high accuracy in predicting when a job will start executing. Thus, SOPHIA is able to drive long-horizon reconfiguration plans. Each job is divided into phases: a write-heavy phase resembling an upload phase of new data, a read-heavy phase resembling executing analytical queries to the cluster, and a third, write-heavy phase akin to committing the analysis results. However, some jobs can be recurring (as shown in [1, 21]) and running against already uploaded data. These jobs will execute the analysis phase directly, skipping the first phase. The size of each phase is a random variable with U(200,100K) operations, and whenever a job finishes, a new job is selected from the queue and executed. We vary the level of concurrency and have an equal mix of the

two types of jobs and monitor the aggregate workload. Figure 11 in Supplemental Material shows the synthetic traces for three job sizes. With increase in concurrency, the aggregate pattern becomes smoother and the latency of individual jobs increases.

6 Experimental Results

Here we evaluate the performance of SOPHIA under different experimental conditions for the 3 applications. We use a simple query model typical for NoSQL databases and is in contrast to complex analytics queries supported by more complex database engines. Hence, our throughput is defined as the number of queries per second. In all experiments, we collect both throughput and tail latency (p99) performance metrics. However, since the two parameters have an almost perfect inverse relationship in all experiments, we omit tail latency (except in Figures 4 and 6). We evaluate SOPHIA on Amazon EC2 using instances of size M4.xlarge with 4 vCPU's, 16 GB of RAM, provisioned IOPS (SSD) EBS for storage and network bandwidth of 0.74 Gbits/s for all Cassandra servers and workload drivers. Each node is loaded with 6 GB of data initially (SOPHIA's performance is evaluated with greater data volumes in Experiment 4). We use multiple concurrent clients to saturate the database servers and aggregate the throughput and tail latency observed by every client.

Baseline Comparisons

We compare the performance of SOPHIA to baseline configurations (1-5). We consider 3 variants of SOPHIA (6-8).

(1) Default: The default configuration that ships with Cassandra. This configuration favors write-heavy workloads by design [48].

(2) Static Optimized: This baseline resembles the static tuner (RAFIKI) when queried to provide the one *constant* configuration that optimizes for the entire future workload. This is an impractically ideal solution since it is assumed here that the future workload is known perfectly. However, non-ideally no configuration changes are allowed dynamically.

(3) Naïve Reconfiguration: Here, when the workload changes, RAFIKI's provided reconfiguration is always applied, instantiated by concurrently shutting down all server instances, changing their configuration parameters, and restarting all of them. Practically, this makes data unavailable and may not be tolerable in many deployments such as user-facing applications. The static configuration tuners are silent about when the optimal configurations determined by them must be applied and this baseline is a logical instantiation of all of the prior work.

(4) ScyllaDB: The performance of NoSQL database ScyllaDB [57] in its vanilla form. ScyllaDB is touted to be a much faster (10X or higher) drop-in replacement to Cassandra [56]. This stands in for other self-tuning databases [30].

(5) Theoretical Best: This baseline resembles the theoretically best achievable performance over the predicted workload period. This is simulated by assuming Cassandra is running with the optimal configuration at any point of time and not penalizing it for the cost of reconfiguration. This serves as an upper bound for the performance.

(6) SOPHIA with Oracle: This is SOPHIA with a fully accurate workload predictor.

(7) SOPHIA-AGGRESSIVE: A variant from SOPHIA that prefers faster reconfiguration over data availability and is used only when RF=CL. SOPHIA-AGGRESSIVE violates the availability requirement by reconfiguring all servers at the same time. Unlike Naïve, it uses the CBA model to decide when to reconfigure, and therefore it does not execute reconfiguration every time the workload changes.

(8) SOPHIA: This is our complete system.

Major Insights

We draw some key insights from the experimental results. First, globally shared infrastructures with black-box jobs only allow for short-horizon workload predictions. This causes SOPHIA to take single-step reconfiguration plans and limits its benefit over a static optimized approach (Figure 3). In contrast, when job characteristics can be predicted well (bus tracking and data analytics applications), SOPHIA achieves significant benefit over both default and static optimized cases (Figures 4 and 5). This benefit stays even when there is significant uncertainty in predicting the exact job characteristics as shown in Figure 9. Second, Cassandra can be used in preference to the recent popular drop-in ScyllaDB, an auto-tuning database, with higher throughput across the entire range of workload types, as long as we overlay a dynamic tuner, such as SOPHIA, atop Cassandra (Figures 3 and 5). Third, as the replication factor increases while the number of server are fixed, the reconfiguration time of SOPHIA decreases, thus improving its benefit (Figure 7). Contrarily, as CL increases, the benefit of SOPHIA shrinks (Figure 7).Finally, SOPHIA is applied to a different NoSQL database, Redis, and solves a long-standing configuration problem with it, one which has caused Redis to narrow its scope to being an in-memory database only (Figure 10).

Experiment 1: MG-RAST Workload

We present our experimental evaluation with 20 test days of MG-RAST data. To zoom into the effect of SOPHIA with different levels of dynamism in the workload, we segment the workload into 4 scenarios and present those results in addition to the aggregated ones.

Workload Prediction Model: We created 16,512 training samples composed of $T_d = 5min$ steps across the 60 days MG-RAST workloads. We compare the performance of a first-order and a second-order Markov Chain model. We represent the states as the proportion of read operations during the T_d interval. We use a quantization level of 10% in the read ratio between different states. We categorize

the test days into 4: “Slow”, “Medium”, and “Fast”, by the frequency of switching from the read- to the write-intensive workloads and this maps to the average read ratios (RR) shown in Table 1. “Write” represents days with long write-heavy periods. Table 1 shows the prediction RMSE for the four representative workload scenarios. Because of the lack of application-level knowledge, in addition to the well-known uncertainty in job execution times in genomics pipelines [40], the Markov Chain model only provides accurate predictions for short time intervals. Moreover, increasing the order of the model has very little impact on the prediction performance and also increases the number of states (11 states in the First-order model vs. 120 states in the Second-order model). We also tried to train a more complex model (RNN) but its prediction quality was similar. We notice that the best accuracy is for the “Slow” scenario, whereas it drops below 50% for “Medium”, and it is always below 50% for the “Fast” and “Write” scenarios. Because the “Slow” scenario is the most common (observed 74% of time in the training data), we use a value of $T_L = 5min$.

Table 1: RMSE for predicting MG-RAST and Bus-Tracking workloads.

MG-RAST					
MC-Order	First		Second		RR
Frequency	5m	10m	5m	10m	-
Slow	34.4%	56%	34%	55%	70%
Medium	59%	90%	59%	89%	50%
Fast	66%	93%	63%	89%	45%
Write	52.8%	76.1%	51.5%	75.5%	35%
Aggregate	43.7%	68.7%	43.4%	68.2%	-

Bus-Tracking		
Lookahead	First	Second
15m	6.9%	7.12%
1h	7.4%	7.4%
2h	7.9%	7.4%
5h	10%	7.5%
10h	13.7%	8%
#States	117	647

Performance Comparison:

Now we show the performance of SOPHIA with respect to the four workload categories. We first present the result with the smallest possible number of server instances, 4, run with operational MG-RAST’s parameters RF=3 and CL=1 [35]. We show the result in terms of total operations for each test workload as well as a weighted average “combined” representation that models behavior for the entire MG-RAST workload. Figure 3 shows the performance improvements for our test cases.

From Figure 3, we see that SOPHIA always outperforms naïve in total ops/s (average of 31.4%) and individually in read (31.1%) and write (33.5%) ops/s. SOPHIA also outperforms the default for the slow and the mid frequency cases, while it slightly under performs in the fast frequency case. The average improvement due to SOPHIA across the 4 categories is 20.4%. The underperformance for the fast case is due to increased prediction error. Naïve baseline has a significant loss compared to default: 21.6%. The static optimized configuration (which for this workload favors read-heavy pattern) has a slightly higher throughput over SOPHIA by 6.3%. This is because the majority of the selected samples are read periods (RR=1), which hides the gain that SOPHIA achieves for write periods. However, we see that with respect to write operations, SOPHIA achieves 17.6% higher throughput than the static optimized configuration. Increased write

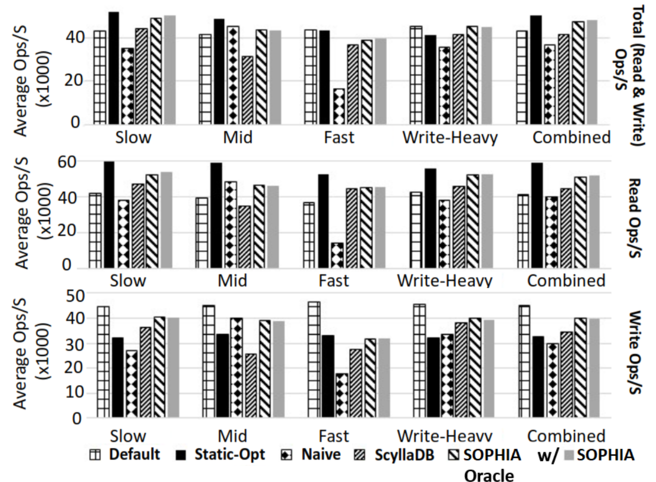

Figure 3: Improvement for four different 30-minute test windows from MG-RAST real traces over the baseline solutions.

throughput is critical for MG-RAST to support the bursts of intense writes. This avoids unacceptable queuing of writes, which can create bottlenecks for subsequent jobs that rely on the written shared dataset. Moreover, we observe that SOPHIA performs within 2-3% to SOPHIA w/ Oracle in all scenarios, which shows the minor impact of the workload predictor accuracy. For instance, SOPHIA w/ Oracle shows a 2% reduction in performance compared to SOPHIA in the slow trace. This is because Oracle has perfectly accurate predictions for $T_L = 5min$ only. With this very short lookahead, SOPHIA makes greedy reconfiguration decisions, and hence does not achieve globally optimal performance over other baselines.

ScyllaDB has an auto-tuning feature that is supposed to continuously react to changes in workload characteristics and the current state (such as, the amount of dirty memory state). ScyllaDB is claimed by its developers to outperform Cassandra in all workload mixes by an impressive 10X [56]. However, this claim is not borne out here and only in the read-heavy case (the “Slow” scenario) does ScyllaDB outperform. Even in this case, SOPHIA is able to reconfigure Cassandra at runtime and turn out a performance benefit over ScyllaDB. We conclude that based on this workload and setup, a system owner can afford to use Cassandra with SOPHIA for the *entire range* of workload mixes and not have to transition to ScyllaDB.

Experiment 2: Tiramisu Workload

We evaluate the performance of SOPHIA using the bus-tracking application traces. Figure 4 shows the gain of using SOPHIA over the various baselines. In this experiment, we report the normalized average Ops/s instead of the absolute average Ops/s metric. This means we normalize each of the 4 operation’s throughputs by dividing by the maximum Ops/s seen under a wide variety of configurations and then average the 4 normalized throughputs. The reason for

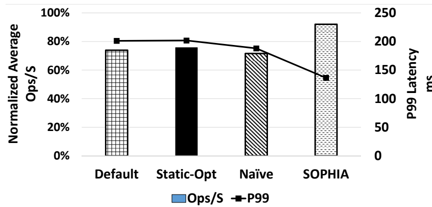

Figure 4: Gain of applying SOPHIA *to the bus-tracking application. We use 8 Cassandra servers with RF=3, CL=1. A 100% on the Y-axis represents the theoretical best performance.* SOPHIA *achieves improvements of 24.5% over default, 21.5% over Static-Opt, and 28.5% over naïve.*

Figure 5: Improvement for HPC data analytics workload with different levels of concurrency. We notice that SOPHIA *achieves higher average throughput over all baselines*

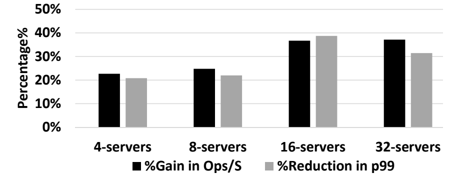

Figure 6: Improvement with scale using HPC workload with 5 jobs with RF=3 and CL=1. SOPHIA *provides consistent gains across scale because the cost of reconfiguration does not change with scale (for the same RF and CL). The higher gains for 16 and 32 servers is due to the use of M5 instances, which can be exploited by* SOPHIA *better than Static-Opt.*

this is that for this workload, different operations have vastly different throughput scales. For example, when the workload switches to a Scan-heavy phase, the performance of the cluster varies from 34 Ops/s to 219 Ops/s depending on the configuration of the cluster. For an Update-heavy phase, the performance varies from 1,739 Ops/s to 5,131 Ops/s. This is because Scan is a much heavier operation for the DBMS compared to Update.

SOPHIA outperforms default configuration by 24.5%, Static-Opt by 21.5%, and Naïve by 28.5%. The gains are higher because SOPHIA can afford longer lookahead times with accurate workload prediction. We notice that Naïve is achieving a comparable performance to both Default and Static-Opt configurations, unlike MG-RAST. This is because the frequency of workload changes is lower here. However, Naïve still renders the data unavailable during the reconfiguration period.

Workload Prediction Model: Unlike MG-RAST, the bus-tracking application traces show a daily pattern which allows our prediction model to provide longer lookahead periods with high accuracy (Table 1). We use a Markov Chain prediction model to capture the workload switching behavior. We start by defining the state of the workload as the proportion of each operation type in an aggregation interval (15 minutes in our experiments). For example, Update=40%, Read=20%, Scan=40%, Insert=0% represents a state of the workload. We use a quantization level of 10% in any of the 4 dimensions to define the state. We use the second-order Markov Chain with a lookahead period of 5 hours as this is when our prediction error is $\leq$ 8%. As expected theoretically, the second order model is more accurate at all lookahead times, since there is enough training data available for training the models. Seeing the seeming regular diurnal and weekly pattern in the workload, we create two simple predictor straw-men that uses only the current time-stamp or the current time-stamp and day of the week as input features to perform prediction. The predicted workload is the average of the mixtures at the previous 10 points. These predictors have unacceptably high RMSE of 31.4% and 24.0%. Therefore, although the workload is showing a pattern, we cannot generate the optimal plan once and use it for all subsequent days. Therefore, online workload monitoring and prediction is needed to achieve the best performance

Experiment 3: HPC Data Analytics

We evaluate the performance of SOPHIA using HPC data analytics workload patterns described in Section 5. Here our lookahead is the size of the job queue, which is conservatively taken as 1 hour. Figure 5 shows the result for the three levels of concurrency (1, 5, and 10 jobs). We see that SOPHIA outperforms the default for all the three cases, with average improvement of 30%. In comparison with Static-Opt (which is a different configuration in each of the three cases), we note that SOPHIA outperforms for the 1 job and 5 jobs cases by 18.9% and 25.7%, while it is identical for the 10 jobs case. This is because in the 10 jobs case, the majority of the workload lies between RR=0.55 and RR=0.85, and in this case, SOPHIA switches only once: from the default configuration to the same configuration as Static-Opt. We notice that SOPHIA achieves within 9.5% of the theoretical best performance for all three cases. We notice that SOPHIA achieves significantly better performance over Naïve by 27%, 13%, and 122% for the three cases. Naïve, in fact, degrades the performance by 32.9% (10 concurrent jobs). In comparison with ScyllaDB, SOPHIA achieves a performance benefit of 17.4% on average, which leads to a similar conclusion as in MG-RAST about the continued use of Cassandra.

Experiment 4: Scale-Out & Greater Volume

Figure 6 shows the behavior of SOPHIA with increasing scale using the data analytics workload. We show the comparison between SOPHIA and Static-Opt (all other baselines performed worse than Static-Opt). We use a weak scaling pattern, i.e., keeping the amount of data per server fixed while still operating close to saturation. We increase the number of shooters as well to keep the request rate per server fixed. By our design (Sec. 4.5), the number of reconfiguration steps stays constant with scale. We notice that the network bandwidth needed by Cassandra's gossip protocol increases with the scale of the cluster, causing the

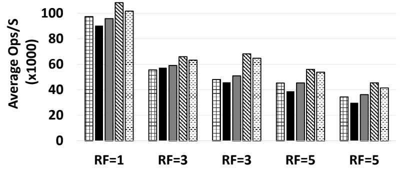

Figure 7: Effect of varying RF and CL on system throughput. We use a cluster of 8 nodes and compare the performance of SOPHIA *to Default, Static-Opt, and naïve.* SOPHIA *outperforms the static baselines and approaches the theoretical best as RF–CL increases.*

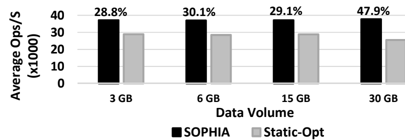

Figure 8: Effect on increasing data volume per node. We use a cluster of 4 servers and compare the performance to the static optimized. The results show that SOPHIA*'s gain is consistent with increasing data volumes per node.*

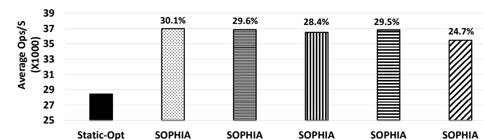

Figure 9: Effect of noise in workload prediction on the performance of SOPHIA *on the data analytics workload with level of concurrency = 5. The percentage represents the amount of noise added to the predicted workload pattern.*

network to become the bottleneck in the case of 16 and 32 servers when M4.xlarge instances are used. Therefore, we change the instance type to M5.xlarge in these cases (network bandwidth of 10 Gbit/s compared to 0.74 Gbit/s). The results show that SOPHIA's optimal reconfiguration policy has a higher performance over Static-Opt across all scales. Moreover, we see a higher gain in the cases of 16 and 32 servers since M5 instances have higher CPU power than M4 ones. This extra CPU capacity allows for faster leveled compaction, which is used by SOPHIA's plan (while Static-Opt uses size-tiered compaction), and hence leads to greater performance difference for reads.

We also evaluate SOPHIA with the same workload when the data volume per node increases. We vary the amount of data loaded initially into each node (in a cluster of 4 nodes) and measure the gain over Static-Opt in Figure 8. For the 30GB case, the data volume grows beyond the RAM size of the used instances (M4.xlrage with 16 GB RAM). We notice that the gain from applying SOPHIA's reconfiguration plan is consistent with increasing the data volume from 3 GB to 30 GB. We also notice that the gain increases for the case of 30 GB. This is also due to the different compaction methods used by Static-Opt (size-tiered) and SOPHIA (Leveled compaction), the later can provide better read performance with increasing data volumes. However, this benefit of Leveled compaction was not captured by RAFIKI predictions, which was trained on a single node with 6 GB of data. This can be addressed by either replacing RAFIKI by a data volume-aware static tuner, or re-training RAFIKI when a significant change in data volume per node occurs.

Experiment 5: Varying RF and CL

We evaluate the impact of applying SOPHIA to clusters with different RF and CL values. We use the HPC workload with 5 concurrent jobs. We fix the number of nodes to 8 and vary RF and CL as shown in Figure 7 (CL quorum implies CL = $\lceil RF/2 \rceil$). We notice that SOPHIA continues to achieve better performance than all 3 static baselines for all RF, CL values. For RF=1, CL=1, we use SOPHIA-AGGRESSIVE because when RF=CL, we cannot reconfigure the cluster without degrading availability. The key observation is that SOPHIA's performance gets closer to the *Theoretical best* as RF-CL becomes higher (compare the RF=3,CL=1 to the RF=5,CL=1 case). This is because the number of steps SOPHIA needs to perform the reconfiguration is inversely proportional to RF-CL as discussed in Sec. 4.5). This allows SOPHIA to react faster to changes in the applied workload and thus achieve better performance. Moreover, we notice that the performance of the cluster degrades with increasing RF or CL. Increasing RF increases the data volume stored by each node, which increases the number of SSTables and hence reduces the read performance. Also increase in CL requires more nodes to respond to each request before acknowledgment to the client, which also reduces the performance.

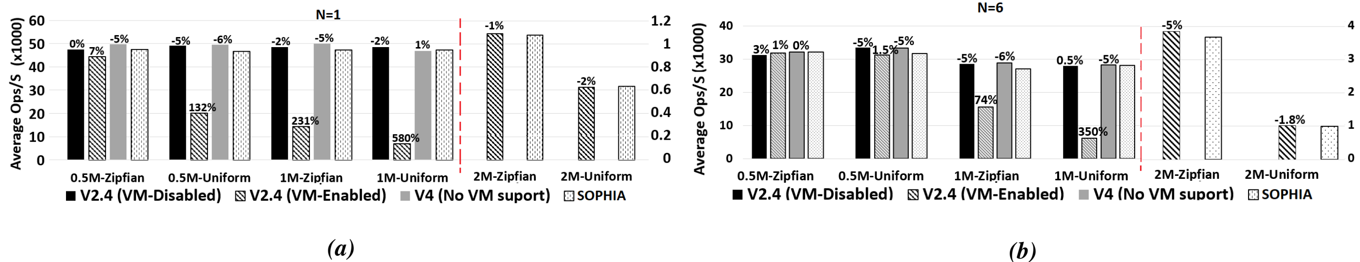
Experiment 6: Noisy Workload Predictions

We show how sensitive SOPHIA is to the level of noise in the predicted workload pattern. We use the HPC workload with 5 concurrent jobs. In HPC queues, there are two typical sources of such noise—an impatient user removing a job from the queue and the arrival of hitherto unseen jobs. We add noise to the predicted workload pattern $\sim U(-R,R)$, where R gives the level of noise. The resulting value is bounded between 0 and 1.

From Figure 9, we see that adding noise to SOPHIA slightly reduces its performance. However, such noise will not cause significant changes to SOPHIA's optimal reconfiguration plan. This is because SOPHIA treats each entry in the reconfiguration plan as a binary decision, i.e., reconfigure if Benefit $\geq$ Cost. So even if the values of both Benefit and Cost terms change, the same plan takes effect as long as the inequality still holds. This allows SOPHIA to achieve significant improvements for long-term predictions even with high noise levels.

Experiment 7: Redis Case Study

We now show a case study with the popular NoSQL database Redis, which has a long-standing pain point in setting a performance-critical parameter against changing workloads. Large-scale processing frameworks such as Spark can de-



(a) *(b)*

Figure 10: Impact of tuning Redis' VM configuration parameters with SOPHIA ***with the data analytics workload. The percentage improvement of*** SOPHIA ***is shown on each bar and the right Y-axis is for the 2M jobs. A missing bar represents a failed job. We notice that the current Redis fails for large workloads (2M), while*** SOPHIA ***achieves the best of both worlds***

liver much higher performance when combined with Redis due to its shared distributed memory infrastructure [67, 38]. Redis is an in-memory data store (stores all keys and values in memory) while writing to persistent storage is only supported for durability. However, in its earlier versions (till V2.4), Redis used to offer a feature called *Virtual Memory* [36]. This feature allowed Redis to work on datasets larger than the available memory by swapping rarely used values to disk, while keeping all keys and hot values in memory. Since V2.4, this feature was removed as it caused serious performance degradation in many Redis deployments due to non-optimal setting as reflected in many posts in discussion forums [59, 25, 60]. We use SOPHIA to tune this feature and compare the performance to three baselines: (1) Redis V2.4 with VM-disabled (Default configuration), (2) Redis V2.4 with VM-enabled, (3) Redis V4 with default configuration (no VM support, most production-proven).

To tune Redis' *VM*, we investigate the impact of two configuration parameters: (1) *vm-enable*: a Boolean parameter that enables or disables the feature. (2) *vm-max-memory*: the memory limit after which Redis starts swapping least-recently-used values to disk. These features cannot be reconfigured without a server restart.

We tune the performance of Redis for simulated data analytics workloads that vary with respect to job sizes and access patterns. We use the popular YCSB (Yahoo! Cloud Serving Benchmark) tool [12] to simulate HPC workloads as in [28, 24]. We collect 128 data points for jobs that vary with respect to their sizes (0.5M, 1M, 2M), their access patterns (i.e., read-heavy vs write-heavy) and also their request distribution (i.e., Uniform vs Zipfian). We use 75% of the data points (selected uniformly) to train a linear regression model and 25% for testing. The model provides accurate prediction of throughput for any job and configuration (avg. R^2=0.92). Therefore, we use this simpler model in place of Rafiki.

Redis can operate in `Stand-alone` mode as well as a `Cluster` mode [37]. In `Cluster` mode, data is automatically sharded across multiple Redis nodes. We show the gain of using our system with Redis for both modes of operation. No replication is used for `Stand-alone` mode. Whereas for `Cluster` mode, we use a replication factor of 1 (i.e., a single slave per master). We use AWS servers of type C3.Large with 2 vCPUs and 3.75GB RAM each. Selecting such a small RAM server demonstrates the advantage of using *VM* with jobs that cannot fit in memory—1.8M records fit in the memory. We evaluate the performance SOPHIA on a single server (Figure 10a) as well as a cluster of 6 servers with 3 masters and 3 slaves (Figure 10b) and report the average throughput per server. From Figure 10 we see that for all record sizes and request distributions, SOPHIA performs the best or close to the best. If records fit in memory, then the no VM configuration is better. For Uniform distribution, VM performs worst, because records often have to be fetched from disk. If records do not fit in memory, the no VM options (including the latest Redis) will simply fail (hence the lack of a bar for 2.0M records). Thus, SOPHIA, by automatically selecting the right parameters for changing workloads, can achieve the best of both worlds: fast in-memory database, and leverage disk in case of spillover.

7 Related Work

Reconfiguration for dynamic workloads. A few systems such as Rafiki [45], Outtertune [64], and SmartConf [65] have been proposed to automatically find the optimal software configurations for a given workload. All these systems assume that the workload change is a long-term, and for which reconfiguring the system is always beneficial. However, we show that in many real-world workloads, both long-term and short-term changes are observed and therefore SOPHIA decides when and how to apply the new configurations to achieve globally optimal performance, while respecting the user's availability requirements.

Reconfiguration in databases. Several works proposed online reconfiguration for databases where the goal is not to update the configuration settings, but to control how the data is distributed among multiple server instances [14, 6, 22, 18, 66]. Among these, Morphus [22] targets MongoDB but cannot handle Cassandra due to its peer-to-peer topology and sharding. Tuba [5] reconfigures geo-replicated key-value stores by changing locations of primary and secondary replicas to improve overall utility of the storage system. Rocksteady [34] is a data migration protocol for in-memory databases to keep tail latency low with respect to workload changes. However, no parameter tuning

or cost-benefit analysis is involved. A large body of work focused on choosing the best logical or physical design for static workloads in DBMS [13, 10, 70, 26, 11, 63, 2, 53, 54]. Another body of work improves performance for static workloads by finding correct settings for DBMS performance knobs [17, 16, 45, 69, 64]. SOPHIA performs *online* reconfiguration of the performance tuning parameters of distributed databases for *dynamic* workloads.

Reconfiguration in distributed systems and clouds. Several works have addressed the problem in the context of traditional distributed systems [29, 3] and cloud platforms [41, 68, 47, 46]. Some solutions present a theoretical approach, reasoning about correctness for example [3], while some present a systems-driven approach such as performance tuning for MapReduce clusters [41, 4]. BerkeleyDB [52] models probabilistic dependencies between configuration parameters. A recent work, *SmartConf* [65] provides a rigorous control-theoretic approach to continuously tune a distributed application in an application-agnostic manner. However, it cannot consider dependencies among the performance-critical parameters and cannot handle categorical parameters.

8 Conclusion

Current static tuners can provide close to optimal configuration for a static workload. However, they cannot determine whether and when to perform a configuration switch to maximize benefit over a future time horizon with changing workloads. We design SOPHIA to perform such reconfiguration while maintaining data availability and respecting the consistency level requirement. Our fundamental technical contribution is a cost-benefit analysis that analyzes the relative cost and the benefit of each reconfiguration action and determines a reconfiguration plan for a future time window. It then develops a distributed protocol to gracefully switch over the cluster from the old to the new configuration. We find benefits of SOPHIA applied to three distinct workloads (a metagenomics portal, a bus-tracking application, and a data analytics workload) over the state-of-the-art static tuners, for two NoSQL databases, Cassandra and Redis. Our work uncovers two big open challenges. How to do anticipatory configuration changes for future workload patterns? How to handle heterogeneity in the cluster, i.e., one where each server instance may have its own configuration and may contribute differently to the overall performance?

9 Supplemental Material

9.1 Cost-Benefit Analysis Derivation

Qualitatively, the benefit summed up over the time window is the increase in throughput due to the new optimal configuration option relative to the current configuration option.

$$B = \sum_{k \in [0, T_L]} H_{\text{sys}}(\boldsymbol{W}(k), \boldsymbol{C}^T_{\text{sys}}(k)) \tag{7}$$

where $\boldsymbol{W}(k)$ is the k-th element in the time-varying workload vector $\boldsymbol{W}$ and $\boldsymbol{C}^T_{\text{sys}}$ is the time-varying system configuration derived from $\boldsymbol{C}^{\Delta}_{\text{sys}}$. Likewise, the cost summed up over the time window is the loss in throughput incurred during the transient period of reconfiguration.

$$\begin{aligned} L &= \sum_{k \in [1,M]} \frac{\cancel{R}}{\cancel{N_s}} \cdot H_{\text{sys}}(\boldsymbol{W}(t_k), \boldsymbol{C}_k) \cdot \frac{\cancel{N_s}}{\cancel{R}} \cdot T_r \\ &= \sum_{k \in [1,M]} H_{\text{sys}}(\boldsymbol{W}(t_k), \boldsymbol{C}_k) \cdot T_r \end{aligned} \tag{8}$$

where $\boldsymbol{C}_k$ the configuration specified by the k-th entry of the reconfiguration plan $\boldsymbol{C}^{\Delta}_{\text{sys}}$, and T_r is the number of seconds a single server is offline during reconfiguration.

9.2 Synthetic HPC Workloads

For long-horizon reconfiguration plans, we simulate synthetic workloads representative of batch data analytics jobs, submitted to a shared HPC queue. We integrate SOPHIA with a job scheduler (like PBS [27]), that examines jobs while they wait in a queue prior to execution. Thus, the scheduler can profile the jobs waiting in the queue, and hence forecast the aggregate workload over a lookahead horizon, which is equal to the length of the queue. We model the jobs on data analytics jobs submitted to a Microsoft Cosmos cluster [21]

Figure 11 shows the simulated workload pattern for HPC Analytics case. We vary the level of concurrency and collect the aggregate workload observed by the NoSQL datastore.

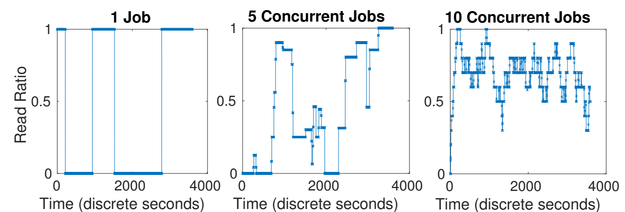

Figure 11: Simulated Workload patterns for 1, 5, and 10 concurrent jobs

libmpk: Software Abstraction for Intel Memory Protection Keys (Intel MPK)

Soyeon Park Sangho Lee[†] Wen Xu Hyungon Moon[*] Taesoo Kim

Georgia Institute of Technology
[†]*Microsoft Research*

Abstract

Intel Memory Protection Keys (MPK) is a new hardware primitive to support thread-local permission control on groups of pages without requiring modification of page tables. Unfortunately, its current hardware implementation and software support suffer from security, scalability, and semantic problems: (1) vulnerable to protection-key-use-after-free; (2) providing the limited number of protection keys; and (3) incompatible with `mprotect()`'s process-based permission model.

In this paper, we propose `libmpk`, a software abstraction for MPK. It virtualizes the hardware protection keys to eliminate the protection-key-use-after-free problem while providing accesses to an unlimited number of virtualized keys. To support legacy applications, it also provides a lazy inter-thread key synchronization. To enhance the security of MPK itself, `libmpk` restricts unauthorized writes to its metadata. We apply `libmpk` to three real-world applications: OpenSSL, JavaScript JIT compiler, and Memcached for memory protection and isolation. Our evaluation shows that it introduces negligible performance overhead (<1%) compared with the original, unprotected versions and improves performance by 8.1× compared with the secure equivalents using `mprotect()`. The source code of `libmpk` is publicly available and maintained as an open source project.

1 Introduction

Maintaining and enforcing memory access permission is an important duty of OSes and CPUs. Traditionally, they have used page tables to specify whether processes have rights to read from, write to, or execute specific memory pages. OSes can change access permission by updating page-table entries (PTEs) and flushing corresponding translation lookaside buffer (TLB) entries to reload them. In addition to page tables, some CPUs, e.g., ARM [5] and IBM Power [18], allow OSes to maintain the permission of a *page group* together by assigning the same *key* to the correlated pages and controlling the key's permission. To modify the permission of the page groups, OSes should, on behalf of the process, change the permission of the corresponding registers.

Recently, Intel deployed a similar key-based permission control, called Intel Memory Protection Keys (Intel MPK) [20], that allows a *userspace* process to change the permission of the page groups. MPK has three key benefits over page-table-based mechanisms: (1) performance, (2) group-wise control, and (3) per-thread view. First, MPK utilizes a protection key rights register (`PKRU`) to maintain the access rights of individual keys associated with specific pages: read/write, read-only, or no access. Processes only need to execute a non-privileged instruction (`WRPKRU`) to update `PKRU`, which takes less than 20 cycles (§2.3) and requires no TLB flush and context switching. Note that `PKRU` and page-table permissions cannot override each other, so the *effective permission* is the intersection of both.

Second, MPK can change the access rights of up to 16 different *page groups* at once, where each group consists of pages associated with the same key[1]. This group-wise control allows applications to change access rights to page groups according to the types and contexts of data stored in them (e.g., per-session data of a web server).

Third, MPK allows each thread (i.e., each hyperthread) to have a unique `PKRU`, realizing per-thread memory view. Accordingly, even if two threads share the same address space, their access rights to the same page can be different.

Although MPK is a promising primitive in concept, its current hardware implementation as well as standard library and kernel support suffer from three problems: (1) *security*, (2) *scalability*, and (3) subtle *semantic* differences, hindering its broader adoption. First, we found that MPK suffers from the *protection-key-use-after-free* problem. The Linux kernel provides two system calls, `pkey_alloc()` and `pkey_free()`, to allocate and de-allocate protection keys, respectively. During key de-allocation (`pkey_free()`), however, it does not invalidate pages associated with a de-allocated key, resulting in ambiguity when the de-allocated key is re-allocated and assigned to different pages later.

Second, MPK fails in scaling because `PKRU` can manage only up to 16 protection keys because of its hardware limitation. When an application tries to allocate more than 16 protection keys, `pkey_alloc()` simply fails, implying that the application itself should implement its own mechanism to

[1]The default group (0) has a special purpose, so only 15 groups are available for general uses.

multiplex these protection keys.

Third, the semantic of MPK is different from the conventional `mprotect()`, i.e., thread-view versus process-view, which results in potential security and performance problems. For example, the Linux kernel implements an execute-only memory with MPK by disabling read access through `PKRU` and allowing execution through a page table: `mprotect(addr, len, PROT_EXEC)`. Although this feature is invoked via `mprotect()`, it only changes the `PKRU`'s permission of the calling thread, meaning that other threads sharing the same address space can still read the execute-only memory. In other words, it is non-trivial to apply MPK securely and efficiently to legacy applications that rely on a process-level memory permission model.

In this paper, we propose `libmpk`, a secure, scalable, and semantic-compatible software abstraction to fully utilize MPK in a practical manner. In particular, `libmpk` implements (1) *protection key virtualization* to eliminate the protection-key-use-after-free problem and to support the unrestricted number of memory page groups, (2) *lazy inter-thread key synchronization* to selectively ensure per-process semantics with MPK, allowing us to substitute `mprotect()` in an efficient and compatible manner, and (3) *metadata integrity* to ensure the integrity of the mapping information while minimizing the number of system call invocations. `libmpk` consists of a userspace library mainly for efficient permission change and a kernel module mainly for synchronization and metadata integrity.

To show the effectiveness and practicality, we apply `libmpk` to three real-world applications: OpenSSL library, JavaScript just-in-time (JIT) compiler, and Memcached. First, we modify the OpenSSL library to create secure memory pages for storing cryptographic keys to mitigate information leakage. Second, we modify three JavaScript JIT compilers (i.e., SpiderMonkey, ChakraCore, and v8) to protect the code cache from memory corruption by enforcing the W⊕X security policy. Third, we modify Memcached to secure almost all its data, including the slab and hash table, whose size can be several gigabytes. The evaluation results show that `libmpk` and its applications have negligible overhead (<1%). Furthermore, `libmpk` is 1.73–3.78× faster than `mprotect()` when changing the permission of 1–1,000 pages at the view of a process, and, especially, the throughput of Memcached with `libmpk` is 8.1× higher than that of Memcached with `mprotect()`.

We summarize the contributions of this paper as follows:

- **Comprehensive study.** We study the design, functionality, and characteristics of Intel MPK in detail. We identify the critical challenges of utilizing MPK in terms of security, scalability, and semantics.
- **Software abstraction.** We design and implement `libmpk`, a software abstraction to fully utilize MPK. The protection key virtualization, metadata protection, and inter-thread key synchronization of `libmpk` allow applications to effectively overcome the three challenges.
- **Case studies.** We apply `libmpk` to OpenSSL library, JavaScript JIT compiler, and Memcached to show its effectiveness and practicality. `libmpk` secures them with a few modifications and negligible overhead.

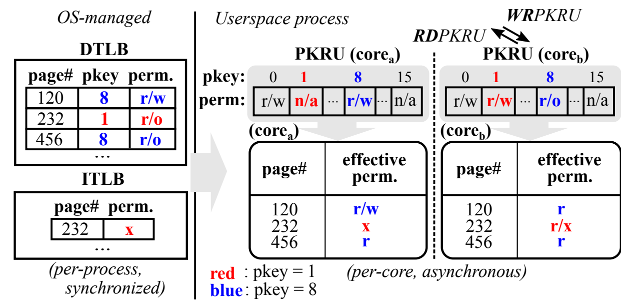

Figure 1: An example showing how MPK checks the permission of a logical core (hyperthread) on a specific memory page according to PKRU and page permissions. The intersection of the permissions determines whether a data access will be allowed. An instruction fetch is independent of the PKRU.

2 Intel MPK Explained

In this section, we describe the hardware design of Intel MPK and current kernel and library support. Also, we check the performance characteristics of MPK to show its efficiency.

2.1 Hardware Primitives

Intel MPK updates the permission of a group of pages by associating a protection key to the group and changing the access rights of the protection key instead of individual memory pages (Figure 1).

Protection key field in page table entry. MPK assigns a unique protection key to a memory page group to update its permission at the same time. MPK exploits the previously unused four bits of each page table entry (from 32nd to 35th bits) to store a memory page's corresponding key value. Thus, MPK supports up to 16 different page groups. Since only supervised code can access and change PTEs, the Linux kernel (from version 4.6) starts to provide a new system call, `pkey_mprotect()`, to allow applications to assign or change the keys of their memory pages (§2.2).

Protection key rights register (`PKRU`). MPK uses the value of `PKRU` to determine its access right to each page group. Two bits representing the right are *access disable* (AD) and *write disable* (WD) bits. The value of (AD, WD) represents a thread's permission to a page group: read/write $(0,0)$, read-only $(0,1)$, or no access $(1,x)$. `PKRU` exists for each hyperthread to provide a per-thread view.

Instruction set. MPK introduces two new instructions to manage the `PKRU`: (1) `WRPKRU` to update the protection information of the `PKRU` and (2) `RDPKRU` to retrieve the current protection information from the `PKRU`. `WRPKRU` uses three registers as input: the `EAX` register containing new protection

Name	Cycles	Description
pkey_alloc()	186.3	Allocate a new pkey
pkey_free()	137.2	Deallocate a pkey
pkey_mprotect()	1,104.9	Associate a pkey key with memory pages
pkey_get()/RDPKRU	0.5	Get the access right of a pkey
pkey_set()/WRPKRU	23.3	Update the access right of a pkey
Ref. mprotect(): 1,094.0 / MOVQ (rbx to rdx): 0.0 / MOVQ (rdx to xmm): 2.09		

Table 1: Overhead of MPK instruction, system calls, and standard library APIs. *ref* shows the overhead of mprotect() and normal register move instructions for comparison. We averaged 10 runs of microbenchmarks, where each one executes individual instruction, system call, or API 10 million times while measuring the latency with the RDTSCP instruction.

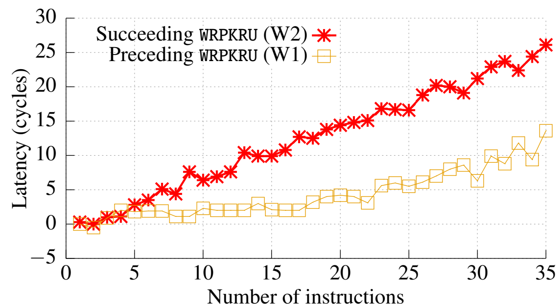

Figure 2: Effect of WRPKRU serialization on simple (i.e., ADD) instructions either preceding or succeeding WRPKRU (average of 10 million repetitions).

information to overwrite the PKRU, and the other two registers, ECX and EDX, filled with zeroes. RDPKRU also uses the three registers for its operation: it returns the current PKRU value via the EAX register while overwriting the EDX register with 0. The ECX register also should be filled with zeroes to execute RDPKRU correctly. Note that the actual usage of ECX and EDX registers is undocumented.

2.2 Kernel Integration and Standard APIs

The Linux kernel has supported MPK since version 4.6, and glibc has supported MPK since version 2.27. They focus on how to manage protection keys and how to assign them to particular PTEs. The Linux kernel provides three new system calls: pkey_mprotect(), pkey_alloc(), and pkey_free(). The kernel also changes the behavior of mprotect() to provide execute-only memory. glibc provides two userspace functions, pkey_get and pkey_set, to retrieve and update the access rights of a given protection key. Table 1 summarizes the APIs.

pkey_mprotect(). The pkey_mprotect() system call extends the mprotect() system call to associate a protection key with the PTEs of a specified memory region while changing its page protection flag. Interestingly, pkey_mprotect() does not allow a user thread to reset a protection key to zero, the default protection key value assigned to newly created memory pages such that it should be public to avoid accidental application crashes. We anticipate that resetting a key to zero is prohibited to avoid such potential crashes made by mistakes (i.e., denying access to the key zero).

pkey_alloc() and pkey_free(). The Linux kernel provides two other new system calls to allocate and de-allocate memory protection keys: pkey_alloc() and pkey_free(). When a user thread invokes pkey_alloc() with access right, the kernel allocates and returns a protection key with corresponding permission according to a 16-bit bitmap that tracks which protection keys are allocated. When a user thread invokes pkey_free(), the kernel simply marks the freed key as available in the bitmap. The pkey_mprotect() function examines the bitmap afterward to prohibit the use of non-allocated keys.

Execute-only memory. The Linux kernel supports execute-only memory with MPK. If a user thread invokes mprotect() only with PROT_EXEC, the kernel (1) allocates a new protection key, (2) disables the read and write permission of the key, and (3) assigns the key to the given memory region.

2.3 Quantifying Characteristics of Intel MPK

To evaluate the overhead and benefits of MPK, we measure (1) the overhead of the MPK instructions, (2) the overhead of the MPK system calls, and (3) the overhead of mprotect() for contiguous memory and sparse memory.

Environment. Our system consists of two Intel Xeon Gold 5115 CPUs (each CPU has 20 logical cores at 2.4 GHz) and 192GB of memory. Linux kernel version 4.14 configured for MPK is installed to this system.

Instruction latency. We measure the latency of RDPKRU and WRPKRU to identify their micro-architectural characteristics. Table 1 summarizes the results. The latency of RDPKRU is similar to that of reading a general register, but the latency of WRPKRU is high. We anticipate that WRPKRU performs serialization (e.g., pipeline flushing) to avoid potential memory access violation resulting from out-of-order execution. To confirm this, we insert various numbers of ADD instructions before (W1) and after (W2) WRPKRU and measure the overall latency (Figure 2). The results show that W2 is always slower than W1, implying that the instructions executed right after WRPKRU fail to benefit from out-of-order execution because of the serialization.

System calls. We measure the latency of the four Linux system calls for MPK (Table 1). The latency of mprotect() and pkey_mprotect() on a 4 KB page is almost the same because they all rely on do_mprotect_pkey() internally. pkey_alloc() and pkey_free() are fast since they involve only simple operations in the kernel, and the domain switching between kernel and userspace dominates their time costs.

Contiguous versus sparse memory pages. Using MPK to change page permission involves only an update on the PKRU and thus is independent of the number of targeted pages and their sparseness. To show the performance benefit of MPK over mprotect(), we check how the number and sparseness of the targeted pages affect the performance of mprotect().

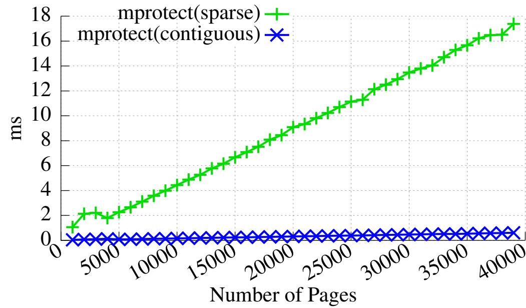

Figure 3: Overhead of `mprotect()` on contiguous and sparse memory (average cost of 10 million repetitions). Protecting contiguous pages takes less time than protecting sparse pages.

To construct contiguous memory pages, we call `mmap()` one time with certain memory size. For sparse memory pages, we call `mmap()` several times with one page size. Figure 3 shows that the overhead of `mprotect()` increases in proportion to the number of pages. The number of pages affects how many virtual memory areas (VMAs) [10] `mprotect()` needs to look up for permission update. Moreover, the overhead of `mprotect()` on sparse memory pages is high because multiple `mprotect()` calls introduce frequent context switchings between kernel and userspace.

Summary. Intel MPK allows a thread to rapidly change the per-thread access rights to a group of pages associated with the same protection key by updating a thread-local register `PKRU` which only takes around 20 cycles. Its performance is independent of the number of pages composing a group and their sparseness, unlike `mprotect()`.

3 Challenges of Utilizing Intel MPK

In this section, we explain the challenges of using MPK in terms of security, scalability, and synchronization.

3.1 Potential Security Problem

The existing OS support of MPK [3] suffers from the protection-key-use-after-free problem. In particular, `pkey_free()` just removes a protection key from a key bitmap and does not update the corresponding PTEs. Regardless of whether a key could already be associated with some pages, the kernel will allocate the key if it is freed by `pkey_free()`. If a program obtains a key that is still associated with some memory pages through `pkey_alloc()`, the new page group will include unintended pages that it is supposed to have. A developer can face this vulnerable situation unconsciously, as current kernel implementation neither handles this automatically nor checks if a free key is still associated with some pages. The developer community also recognized the problem and recommends not to free the protection keys [2, 13]. Handling this problem superficially (i.e., wiping protection keys in PTE) without a fundamental design change of memory management in the kernel will introduce huge performance overhead because it requires traversing the page table and VMAs to detect entries associated with a freed key to update them and flushing all corresponding TLB entries.

3.2 Limited Hardware Resources

Currently, MPK relies on a 32-bit `PKRU` such that it supports up to 16 keys. Developers are responsible for ensuring that an application never creates more than 16 page groups at the same time. This implies that developers have to examine at runtime the number of active page groups, which are used by both the application itself and the third-party libraries it depends on. Otherwise, the program may fail to properly benefit from MPK. This issue undermines the usability of MPK and discourages developers from utilizing it actively. Using a large register (e.g., 1024 bits) does not scale because MPK needs additional storage to associate keys with pages. For example, to support 512 protection keys, nine bits are necessary for each PTE, requiring enlarged page tables, shrunken address bits, or separate storage.

3.3 Semantic Differences

To change the permission of any page group, MPK modifies the value of the `PKRU`. However, the value is effective only in a single thread because `PKRU` is thread-local intrinsically as a register. As a result, different threads in a process can have different permissions for the same page group. This thread-local inherence helps to improve security for the applications that require isolation on memory access among different threads, but hinders MPK from optimizing and improving `mprotect()`. `mprotect()` semantically guarantees that page permissions are synchronized among all threads in a process on which particular applications rely. This not only makes it difficult to accelerate `mprotect()` with MPK, but also breaks the guarantee of execute-only memory implemented on mprotect in the latest kernel. `mprotect()` supporting executable-only memory relying on MPK does not consider synchronization among threads, which developers basically expect of `mprotect()`. Even when the kernel successfully allocates a key for the execute-only page, another thread might have a read access to it due to a lack of synchronization. To make MPK a drop-in replacement of `mprotect()` for both security and usability, developers need to synchronize the `PKRU` values among all the threads.

4 Software Abstraction of libmpk

`libmpk` provides a secure and usable abstraction for MPK by overcoming the challenges (§3). A developer can use MPK easily by either adding calls to `libmpk` APIs or replacing existing `mprotect()` calls with those of `libmpk`. By decoupling the protection keys from APIs, `libmpk` is immunized against protection-key-use-after-free. Also, `libmpk` allows an application to create more than 16 page groups by virtualizing the protection keys and provides a lightweight inter-thread `PKRU` synchronization mechanism. Figure 4 illustrates an overview of `libmpk`. The current version of `libmpk` consists of 1.5k

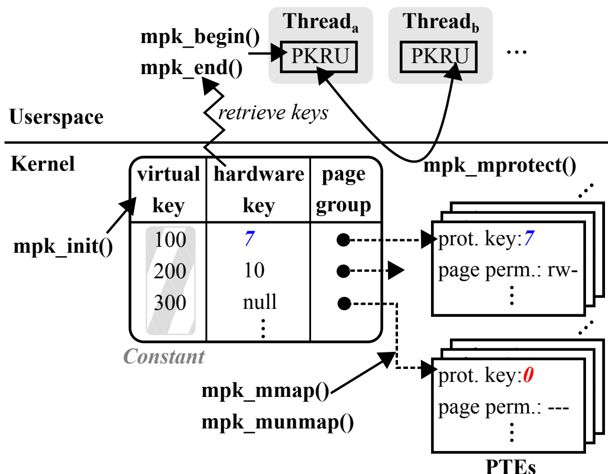

Figure 4: `libmpk` overview. `mpk_init()` pre-allocates hardware keys and initializes the metadata table. `mpk_mmap()` creates a page group with metadata, and `mpk_munmap()` destroys the page group and the corresponding metadata. `mpk_begin()` and `mpk_end()` provide domain-based thread-local isolation. `mpk_mprotect()` synchronizes permission changes globally.

```
1  #define GROUP_1 100
2  #define GROUP_2 101
3
4  int domain_based_isolation () {
5    mpk_init(-1); // default eviction rate: 100%
6    char* addr = (char *)mpk_mmap(GROUP_1, NULL, 0x1000,
7      PROT_READ | PROT_WRITE, MAP_ANONYMOUS | MAP_PRIVATE, -1, 0);
8    // page permission: rw- & pkey permission: --
9
10   mpk_begin(GROUP_1, PROT_READ | PROT_WRITE);
11   // page permission: rw- & pkey permission: rw
12
13   // write data in GROUP_1
14
15   mpk_end(GROUP_1);
16   // page permission: rw- & pkey permission: --
17
18   printf("%s\n", addr); // SEGMENTATION FAULT
19 }
20
21 int quick_permission_change () {
22   mpk_init(0.5); // set cache eviction rate: 50%
23   void* addr = mpk_mmap(GROUP_2, NULL, 0x1000,
24     PROT_READ | PROT_WRITE, MAP_ANONYMOUS | MAP_PRIVATE, -1, 0);
25   // page permission: rw- & pkey permission: --
26
27   mpk_mprotect(GROUP_2, PROT_READ | PROT_WRITE | PROT_EXEC);
28   // page permission: rwx & pkey permission: rw
29 }
```

Figure 5: Example code for `libmpk` APIs.

Name	Argument	Description
`mpk_init()`	`evict_rate`	Initialize `libmpk` with an eviction rate
`mpk_mmap()`	`vkey`, `addr`, `len`, `prot` `flags`, `fd`, `offset`	Allocate a page group for a virtual key
`mpk_munmap()`	`vkey`	Unmap all pages related to a given virtual key
`mpk_begin()`	`vkey`, `prot`	Obtain thread-local permission for a page group
`mpk_end()`	`vkey`	Release the permission for a page group
`mpk_mprotect()`	`vkey`, `prot`	Change the permission for a page group globally
`mpk_malloc()`	`vkey`, `size`	Allocate a memory chunk from a page group
`mpk_free()`	`size`	Free a memory chunk allocated by `mpk_malloc()`

Table 2: `libmpk` APIs.

lines of C/C++ code in total.

Goals. To utilize MPK for domain-based isolation and as a substitute for `mprotect()`, we have to overcome the three challenges: (1) insecure key management, (2) hardware resource limitations, and (3) different semantics from `mprotect()`. `libmpk` adopts two approaches: (1) *key virtualization*, and (2) *inter-thread key synchronization*, which effectively solve the challenges. `libmpk` also protects its internal metadata from corruption.

4.1 Threat Model and Assumptions

`libmpk` has the following threat model and assumptions, in accordance with prior studies [21, 33, 35].

`libmpk` aims to prevent an adversary from reading from or writing in sensitive pages through memory corruption vulnerabilities. `libmpk` achieves this goal by protecting the sensitive pages with new MPK APIs and preventing the adversary from arbitrarily executing the `WRPKRU` instruction. We assume that a program should solely use the `libmpk` APIs to utilize MPK in a controlled manner. That is, the program should not use conventional MPK APIs together with the `libmpk` APIs. Also, any uncontrolled execution of the `WRPKRU` instruction should be prohibited by using existing countermeasures, such as data execution prevention [1], control-flow integrity [4, 22, 23, 38], and call gate [35].

4.2 libmpk API

`libmpk` provides eight APIs, shown in Table 2. To utilize `libmpk`, an application first calls `mpk_init()` to obtain all the hardware protection keys from the kernel and initialize its metadata. `mpk_mmap()` allocates a page group for a virtual key, which should be a constant integer that the developer passes. `mpk_munmap()` destructs a page group by freeing a virtual key for the group and unmaps all the pages. `libmpk` maintains the mappings between virtual keys and pages to avoid scanning all pages at this destruction step. On top of these, `libmpk` also provides simple heap over each page group (`mpk_malloc()` and `mpk_free()`), so that a developer can also use one or more page groups to create a heap memory region for sensitive data.

`libmpk` provides two usage models for developers. The first model, a thread-local domain-based isolation model, allows an application to temporarily grant permission to a page group only for the calling thread. `mpk_begin()` and `mpk_end()` are the APIs for this model, which make a page group accessible and inaccessible, respectively. The second model allows an application to quickly change the access rights to a page group by replacing `mprotect()` with `mpk_mprotect()`. Figure 5 shows an example of utilizing `libmpk` APIs.

4.3 Protection Key Virtualization

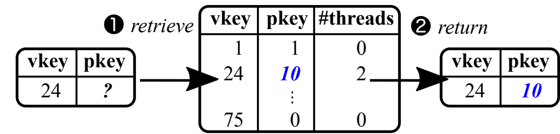
`libmpk` enables an application to create more than 16 page groups by virtualizing the hardware protection keys. When an application creates a new page group by calling `mpk_mmap()`, a virtual key passed as argument is associated with newly

allocated metadata for the new group. The application uses the virtual key to obtain or release the permission, or free the group, while being prohibited from manipulating hardware keys. The exact physical key that a page is associated with is hidden from the program and developer.

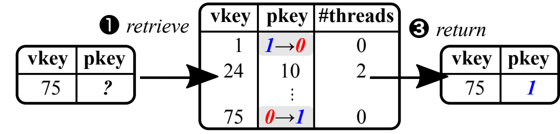
`libmpk` maintains the mappings between virtual and hardware keys through a cache-like structure (Figure 6). If a virtual key is already associated with a hardware key, the virtual key exists inside the cache and further access to it produces a few latencies. Otherwise, `libmpk` evicts another virtual key or does nothing but just invokes `mprotect()` for performance to change page permission. The frequency of eviction or calling `mprotect()` is determined by the eviction rate. The cache guarantees that a frequently updated virtual key will be mapped with a hardware key since it has a high possibility to be placed into the cache.

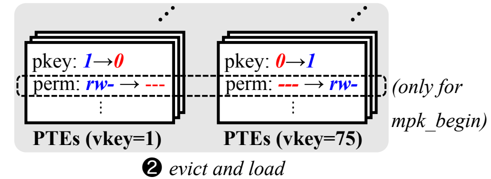
`libmpk` provides two policies to determine the mappings between virtual and hardware keys. When an application grants permission to a page group thread-locally by calling `mpk_begin()`, `libmpk` always maps the group's virtual key with a hardware key and uses it to grant access to the *calling thread*. `libmpk` maintains the mapping until the thread calls `mpk_end()` to release the access. For this reason, `libmpk` does not ensure that a calling thread always obtains the access due to hardware limitations. That is, if all hardware keys are actively used, `libmpk` is no longer able to provide any key. In this case, `mpk_begin()` raises an exception and lets the calling thread handle it (e.g., sleeps until a key is available). If a page group is not used by a thread, `libmpk` evicts the group by changing its protection key to 0 (default) and revoking its page permission to disallow subsequent accesses.

The second policy, `mpk_mprotect()`, also needs to map the virtual key to a hardware key, but not exclusively. Even when the page group is accessible, `libmpk` can unmap a hardware key and rely solely on the page attributes because all threads have the access. Hence, `libmpk` maps only the page groups whose access rights change frequently. If `libmpk` fails to find an available hardware key when it handles `mpk_mprotect()`, it unmaps and uses the least recently used (LRU) key for handling `mpk_mprotect()`. The hardware key of the evicted page group turns to 0. To avoid excessive overhead resulting from frequent unmapping, a developer can configure an *eviction rate* to control whether a hardware key has to be evicted according to how frequently its permission updates. In our approach, enforcing executable-only permission is not straightforward because a conventional approach (i.e., `mprotect()`) does not support executable-only permission. Therefore, `mpk_mprotect()` reserves one key for execute-only pages when an application creates them first, and does not evict this key until all executed-only pages disappear. Every incoming executable-only permission request is guaranteed to get a hardware protection key to achieve executable-only permission. If `mpk_mprotect()` has already been invoked for executable-only page groups, further requests will merge the



(a) Hit case: ❶ A thread calls `mpk_begin()` or `mpk_mprotect()` with a vkey; ❷ `libmpk` returns the corresponding pkey immediately.





(b) Miss case: ❶ A thread retrieves a vkey, but no corresponding pkey exists (pkey=0); ❷ `libmpk` evicts the LRU pkey. In addition, `mpk_begin()` updates the page permission of the evicted and loaded page groups using `mprotect()`; ❸ `libmpk` returns the new pkey.

Figure 6: Key virtualization in `libmpk`. *vkey* and *pkey* represent a virtual key and its corresponding hardware protection key associated with a page group. #threads indicates the number of threads running parallel inside a particular domain.

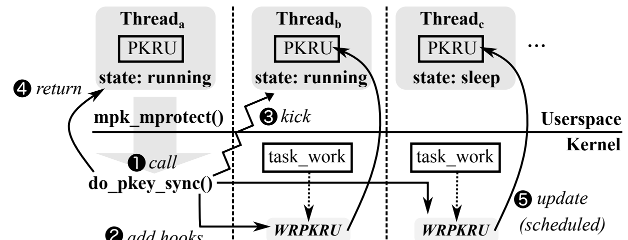


Figure 7: `PKRU` synchronization: ❶ `mpk_mprotect()` calls `do_pkey_sync()` to update the `PKRU` values of remote threads; ❷ `do_pkey_sync()` adds hooks to the threads' `task_work`; ❸ `do_pkey_sync()` kicks all the running threads for synchronization; ❹ `do_pkey_sync()` returns to its caller; ❺ The threads update their `PKRU`s when they are scheduled to run.

incoming page groups with the existing executable-only ones to utilize the reserved key.

The integrity of `libmpk` metadata (e.g., the mappings between virtual and hardware keys, and the page group information) is important to prevent attackers from manipulating `libmpk`'s protection. For the metadata integrity, `libmpk` maps each metadata physical page into two virtual pages: a read-only page for its userspace code and a writable page for its kernel-space code. Updating the metadata can be done only by the `libmpk` kernel module and slightly modified system calls (e.g., `mmap()`, `munmap()`, and `mprotect()`). Most of simple metadata retrieval can be done by the userspace code to avoid unnecessary user-kernel mode switches.

Application	Protection	Protected data	#pkeys	#vkeys	Changed LoC
OpenSSL	Isolation	Private key	1	1	83
JIT (key/page)	W⊕X	Code cache	15	> 15	CC 10 | SM 18
JIT (key/process)	W⊕X	Code cache	1	1	CC 18 | SM 24 | v8 134
Memcached	Isolation	Slab, hashtable	2	2	117

Table 3: Three real-world applications of `libmpk`. To enable W⊕X in JavaScript engines, we use two approaches, including using a virtual key for every page in the code cache (*One key per page*) and using a single protection key for all the pages in the code cache (*One key per process*). **CC**, **SM**, and **v8** indicate Microsoft ChakraCore, Mozilla SpiderMonkey, and Google v8, respectively. **pkeys** and **vkeys** stand for protection keys and virtual keys, respectively.

4.4 Inter-thread Key Synchronization

`libmpk` implements an inter-thread `PKRU` synchronization technique, `do_pkey_sync()`, in `mpk_mprotect()` for two purposes: (1) to ensure no thread has the read access to an execute-only page and (2) to replace existing page-table-based `mprotect()` for performance. `do_pkey_sync()` guarantees that a `PKRU` update is globally visible and effective as soon as it returns. Intuitively, this requires a synchronous inter-thread communication; the calling thread needs to send messages to the other threads and wait until they update the `PKRU` value and acknowledge it, which suffers from a high cost.

We minimize the inter-thread `PKRU` synchronization latency in a *lazy* manner, leveraging the fact that the `PKRU` values are utilized in the userspace. If a remote thread is not currently being scheduled, it does not need the up-to-date `PKRU` value immediately. Even if the thread is currently being scheduled, we only need to update its `PKRU` value when it returns to the userspace. If the calling thread can create a hook that the other threads will invoke right before jumping back to the userspace and ensure that they are not in the userspace, we can guarantee that all the other threads have the new `PKRU` value when `do_pkey_sync()` returns. Figure 7 illustrates the overall procedure of `mpk_mprotect()`. `do_pkey_sync()` utilizes an existing hooking point in the Linux kernel to enforce the remote threads to update the `PKRU` values right before returning to the userspace and ensures that all threads use the new `PKRU` value by sending rescheduling interrupts. In Linux, a thread can register a list of callback functions (`task_work`) that are invoked at designated points (e.g., when returning to the userspace) by calling `task_work_add()`. In this way, `do_pkey_sync()` guarantees that all the remote threads eventually acquire the new `PKRU` value. Although `do_pkey_sync()` still needs to send inter-processor interrupts to ensure that no other thread uses the old `PKRU` value after a certain point, our evaluation shows that the overall latency of `mpk_mprotect()` is less than that of `mprotect()` (§6.2).

5 Applications

We demonstrate the security benefit, efficiency, and usability of `libmpk` by augmenting three types of popular applications: an SSL library, three JavaScript Just-in-time (JIT) compilation engines, and an in-memory key-value store. Table 3 summarizes the mechanisms (e.g., page isolation or W⊕X) that we aim to provide as well as the protected data (e.g., key or code). Evaluation results are described in §6.

5.1 OpenSSL

OpenSSL is a popular open-source library implementing the secure sockets layer (SSL) and transport layer security (TLS) protocols. Since it manages sensitive information (e.g., private keys and encrypted data), its information leakage bugs are security-critical. For example, OpenSSL's Heartbleed bug [26] allowed attackers the chance to leak sensitive data from millions of web servers.

We apply `libmpk` to OpenSSL to protect its private keys from potential information leakage by storing the keys in isolated memory pages. More specifically, the isolated memory pages are protected by single pkey or multiple pkeys assigned per private key to show the trade-off between performance and security. First, we identify all the data types that store private keys (e.g., `EVP_PKEY`) and replace their heap memory allocation function from `OpenSSL_malloc()` to `mpk_malloc()` for single pkey or `mpk_mmap()` for multiple pkeys to store them in an isolated memory region. Next, we locate all the functions that access private keys (e.g., `pkey_rsa_decrypt()`) and modify them to access the isolated memory region by inserting `mpk_begin()` and `mpk_end()` before and after their call sites. Note that assigning pkey per private key offers finer-grained security, which minimizes the attack window for the isolated memory region. For example, even if a function whose call site is located between `mpk_begin()` and `mpk_end()` has a memory leakage bug, it cannot access any other isolated pages except the single page isolated with the pkey provided to `mpk_begin()` as argument.

5.2 Just-in-time (JIT) Compilation

JIT compilation dynamically translates interpreted script languages, e.g., JavaScript and ActionScript, into native machine code or bytecode to avoid the overhead of full compilation and repeated interpretation. Technically, it relies on writable code, resulting in potential arbitrary code execution. To support JIT compilation, the *code cache* that stores code generated at runtime needs to be writable for a JIT compilation thread and be executable for an execution thread. Thus, if attackers compromise the JIT compilation thread, they can make the execution thread execute the code they provide.

ChakraCore [27] and SpiderMonkey [28] mitigate the above-mentioned problem by enforcing the W⊕X security policy on the code cache with `mprotect()`. They make the code cache writable while disallowing execution when they are updating code, and, after it has updated, they make the code cache executable while disallowing write. However, they can suffer from *race condition attacks* [33] because they use `mprotect()` to change page permissions; that is, when a

thread makes the code cache writable with `mprotect()`, other threads compromised by attackers can also manipulate the code cache with the same permission.

We apply `libmpk` to the three popular JavaScript engines (SpiderMonkey, ChakraCore, and v8) to enforce the W⊕X security policy without the race condition problem while ensuring better performance. We propose two approaches to implement the W⊕X policy with `libmpk`.

One key per page. A context-free solution is to replace `mprotect()` with `libmpk` APIs to perform fast permission switches on targeted pages in the code cache. All the protection keys are initialized with read-only permission when a new thread is created. We dedicate *one protection key* to *one page* when it is the first time to be re-protected via `mprotect()` and change its page permission to `rwx`. Later, we only need to call `mpk_begin()` and `mpk_end()` before and after when the JIT compiler updates the corresponding page. Based on the observation that generally only one page is updated at a time, we still invoke `mprotect()` if multiple pages change permission.

One key per process. Another approach is to use a single protection key for the entire code cache. When pages are first committed from the preserved memory region into the code cache, they are assigned with the protection key and their page permission is set to `rwx`. Whenever any page in the code cache is to be updated, the script engine needs to call `mpk_begin()` and `mpk_end()`. Although more pages become temporarily writable, the security of the code cache is ensured thanks to the per-thread view of the protection key.

5.3 In-Memory Key-Value Store

In-memory key-value stores, such as Memcached, are widely used to manage a large amount of data in memory to ensure low latency and high throughput. With a high requirement for performance, such key-value stores normally avoid using security techniques whose performance depends on input size (e.g., `mprotect()` and encryption) to protect stored data. This implies that, if an in-memory key-value store has arbitrary read or write vulnerabilities, attackers are able to leak or corrupt sensitive information stored inside.

`libmpk` manages to efficiently mitigate such attacks. To demonstrate this, we apply `libmpk` to Memcached. `libmpk` protects Memcached's slabs that contain values and hash tables that maintain key-value mappings by replacing Memcached's `malloc()` function with `mpk_malloc()`, and wraps the call sites of all the legitimate functions (e.g., `ITEM_key()` and `assoc_find()`), which operate on protected data with `mpk_begin()` and `mpk_end()`. Note that we assign two different keys to slabs and hash tables, to narrow the attack surface. It is possible to use more keys to secure slabs in a fine-grained manner, e.g., differentiating them according to their sizes. More importantly, `libmpk`'s performance is independent of the size of memory to protect, and thereby efficiently works with Memcached even when protecting data of several gigabytes.

6 Evaluation

In this section, we evaluate `libmpk` in terms of its security implication and performance by answering the following questions:

- What security guarantees does `libmpk` provide? (§6.1)
- Does `libmpk` solve the security, scalability, and semantic-gap problems of existing MPK APIs without introducing much performance overhead? (§6.2)
- Does `libmpk` have negligible performance impact and outperform `mprotect()` in real-world applications? (§6.3)

The same system environment explained in §2.3 is used for performance evaluations.

6.1 Security Evaluation

We first evaluate the security benefits from `libmpk` regarding memory protection and isolation. For OpenSSL and Memcached, `libmpk` provides domain-based isolation to protect memory space that stores sensitive data. The permission for the particular memory space set by `libmpk` is locally effective, which also prevents malicious accesses from other compromised threads. In particular, exploiting a memory corruption bug to leak or ruin sensitive data stored in the isolated pages is killed by segmentation faults resulting from the lack of permission. To verify this, we mimic the Heartbleed vulnerability by deliberately introducing a heap-out-of-bounds read bug and inserting a decoy private key placed next to the victim heap region. When the vulnerability is triggered, OpenSSL hardened by `libmpk` crashes with invalid memory access. However, `libmpk` cannot fully mitigate memory leakage that originates inside the protected domain. Thus, developers should carefully design the domain to minimize the potential attack surface when using `libmpk` in their applications.

JavaScript JIT compilers can use `libmpk` to guarantee W⊕X for JIT code pages. Unlike `mprotect()`, `libmpk` is immune to race condition attacks launched by compromised threads running in parallel resulting from the thread-local effectiveness of protection keys. When the JIT compiler uses `libmpk` to switch the permission of a code page for updates, other threads controlled by attackers cannot write malicious shellcode into the page simultaneously. To verify this, we introduce two custom JavaScript APIs for arbitrary memory read and write to SpiderMonkey and ChakraCore, and test a simple PoC that leverages these two APIs to locate a JIT code page and write shellcode into it. Both engines crash with a segmentation fault at the end.

6.2 Microbenchmarks

We run several microbenchmarks to understand the performance behavior of APIs in `libmpk`.

Cache performance. `libmpk` introduces a cache to enable protection on more than 16 page groups, whose performance

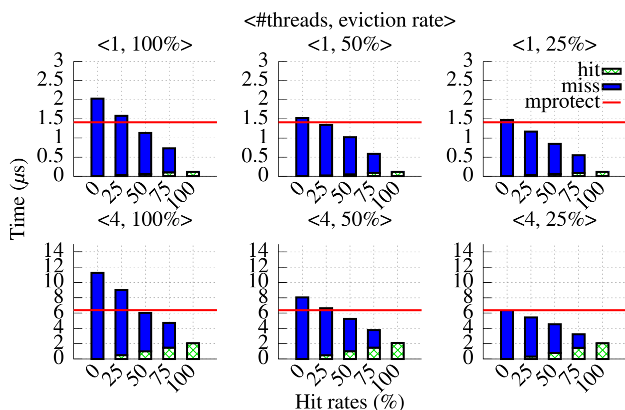

Figure 8: Latency of `libmpk`'s key cache with various hit rates, eviction rates, and different number of threads. `mpk_mprotect()` and `mprotect()` are invoked on a 4 KB page. Red line marks the overhead of `mprotect()`. When the hit rate is 100%, `mpk_mprotect()` is 12.2× faster than `mprotect()` for one thread and 3.11× faster for four threads.

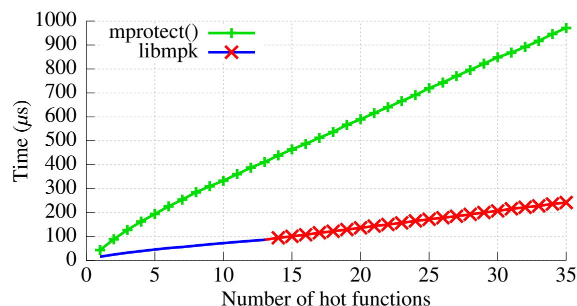

Figure 9: Average time cost to update permission when original and modified ChakraCore JIT-compile an increasing number of hot functions demanding distinct virtual keys.

is affected by its eviction rate and hit rate and the number of virtual keys in use. We run the following two microbenchmarks to check the cache performance.

Hit rate and eviction rate. The first benchmark measures cache performance with different hit rates, eviction rates, and number of threads. We run the benchmark with both one thread and four threads, where each thread warms up by filling the key cache to evade cold miss and invokes `mpk_mprotect()` on one page for a hundred times after 15 entries are filled. Figure 8 presents the evaluation results, where (1) the green box indicates the overhead incurred by the cache hit, which is dominated by the time cost on `WRPKRU` and maintaining internal data structures; (2) the blue box indicates the overhead incurred by the cache miss, which is dominated by the time cost on key eviction. More specifically, `mpk_mprotect()` needs to unset the protection key that is to be evicted and bind a new virtual key to it. We test the microbenchmark with three eviction rates that indicate the ratio of cache misses that eventually leads to key eviction. If a cache miss occurs without key eviction, `mprotect()` is invoked to change the permission of the pages.

Experimental results show that `mpk_mprotect()` outperforms `mprotect()` except when the cache hit rate is below 25% with an eviction rate above 50%. This is because, unlike `mprotect()`, `mpk_mprotect()` does not merge and split the VMAs of targeted pages. It becomes slow when being tested with four threads, but is still comparable with `mprotect()`, whose latency also increases in a multi-threading program.

Number of virtual keys. To evaluate how the number of used virtual keys affects the cache performance of `libmpk`, we re-implement W⊕X in ChakraCore in a *one-key-per-page* approach (see §5.2) and set the eviction rate as 100%. To introduce an increasing number of pages to be protected (i.e., an increasing number of virtual keys to be used) during the execution of ChakraCore, we design a simple microbenchmark. The microbenchmark consists of a set of JavaScript files, and the *i*th file contains *i* hot functions being invoked for 100,000 times. For each hot function, ChakraCore allocates one new executable page to store the native code and performs nine permission switches on the page through one virtual key at runtime. Without any hot function, ChakraCore allocates one page in the code cache. We run the original ChakraCore (version 1.9.0.0-beta) and the modified one with our microbenchmarks, and record the time cost of changing permission of the pages in the code cache (i.e., the execution time of `VirtualProtect()` and that of `mpk_begin()` and `mpk_end()`) in total. Each JavaScript file is executed 200 times, and the average time is presented in Figure 9.

The result shows that with the `libmpk`-based implementation of W⊕X, the time cost on permission switches linearly increases when more hot functions are emitted and thus more virtual keys are allocated to protect the code pages of the hot functions. In particular, after 15 virtual keys are allocated (marked in red), the time cost increases slightly faster than before (marked in blue) as a result of cache eviction. Nevertheless, the ChakraCore hardened by `libmpk` still outperforms by 3.2× the original ChakraCore using `mprotect()` to enforce W⊕X.

Memory overhead. `libmpk` dedicates memory space to store its internal data structures for maintaining the metadata of these page groups under protection (see §4.3). Each `mpk_mmap()` allocates 32 bytes of memory to store the information of a new page group (e.g., base address and size). `libmpk` maintains a hashmap to store the mapping between virtual keys and hardware keys for fast query and access. In the current implementation, we pre-allocate 32 KB of memory for the hashmap, and its size will automatically expand when a program invokes `mpk_mmap()` more than about 4,000 times.

Synchronization latency. Figure 10 shows the latency of inter-thread permission synchronization using `mpk_mprotect()` and `mprotect()` on memory of varying sizes.

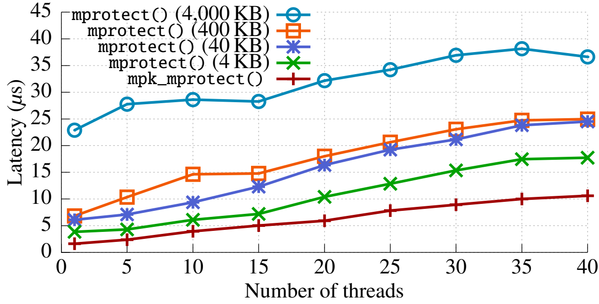

Figure 10: Latency of inter-thread permission synchronization using `mpk_mprotect()` and `mprotect()` calls on memory of varying sizes. `mpk_mprotect()` outperforms `mprotect()` 1.73× for a single page and 3.77× for 1,000 pages.

`mpk_mprotect()` is 1.73× faster than `mprotect()` when updating the permission of a single page. The latency of `mprotect()` increases with the number of pages it changes due to the expensive operations of managing VMAs. Compared to `mpk_mprotect()`, `mprotect()` costs at least 3.78× to change the permission of 1,000 pages. The performance overhead of `mpk_mprotect()` is independent of the number of pages whose permission has been updated. Figure 10 also shows that when there are many threads, the latency of both `mprotect()` and `mpk_mprotect()` increases; `mprotect()` flushes more TLBs, whereas `mpk_mprotect()` creates many hooks in the kernel.

6.3 Application Benchmarks

We measure the performance overhead of `libmpk` in practice by evaluating three applications proposed in §5.

OpenSSL. The Apache HTTP server [12] (`httpd`) uses OpenSSL to implement SSL/TLS protocols. To evaluate the overhead caused by `libmpk`, which is introduced to protect private keys, we use ApacheBench to test `httpd` with both the original OpenSSL library and the modified one with `libmpk`. ApacheBench is launched 10 times and each time sends 1,000 requests of different sizes from four concurrent clients to the server. We choose the DHE-RSA-AES256-GCM-SHA256 algorithm with 1024-bit keys as a cipher suite in the evaluation.

Figure 11 presents the evaluation result. On average, `libmpk` introduces 0.58% and 4.82% performance overhead, respectively, in terms of the throughput. In the single pkey case, the negligible overhead mainly comes from internal data structure maintenance in `libmpk`. In the multiple pkeys case, `httpd` utilizes more than 1,000 pkeys, as it allocates a new pkey while creating a new session. These pkeys are maintained by cache invoke eviction, so the multiple pkeys generates higher overhead than the single pkey case.

Just-in-time compilation. We applied two proposed W⊕X solutions based on `libmpk`, namely, *one key per page* and *one key per process* (§5.2) to both SpiderMonkey (version 59.0) and ChakraCore (version 1.9.0.0-beta) and evaluated their performance with the Octane benchmark [15], which involves heavy JIT-compilation workloads at runtime. Each

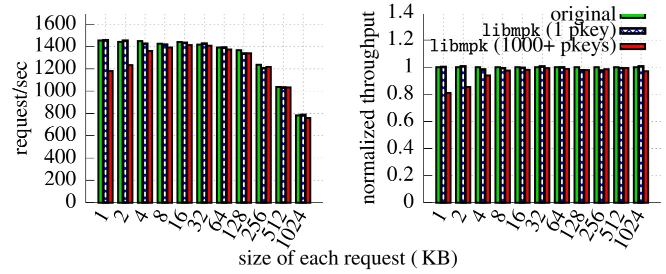

Figure 11: Throughput of original `httpd` and `httpd` hardened by `libmpk`. Protecting private keys with single pkey and 1000+ pkeys, `libmpk` slows down `httpd` by at most 2.52% and 18.84% respectively. The averages of overhead are 0.58% and 4.82% respectively.

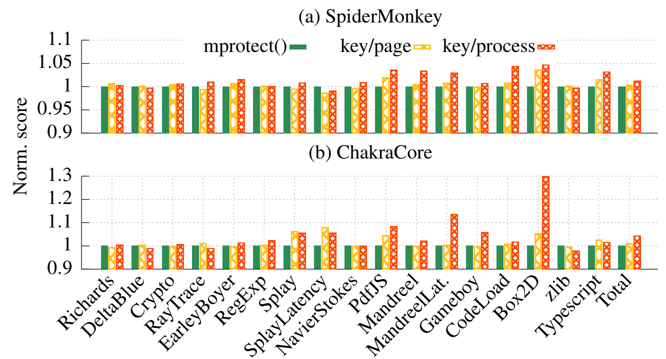

Figure 12: Octane benchmark scores of SpiderMonkey and ChakraCore with original and `libmpk`-based W⊕X solutions. `libmpk` outperforms the original, `mprotect()`-based defense by at most 4.75% (SpiderMonkey) and 31.11% (ChakraCore).

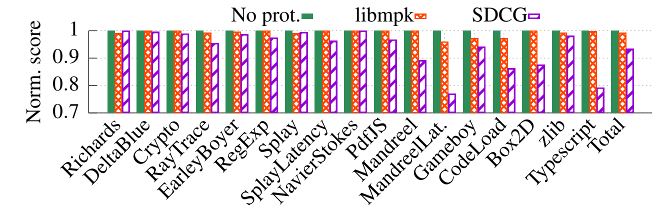

Figure 13: Octane benchmark scores of original v8 and two modified versions of v8 ensuring W⊕X by SDCG and `libmpk`. `libmpk` only introduces 0.81% overall performance overhead for W⊕X in v8, compared with 6.68% caused by SDCG.

JavaScript program in the benchmark was directly executed by the original and modified script engines for 20 times, and we calculated the average score (Figure 12).

For SpiderMonkey, both `libmpk`-based approaches outperform the `mprotect()`-based approach on the total score, namely, 0.38% and 1.26%, which is consistent with the claim from Firefox developers that enabling W⊕X with `mprotect()` in SpiderMonkey introduces less than 1% overhead for the Octane benchmark. The reason is that SpiderMonkey is designed to get rid of unnecessary `mprotect()` calls when its JIT compiler works. The performance scores of nearly all

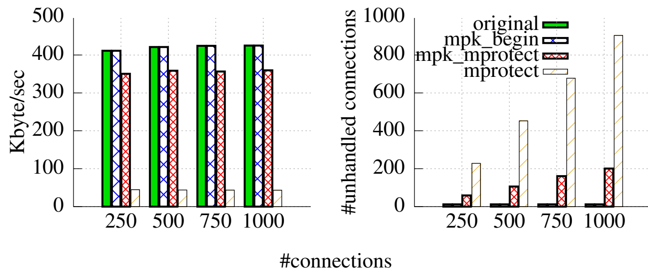

Figure 14: Throughput and unhandled concurrent connections of original Memcached and three versions of Memcached whose key-value pairs are protected by `mpk_begin()`, `mpk_mprotect()`, and `mprotect()`. `mpk_begin()`'s overhead is negligible compared to the original. `mpk_mprotect()` outperforms `mprotect()` 8.1× while ensuring the same semantics.

the programs increase through *one key per page* (at most 3.60% on `Box2D`) and *one key per process* (at most 4.75% on `Box2D`), except for `SplayLatency` protected by *one key per page* (dropped by 1.36%). `SplayLatency` becomes worse because it barely updates the code cache such that the initial overhead to associated keys with pages cannot be hidden.

Our two `libmpk`-based approaches improve ChakraCore by 1.01% and 4.39% on the total score of the Octane benchmark, respectively. ChakraCore is suitable for `libmpk`-based W⊕X solutions since it only makes one page writable per time regardless of emitted code size. *One key per page* increases the performance score of ChakraCore at most 7.96% when testing `SplayLatency`, while *one key per process* improves the performance by at most 31.11% on `Box2D`. Similar to the results of SpiderMonkey, we observe a few performance degradations when benchmarks rarely update code cache.

For v8, we compare our approach with a `mprotect()`-based scheme, SDCG [33]. SDCG protects the JIT code pages of v8 with W⊕X by emitting the code in a dedicated process. No other processes can change the code pages. To demonstrate the performance advantage of our in-process `libmpk`-based approaches, which are free of race condition attacks, we applied one of our approaches, *one key per process*, to Google v8 (version 3.20.17.1 used in [33]) and evaluated the performance through the Octane benchmark as well. Figure 13 presents the performance comparison among the original v8, v8 with SDCG, and v8 with `libmpk`. Note that originally, v8 has not deployed W⊕X to protect its code cache so far. Our approach only introduces 0.81% overall performance loss, compared with 6.68% caused by SDCG.

To summarize, our `libmpk`-based approaches, which are free of the race condition attacks, outperform the `mprotect()`-based approach currently applied in practice to enforce W⊕X protection on code cache pages with negligible overhead.

In-memory key-value store. To study the performance overhead of `libmpk` when protecting large memory, we evaluate the modified Memcached whose key-value pairs are isolated by `libmpk`. More specifically, the modified Memcached preallocates 1 GB memory, which is used instead of slab pages allocated by glibc `malloc()` to store key-value pairs. Besides the original Memcached, we also evaluate the Memcached whose key-value pairs are protected by `mprotect()`. To study the performance of `mpk_mprotect()` in real-world applications, we also create the Memcached guarded by `libmpk` with permission synchronized as another evaluation target for comparison. Each aforementioned version of Memcached launches with four concurrent threads, and we connect to it remotely through `twemperf` [34]. We create from 250 to 1,000 connections per second, and 10 requests are sent during each connection.

Figure 14 presents the evaluation results. The modified Memcached hardened by `libmpk` only has 0.01% overhead in terms of data throughput and almost no overhead regarding concurrent connections processed per second, which indicates that `libmpk` performs well even when protecting a huge number of pages. By contrast, `mprotect()` introduces nearly 89.56% overhead in terms of data throughput when protecting 1 GB memory in Memcached and a large number of unhandled concurrent connections accumulate in this case. This is because `mprotect()` involves page table traversing, which is considered expensive when dealing with a large number of pages. To evaluate the synchronization service of `libmpk` in practice, we also run Memcached protected by `mpk_mprotect()`. This design ensures the same semantics but outperforms `mprotect()` 8.1× regarding throughput.

`libmpk` provides the same functionality of `mprotect()` with much better performance when protecting huge memory. Moreover, in multi-threading applications, using `mprotect()` to ensure in-thread memory isolation requires lock, which is not required when using `libmpk` because of its inherent property.

7 Discussion

In this section, we discuss a potential attack on both Intel MPK and `libmpk`.

Rogue data cache load (Meltdown). We found that Intel MPK can suffer from the rogue data cache load, also known as the Meltdown attack [19,24]. The Meltdown attack is possible because current Intel CPUs check the access permission to a specific memory page after they have loaded it into the cache. MPK is not an exception because Intel CPUs check the access rights of `PKRU` when checking the page permission at the same pipeline phase. This allows attackers to infer the content of a present (accessible) page even when its protection key has no access right. Since Intel is considering hardware-level mitigation techniques [19], we believe this problem will be solved in the near future.

8 Related Work

MPK applications. While conducting our study, we noticed that there were a few ongoing studies using MPK to achieve different goals. Burow et al. [8] leverage both MPK

and memory protection extension (MPX) to efficiently isolate the shadow stack. ERIM [35] utilizes MPK to isolate sensitive code and data. MemSentry [21] provides a unified memory isolation framework to use various hardware features, including MPK and Memory Protection Extensions (MPX), with the same interface. XOM-Switch [39] relies on MPK to enable execute-only memory for unmodified binaries, and IskiOS [16] leverages MPK and kernel page table isolation (KPTI) to enforce execute-only memory in kernel. Our effort to provide a software abstraction for MPK is orthogonal to these studies, which are all potential applications of `libmpk`. These schemes can leverage `libmpk` to achieve secure and scalable key management to create as many sensitive memory regions as required securely.

Memory protection with other hardware features. Other hardware features exist for efficient memory protection such as ARM Domain [5] and IBM Storage Protection [18], which have a similar concept to MPK. For instance, ARMlock [40], FlexDroid [31], and Shreds [9] rely on Domain to isolate untrusted program modules, third-party libraries, and sensitive code modules, respectively. `libmpk` helps to port these applications from ARM to the Intel platform.

Software-based fault isolation (SFI). SFI [36] prohibits unintended memory accesses by inserting address masking instructions just before load and store instructions. This idea motivates many applications to utilize and further optimize it. Sandboxing mechanisms, such as Native Client (NaCl) [14, 30], relies on SFI to isolate untrusted code. Code-Pointer Integrity [23] also uses SFI to protect the code pointers from unsanitized memory accesses. SFI enables an application to partition its memory into multiple regions, but the cost of address masking limits the shape of partitions, which are commonly contiguous pieces of memory. By contrast, MPK enables an application to partition the memory into the regions with arbitrary shape. Further, the overhead of SFI on address masking increases by the number of isolated memory regions, unlike MPK.

Multiple virtual address spaces. Using multiple virtual address spaces for a single program can protect the memory of sensitive or untrusted components from the others. Some systems [7, 17, 29, 37] rely on multiple page tables to isolate the memory of threads in a single process from each other. Other systems [6, 11, 25] also provide different memory views to individual threads or small execution units using separated page tables. Kenali [32] uses a page-table-based isolation mechanism to protect sensitive data in which a separate page table is created for each thread. Unlike `libmpk`, these mechanisms suffer from non-negligible performance overhead resulting from slow and frequent page table switches.

9 Conclusion

Intel MPK supports efficient per-thread permission control on groups of pages. However, its hardware implementation and software support suffer from security, scalability, and semantic-gap problems. `libmpk` proposes a secure, scalable, and semantic-gap-mitigated software abstraction of MPK for developers to perform fast memory protection and domain-based isolation in their applications. Evaluation results show that `libmpk` incurs negligible performance overhead (<1%) for domain-based isolation and better performance for a substitute of `mprotect()` when adopted to real-world applications: OpenSSL, JavaScript JIT compiler, and Memcached.

Effective Static Analysis of Concurrency Use-After-Free Bugs in Linux Device Drivers

Abstract

In Linux device drivers, use-after-free (UAF) bugs can cause system crashes and serious security problems. According to our study of Linux kernel commits, 42% of the driver commits fixing use-after-free bugs involve driver concurrency. We refer to these use-after-free bugs as *concurrency use-after-free bugs*. Due to the non-determinism of concurrent execution, concurrency use-after-free bugs are often more difficult to reproduce and detect than sequential use-after-free bugs.

In this paper, we propose a practical static analysis approach named DCUAF, to effectively detect concurrency use-after-free bugs in Linux device drivers. DCUAF combines a local analysis analyzing the source code of each driver with a global analysis statistically analyzing the local results of all drivers, forming a *local-global analysis*, to extract the pairs of driver interface functions that may be concurrently executed. Then, with these pairs, DCUAF performs a *summary-based lockset analysis* to detect concurrency use-after-free bugs. We have evaluated DCUAF on the driver code of Linux 4.19, and found 640 real concurrency use-after-free bugs. We have randomly selected 130 of the real bugs and reported them to Linux kernel developers, and 95 have been confirmed.

1 Introduction

Use-after-free (UAF) bugs in device drivers are often dangerous. They not only cause system crashes, but also can be exploited by hackers to attack the operating system [7, 39, 40]. Among use-after-free bugs, *concurrency use-after-free bugs*, which are due to concurrent execution, are more difficult to detect. Indeed, they are not always triggered at runtime due to the non-determinism of concurrent execution. According to our study of Linux kernel commits, 42% of the driver commits fixing use-after-free bugs involve driver concurrency, and nearly all of these concurrency use-after-free bugs appear to have been found by manual inspection or runtime testing.

To detect use-after-free bugs, many approaches use dynamic analysis [6, 25, 33, 36, 45] to monitor memory accesses at runtime. However, the code coverage and detection results of these approaches heavily rely on the tested workloads. Several approaches [41, 42, 44] use static analysis to detect use-after-free bugs. They can cover much code and find many possible bugs without running the tested programs. However, these approaches are designed to detect use-after-free bugs that occur within sequential execution instead of those due to concurrency. Some static approaches [12, 13, 17, 37, 38] for detecting data races in device drivers can find concurrency use-after-free bugs. However, when identifying which driver functions may be concurrently executed, they assume that all driver interface functions can be concurrently executed [13, 37, 38] or rely on manual guidance [12, 17]. These strategies can introduce many false positives or require much manual work. They often report many data races, but many of the reported races are benign or false positives, and only a few are real concurrency use-after-free bugs.

In this paper, we propose DCUAF, a static analysis approach to detect concurrency use-after-free bugs in Linux device drivers. DCUAF first uses a local-global strategy to extract *concurrent function pairs*, namely the pairs of driver interface functions that can be executed concurrently. Then, with these function pairs, DCUAF performs a summary-based lockset analysis to detect concurrency use-after-free bugs. Our local-global strategy has two stages. In the local stage, DCUAF scans the code of each driver, and identifies calls to lock-acquiring functions, such as `spin_lock`. According to these calls and the driver's function call graph, DCUAF extracts *local concurrent interface pairs*, namely the pairs of driver interfaces that may be concurrently executed for the driver. In the global stage, DCUAF gathers the local concurrent interface pairs of all drivers and performs a statistical analysis to identify the pairs of driver interfaces that are frequently considered to be concurrently executed, from which it produces *global concurrent interface pairs*. Using these interface pairs, for each driver, DCUAF identifies the driver interface functions associated with these pairs as concurrent function pairs for this driver. For each driver function in a concurrent function pair, our lockset analysis analyzes each

variable access in the driver function, and records the lockset that protects this access. Then, for each pair of accesses in the functions of a concurrent function pair, the analysis compares their variables and locksets, and reports concurrency use-after-free bugs. To improve accuracy, our lockset analysis is inter-procedural, context-sensitive and flow-sensitive, and it maintains function summaries to reduce repeated analysis.

We have implemented DCUAF using Clang 6.0 [9] for Linux drivers. DCUAF is fully automatic, given the set of driver source files in the kernel. Overall, we make four main contributions:

- We perform a study of Linux kernel commits, and find that 42% of driver commits fixing use-after-free bugs involve concurrency. Moreover, we infer that nearly all of these concurrency use-after-free bugs have been found by manual inspection or runtime testing. To find more concurrency use-after-free bugs in device drivers, we propose to explore static analysis.
- We propose DCUAF, to detect concurrency use-after-free bugs in device drivers. To our knowledge, DCUAF is the first systematic static approach that targets concurrency use-after-free bugs in device drivers.
- We propose a novel local-global strategy to extract concurrent function pairs.
- We evaluate DCUAF on device drivers in Linux 3.14 and 4.19, and find 559 and 679 concurrency use-after-free bugs, respectively. We manually check these bugs, and find that 526 and 640 bugs are real, respectively. 35 of the real bugs found in Linux 3.14 have been fixed in Linux 4.19. We have randomly selected 130 of the real bugs in Linux 4.19, and reported them to Linux kernel developers. 95 of these bugs have been confirmed.

The remainder of this paper is organized as follows. Section 2 introduces the background. Section 3 shows the challenges of detecting concurrency use-after-free bugs in Linux device drivers and our key techniques to address these challenges. Section 4 introduces DCUAF. Section 5 presents the evaluation. Section 6 discusses how to apply our approach to other kinds of driver problems. Section 7 gives related work, and Section 8 concludes.

2 Background

We first introduce the Linux driver interface model, and then motivate our work by a concurrency use-after-free bug in a Linux driver and by our study of Linux kernel commits.

2.1 Linux Driver Interface Model

A Linux device driver needs to implement some specified *driver interfaces*, including *kernel-driver interfaces* and *interrupt handler interfaces*. A kernel-driver interface is invoked by non-driver threads through function calls when the driver communicates with related management code in the kernel, and an interrupt handling interface is called when a hardware interrupt occurs. We call the driver functions implemented for these driver interfaces *driver interface functions*. The driver interface functions are assigned to driver interfaces through specific data structure fields or specific kernel interfaces. The driver interface functions form the entry points of the driver, so all other functions defined in the driver are called by them. From the kernel's point of view, different drivers of the same device class should have the same functionalities, so drivers in the same device class share the same driver interfaces.

Figure 1 shows two typical Ethernet controller drivers (*dl2k* and *ne2k-pci*) in Linux 4.19. These drivers both define a net_device_ops data structure, containing some function pointer fields. Each network controller driver uses this data structure to communicate with network management code in the kernel, and each function pointer field represents a kernel-driver interface that performs a specific functionality of the driver. For example, in the net_device_ops data structure, the field `ndo_open` is used to open a network device, the field `ndo_stop` is used to close a network device, and the field `ndo_start_xmit` is used to transmit data packets. These drivers also both call a kernel interface `request_irq`, to register their interrupt handler functions through a function pointer argument. According to the functionalities of these driver interfaces, for a given network device instance, the interface net_device_ops.`ndo_start_xmit` can be concurrently executed with the interrupt handler function, but the interface net_device_ops.`ndo_open` is never concurrently executed with the interface net_device_ops.`ndo_stop`. However, whether two driver interfaces can be concurrently executed is often poorly documented in the Linux kernel.

Based on this driver interface model, *driver concurrency is often determined by the concurrent execution of driver interfaces.* Thus, to detect concurrency problems in device drivers, we need to know which driver interfaces can be concurrently executed. We refer to driver interfaces that can be concurrently executed as *concurrent interface pairs*.

2.2 Concurrency Use-After-Free Bug

Use-after-free (UAF) bugs are known to be hard to debug. If the freed memory is not reallocated, and thus not reinitialized, before the use, there is no visible problem, so the bug can linger. If the freed memory is reallocated and reinitialized before the use, then a read use can return an unexpected value and a write use can destroy data relied on by another part of the program. These problems are compounded in the case of kernel code, as the memory can be reinitialized by a different process, allowing information leaks. Some recent works [39, 40] have discussed how to exploit use-after-free bugs to attack an operating system.

443. }
```

Figure 1: Examples of driver interfaces.

We motivate our work by a real concurrency use-after-free bug in the Linux *cw1200* wireless controller driver. The *cw1200* driver manages the ST-Ericsson CW1200 wireless controller that is used in many embedded systems. The bug was introduced in Linux 3.11 (Sep. 2013) and was fixed 5 years later (Dec. 2018) by us, based on a report generated by DCUAF. Figure 2 shows the driver code related to this bug in Linux 4.19. In the ieee80211_ops data structure, as the driver interfaces represented by the fields `hw_scan` and `bss_info_changed` can be executed concurrently, the driver interface functions `cw1200_hw_scan` and `cw1200_bss_info_changed` can be executed concurrently. In *scan.c*, the function `cw1200_hw_scan` calls `dev_kfree_skb` to free `frame.skb` on line 126, without holding the lock `priv->conf_mutex`. In *sta.c*, the function `cw1200_bss_info_changed` calls `cw1200_upload_beacon`, which reads `frame.skb` on line 2221, while holding the lock `priv->conf_mutex`. Because the free operation is performed without holding a lock but the read operation is performed while holding a lock, a concurrency use-after-free bug may occur. To fix this bug, our commit [2] moved the call to `mutex_unlock` in `cw1200_hw_scan` behind the call to `dev_kfree_skb`.

This example illustrates some reasons why concurrency use-after-free bugs occur in device drivers: (1) Determining which driver interfaces can be executed concurrently requires substantial driver knowledge. In the example, without knowing wireless controller drivers in the Linux kernel well, it may be hard to know that the driver interfaces represented by the fields `hw_scan` and `bss_info_changed` can be executed concurrently. (2) Concurrency use-after-free bugs are not always

```

          ......
2238. }
```

Figure 2: A reported bug in the *cw1200* driver in Linux 4.19.

triggered in real execution and are hard to reproduce. In the example, `cw1200_hw_scan` and `cw1200_bss_info_changed` are not always concurrently executed at runtime. (3) Multiple functions needs to be considered, including the concurrently executed driver interface functions and the functions they call. In the example, three driver functions are involved.

2.3 Our Study of Linux Kernel Commits

To understand the state of the art in detecting use-after-free bugs in the Linux kernel, we study the Linux kernel commits to the mainline kernel [27]. We select the non-merge commits from Jan. 2016 to Dec. 2018 that fix use-after-free bugs, by searching (`git --grep`) for "use after free"and "use-after-free" in the log message, resulting in 949 commits. From them, we identify the driver commits, i.e., those affecting the *drivers* or *sound* directories. For the driver commits, we then study the log messages and code changes to determine: (1) whether the reported bugs are concurrency use-after-free bugs; (2) whether the reported bugs were detected by tools. Table 1 shows the results.

As shown in the table, 49% of the use-after-free related commits are for device drivers. Moreover, 42% of the use-after-free driver commits involve concurrency. Around 65% of the driver use-after-free commits, whether or not they involve concurrency, mention the use of tools, including KASAN [19], Syzkaller [34], Coverity [11], Coccinelle [30] and LDV [24].

Time	Commits	Drivers	Concurrency	Tool
2016 (Jan-Dec)	186	111	42 (38%)	26
2017 (Jan-Dec)	478	205	87 (42%)	49
2018 (Jan-Dec)	285	145	66 (46%)	52
Total	949	461	195 (42%)	127

Table 1: Linux kernel commits fixing use-after-free bugs.

Tool	KASAN	Syzkaller	Coverity	Coccinelle	LDV
Type	Runtime	Runtime	Static	Static	Static
Commit	92	28	4	2	1
Concurrency	38	18	0	0	0

Table 2: Use-after-free bugs found by different analyses and testing tools.

For the remaining driver use-after-free commits, we infer that the reported bugs in these commits are found by manual inspection of the source code and execution failures.

Table 2 breaks down the tool results by the specific tools. KASAN and Syzkaller are runtime testing tools. 120 of the commits fix the bugs found by these tools, including 56 that fix concurrency use-after-free bugs. Coverity, Coccinelle and LDV are static analysis tools. Only 7 of the commits fix bugs found by these tools, with no bug involving concurrency.

From the results, we can infer that nearly all of reported use-after-free bugs in released kernels have been found by manual inspection or runtime testing. However, runtime testing heavily relies on workloads to cover code, and thus it may miss many real bugs in practice. For this reason, it is important to explore static analysis as an alternative to detect concurrency use-after-free bugs in device drivers, but no systematic static tool has yet been proposed. Thus, we aim to design an effective static approach to solve this problem.

3 Challenges and Key Techniques

Our basic idea is to first extract *concurrent function pairs*, namely the pairs of driver interface functions that can be executed concurrently, and then perform a lockset analysis on these pairs of functions to detect concurrency use-after-free bugs. Implementing this idea requires addressing two main challenges:

C1: Extracting concurrent function pairs. Determining which driver functions may be concurrently executed requires substantial driver knowledge. Moreover, the Linux kernel documentation often lacks explicit descriptions about the concurrency of driver interfaces, and thus driver developers may err when implementing the code.

C2: Accuracy and efficiency of code analysis. The Linux driver code base is very large, amounting to 12.6M code lines in our tested version Linux 4.19. Thus, the lockset analysis can be quite time-consuming.

To solve the above challenges, we propose two key techniques. For *C1*, we propose a local-global strategy to extract concurrent function pairs from driver source files in the kernel. For *C2*, we propose a summary-based lockset analysis to detect concurrency use-after-free bugs.

3.1 Local-Global Strategy

Reviewing the example in Figure 2 suggests the following strategy: *concurrent interface pairs could be inferred according to the lock-acquiring function calls in driver interface functions.* In Figure 2, `cw1200_bss_info_changed` and `cw1200_hw_scan` both call `mutex_lock` with a lock variable `priv->conf_mutex`. This information suggests that these two driver functions may be concurrently executed. From this information, we could infer that the related driver interfaces `hw_scan` and `bss_info_changed` in the data structure ieee80211_ops may be a concurrent interface pair. But this kind of inference can be wrong in two common cases:

Case 1. It is possible that two functions that acquire the same lock are actually never concurrently executed. Figure 3 shows an example in the `e100` Ethernet controller driver. The driver functions `e100_enable_irq` and `e100_disable_irq` both call the lock-acquiring function `spin_lock_irqsave` with the same lock variable `nic->cmd_lock`, but they are also both called by the driver function `e100_netpoll`. This suggests that the spinlock acquired in `e100_enable_irq` and `e100_disable_irq` is used by `e100_netpoll` to synchronize with other driver functions, not to synchronize the calls to these two functions with each other.

```
FILE: linux-4.19/drivers/net/ethernet/intel/e100.c
616. static void e100_enable_irq(...) {
         ......
620.     spin_lock_irqsave(&nic->cmd_lock, flags);
         ......
623.     spin_unlock_irqsave(&nic->cmd_lock, flags);
624. };

626. static void e100_disable_irq(...) {
         ......
630.     spin_lock_irqsave(&nic->cmd_lock, flags);
         ......
633.     spin_unlock_irqsave(&nic->cmd_lock, flags);
634. };
-----------------------------------------------
2238. static void e100_netpoll(...) {
          ......
2242.     e100_disable_irq();
          ......
2245.     e100_enable_irq();
2246. }
```

Figure 3: Part of the *e100* driver in Linux 4.19.

Case 2. For two given driver interfaces, only a few of the drivers having the both driver interfaces acquire the same lock in these two driver interfaces, but most drivers do not. Table 3 shows some examples. The first and second columns show the names of involved driver interfaces; the third column shows the number of driver source files that have both

Driver Interface 1	Driver Interface 2	Both	Concurrent
spi_driver.probe	spi_driver.remove	227	3
file_operations.open	file_operations.llseek	462	3
watchdog_ops.start	watchdog_ops.stop	75	1
net_device_ops.ndo_open	ethtool_ops.get_link	124	2

Table 3: Example drivers having the same driver interfaces.

the involved driver interfaces; the fourth column shows the number of driver source files where the involved driver interfaces both acquire the same lock. For example, 227 driver source files have the driver interfaces spi_driver.`probe` and spi_driver.`remove`, but only 3 acquire the same lock in both driver interfaces. Indeed, spi_driver.`probe` is used to initialize an SPI device while spi_driver.`remove` is used to remove a running SPI device, and a device cannot be initialized and removed at the same time. Thus, the two driver interfaces should not be concurrently executed.

To handle the above two cases, we collect information about the lock usage of each driver as *local* information, and then combine the information about all drivers to perform a *global* statistical analysis. Based on this idea, we propose a *local-global strategy* to extract concurrent function pairs from driver code. The local and global stages handle *Case 1* and *Case 2*, respectively.

Local stage. In this stage, our strategy analyzes each driver source file, and extracts *local concurrent interface pairs*, namely the pairs of driver interfaces that may be concurrently executed for each driver. Figure 4 defines this stage, which has three steps:

Step 1. This step identifies the pairs of possible concurrently executed functions in each driver source file. Firstly, this step clears the result set *pos_func_pair_set*, and collects the set of lock-acquiring function calls as the set *lock_call_-set* (lines 1-2). Secondly, this step performs an alias analysis and checks each call in the set *lock_call_set* (lines 4-15). We identify whether the locks are the same by checking whether the related lock variables are aliased. If two different calls in the set have an aliased lock variable, their callers are considered as a pair of possible concurrently executed functions for the source file. In this case, the pair of callers is added to *pos_func_pair_set*. Finally, this step returns the final value of *pos_func_pair_set* (line 17).

Our alias analysis is field-based [16] and focuses on the lock variables stored in data structure fields. We take this strategy for two reasons. Firstly, drivers often use data structure fields to share data (such as locks) between different functions, as illustrated in Figures 2 and 3. Secondly, a variable stored in a data structure field can be explicitly distinguished from other variables using the data structure type and field name. However, for some lock frameworks, their lock-acquiring functions do not have any argument, such as `rcu_read_lock`. Thus, our analysis does not support these lock frameworks at present.

Step 2. This step filters out the pairs of possible concurrently executed functions that may actually not be executed concurrently. For each pair of possible concurrently executed functions, this step collects and checks the sets of their ancestors in the call graph (lines 2-5). Note that "ancestor" here include callers, callers of the callers, etc. Common ancestors are only collected up to the point of encountering a function that has no caller in the driver but instead is only assigned to a function pointer. As described in Section 2.1, a driver interface that forms an entry point of the driver is often presented as a function pointer stored in a data structure field. If the two driver functions have a common ancestor, the pair of the two functions is deleted from the set *pos_func_pair_set* (line 6), to avoid the possible false positives exemplified by *Case 1*. Finally, this step returns *pos_func_pair_set* (line 9).

```
Step 1: Get the pairs of possible concurrently executed functions
 1: pos_func_pair_set := ø;
 2: lock_call_set := GetLockCall();
 3: for i := 0 to SizeOf(lock_call_set) - 1 do
 4:     lock_call1 := lock_call_set[i];
 5:     lock_var1 := GetLockVar(lock_call1);
 6:     caller_func1 := GetCallerFunc(lock_call1);
 7:     for j := i + 1 to SizeOf(lock_call_set) - 1 do
 8:         lock_call2 := lock_call_set[j];
 9:         lock_var2 := GetLockVar(lock_call2);
10:         caller_func2 := GetCallerFunc(lock_call2);
11:         if lock_var1 is aliased to lock_var2 then
12:             func_pair := <caller_func1, caller_func2>
13:             Add func_pair to pos_func_pair_set;
14:         end if
15:     end for
16: end for
17: return pos_func_pair_set;

Step 2: Filter out may-false pairs of concurrently executed functions
 1: foreach func_pair in pos_func_pair_set do
 2:     <caller_func1, caller_func2> := GetFuncPair(func_pair);
 3:     func_set1 := GetAncestorFunc(caller_func1);
 4:     func_set2 := GetAncestorFunc(caller_func2);
 5:     if func_set1 ∩ func_set2 ≠ ø then
 6:         Delete func_pair from pos_func_pair_set;
 7:     end if
 8: end foreach
 9: return pos_func_pair_set;

Step 3: Get local concurrent interface pairs
 1: local_interface_pair_set := ø;
 2: foreach func_pair in pos_func_pair_set do
 3:     <caller_func1, caller_func2> := GetFuncPair(func_pair);
 4:     interface_set1 := GetDriverInterface(caller_func1);
 5:     interface_set2 := GetDriverInterface(caller_func2);
 6:     foreach interface1 in interface_set1 do
 7:         foreach interface2 in interface_set2 do
 8:             if interface1 == interface2 then
 9:                 continue;
10:             end if
11:             interface_pair := <interface1, interface 2>
12:             Add interface_pair to local_interface_pair_set;
13:         end foreach
14:     end foreach
15: end foreach
16: return local_interface_pair_set;
```

Figure 4: The local stage.

Step 3. From the remaining pairs of possible concurrently executed functions, this step extracts the local concurrent interface pairs for the driver. For each function in a pair of possible concurrently executed functions, this step gets the set of driver interfaces that call this function (lines 3-5). Then, this step computes the Cartesian product of the two sets of driver interfaces, omitting the pairs where both driver interfaces are the same (lines 6-14) to avoid the case that different driver functions are assigned to the same driver interface.

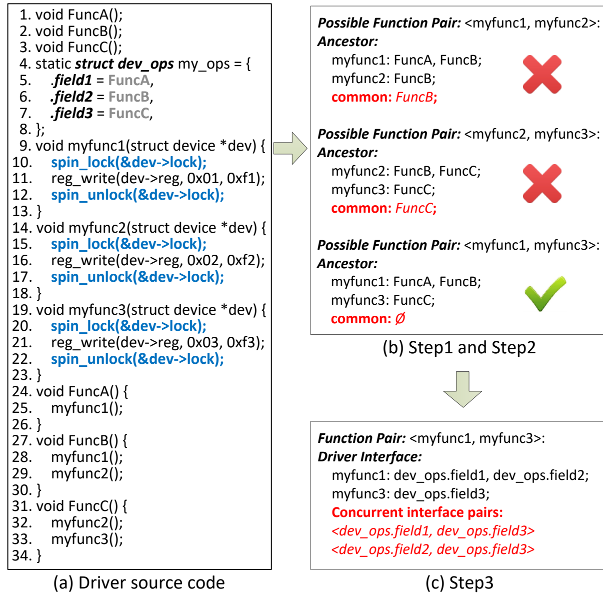

Figure 5: Example of performing the local stage.

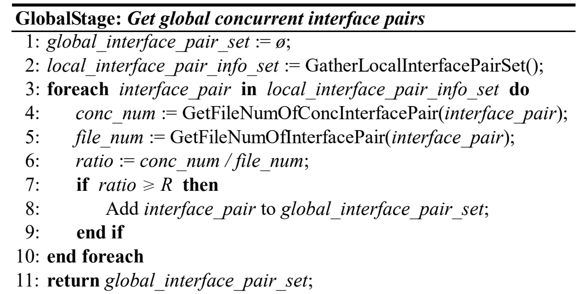
Example. To illustrate the local stage, we use some driver-like code shown in Figure 5. In Figure 5(a), the data structure dev_ops has three fields `field1`, `field2` and `field3`, and each of them stores a driver function, namely `FuncA`, `FuncB` and `FuncC`. *Step 1* identifies three lock-acquiring function calls on lines 10, 15 and 20, with the same lock `dev->lock`. Thus, this step gets three pairs of possible concurrently executed functions, namely `<myfunc1, myfunc2>`, `<myfunc2, myfunc3>` and `<myfunc1, myfunc3>`. Then, as shown in Figure 5(b), for each pair, *Step 2* checks the ancestors of the involved functions. `myfunc1` and `myfunc2` have a common caller `FuncB`, and `myfunc2` and `myfunc3` have a common caller `FuncB`, and thus the two pairs are filtered out, leaving only `<myfunc1, myfunc3>`. Finally, as shown in Figure 5(c), *Step 3* uses this function pair to get two lock concurrent interface pairs.

Note that the local stage assumes that a driver function or interface cannot be concurrently executed with itself. The main reason is that only analyzing the lock usage in a function is insufficient to infer whether this function can be concurrently executed with itself. However, this case indeed exists for some drivers, and may make our strategy miss some real local concurrent interface pairs.

Global stage. In this stage, with the local concurrent interface pairs of each driver, we perform a statistical analysis to extract *global concurrent interface pairs* for all drivers.

As shown in Figure 6, this stage first clears the result set *global_interface_pair_set*, and gathers the local concurrent interface pairs of all drivers (lines 1-2). Secondly, this stage handles each concurrent interface pair *interface_pair* in the gathered set (lines 4-9). It calculates the percentage of source files containing the two driver interfaces that have the two driver interfaces as an extracted local concurrent interface pair. This percentage is represent as *ratio* in Figure 6. If *ratio* $\geqslant R$ (a given threshold), *interface_pair* is considered as a global concurrent interface pair, and is added to the set *global_interface_pair_set*. Finally, this stage returns the final value of *global_interface_pair_set* (line 11).



GlobalStage: ***Get global concurrent interface pairs***

```
1: global_interface_pair_set := ø;
2: local_interface_pair_info_set := GatherLocalInterfacePairSet();
3: foreach interface_pair in local_interface_pair_info_set do
4:     conc_num := GetFileNumOfConcInterfacePair(interface_pair);
5:     file_num := GetFileNumOfInterfacePair(interface_pair);
6:     ratio := conc_num / file_num;
7:     if ratio ⩾ R then
8:         Add interface_pair to global_interface_pair_set;
9:     end if
10: end foreach
11: return global_interface_pair_set;
```

Figure 6: The global stage.

In this stage, the value of the threshold R is important, because the number of extracted global concurrent interface pairs decreases as R becomes larger. Increasing R may cause more false global concurrent interface pairs to be dropped, but more real interface pairs may be missed. We study the impact of the value of R in Section 5.3.

With the extracted global concurrent interface pairs, we identify concurrent function pairs for each driver. Specifically, given two driver interfaces in a driver, if they are in a global concurrent interface pair, the two driver functions associated with these driver interfaces are identified as a concurrent function pair for this driver.

3.2 Summary-Based Lockset Analysis

To improve accuracy and efficiency, our summary-based lockset analysis has the following properties: (1) The analysis is context-sensitive and inter-procedural, in order to maintain locksets and detect bugs across functions calls. (2) The analysis is flow-sensitive to improve accuracy. (3) The analysis uses function summaries to reduce repeated analysis and improve efficiency. (4) The analysis is field-based, and it focuses on the variables stored in data structure fields.

Given driver source code and a concurrent function pair, our lockset analysis has two steps:

Step 1. For each driver function in the concurrent function pair, this step collects the lockset of each variable access (read or write). During the collection, this step uses function summaries to handle called driver functions. Each function summary has the function name, source file name and a set that stores the information about all variable accesses in the function, including the accessed variable, the lockset of the access, the code path that reaches the access from the start of the function and the location of the access.

Figure 7 shows the treatment of a called function *func* by the caller *caller*, with *caller*'s function summary *caller_sum*, the collected lockset *lockset_caller* and the code path *path_info_caller* through *caller* when reaching the call to *func*. Firstly, this step checks whether there is already a call to *func* in the current path by searching *path_info_caller* (lines 1-3). If so, this step returns to avoid infinite looping on recursive calls. Secondly, this step searches the stored function summaries to check whether *func* has been handled (line 4). If so, this step directly uses its function summary *func_sum*. Otherwise, this step performs flow-sensitive analysis to collect information about variable accesses in *func* and then stores *func*'s function summary *func_sum* (lines 5-8). Thirdly, whether an existing function summary is found or a new one is created, this step gets the set *access_info_set* that stores the information about all variable accesses in *func* (line 9). Fourthly, for each variable access in *access_info_set*, this step concatenates its lockset and code path to the end of the *caller*'s lockset and code path, and then stores the information about this variable access in the function summary *caller_sum* (lines 10-16). Using function summaries, repeated flow-sensitive analyses of function definitions are reduced, which can improve the efficiency of the lockset analysis.

```
HandleFunc(func, caller_sum, lockset_caller, path_info_caller)
1: if func exists in path_info_caller then
2:     return;
3: end if
4: func_sum := FindFuncSummary(func);
5: if func_sum == ø then
6:     func_sum := AnalyzeFuncSummary(func);
7:     StoreFuncSummary(func_sum);
8: end if
9: access_info_set := GetAccessInfoSet(func_sum);
10: foreach access_info in access_info_set do
11:     lockset := lockset_caller + GetLockSet(access_info);
12:     path_info := path_info_caller + GetPathInfo(access_info);
13:     SetLockSet(access_info, lockset);
14:     SetPathInfo(access_info, path_info);
15:     AddAccessInfo(access_info, caller_sum);
16: end foreach
```

Figure 7: Handling a called function in our lockset analysis.

Step 2. For each pair of variable accesses in the driver functions of a concurrent function pair, this step compares the accessed variables and held locksets, and reports a concurrency use-after-free bug if: (1) the accessed variables are the same; (2) the intersection of the locksets is empty; (3) one of the accessed variable is used as an argument of a call to a memory freeing function. If both of the accessed variables are used as an argument of a call to a memory freeing function, a double-free bug is also reported.

4 Approach

Based on the two key techniques in Section 3, we propose a practical static approach named DCUAF, to detect concurrency use-after-free bugs in Linux device drivers. We implement DCUAF using Clang 6.0 [9], and perform static analysis on the LLVM bytecode of the driver code. Figure 8 shows the overall architecture of DCUAF.

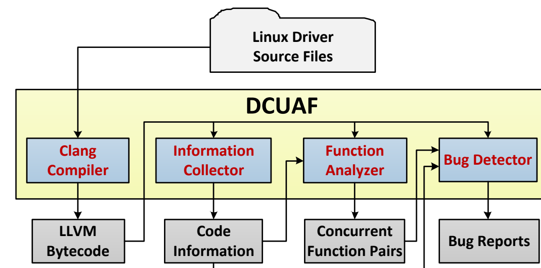


Figure 8: Overall architecture of DCUAF.

Based on this architecture, DCUAF has four phases:

P1: Source code compilation. In this phase, the *Clang compiler* compiles the driver source files and generates their LLVM bytecode files. Because a driver can be implemented across multiple source files, a driver function can call another driver function that is defined in another source file. During linking, DCUAF thus records the set of related source files. This set is used to locate the definition of a called function that is not in the same source file as the caller function.

P2: Code information collection. In this phase, the *information collector* analyzes each LLVM bytecode file, and records code information in a database. The information includes the name and position of each function definition and interrupt handler function, driver functions assigned to function pointers that are stored in data structure fields, the callee and caller functions of each function call, etc. The collected information is used in the remaining phases.

P3: Concurrent function pair extraction. In this phase, with the collected information, the *function analyzer* uses our local-global strategy to analyze LLVM bytecode files. It produces concurrent function pairs for each driver.

P4: Bug detection. In this phase, with the collected code information and extracted concurrent function pairs, the *bug detector* performs our summary-based lockset analysis to analyze each LLVM bytecode file and detect concurrency use-after-free bugs. Some reported bugs may be repeated, when the two bugs are associated with the same driver function and end up at the same variable access but differ in their code paths. Thus, the bug detector also filters out such repeated bug reports, by checking the positions of variable accesses.

Parallelism. The phases P1, P2 and P4 can work on individual LLVM bytecode files independently, and thus they can be parallelized straightforwardly. In P3, the local stage also works on individual LLVM bytecode files, and thus it can be parallelized, too. Only the global stage must be carried out in a single thread to perform the statistical analysis of the collected information. Because this stage does not require processing LLVM bytecode files, it is fast. Thus, overall, DCUAF can greatly benefit from parallelism.

5 Evaluation

We evaluate DCUAF on the source code of Linux device drivers. To cover different kernel versions, we select an old version 3.14 (released in March 2014) and a recent version 4.19 (released in October 2018). Table 4 shows information about the driver code in these kernel versions.

Description	Linux 3.14	Linux 4.19
Release time	March 2014	October 2018
Driver source files (.c)	11.2K	16.6K
Driver source code lines	6.7M	9.5M

Table 4: Properties of the evaluated driver code.

We run the experiments on a Lenovo x86-64 PC with four Intel i5-3470@3.20G processors and 8GB memory. We use the kernel configuration *allyesconfig* to enable all device drivers that can be compiled for the x86 architecture. We compile the driver code using the Clang 6.0 compiler [9]. Because DCUAF can work in parallel, we configure DCUAF to run on 4 threads.

5.1 Extracting Concurrent Function Pairs

DCUAF first uses our local-global strategy to extract concurrent function pairs. In the global strategy, we set $R = 0.2$. Table 5 shows the results for Linux 3.14 and 4.19.

The results show that DCUAF can scale to large code bases. It handles 5.1M and 7.9M source code lines in 7.9K and 13.1K source files in Linux 3.14 and 4.19, respectively, within 20 minutes. The remaining 1.6M and 1.8M source code lines in 3.3K and 3.5K source files in Linux 3.14 and 4.19 are not handled, because they are not enabled by *allyesconfig* for the x86 architecture.

Description		3.14	4.19
Code handling	Handled source files (.c)	7957	13100
	Handle code lines	5.1M	7.9M
Local stage	Dropped function pairs	61.4K	99.8K
	Remaining function pairs	40.7K	67.8K
Global stage	Candidate concurrent interface pairs	7354	11793
	Global concurrent interface pairs	694	1497
	Extracted concurrent function pairs	15.6K	69.5K
Time usage	Code information collection	10m16s	12m20s
	Local stage	4m36s	5m23s
	Global stage	10s	15s
	Total	14m52s	17m58s

Table 5: Results of extracting concurrent function pairs.

The results also show that our local-global strategy is effective in extracting concurrent function pairs. For example, for Linux 4.19, our strategy extracts 1497 global concurrent interface pairs from the 11,793 candidate concurrent interface pairs identified in the local stage. The remaining interface pairs are not extracted, because they are not identified as being able to execute concurrently by our strategy. For example, DCUAF deletes nearly all interface pairs related to driver initialization and removal (like `probe` and `remove`), which cannot run concurrently in real execution.

Table 6 shows a few of the extracted global concurrent interface pairs in Linux 4.19. The first and second columns show the names of the involved driver interfaces; the third column shows the number of driver source files that have both the involved driver interfaces; the fourth column shows the number of driver source files where the local stage identifies the involved driver interfaces as a concurrent interface pair.

Driver Interface 1	Driver Interface 2	Both	Concurrent
tty_operations.write	tty_operations.put_char	14	12
hc_driver.urb_enqueue	hc_driver.endpoint_disable	16	9
ieee80211_ops.bss_info_changed	ieee80211_ops.hw_scan	12	7
uart_ops.set_termios	console.write	21	14
Interrupt handler	snd_pcm_ops.trigger	49	25

Table 6: Examples of global concurrent interface pairs.

5.2 Detecting Bugs

With the extracted concurrent interface pairs, DCUAF runs our summary-based lockset analysis to detect concurrency use-after-free bugs. To validate whether DCUAF can find known bugs, we use it to check Linux 3.14 drivers. To validate whether DCUAF can find new bugs, we use it to check Linux 4.19 drivers. We also manually check all found bugs to validate accuracy. The results are shown in Table 7.

Description		3.14	4.19
Bug detection	Filter repeated	348	390
	Final detected (real / all)	526 / 559	640 / 679
	Double free (real / all)	82 / 89	117 / 132
	Interrupt handler (real / all)	25 / 25	23 / 23
Time usage		8m43s	10m15s

Table 7: Results of detecting bugs.

The results show that DCUAF finds 559 concurrency use-after-free bugs in Linux 3.14. We identify 526 of them as real bugs that are in 108 source files. Among these bugs, 35 have been fixed in Linux 4.19. Thus, DCUAF can find known bugs.

The results show that DCUAF finds 679 concurrency use-after-free bugs in Linux 4.19. We identify 640 of them as real bugs that are in 132 source files. Among these bugs, 372 are also found in Linux 3.14, and thus they have been present for at least 4.5 years. We have randomly selected 130 of these real bugs, and reported them to Linux kernel developers. 95 of them have been confirmed, and 12 of our patches that fix 42 real bugs have been applied (such as commits [1] and [3]) in the kernel code. Thus, DCUAF can find new bugs.

Among the bugs found by DCUAF, many are also double-free bugs. Specifically, DCUAF finds 89 and 132 double-free bugs in Linux 3.14 and 4.19, respectively, and we identify 82 and 89 of them as real bugs. Furthermore, DCUAF finds 25 and 23 bugs that involve interrupt handling in Linux 3.14 and 4.19, respectively, and we identify all of them as real bugs.

Over 60% of the real bugs found by DCUAF are in network, TTY, character and ISDN drivers. Specifically, 359 and 455 of the found real bugs are in these drivers in Linux 3.14 and 4.19, respectively, amounting to 68% and 71% of all found real bugs. Indeed, compared to other drivers, these drivers have more driver functions that can be concurrently executed.

Figure 9: A confirmed bug in the *r8a66597* driver.

Figure 9 shows a new confirmed bug found by DCUAF in the Linux 4.19 *r8a66597* driver. The *r8a66597* driver manages the Renesas R8A66597 USB host controller that is used in many embedded systems with USB ports. In the data structure hc_driver, the driver interfaces represented by the fields `urb_enqueue` and `endpoint_disable` are extracted as a global concurrent interface pair (the second row in Table 6) by our local-global strategy. Accordingly, DCUAF considers that the driver functions `r8a66597_urb_enqueue` and `r8a66597_endpoint_disable` may be concurrently executed. In `r8a66597_endpoint_disable`, the variable `hep->hcpriv` is freed on line 1995 without holding the spinlock `r8a66597->lock`. But in `r8a66597_urb_enqueue`, this variable is read on line 1905 while holding the spinlock `r8a66597->lock`. Thus, a concurrency use-after-free bug may occur. The bug report generated by DCUAF shows the related call paths, including the positions of the free, read and lock-acquiring operations. To fix this bug, we move the call to `spin_lock_irqsave` (line 2000) before the call to `kfree` (line 1995). Our patch[1] making this change has been applied by the Linux kernel maintainers.

The found bug in Figure 9 was introduced in Linux 2.6.22 (Jul. 2007), and had existed for over 11 years. Indeed, the USB related documentations in the Linux kernel [35] does not mention that the driver interfaces `urb_enqueue` and `endpoint_disable` can be concurrently executed.

5.3 Result Variation

As described in Section 3.1, the value of R is important. The above results are obtained with $R = 0.2$. To see the variation caused by R, we test $R = 0.1, 0.2, 0.3, 0.4$ and 0.5 on the Linux 4.19 drivers. Figure 10 shows the results.

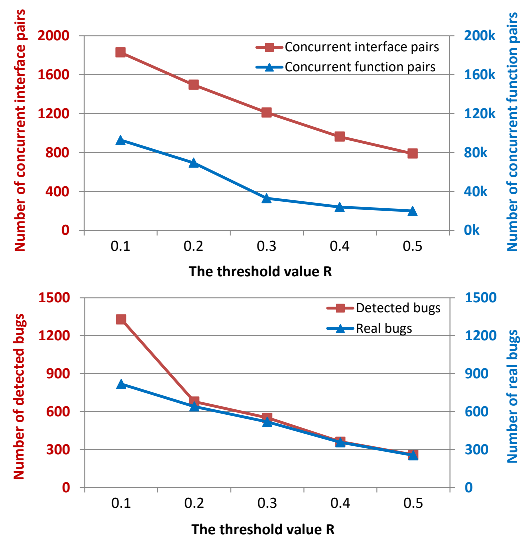

Figure 10: Variation of results by changing the value of R.

The numbers of extracted global concurrent interface pairs and extracted concurrent function pairs both decrease when R becomes larger. In this case, more false concurrent interface pairs and concurrent function pairs are dropped, but more of the dropped pairs are actually real concurrent interface pairs and concurrent function pairs, and thus the bugs involving these pairs are missed. Thus, if the value of R is too small, many false positives will be introduced, and if the value of R is too big, many false negatives will be introduced.

5.4 False Positive and Negative Analysis

5.4.1 False Positives

DCUAF reports 33 and 39 false bugs in Linux 3.14 and 4.19, resulting in false positive rates of 5.9% and 5.7% respectively. These false bugs are introduced for the following reasons:

Firstly, the alias analysis in our lockset analysis is field-based. It cannot distinguish between different variables stored in the same data structure field, and thus it may identify different variables (for locks and data uses) as the same. This reason causes DCUAF to report 12 and 19 false bugs in Linux 3.14 and 4.19.

Secondly, our lockset analysis is flow-sensitive but does not validate path conditions. Thus, it may search infeasible code paths when detecting bugs. This reason causes DCUAF to report 8 and 5 false bugs in Linux 3.14 and 4.19.

Finally, our lockset analysis only handles lock-related function calls, but does not consider other kinds of synchronization. For example, the kernel interface `synchronize_irq` is used to wait until the end of an interrupt handler. Thus, code after the call to `synchronize_irq` should never be concurrently executed with an interrupt handler. But our lockset analysis does not consider this case. This reason causes DCUAF to report 13 and 15 false bugs in Linux 3.14 and 4.19.

Besides the reasons for the false positives observed in our evaluation, there are some other potential reasons for false positives that we have not yet observed in practice. For example, the value of R in our local-global strategy can largely influence the accuracy of extracting concurrent function pairs. If R is not properly set, some extracted global concurrent interface pairs and concurrent function pairs may be false. Moreover, unnecessary locks acquired in the driver code can also influence the accuracy of extracting concurrent function pairs. This case can occur when two driver functions should not be concurrently executed, but they acquire the same lock, because the driver developer is too conservative. Indeed, it has been observed that the Linux kernel does not provide systematic documentation about where locks should be used [28]. Unnecessary locks may cause DCUAF to identify the two driver functions as a concurrent function pair.

5.4.2 False Negatives

To analyze the false negatives of DCUAF, we compare its bug reports with the driver commits fixing concurrency use-after-free bugs identified in Section 2.3. Specifically, we focus on the commits in the few months after the release of Linux 4.19 in October 2018, *i.e.*, between October and December in 2018, resulting in 22 commits. DCUAF finds the bugs in 6 of these commits (including the commit in Figure 2), but misses the bugs in the remaining 16 commits. These bugs are missed for the following reasons:

Firstly, DCUAF lacks function pointer analysis in the local-global strategy and lockset analysis, and thus cannot build complete call graphs of the driver code. As a result, it cannot find real bugs involving code reached through function pointers. This reason causes DCUAF to miss the bugs in 2 commits.

Secondly, our alias analysis is field-based, and may err in complex cases, such as the cases involving function arguments and pointer assignments. It may identify two identical variables (for locks and data uses) as different variables. This reason causes DCUAF to miss the bugs in 4 commits.

Thirdly, our local-global strategy neglects some real cases of driver concurrency. For example, the strategy does not consider that a driver function can be concurrently executed with itself, or that driver functions can create new kernel threads. This reason causes DCUAF to miss the bugs in 2 commits.

Finally, DCUAF does not handle some other cases in driver code, which causes it to miss the bugs in 8 commits. For example, the RCU lock-acquiring functions do not have any argument, so DCUAF cannot use a lock argument to perform static analysis and find related bugs. Moreover, DCUAF does not consider the multi-queue framework that is used in some network and storage drivers. Besides, DCUAF does not consider reference count puts as possible freeing operations.

5.5 Sensitivity Analysis

DCUAF uses two key techniques: a local-global strategy to extract concurrent function pairs in driver code, and a summary-based lockset analysis to reduce repeated analysis. To better understand the value of these two techniques, we modify DCUAF to remove each of them, and evaluate each resulting tool on Linux 4.19 drivers.

Dropping the local-global strategy. We implement two tools by respectively following two assumptions used by previous approaches for detecting data races [37, 38]: (1) all driver interfaces can be concurrently executed; (2) driver interfaces whose field names containing some common keyword pairs for device initialization and deinitialization, including <probe, remove>, <start, stop>, <open, close>, <init, fini> and <resume, suspend>, cannot be concurrently executed . These amount to 257 pairs of driver interfaces. The first tool runs for 350 minutes and reports around 50K bugs. The second tool runs for 302 minutes and reports around 42K bugs. We found that most of the reported bugs found by these tools are false, because many involved driver interfaces that are never concurrently executed. Thus, our local-global strategy indeed reduces false positives in bug detection.

Dropping the summary-based lockset analysis. We implement this tool by dropping function summaries, keeping only the names of functions previously analyzed in the current execution path to avoid infinite loops due to recursion. The resulting tool runs for 850 minutes and then aborts due to insufficient memory. Thus, our summary-based analysis indeed improves the efficiency of the analysis.

6 Discussion

In this section, we discuss how our approach may apply to other kinds of driver problems.

Other concurrency bugs. DCUAF can be used to detect other kinds of concurrency bugs in drivers, by modifying the lockset analysis. For example, it can detect a data race in two driver functions that can be concurrently executed. We have implemented such a prototype approach based on DCUAF. It reports around 149K data races in Linux 4.19 drivers. However, many of the reported data races are benign. Thus, we have focused on a specific kind of serious concurrency bug, namely concurrency use-after-free bugs.

Violations of other properties of driver interfaces. In fact, which driver interfaces can be concurrently executed is an important property of driver interfaces. To identify this property, in DCUAF, we first collect specific code information in each driver and then perform a statistical analysis of the collected information. This idea can be used to identify other important properties of driver interfaces and detect related violations. An example property is whether a driver interface can sleep. If a driver interface is called in atomic context [10], this driver interface cannot call any function that can sleep. Otherwise, a sleep-in-atomic-context (SAC) bug will occur, which can cause a system hang or crash [4]. Following our local-global strategy in DCUAF, for a given driver interface, we can first collect the information about whether the related driver function calls sleep-able functions in each driver; then we can perform a statistical analysis of all the collected information to infer whether this driver interface is in atomic context; and finally using the inference results, we can detect SAC bugs.

7 Related Work

7.1 Detecting Use-After-Free Bugs

Many approaches [6,25,33,36,45] for detecting use-after-free bugs are based on dynamic analysis. They monitor memory accesses at runtime and report bugs according to exact runtime information. They can detect both sequential and concurrency use-after-free bugs. For example, DangSan [36] is an effective use-after-free detection system that can efficiently scale to large numbers of pointer writes and to many concurrent threads. To reduce the runtime overhead of monitoring pointer tracking, DangSan uses a lock-free design inspired by log-structured file systems. This design refrains from using complicated shared data structures and simply opts for append-only per-thread logs for each object in the common case. However, these approaches require workloads that can achieve good code coverage and bug-detection results, and they often introduce runtime overhead.

Several approaches [41, 42, 44] use static analysis to detect use-after-free bugs in user-mode applications. For example, UAFChecker [44] combines taint analysis and symbolic execution to find use-after-free bugs inter-procedurally. CRED [42] is an efficient pointer-analysis-based static analysis to detect use-after-free bugs in large code bases. It uses a spatio-temporal context reduction technique to reduce the exponential number of considered contexts in code analysis. It also uses a multi-stage analysis to efficiently filter out false alarms, and uses a path-sensitive demand-driven method to find the required points-to information.

These static approaches target use-after-free bugs that occur within sequential execution. To do this, they start dataflow analysis from a given free operation, and check whether there is a subsequent use operation. However, they do not consider bugs caused by concurrent execution. Different from these approaches, DCUAF targets concurrency use-after-free bugs. To do this, DCUAF starts alias analysis from two driver functions that may be concurrently executed. Besides, these approaches target user-mode applications, while DCUAF targets device drivers by considering the driver interface model.

7.2 Detecting Concurrency Problems

To detect concurrency problems in device drivers, many existing approaches are based on dynamic analysis or static analysis:

Dynamic analysis. Related dynamic analysis approaches are sampling-based [15, 18] or lockset-based [8, 20, 32]. DataCollider [15] is an effective sampling-based approach to detect data races in the Windows kernel. It randomly samples memory accesses at runtime. To increase the possibility of capturing concurrent accesses to identical memory addresses, it delays the current running thread for a short time, and uses hardware breakpoints to trap any second access during delay. If a second access happens and at least one is a write, a real data race is detected. Eraser [32] was the first lockset-based approach for detecting data races. It instruments binary code to perform runtime monitoring of shared-variable accesses for each running thread, and detects data races by maintaining and checking locksets of shared variables during execution.

Dynamic approaches require associated hardware devices to actually run the tested drivers, which may be hard to obtain in practice. Besides, due to the non-determinism of concurrent execution, they may miss many real concurrency bugs.

Static analysis. Most related static analysis approaches [12, 13, 17, 29, 37, 38] are based on static lockset analysis. RacerX [13] is a well-known static lockset-based approach for detecting data races and deadlocks in OS kernel code. It uses an inter-procedural, flow-sensitive and context-sensitive analysis to maintain and check locksets in code paths, and detects data races and deadlocks. It also ranks the reported bugs. WHOOP [12] is an efficient static lockset-based approach for detecting data races in device drivers. It uses a symbolic pairwise lockset analysis to attempt to prove a driver race-free. It also uses a sound partial-order reduction to accelerate CORRAL [21], an existing concurrency-bug detector.

These static approaches target general concurrency bugs such as data races and atomicity violations, and they often have many false positives (for example, the work on RacerX [13] reports a false positive rate of nearly 50%). They do not focus on concurrency use-after-free bugs. Besides, they assume that all driver interface functions can be concurrently executed [13, 37, 38] or rely on manual guidance [12, 17], which can introduce many false positives or require much manual work. Different from these approaches, DCUAF targets concurrency use-after-free bugs, and uses a local-global strategy to accurately and automatically extract concurrent function pairs from driver source code.

7.3 Mining Code Rules in Systems Software

Some approaches mine implicit code rules in systems software, and then use the mined rules to detect related bugs. They mine rules by statistically analyzing source code [14, 23, 26, 31, 46] or execution traces [5, 22, 43]. PR-Miner [26] uses data mining techniques to extract implicit programming rules from the source code of large code bases. It extracts frequent function-call patterns that occur within a single function. Using the extracted rules, it detects related violations in the source code. PairCheck [5] uses software fault injection to generate test cases that cover error handling code in device drivers, and then runs these test cases to mine resource-acquire and -release rules from execution traces. Using the mined rules, it detects resource leaks in error handling code.

These approaches focus on code rules that occur within sequential execution, such as resource-acquire and -release pairs [5, 31] and function-call sequences [26, 43], but do not consider code rules involving concurrency. Inspired by these approaches, DCUAF uses a statistical analysis of driver code information when extracting concurrent function pairs.

8 Conclusion

In this paper, we have proposed a practical static analysis approach named DCUAF, to effectively and automatically detect concurrency use-after-free bugs in Linux device drivers. DCUAF uses two key techniques: (1) a local-global strategy to extract the pairs of driver interface functions that may be concurrently executed as concurrent function pairs; (2) a summary-based lockset analysis to detect concurrency use-after-free bugs, given two driver functions that may be concurrently executed. We have evaluated DCUAF on the driver code of Linux 4.19, and found 640 real concurrency use-after-free bugs. We have randomly selected 130 of these real bugs and reported them to Linux kernel developers, and 95 have been confirmed.

DCUAF can be improved in some aspects. Firstly, the code analysis in DCUAF can be improved to reduce false positives. For example, DCUAF does not consider path conditions and non-lock-related synchronization primitives in its lockset analysis. Secondly, DCUAF still misses concurrency use-after-free bugs involving complex patterns, such as using reference counters to free objects. Runtime testing tools such as KASAN [19] have found some such bugs in Linux drivers. We will consider these complex patterns in our lockset analysis to find more concurrency use-after-free bugs. Thirdly, besides concurrency use-after-free bugs, DCUAF can be applied to other driver problems, including other concurrency bugs such as data races and violations of other properties of driver interfaces such as sleep-in-atomic-context bugs. Finally, DCUAF only checks Linux drivers at present. We will port DCUAF in other operating systems (such as FreeBSD and NetBSD) to check their driver code.

Acknowledgment

We thank our shepherd Nadav Amit and the anonymous reviewers for their helpful advice on the paper. We also thank the Linux kernel developers who gave useful feedback to us.

Abstract

Modern operating systems are monolithic. Today, however, lack of isolation is one of the main factors undermining security of the kernel. Inherent complexity of the kernel code and rapid development pace combined with the use of unsafe, low-level programming language results in a steady stream of errors. Even after decades of efforts to make commodity kernels more secure, i.e., development of numerous static and dynamic approaches aimed to prevent exploitation of most common errors, several hundreds of serious kernel vulnerabilities are reported every year. Unfortunately, in a monolithic kernel a single exploitable vulnerability potentially provides an attacker with access to the entire kernel.

Modern kernels need isolation as a practical means of confining the effects of exploits to individual kernel subsystems. Historically, introducing isolation in the kernel is hard. First, commodity hardware interfaces provide no support for efficient, fine-grained isolation. Second, the complexity of a modern kernel prevents a naive decomposition effort. Our work on Lightweight Execution Domains (LXDs) takes a step towards enabling isolation in a full-featured operating system kernel. LXDs allow one to take an existing kernel subsystem and run it inside an isolated domain with minimal or no modifications and with a minimal overhead. We evaluate our approach by developing isolated versions of several performance-critical device drivers in the Linux kernel.

1 Introduction

Modern operating system kernels are fundamentally insecure. Due to rapid development rate (the de-facto industry standard Linux kernel features over 70 thousand commits a year), a huge codebase (the latest version of the Linux kernel contains over 17 million lines of unsafe C/C++ and assembly code[1]), and inherent complexity (typical kernel code adheres to multiple allocation, synchronization, access control, and object lifetime conventions) bugs and vulnerabilities are routinely introduced into the kernel code. In 2018, the Common Vulnerabilities and Exposures database lists 176 Linux kernel vulnerabilities that allow for privilege escalation, denial-of-service, and other exploits [20]. This number is the lowest across several years [19].

Even though a number of static and dynamic mechanisms have been invented to protect execution of the low-level kernel code, e.g., modern kernels deploy stack guards [18], address space layout randomization (ASLR) [45], and data execution prevention (DEP) [72], attackers come up with new ways to bypass these protection mechanisms [8, 35, 45, 49, 51, 57–59, 71]. Even advanced defense mechanisms that are yet to be deployed in mainstream kernels, e.g., code pointer integrity (CPI) [1, 53] and safe stacks [14, 53], become vulnerable in the face of data-only attacks combined with automated attack generation tools [46, 77]. In a monolithic kernel, a single vulnerability provides an attacker with access to the entire kernel. An attacker can redirect control to any part of the kernel and change any data structure escalating its privileges [46, 77].

Modern kernels need isolation as a practical means of confining the effects of individual vulnerabilities. However, introducing isolation in a kernel is hard. First, despite many advances in the architecture of modern CPUs, low-overhead hardware isolation mechanisms [74–76] did not make it into commodity architectures. On modern machines, the minimal call/reply invocation that relies on traditional address-spaces for isolation [26] takes over 834 cycles (Section 5). To put this number into perspective, in the Linux kernel a system call that sends a network packet through the network stack and network device driver takes 2299 cycles. A straightforward isolation of a network device driver which requires two domain crossings on the packet transmission path (Section 4), would introduce an overhead of more than 72%.

Second, the complexity of a shared-memory kernel that accumulates decades of development in a monolithic setting

prevents a trivial decomposition effort. Decomposition requires cutting through a number of tightly-connected, well-optimized subsystems that use rich interfaces and complex interaction patterns. Two straightforward isolation strategies—developing isolated subsystems from scratch [21, 24, 31] or running them inside a full copy of a virtualized kernel [11, 16, 30, 60]—result in either a prohibitively large engineering effort or overheads of running a full copy of a kernel for each isolated domain.

Our work on Lightweight Execution Domains (LXDs) takes a step towards enabling isolation in a full-featured operating system kernel. LXDs allow one to take an existing kernel subsystem and run it inside an isolated domain with minimal or no modifications and with a minimal overhead. While isolation of core kernel subsystems, e.g., a buffer cache layer, is beyond the scope of our work due to tight integration with the kernel (i.e., complex isolation boundary and frequent domain crossings), practical isolation of device drivers, which account for over 11 millions lines of unsafe kernel code and significant fraction of kernel exploits, is feasible.

Compared to prior isolation attempts [9, 12, 15, 27, 32–34, 40–43, 66, 68, 69], LXDs leverage several new design decisions. First, we make an observation that synchronous cross-domain invocations are prohibitively expensive. The only way to make isolation practical is to leverage asynchronous communication mechanisms that batch and pipeline multiple cross-domain invocations. Unfortunately, explicit management of asynchronous messages typically requires a clean-slate kernel implementation built for explicit message-passing [5, 42]. LXDs, however, aim to enable isolation in commodity OS kernels that are originally monolithic (commodity kernels accumulate decades of software engineering effort that is worth preserving). To introduce asynchronous communication primitives in the code of a legacy kernel, LXDs build on the ideas from asynchronous programming languages [3,13,39]. We develop a lightweight asynchronous runtime that allows us to create lightweight cooperative threads that may block on cross-domain invocations and hence implement batching and pipelining of cross-domain calls in a way transparent to the kernel code.

Second, to break the kernel apart in a manner that requires only minimal changes to the kernel code, we develop *decomposition patterns*, a collection of principles and mechanisms that allow decomposition of the monolithic kernel code. Specifically, we support decomposition of typical idioms used in the kernel code—exported functions, data structures passed by reference, function pointers, etc. To achieve such backward compatibility, decomposition patterns define a minimal runtime layer that hides isolated, share-nothing environment by synchronizing private copies of data structures, invoking functions across domain boundaries, implementing exchange of pointers to data structures and functions, handling dispatch of cross-domain function calls, etc. Further, to make our approach practical, we develop an interface definition language (IDL) that generates runtime glue-code code required for decomposition.

Finally, similar to existing projects [54, 67], we make an observation that on modern hardware cross-core communication via the cache coherence protocol is faster then crossing an isolation boundary on the same CPU. By placing isolated subsystems on different cores it is possible to reduce isolation costs. While dedicating cores for every isolated driver is impractical, the ability to run several performance-critical subsystems, e.g., NVMe block and network device drivers, with the lowest possible overhead makes sense.

We demonstrate practical isolation of several performance-critical device drivers in the Linux kernel: software-only network and NVMe block drivers, and a 10Gbps Intel ixgbe network driver. Our experience with decomposition patterns shows that majority of the decomposition effort can be done with no modification to the kernel source. We hope that our work—general decomposition patterns, interface definition language, and asynchronous execution primitives—will gradually enable kernels that employ fine-grained isolation as the first-class abstraction. At the moment, two main limitations of LXDs are 1) requirement of a dedicated core for each thread of an isolated driver (Section 5), and 2) manual development of the IDL interfaces. We expect to relax both of the limitations in our future work.

2 Background and Motivation

The concept of decomposing operating systems for isolation and security is not new [9,12,15,27,32–34,40–43,66,68,69]. In the past, multiple projects tried to make isolation practical in both microkernel [9, 27, 41–43, 68] and virtual machine [12, 15, 33, 66] systems. SawMill was a research effort performed by IBM aimed at building a decomposed Linux environment on top of the L4 microkernel [34]. SawMill was an ambitious effort that outlined many problems of fine-grained isolation in OS kernels. SawMill relied on a synchronous IPC mechanism and a simple execution model in which threads migrated between isolated domains. Unfortunately, the cost of a synchronous context switch more than doubled in terms of CPU cycles over the last two decades [26]. Arguably, with existing hardware mechanisms the choice of a synchronous IPC is not practical (on our hardware a bare-bone synchronous call/reply invocation takes over 834 cycles on a 2.6GHz Intel machine; a cache-coherent invocation between two cores of the same die takes only 448-533 cycles, moreover, this number can be reduced further with batching (Section 5)). Furthermore, relying on a generic Flick IDL [25], SawMill required re-implementation of OS subsystem interfaces. In contrast, LXDs's IDL is designed with an explicit goal of backward compatibility with the existing monolithic code, i.e., we develop mechanisms that allow us to transparently support decomposition of typical code patterns used in the kernel, e.g., registration of interfaces as function pointers, passing data structures by reference, etc.

Nooks further explored the idea of isolating device drivers in the Linux kernel [69]. Similar to SawMill, Nooks relied on the synchronous cross-domain procedure calls that are prohibitively expensive on modern hardware. Nooks maintained and synchronized private copies of kernel objects, however, the synchronization code had to be developed manually. Nooks' successors, Decaf [64] and Microdrivers [32] developed static analysis techniques to generate glue code directly from the kernel source. LXDs do not have a static analysis support at the moment. We, however, argue that IDL is still an important part of a decomposed architecture—IDL provides a generic intermediate representation that allows us to generate glue code for different isolation boundaries, e.g., cross-core invocations, address-space switches, etc.

OSKit developed a set of decomposed kernel subsystems out of which a full-featured OS kernel could be constructed [29]. While successful, OSKit was not a sustainable effort—decomposition glue code was developed manually, and required a massive engineering effort in order to provide compatibility with the interface of Component Object Model [17]. OSKit quickly became outdated and unsupported.

Rump kernels develop glue code that allows execution of unmodified subsystems of the NetBSD kernel in a variety of executable configurations on top of a minimal execution environment [48], e.g., as a library operating system re-composed out of Rump kernel subsystems. Rump's glue code follows the shape of the kernel subsystems and hence provides compatibility with unmodified kernel code that ensures maintainability of the project. LXDs follow Rump's design choice of ensuring backward compatibility with unmodified code, but aim at automating the decomposition effort. Specifically, LXDs rely on decomposition patterns and IDL to extract unmodified device drivers from the kernel source and seamlessly enable their functionality for the monolithic kernel.

User-level device drivers [11, 21, 24, 30, 60] allow execution of device drivers in isolation. Two general approaches are used for isolating the driver. First, it is possible to run an unmodified device driver on top of a device driver execution environment that provides a backward compatible interface of the kernel inside an isolated domain [24]. Unfortunately, development of a kernel-compatible device driver execution environment requires a large engineering effort. Sometimes, backward compatibility is sacrificed to simplify development, but in this case the device driver or a kernel subsystem have to be re-implemented from scratch [31]. LXDs aim to provide a general framework for automating development of custom backward compatible device driver environments. With a powerful IDL, fast communication primitives, and asynchronous threads, LXDs enable nearly transparent decomposition of kernel code.

Alternatively, the device driver environment is constructed from a partial or complete copy of the kernel that can host the isolated driver on top of a VMM [11, 30, 60] or inside a user process [11, 48]. Unfortunately, a virtualized kernel [11, 30, 60] extends the driver execution environment with a nested copy of multiple software layers, e.g., interrupt handling, thread scheduling, context-switching, memory management, etc. These layers introduce overheads of tens of thousands of cycles on the critical data-path of the isolated driver, and provide a large attack surface. A library operating system that provides full or partial compatibility with the original kernel can be used as an execution environment for the isolated device driver [48, 62, 70]. Smaller and lighter compared to the full kernel, library operating systems eliminate performance overheads of the full kernel. LXDs provide ability to run an unmodified device driver in a very minimal kernel environment hence achieving lean data path of a custom-built device driver execution environment.

3 LXDs Architecture

LXDs execute as a collection of isolated domains running side by side with the monolithic kernel (Figure 1). This design allows us to enable isolation incrementally, i.e., develop isolated device drivers one at a time, and seamlessly enable their functionality in the monolithic kernel.

Each LXD is developed as a loadable kernel module. An unmodified source of the isolated driver is linked against the two components that provide a backward compatible execution environment for the driver: 1) the glue code generated by the IDL compiler Figure 1, ⑥), and 2) a minimal library, libLXD (Figure 1, ⑦), that provides common utility functions normally available to the driver in a monolithic kernel, e.g., memory allocators, synchronization primitives, routines like memcpy(), etc.

LXDs rely on hardware-assisted virtualization (VT-x) for isolation. The choice of the hardware isolation mechanism is orthogonal to the LXDs architecture. VT-x, however, implements convenient interface for direct assignment of PCIe devices to isolated domains, and direct interrupt delivery (support for which we envision in the future). On the critical path LXDs rely on asynchronous cross-core communication primitives, and hence the cost of transitions to and from the VT-x domain (which is higher than a regular context switch) is acceptable.

LXDs are created and managed by a small microkernel that runs inside the commodity operating system kernel (Figure 1, ⑧). The LXD microkernel follows design of the L4 microkernel family [26]: it is centered around a pure capability-based synchronous IPC that explicitly controls authority of each isolated subsystem. The synchronous IPC is used for requesting microkernel resources, and exchange of capabilities, e.g., establishing regions of shared memory that are then used for fast asynchronous channels. Each LXD starts with at least one synchronous IPC channel that allows the LXD to gain more capabilities, exchange capabilities to its memory pages with the non-isolated kernel, and establish fast asynchronous communication channels.

To provide an interface of the isolated driver inside the

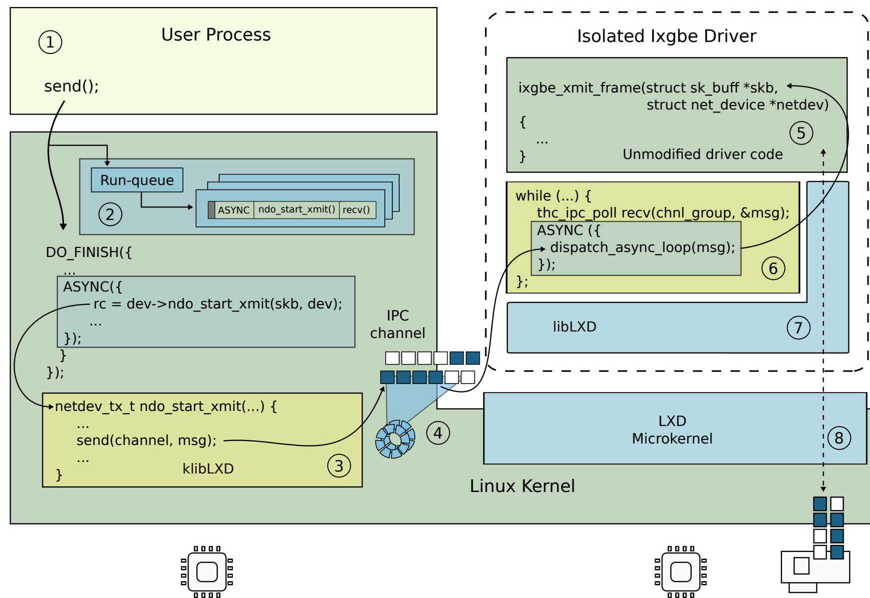

Figure 1: LXDs architecture (isolated ixgbe network driver).

monolithic kernel, every LXD loads the corresponding klibLXD module (Figure 1, ③). The klibLXD is automatically generated by the IDL compiler. The glue code inside klibLXD transparently marshals arguments of cross-domain invocations to the actual isolated driver.

In the example of the isolated ixgbe driver (Figure 1), a user process invokes an unmodified send() system call initiating transmission of the network packet through the isolated device driver (Figure 1, ①). The monolithic kernel relies on the interface of the isolated ixgbe driver (a collection of function pointers registered by the driver with the kernel) to pass the packet to the device (dev−>ndo_start_xmit()). The dev−>ndo_start_xmit() function pointer is implemented by the glue code of the klibLXD module. Internally, the glue code relies on the low-level send and receive primitives of the asynchronous communication channels to send the message to the isolated driver. The message reaches the isolated driver where it is processed by the dispatch loop generated by the IDL compiler (Figure 1, ⑥). The dispatch loop then invokes the actual ixgbe_xmit_frame() function of the unmodified ixgbe driver (Figure 1, ⑤).

Transparent decomposition LXDs rely on a collection of decomposition patterns to break the code of a monolithic system and emulate a shared-memory environment for isolated subsystems (Section 4). In LXDs, isolated subsystems do not share any state that might break isolation guarantees, e.g., memory pointers, indexes into memory buffers, etc. Instead, each isolated subsystem maintains its own private hierarchy of data structures. LXDs rely on a powerful IDL to automatically generate all inter-domain communication and synchronization code (Figure 1, ③ and ⑥). In contrast to existing IDLs used for constructing multi-server [25, 38] and distributed systems [23, 50, 61, 73] the main design goal behind the LXDs' IDL is backward compatibility with unmodified code. The IDL is designed to generate caller and callee stubs that hide details of inter-domain communication and synchronization of data structures.

Asynchronous runtime Compared to the monolithic kernel, a decomposed environment requires a cross-domain invocation in place of a regular procedure call for every function that crosses the boundary of an isolated domain. On modern hardware the overhead of such crossings is prohibitively expensive. LXDs include a minimal runtime built around lightweight asynchronous threads that aims to hide overheads of cross-domain invocations by exploiting available request parallelism. Specifically, the ASYNC() primitive creates a lightweight cooperative thread that yields execution to the next thread when blocked on the reply from an isolated domain (Figure 1, ②). Asynchronous threads allow us to introduce asynchrony to the kernel code in a transparent manner.

Cross-core IPC To reduce overheads of crossing domain boundaries, LXDs schedule isolated subsystems with tight latency and throughput requirements, i.e., network and block device drivers, on separate CPU cores. The reason is that on modern hardware cross-core communication via cache coherence is faster than a context switch on the same CPU. LXDs rely on efficient cross-core communication channels to send messages across isolated subsystems (Figure 1, ④).

3.1 Interface Definition Language

We develop a collection of *decomposition patterns*— a collection of principles and mechanisms, e.g., remote references, projections, and hidden arguments, that allow isolation of typical code patterns used in the kernel, e.g. exported functions, data structures passed by reference, registration of interfaces

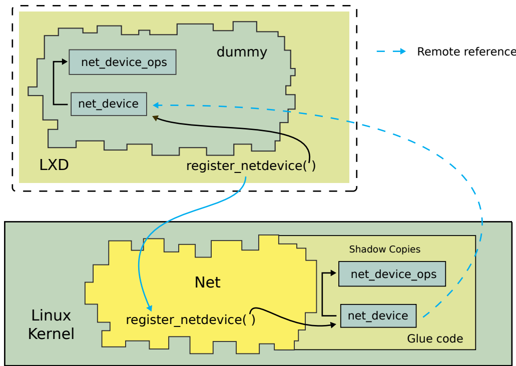

Figure 2: Private object hierarchies.

as function pointers, etc. To support implementation of decomposition patterns, we develop a powerful IDL that generates all inter-domain communication code.

Modules The IDL describes each subsystem as a *module*, i.e., a collection of functions exported and imported by an isolated driver or the kernel. To illustrate decomposition patterns and the design of the IDL, we consider an example of a minimal dummy network device driver [44]. The following IDL is used to define the dummy module.

```
include <net.idl>
module dummy() {
    require net;
}
```

By itself the dummy module does not export any functions. Instead it relies on the net interface provided by the kernel to register itself with the kernel, i.e., register a collection of function pointers that provide the driver-specific implementation of the network device interface. The kernel uses these function pointers to invoke the isolated dummy device driver.

The require keyword instructs the IDL compiler to import the net module into the context of the dummy module. At a high level, the compiler is instructed to generate glue code required for remote invocations of the functions exported by the net module.

A typical network interface defines a collection of functions that implement a specific kernel interface. For example, the net module defines the interface of the network subsystem, i.e., a collection of functions that allow network device drivers to register with the kernel.

```
module net() {
  rpc int register_netdevice(projection net_device *dev);
  rpc void ether_setup(projection net_device *dev);
  ...
}
```

From the above module definition the IDL generates code for caller stubs of the net interface so the isolated dummy module can transparently invoke functions of the interface. The IDL also generates the dispatch loops for both the dummy LXD and kLXD so both isolated subsystem and non-isolated kernel can process remote function invocations from each other.

Data structures In LXDs, isolated device drivers and the kernel do not share any state that might break isolation guarantees. Instead, each isolated subsystem maintains its own private hierarchy of data structures. In our example, the register_netdev() function takes a pointer to the net_device data structure that describes the network device. Since net_device is allocated inside the isolated dummy driver, a corresponding shadow copy will be created by the glue code in the non-isolated kernel (Figure 2).

The shadow hierarchies are synchronized upon function invocations. LXDs provide support for transparent synchronization of shadow data structure copies across domains with the mechanism of *projections*. A projection explicitly defines a subset of fields of the data structure that will be passed to the callee and returned to the caller during the domain invocation.[2]

```
projection <struct net_device> net_device {
  unsigned int flags;
  unsigned int priv_flags;
  ...
  projection net_device_ops [alloc(caller)] *netdev_ops;
}
```

Here, the projection net_device only lists the fields that will be used by the non-decomposed code in the kernel to register a network device. The projection omits the members of struct net_device that are private to the LXD, e.g., pointers to other data structures. The IDL supports lexical scopes, so the same data structure can be projected differently by different functions.

The IDL supports explicit [in] and [out] directional attributes to specify whether each field is marshalled from caller to callee or vice versa. In most cases, however, they are optional. The IDL compiler can infer the default direction from the way the projection is used in the code. In the example above, the default direction is [in]—all fields of the projection are copied from the caller to the callee side, which is decided based on the [alloc(callee)] qualifier that we discuss below.

Allocation of shadow object copies When the register_netdev() function is invoked by the LXD, the callee side of the invocation, i.e., the non-decomposed kernel, does not have a private version of the net_device data structure. The IDL provides support for controlling when remote objects are allocated, looked up, and freed with the alloc, bind, and dealloc qualifiers. The alloc qualifier instructs the IDL to allocate the new data structure of the projected type, i.e., struct net_device. The callee attribute instructs the IDL to perform the allocation on the callee side, as the data structure already exists on the caller side. The allocation attribute also serves as a hint to the compiler to marshal all fields of the projection from the already existing data

[2]Hence defining how a data structure is projected into another domain.

structure on the caller side to the callee (i.e., all fields of the projection above have the implicit [in] attribute). The data structure is deallocated when the dealloc qualifier is used with the projection.

Remote object references In most cases isolated subsystems refer to the same data structure multiple times. For example, the net_device data structure is first registered with the register_netdev() function, then used in a number of functions that attach, turn on, and eventually unregister the device. LXDs provide a mechanism of *remote references* to refer to a specific object across domain boundaries. Similar to a capability in the LXD microkernel, each remote reference is a number that is resolved through a fast hash that is private to each thread of execution. References are transparent to the code, the IDL generates all necessary code to pair every local object with a reference that is used to lookup a corresponding shadow copy in another domain.

Function pointers Many parts of the kernel rely on the concept of an interface that allows dynamic registration of a specific subsystem implementation. In a native language like C an interface is implemented as a data structure with a collection of function pointers that are defined by each subsystem that provides a concrete interface implementation. In our example, net_device_ops is a data structure that defines a collection of function pointers implemented by the network device. We implement support for export of function pointers that cross boundaries of isolated domains. The following code provides a definition of the projection for the net_device_ops data structure.

```
projection <struct net_device_ops> net_device_ops {
  rpc [alloc] int (*ndo_open)(projection netdev_empty [bind] *dev);
  rpc [alloc] int (*ndo_stop)(projection netdev_empty [bind] *dev);
  rpc [alloc] int (*ndo_start_xmit)(projection sk_buff *skb,
                        projection net_device [bind] *dev);
  ...
}
```

For every function pointer, the IDL generates caller and callee stubs that behave like normal function pointers and hide details of cross-domain communication. To implement cross-domain function pointers while providing unmodified function signatures, we implement a concept of *hidden arguments*. For each function pointer, the IDL dynamically generates an executable trampoline in the caller's address space. The caller invokes this trampoline like any other function, however, the trampoline resolves additional hidden arguments as an offset from its own address. The hidden arguments describe which channel to use and passes this information to the cross-domain stub generated by the IDL compiler. A remote reference to a function pointer on the callee side allows the caller to resolve a specific instance of a function pointer.

Implementation We implement the IDL compiler as a source-to-source translator from the LXD IDL to C. To build the compiler, we rely on the formalism of parsing expression grammars (PEG). This choice allows us to design a modular grammar that is easy to extend with new IDL primitives. We use Vembyr PEG parser generator [63] to automate development of a compiler. Vembyr provides a convenient extension interface that allows us to construct an abstract syntax tree (AST) as a set of C++ classes. We then perform a compilation step as a series of passes over the AST, e.g., module import, derivation of directional attributes, etc.. The final pass converts the AST into a concrete syntax tree (CST) that we use to print out the C code.

```
1  DO_FINISH({
2    while (skb) {
3      struct sk_buff *next = skb->next;
4      ASYNC({
5        ...
6        rc = ndo_start_xmit(skb, dev);
7        ...
8      });
9      skb = next;
10   }
11 });
```

Listing 1: Asynchronous threads.

3.2 Asynchronous Execution Runtime

Traditionally, asynchronous communication requires explicit message passing [5, 42]. Programming of asynchronous message-passing systems, however, is challenging as it requires manual management (saving and restoring) of computation as execution gets blocked on remote invocations. In general, message-based systems work well as long as they are limited to a simple run-to-completion loop, but become nearly impossible to program if multiple blocking invocations are required on the message processing path [2, 52]. Further, in a message-passing environment, re-use of existing kernel code becomes hard or even impossible.

With LXDs we aim to satisfy two contradicting goals: 1) utilize asynchrony for cross-domain invocations, and 2) provide backward compatibility with existing kernel code, i.e., avoid re-implementation of the system in a message-passing style. To meet these goals, we implement a lightweight runtime that hides details of asynchronous communication behind an interface of asynchronous threads.

The core of the LXDs asynchronous runtime is built around two primitives: ASYNC() and DO_FINISH(). In Listing 1 the ASYNC() macro creates a new lightweight thread for executing a block of code (lines 4–8) asynchronously. Our implementation is based on GCC macros as it allows us to avoid modifications to the compiler and therefore provides compatibility with the existing kernel toolchain. When ndo_start_xmit() blocks on sending a message to the isolated driver (line 6), the asynchronous runtime continues execution from the next line after the asynchronous block (line 9) and starts the next iteration of the loop creating the new asynchronous thread.

Instead of blocking on the first ndo_start_xmit() cross-domain invocation, we dispatch multiple asynchronous invocations, hence submitting multiple network packets to the driver in a pipelined manner.

Internally, ASYNC() creates a minimal thread of execution by allocating a new stack and switching to it for execution of the code inside of the asynchronous block. ASYNC() creates a continuation, i.e., it saves the point of execution that follows the asynchronous block, which allows the runtime to resume execution when the thread either blocks or finishes. We save the state of the thread, i.e., its callee saved registers, on the stack, and therefore, can represent continuation as a tuple {instruction pointer, stack pointer}. The continuation is added to the run-queue that holds all asynchronous threads that are created in the context of the current kernel thread. When asynchronous thread blocks waiting on a reply from an isolated domain, it invokes the yield() function that again saves the state of the thread by creating another continuation that is added to the run-queue. The yield() function picks the next continuation from the run-queue and switches to it.

The DO_FINISH() macro specifies the scope in which all asynchronous threads must complete. When execution reaches the end of the DO_FINISH() block, the runtime checks if any of unfinished asynchronous threads are still on the run-queue. If yes, the runtime creates a continuation for the current thread knowing that it has to finish the DO_FINISH() block later, and switches to a thread from the run-queue.

Integration with the messaging system Every time a remote invocation blocks waiting on a reply, the asynchronous runtime switches to the new thread. The runtime system checks the reply message ring for incoming messages and whether any of them can unblock one of the blocked asynchronous threads. We implement a lightweight data structure that allows us to resolve response identifiers into pointers to asynchronous threads waiting on the run-queue. If the response channel is empty, the runtime system tries to return to the main thread to dispatch more asynchronous threads, but if the main thread reached the end of the DO_FINISH() block it picks one of the existing threads from the run-queue.

Nested invocations In most cases a cross-domain invocation triggers one or more nested remote invocations back into the caller domain, be it an LXD or a non-isolated kernel. For example, the ndo_start_xmit() triggers invocation of the consume_skb() function that releases the skb after it is sent. We need to process nested invocations in the caller domain. To avoid using an extra thread to dispatch remote invocations, we process nested invocations in the context of the caller thread. We embed a dispatch loop, the optimization we call "sender's dispatch loop", inside the message receive function thc_ipc_poll_recv() in such a way that it listens and processes incoming invocations from the callee.

Implementation ASYNC() and DO_FINISH() leverage functionality of GCC macros that allow us to declare the block of code as a nested function that can be executed on a new stack. We base implementation of the threading runtime on the eager version of AC [39] (in LXDs cross-domain invocations always block, therefore, eager creation of the stack for each asynchronous thread is justified). Besides changing AC to work inside the Linux kernel and integrating it with the LXDs messaging primitives, we employ several aggressive optimizations. To minimize the number of thread switches, we introduce an idea of a "direct" continuation, the continuation that is known to follow the current context of execution, e.g., the instruction following the ASYNC() block. We also defer deallocation of stacks. Normally, the stack cannot be deallocated from the context of the thread that is using it. AC switches into the context of the "idle" scheduler thread and deallocates the stack from there. This, however, introduces an extra context switch. Instead, we maintain the queue of stacks pending de-allocation and deallocate them all at once right when the execution exits the DO_FINISH() block.

3.3 Fast Cross-Core Messaging

Trying to reduce overheads of crossing the isolation boundary, LXDs schedule isolated subsystems on separate CPU cores and use a fast cross-core communication mechanism to send "call" and "reply" invocations between the cores. The performance of cross-core invocations is dominated by the latency of cache coherence protocol, which synchronizes cache lines between cores (a single cache-line transaction incurs a latency of 100-400 cycles [22, 56, 57]). In order to achieve the lowest possible communication overhead, similar to prior projects [5,6,47], we minimize the number of cache coherence transactions. In LXDs, each channel consists of two rings: one for outgoing "call" messages and one for incoming "replies". We configure each message to be the size of a single cache line (64 bytes on our hardware). Similar to FastForward [36], we avoid shared producer and consumer pointers, as they add extra transactions for each message. Instead, we utilize an explicit state flag that signals whether the ring slot is free.

4 Decomposition Case-Studies

To evaluate the generality of LXDs abstractions, we develop several isolated device drivers in the Linux kernel.

4.1 Network Device Drivers

We develop isolated versions of two network drivers: 1) a software-only dummy network driver that emulates an infinitely fast network adapter, and 2) Intel 82599 10Gbps Ethernet driver (ixgbe). The network layer of the Linux kernel has one of the tightest performance budgets among all kernel subsystems. Further, the dummy is not connected to a real network interface, and hence allows us to stress overheads of isolation without any artificial limits of existing NICs.

Decomposed network drivers To isolate the dummy and ixgbe network drivers, we develop IDL specifications of the network driver interface. The IDL specification is 64 lines of

code for the dummy, and 153 lines for the ixgbe driver (110 lines for the network and 43 for the PCIe bus interfaces). Each network device driver registers with the kernel by invoking a kernel function and passing a collection of function pointers that implement an interface of a specific driver. Since ixgbe manages a real PCIe device, it registers with the PCIe bus driver that enumerates all PCIe devices on the bus and connects them to matching device drivers. Therefore, we develop an IDL specification for the PCI bus interface.

In contrast to block device drivers that implement a zero-copy path for block requests, the network stack copies each packet from a user process into a freshly allocated kernel buffer. To ensure a zero-copy transfer of the packet from the kernel to the LXD, we allocate a region of memory shared between the non-isolated kernel and the LXD of the network driver. The kernel allocates memory for the skb payload using the alloc_skb() function. We modify it to allocate payload data from this shared region. Linux does not provide a simple mechanism to configure one of its memory allocators to run on a specified region of memory. We, therefore, develop a lock-free allocator that uses a dedicated memory region to allocate blocks of a fixed size. To enable device access to the region of shared memory where packet payload is allocated, we extend the libLXD and the LXD microkernel with support for the IOMMU interface. We configure the IOMMU to enable access to the packet payload region that is shared between the kernel and the LXD.

The ixgbe device driver uses system timers for several control plane operations. To provide timers inside LXDs, we rely on the timer infrastructure of the non-isolated kernel. Much like any other function pointer, we register the timer callback function pointer with the kernel. The callback caller stub sends an IPC to the isolated driver to trigger the actual callback inside the LXD. Finally, in the native driver, the NAPI polling function is invoked in the context of the softirq thread. We implement softirq threads as asynchronous threads dispatched from the LXD's dispatch loop.

The isolated dummy driver requires two cross-domain calls on the packet transmission path. The first call is invoked by the non-isolated kernel to submit the packet to the driver (ndo_start_xmit()), and the second is called by the driver after the packet was processed by the device and is ready to be released (consume_skb()). To reduce overheads of isolation, we introduce the "half-crossing" optimization. Specifically, for the functions that do not return a value, e.g., consume_skb() that releases the network packet to the kernel, we send the "call" message across the isolation boundary, but do not wait for the arrival of the reply message.

4.2 Multi-Queue Block Device Drivers

We implement a decomposed version of the nullblk block driver [4]. The nullblk driver is not connected to a real NVMe device, but instead emulates the behavior of the fastest possible block device in software.

Linux multi-queue block layer Linux implements a multi-queue (MQ) block layer [7] to support low-latency, high-throughput PCIe-attached non-volatile memory (NVMe) block devices. On par with network adapters, today NVMe is one of the fastest I/O subsystems in the kernel. To fully benefit from the asynchronous multi-queue layer, user-level processes rely on the new asynchronous block I/O interface that allows applications to submit batches of I/O requests to the kernel and poll for completion later. In the case of direct device access, the kernel performs all request processing starting from the system call to leaving the request ready for the DMA in the context of the same process that issued the io_submit() system call. The kernel returns to the process right after leaving request in the DMA ring buffers. Later the process polls for completion of the request by either entering the kernel again, or by monitoring a user-mapped page where the kernel advertises completed requests. Being allocated inside a user-level page, the pointer to the request is passed to the kernel, the kernel "pins" the page ensuring that it does not get swapped out while the request is in-flight. For each request the device driver adds the page containing the request to the IOMMU of the device, hence permitting the direct access to the request payload.

Decomposed block driver Similar to network drivers, we develop IDL specifications of the block driver interface, which consists of 68 lines of IDL code. The isolated nullblk driver requires three cross-domain calls on the I/O path. The first call is invoked by the non-isolated kernel to pass a block request from the block layer to the driver. The driver itself invokes two functions of the non-isolated kernel: blk_mq_start_request() and blk_mq_end_request(). The blk_mq_start_request() function passes the pointer to the request back to the block layer to inform it that request processing has started, and the I/O is ready to be issued to the device. The block layer now associates a timer with this particular request to ensure that if the completion for that request does not arrive in time, it can either abort the I/O operation or try to enqueue the request again. The blk_mq_end_request() allows the driver to inform the block layer that the request is completed by the device, and is ready to go up the block layer back to the user process.

We utilize ASYNC() and DO_FINISH() to implement an asynchronous loop on the submission path. A batch of requests is submitted by the application, hence we dispatch them to the nullblk LXD asynchronously. We provide a detailed analysis of isolation overheads in Section 5.6.

5 Evaluation

We conduct all experiments in the openly-available CloudLab network testbed [65].[3] We utilize CloudLab d820 servers with four 2.2 GHz 8-Core E5-4620 processors and 128 GB RAM. All machines run 64-bit Ubuntu 18.04 Linux with the kernel version 4.8.4. In all experiments we disable hyper-threading,

[3]LXDs are available at https://github.com/mars-research/lxds.

Operation	Cycles (Cycles per request)
Context switch	29-41
1 non-blocking ASYNC()	46
1 blocking ASYNC()	124
4 blocking ASYNC()s	374 (93.5)

Table 1: Overhead of asynchronous threads.

Operation	Cycles
seL4 same-core d820 (without PCIDs)	1005
seL4 same-core c220g2 (with PCIDs)	834
LXDs cross-core r320 (non-NUMA)	448
LXDs cross-core d820 (NUMA)	533

Table 2: Intra-core vs cross-core IPC.

turbo boost, and frequency scaling to reduce the variance in benchmarking.

5.1 Asynchronous Runtime

LXDs rely on the asynchronous runtime to hide the overheads of cross-domain invocations. To evaluate the effectiveness of this design choice, we conduct two sets of experiments that measure and compare overheads of asynchronous threads, and synchronous invocations.

Overhead of asynchronous threads We conduct four experiments that measure overheads of the asynchronous runtime (Table 1). In all tests we run 10M iterations and report an average across five runs. The first test measures the overhead of creating and tearing down a minimal asynchronous block of code that just increments an integer, but does not block. Each iteration takes 46 cycles which includes allocating and deallocating a stack for the new thread, and two stack switches to start and end execution of the thread. In the second test we measure the overhead of switching between a pair of asynchronous threads that takes 29 cycles and uses a sequence of 20 CPU instructions. Out of 20 instructions 16 are memory accesses that touch the first level cache and take two cycles each [28] (six instructions are required to save and restore callee saved registers, and two save and restore instruction pointer and stack registers). If, however, the context switch touches additional metadata, e.g., adds the thread to the runqueue, the overhead of the context switch grows to 41 cycles due to additional memory accesses.

The third and fourth tests measure the overhead of executing one and four blocking ASYNC() code blocks, i.e., each thread executes yield() similar to the IPC path. The overhead of creating one blocking asynchronous block (third test in Table 1) is 124 cycles, which consist of the cost to create and tear down a non-blocking asynchronous thread (46 cycles) and three context switches required to block and unblock the thread, and switch back to the main thread when the DO_FINISH() block is reached. If, however, we execute four asynchronous blocks in a loop the total overhead comes to 374 cycles or 93.5 cycles per one asynchronous block. Overall, we conclude that asynchronous threads are fast, and come close to the speed of manual management of pending invocations in a message-passing system.

Batch size	Cycles (cycles per msg)	
	Manual	ASYNC()
1	533	568
4	876 (219)	1111 (277)
8	1262 (157)	2096 (262)

Table 3: Benefits of manual and ASYNC() batching.

5.2 Same-core vs cross-core IPC

Same-core IPC To understand the benefits of cache-coherent cross-core invocations over traditional same-core address-space switches, we compare LXDs' cross-core channels with the synchronous IPC mechanism implemented by the seL4 microkernel [26]. We choose seL4 as it implements the fastest synchronous IPC across several modern microkernels [55]. As d820 servers do not provide support for tagged TLBs (PCIDs) that improve IPC performance by avoiding an expensive TLB flush on the IPC path, in addition to the d820 machines we report results for the same IPC tests on an Intel E5-2660 v3 10-core Haswell 2.6GHz machine (CloudLab c220g2 server) that implements support for tagged TLBs. To defend against Meltdown attacks, seL4 provides support for a page-table-based kernel isolation mechanism similar to KPTI [37]. However, this mechanism negatively affects IPC performance due to an additional reload of the page table root pointer. Since recent Intel CPUs address Meltdown attacks in hardware, we configure seL4 without these mitigations. On d820 machines without PCIDs support, seL4 achieves the median IPC latency of 1005 cycles (Table 2). On the c220g2 servers with tagged TLBs enabled the IPC latency drops to 834 cycles (Table 2).

Cross-core IPC To measure the overhead of cross-core cache-coherent invocations, we conduct a minimal call/reply test in which a client thread repeatedly invokes a function of a server via an LXD's asynchronous communication channel. Client and server are running on two cores of the same CPU socket. Since multi-socket NUMA machines incur higher cache-coherence overheads and thus have slower cross-domain invocations, in our experiments we a NUMA and a non-NUMA machine with a similar CPU: a four socket d820 NUMA server and a single-socket non-NUMA r320 CloudLab server configured with one 2.1 GHz 8-core Xeon E5-2450 CPU. In all experiments we run 100M call/reply invocations and report an average across five runs (Table 2). On a non-NUMA r320 machine, cross-core IPC takes 448 cycles. On a NUMA d820 machine, this number increases to 533 cycles.

Two additional observations are important. First, communication between hardware threads of the same CPU core takes less time than communication between cores (we measure the overhead of cross-core invocations to be only 105 cycles on the non-NUMA r320 machine and 133 cycles on the NUMA

d820). Typically, however, a single LXD serves requests from multiple cores of the monolithic kernel, and hence only a single core can benefit from proximity to the logical core.

Second, communication outside of the NUMA node incurs high overheads due to crossing inter-socket links. On the d820 server, a cross-socket call/reply invocation takes 1988 cycles over one inter-socket hop, which is higher than overhead of a synchronous same-core IPC. Note that on a batch of 4 and 8 this number drops to 900 and 535 cycles per message respectively. We anticipate that each NUMA node will run a local LXD thread and hence the crossings of NUMA nodes will be rare (this design makes sense as high-throughput isolated subsystems, e.g., network and NVMe drivers, are CPU-bound and anyway require multiple LXD threads to keep up with invocations from multiple kernel threads).

Finally, we make an observation that compared to overheads of synchronous IPC invocations (both on the same core and cross-core) the overheads of asynchronous threads is relatively small (93.5 cycles per-request in a batch of four (Table 1)). Therefore, the use of asynchronous threads for batching and pipelining of multiple cross-domain invocations is justified.

5.3 Message Batching

To evaluate the benefits of aggregating multiple cross-core invocations in a batch, we conduct an experiment that performs call/reply invocations in batches of messages ranging from 1 to 8. On a batch of 4 messages a call/reply invocation takes only 876 cycles, or 219 cycles per invocation on a d820 NUMA machine (Table 3). On a batch of 8 messages the overhead per one call/reply invocation drops to 157 cycles per message. For a batch of messages, the cross-core IPC sends call/reply invocations through independent cache lines. The CPU starts sending the next message right after issuing loads and stores to the hardware load/store queue, but without waiting for completion of the cache-coherence requests effectively pipelining multiple outstanding cache coherence requests.

Composable batching with ASYNC() Finally, we analyze how cross-core invocations are affected if the batches of messages are created by blocking asynchronous threads instead of the manual, message-passing style batching we analyzed above. To evaluate overheads of asynchronous threads, we design an IPC test that performs a series of cross-core function invocations from inside an ASYNC() block (Table 3). We run a loop of length 1, 4, and 8. The body of the loop is an asynchronous code block that invokes a function on another core. Instead of waiting for the reply, each asynchronous thread yields and continues to the next iteration of the loop that dispatches the new asynchronous thread. For the loop of length 1, 4, and 8, compared to the manual batch, ASYNC() introduces overhead ranging from 35 cycles on a batch of one to 105 cycles per message on a batch of 8 (Table 3).

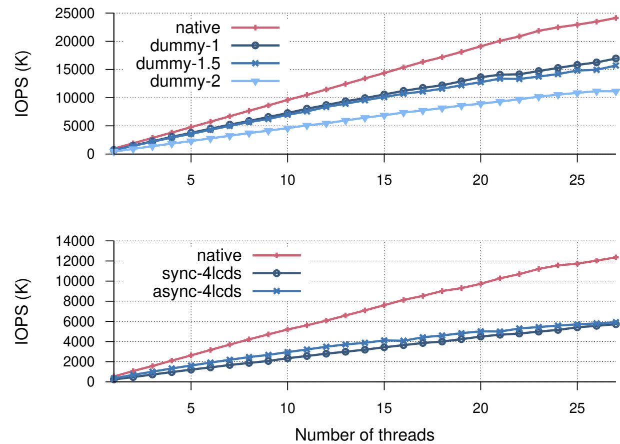

Figure 3: Performance of the dummy driver

5.4 Dummy Device Driver

We utilize the dummy driver as a platform for several benchmarks that highlight overheads of isolation in the context of a "fast" device driver (dummy is a good, representative example of such device driver as it serves an infinitely fast device and is accessed through a well-optimized I/O submission path of the kernel network stack). In all experiments we use the iperf2 benchmark that measures the transmit and receive bandwidth for different payload sizes, and run the tests on d820 servers (Figure 3). We configure the isolated dummy driver with a varying number of cores ranging from one to four in such a manner that one LXD thread runs on each socket of the 4-socket d820 system. Specifically, on a 32-core system, the isolated dummy can support up to 27 iperf threads (i.e., four cores of the system are dedicated to LXD threads, and one core is occupied by the kLXD thread servicing control plane invocations from the LXD). We assign the first six iperf threads to the first socket (one core of the CPU socket is occupied by the LXD thread and one by the kLXD thread), then we assign the next seven iperf threads (7-13) to the next socket, and so on (Figure 3). We report the total number of device driver I/O requests per-second (IOPS) across all threads (we report an average across five runs on the maximum transmission unit (MTU) size packets).

In our first experiment we change dummy to perform only *one* crossing between the kernel and the driver for sending each packet (`dummy-1`, Figure 3). This synthetic configuration allows us to analyze overheads of isolation in the ideal scenario of a device driver that requires only one crossing on the device I/O path. With one application thread the non-isolated driver achieves 956K IOPS (i.e., on average, a well-optimized network send path takes only 2299 cycles to submit an MTU-sized packet from the user process to the network interface). The isolated driver achieves 730K IOPS (76% of the non-isolated performance), and on average requires 3009 cycles to submit one packet. Of course, the isolated driver utilizes one extra core for running the LXD. Isolation adds an overhead of

710 cycles per-packet, which includes the overhead of the IPC and processing of the packet by the driver (in this experiment, LXDs do not benefit from any asynchrony; all packets are submitted synchronously). On 27 threads the isolated driver achieves 70% of the performance of the non-isolated driver. Compared to the configuration with one application thread, the slight drop in performance is due to the fact that each of four LXDs service up to seven application threads which adds overhead to the LXD's dispatch processing loop.

In practice, the dummy driver requires two domain crossings for submitting each packet (Section 4). We evaluate how performance of isolated drivers degrades with the number of crossings by running a version of dummy that performs two full cross-domain invocations (`dummy-2`, Figure 3). On one thread, two crossings add overhead of 1794 cycles per packet. The "half-crossing" optimization, however, reduces the overhead of two crossings from 1794 cycles per-packet to only 814 cycles (`dummy-1.5`, Figure 3).

Asynchronous threads To evaluate the impact of asynchronous communication, we perform the same iperf2 test with a packet size of 4096 bytes. When the packet size exceeds MTU, the kernel fragments each packet into MTU-size chunks suitable for transmission and submits each chunk to the driver individually. In general, multiple domain crossings caused by fragmentation negatively affect performance of the isolated driver. We compare three configurations: a non-isolated dummy driver (`native`, Figure 3), a synchronous version of LXDs (`sync-4-lcds`) and asynchronous version that leverages ASYNC() to invoke the driver in a parallel loop (`async-4-lcds`). Configured with one iperf thread, a non-isolated driver achieves 534K IOPS, i.e., on average it requires 4114 cycles to submit a 4096 byte packet split in three fragments. Performance of the synchronous version of the isolated driver is heavily penalized by the inability to overlap communication, i.e., waiting for LXD replies, and processing of further requests. The synchronous version achieves only 236K IOPS (44% of non-isolated performance). The asynchronous isolated driver is able to benefit from pipelining of three fragmented packets with asynchronous threads (it achieves 341K IOPS or 63.8% of non-isolated performance). Note, that as the number of application threads grows, the benefits of asynchronous threads gradually disappear. With 27 iperf threads both synchronous and asynchronous configurations achieve similar performance (36% and 37% of the native driver respectively). As the number of application threads increases, each core of the isolated driver that processes requests from up to seven iperf threads becomes heavily utilized. Each LXD thread dispatches kernel invocations in a round-robin manner from a set of cross-core communication channels. If all channels are active, the performance of each iperf thread is dominated by the time spent waiting for its turn to be processed by the LXD. On a batch of only three messages, asynchronous threads do not provide sufficient benefits to tolerate this latency.

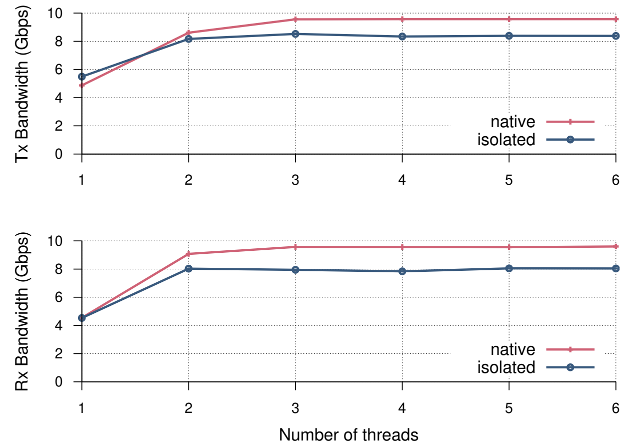

Figure 4: Ixgbe Tx and Rx bandwidth.

5.5 Ixgbe Device Driver

To measure performance of the isolated ixgbe driver, we configure an iperf2 test with a varying number of iperf threads ranging from one to six (Figure 4). On our system, a small number of application threads saturates a 10Gbps network adapter. Configured with one iperf thread, on the MTU size packet the isolated ixgbe is 12% faster compared to the isolated system on the network transmit path, although at the cost of using an extra core. This advantage disappears as the LXD becomes busy handling more than one iperf thread. Nevertheless, from three to seven threads, the isolated driver stays within 6-13% of the performance of the native device driver which saturates the network interface with three and more application threads.

On the receive path, the isolated driver is 1% slower for one application thread. Two factors attribute to performance of the isolated driver: 1) it benefits from an additional core, and 2) it uses asynchronous threads for NAPI polling instead of native threads used by the Linux kernel for handling IRQs. Asynchronous threads provide a faster context switch compared to the native Linux kernel threads. Similar to transmit path, this advantage disappears with larger number of application threads. From two to six threads the isolated driver stays within 12-18% of the performance of the native driver.

To measure the end-to-end latency, we rely on the UDP request-response test implemented by the netperf benchmarking tool. The `UDP_RR` measures the number of round-trip request-response transactions per second, i.e., the client sends a 64 byte UDP packet and waits for the response from the server. The native driver achieves 26688 transactions per second (which equals the round-trip latency of 40μs), the isolated driver is 7% (2.6μs) faster with 24975 transactions per second (round-trip latency of 37.4μs). Again the isolated driver benefits from a faster receive path due to low-overhead context switch of asynchronous threads. As the network is lightly loaded during the latency test even with six application threads the isolated driver remains 3.4μs faster achieving the latency

of 43.4μs versus 46.8μs achieved by the native driver.

5.6 Multi-Queue Block Device Driver

In our block device experiments, we use fio to generate I/O requests. To set an optimal baseline for our evaluation, we chose the configuration parameters that provide the lowest latency path to the driver, so that overheads of isolation are emphasized the most. We use fio's libaio engine to overlap I/O submissions, and bypass the page cache by setting direct I/O flag to ensure raw device performance. Similar to dummy, in isolated configuration, the nullblk LXD fully utilizes one extra core on every CPU socket. We run the same configurations as for dummy, e.g., one LXD thread on each NUMA node. We placing the first six fio threads on the first NUMA node, next seven fio threads on the second NUMA node, and so on, up until 27 fio threads. We vary the number of fio threads from 1 to 27 and report results for two block sizes—512 bytes and 1MB—which represent two extreme points: a very small and a very large data block. For each block size, we submit a set of requests at once ranging the number of requests from 1 to 16 and then poll for the same number of completions. Since the nullblk driver does not interact with an actual storage medium writes perform as fast as reads, hence we utilize read I/O operations in all experiments.

The native driver achieves 295K IOPS for the packet size of 512 bytes and the queue of one (Figure 5). In other words, a single request takes about 7457 cycles to complete. The isolated driver achieves 235K IOPS (or 79% of non-isolated performance). The isolation incurs an overhead of 1904 cycles due to three domain crossings on the critical path. For a queue of 16 requests, the isolated driver benefits from asynchronous threads which allow it to stay within 4% of the performance of the native driver for as long as it stays in one NUMA node (from 1 to 6 fio threads). Both native and isolated drivers suffer from NUMA effects due to the fact that Linux block layer collects performance statistics for every device partition. The blk_mq_end_request() function acquires a per-partition lock and updates several global counters. The native driver faces performance drops when it spills outside of a NUMA node at 9, 17, and 25 fio threads (Figure 5). The isolated driver experiences similar drops at 7, 14, and 21 fio threads. On the block size of 1M, inside one NUMA node the isolated driver stays within 10% of the performance of the native driver for both queues of one and 16 requests. Outside of one NUMA node the performance of both native and isolated drivers suffers from NUMA effects. We speculate that NUMA degradation can be fixed by changing the kernel to use per-core performance counters [10].

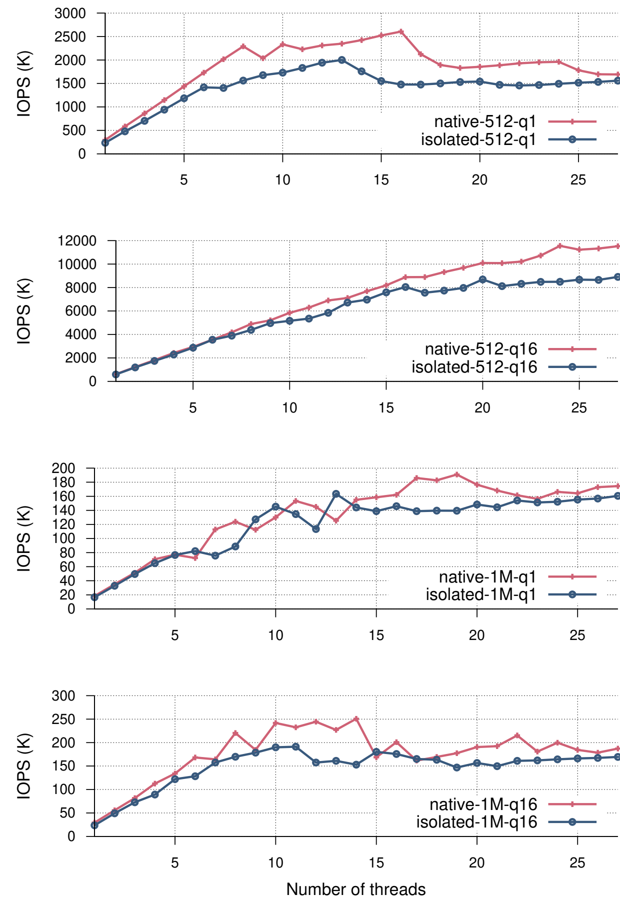

Figure 5: Performance of the nullblk driver

6 Conclusions

LXDs provide general abstractions and mechanisms for isolating device drivers in a full-featured operating system kernel. By employing several design choices—relying on an asynchronous execution runtime for hiding latency of cross-domain invocations, developing general decomposition patterns, and relying on cross-core invocations—we demonstrate the ability to isolate kernel subsystems with tightest performance budgets. We hope that our work will gradually enable kernels to employ practical isolation of most device drivers and other kernel subsystems that today account for the majority of the kernel code.

Acknowledgments

We thank ASPLOS 2018, OSDI 2018, and USENIX ATC 2019 reviewers and our shepherd, Andrew Baumann, for in-depth feedback on earlier versions of the paper and numerous insights. Also we would like to thank the Utah Emulab and CloudLab team, and especially Mike Hibler, for his continuous support and endless patience in accommodating our hardware requests. This research is supported in part by the National Science Foundation under Grant Numbers 1319076, 1527526, and 1817120 and Google.

JumpSwitches: Restoring the Performance of Indirect Branches In the Era of Spectre

Abstract

The Spectre family of security vulnerabilities show that speculative execution attacks on modern processors are practical. Spectre variant 2 attacks exploit the speculation of indirect branches, which enable processors to execute code from arbitrary locations in memory. Retpolines serve as the state-of-the-art defense, effectively disabling speculative execution for indirect branches. While retpolines succeed in protecting against Spectre, they come with a significant penalty — 20% on some workloads.

In this paper, we describe and implement an alternative mechanism: the JumpSwitch, which enables speculative execution of indirect branches on safe targets by leveraging indirect call promotion, transforming indirect calls into conditional direct calls. Unlike traditional inlining techniques which apply call promotion at compile time, JumpSwitches aggressively learn targets at runtime and leverage an optimized patching infrastructure to perform *just-in-time* promotion without the overhead of binary translation.

We designed and optimized JumpSwitches for common patterns. If a JumpSwitch cannot learn safe targets, we fall back to the safety of retpolines. JumpSwitches seamlessly integrate into Linux, and are evaluated in Linux v4.18. We show that JumpSwitches can improve performance over retpolines by up to 20% for a range of workloads. In some cases, JumpSwitches even show improvement over a system without retpolines by directing speculative execution into conditional direct calls just-in-time and reducing mispredictions.

1 Introduction

Spectre is a family of security vulnerabilities first disclosed to the public in January 2018 [38]. Spectre manipulates a processor to speculatively execute code which leaves side-effects that can be observed even after a processor decides the speculation is incorrect and reverses its execution. Spectre attacks have shown that it is practical to extract data which leaks from these observable side-effects, known as side-channels. As a result, both processor manufacturers and software developers have sought to defend against Spectre-style attacks by restricting speculative execution.

In order to execute a Spectre attack, malicious code must be able to control what the processor speculatively executes. While several vectors of attack exist, indirect branches, which enable a processor to execute code from arbitrary locations in memory have been shown to be especially vulnerable. Variant 2 of Spectre, known as "Branch Target Injection" [38], leverages indirect branches by causing the processor to mispredict the branch target and speculatively execute code designed to leave side-effects. To mitigate against this attack, a code sequence known as a *retpoline* [49] was developed, which is used in software and throughout the OS kernels today. Retpolines work by effectively disabling speculative execution of indirect branches. Instead of allowing the processor to speculate on the target of an indirect branch, retpolines force the processor to speculatively execute an infinite loop until the target is known. This is achieved by leveraging return (or `RET`) instructions, which are speculatively executed using a different mechanism than indirect branches.

While retpolines are effective in mitigating against Spectre variant 2, preventing speculative execution of indirect branches comes at a significant cost: in some benchmarks, we observe up to a 20% slowdown due to retpolines, making Spectre variant 2 one of the most expensive Spectre attacks to defend against. Unfortunately, indirect branches are used extensively in software: they are the basis for software indirection, they enable object-oriented constructs such as virtual functions and they are present throughout the OS kernels to enable their modular design. Spectre has made optimizing indirect branches in software more important than ever, since Spectre vulnerable hardware is no longer able to do so.

This paper describes our implementation of an alternative mechanism, the JumpSwitch, which leverages a technique known as indirect call promotion to transform indirect calls into conditional direct calls. Indirect call promotion is often employed by compilers [6, 9] to take advantage of profiling data, or binary translators and JIT engines to avoid expensive lookups in code caches [20]. These techniques alone, however, are insufficient for OS kernels. Mechanisms such as kernel address space layout randomization (KASLR) [45] dynamic modules and JITed code (e.g., eBPF) make it difficult to reliably determine branch targets. Compiler-based approaches such as PDO/FDO "lock" the results in a binary, requiring recompilation for best performance and preventing regressions [40] when the workload changes [54], which may be untenable as most distributions package kernels as binaries. Binary translation of the kernel incurs significant overheads

while restricting functionality, obviating the benefits of indirect call promotion [27].

Building on this observation, JumpSwitches learn execution targets either statically at compile-time or dynamically at runtime and promote indirect calls using *just-in time promotion*, learning targets using a lightweight mechanism as the kernel runs. If correct targets cannot be learned, JumpSwitches fall back to using retpolines. JumpSwitches are fully integrated with the Linux kernel's build system.[1] Through the Linux build infrastructure, we are able to seamlessly update the kernel to leverage JumpSwitches without source code changes. However, to further improve performance, we provide more advanced JumpSwitches known as *semantic JumpSwitches* which are able to take advantage of the rich semantic information available within the kernel such as process tables, and we provide five different types of JumpSwitches tailored for different use cases.

Our evaluation of JumpSwitches shows a performance improvement over retpolines in a variety of workloads by up to 20%. In some cases, we are able to even show improvement on a system without retpolines, so JumpSwitches are useful even if Spectre variant 2 is mitigated in hardware. Since JumpSwitches are implemented within the kernel, they may potentially benefit every workload running on Linux.

While conditional direct calls are vulnerable to Spectre variant 1 ("Bounds Check Bypass") [30,39,49], another Spectre vulnerability which retpolines do defend against, other less expensive mechanisms which JumpSwitches are compatible with, such as static analysis and selective masking/serialization are typically used to defend against Spectre variant 1 [12]. Notably, future "Spectre safe" hardware which do not need retpolines will still be vulnerable to Spectre variant 1 [46] and require Spectre variant 1 mitigations. JumpSwitches provide the same level of safety as this future hardware.

This paper makes the following contributions:

- We explore Spectre and the impact of current and future mitigations on the performance of indirect calls. (§2.1)
- We explore previous work for indirect call promotion and describe how JumpSwitches revisit indirect call promotion in the era of Spectre. (§2.2, §2.4).
- We describe our implementation of JumpSwitches (§3) which features:
  - Five types of JumpSwitches, which are optimized for the common case (generic JumpSwitches) and special use cases (semantic JumpSwitches) (§3.1).
  - A mechanism for learning which updates JumpSwitches outside the path of execution (§3.2).
  - A integration with the Linux kernel which leverages semantic information within the kernel (system calls, process information, `seccomp`) (§3.4).
- We evaluate JumpSwitches and show that they improve performance in real-world benchmarks by up to 20% (§4).
- We conclude with remarks about the future of speculative execution (§5).

[1] We have submitted upstream patches to the Linux kernel, with positive feedback from the Linux community.

2 Indirect Branches

Indirect branches are a basic type of processor instruction which enable programs to dynamically change what code is executed by the processor at runtime. To execute an indirect branch, the processor computes a *branch target*, which determines what instruction to execute after the indirect branch. Since targets are dynamically computed, indirect branches can execute code depending on what data is present. This indirection is most frequently used to enable polymorphism. For example, in C++, different functions may be executed depending on an object's type, or in Linux, different functions may be executed depending on whether an address is IPv4 or IPv6. To enable this functionality, a compiler will generate an indirect branch which computes the correct function as a branch target based on the object's type. Indirect branches are not limited to object-oriented code: they are used by many constructs such as callbacks and jump tables as well.

The use of indirect branches, however, poses a significant problem for modern processors which are heavily pipelined and require a constant instruction stream to achieve maximum performance. With an indirect branch, the processor cannot fetch the next instruction until the branch target is computed, resulting in pipeline stalls that significantly degrade performance. To eliminate these stalls, processors leverage *speculation*, which guesses the branch target and rolls back executed instructions if the guess is later determined to be incorrect. In many processors, speculation is done through a *branch target buffer* (BTB), which serves as a cache for previous branch targets of indirect branches.

The Spectre family of attacks observed that rolling back speculative execution can be incomplete. For example, speculative execution of privileged code could leave memory as a result of that execution in the processor's caches. Timing attacks can be used by an unprivileged process to determine what memory was fetched, resulting in a data leak. Spectre variant 2, known as "Branch Target Injection" specifically targeted indirect branches and the BTB [30,38]. In variant 2, either training the predictor to speculatively execute a malicious branch target or causing a collision in the BTB (which uses a subset of address bits for performance) resulting in an indirect branch speculatively executing code which leaves side-effects in the processor cache. This work focuses on variant 2, and when we refer to Spectre we refer to variant 2 of the attack.

In the next sections, we discuss both current and future mitigations for Spectre and how performance is affected. We then discuss software mechanisms currently used to optimize indirect branches, and present how JumpSwitches enable dynamically optimization of indirect branches while mitigating

```
1  call %rax          call  rax_retpoline

2                  rax_retpoline:
3                      call  target
4                  capture: pause
5                      lfence
6                      jmp  capture
7                  target: mov %rax, [%rsp]
8                      ret
```

Figure 1: Retpolines. Unsafe indirect branches on the left are replaced with a call (line 1) to a retpoline thunk (lines 2-8).

Spectre style attacks. For the rest of this paper, we focus on the Intel x86 architecture. We believe that JumpSwitch can be applied to other Spectre vulnerable architectures, such as AMD, ARM and IBM.

2.1 Spectre Mitigations

Mitigations for Spectre can be categorized into three general categories: software, hardware microcode and hardware.

Software mitigations. Retpolines [49] are the currently preferred method for mitigating Spectre. Retpolines, shown in Figure 1, work by directing speculative execution of indirect branches into an infinite loop. This is achieved by redirecting indirect branches to a thunk which captures the branch target on the return stack buffer (RSB) and uses a `RET` instruction instead of a `CALL`. A `RET` uses a different speculative prediction mechanism which leverages the RSB rather than the vulnerable BTB, so it does not suffer from the same vulnerability as a `CALL` instruction. Speculative execution of the return path will execute lines 4-6, labeled `capture`, which exhausts speculative execution by looping forever. The `PAUSE` instruction on line 4 is used to release processor resources to a hardware simultaneous multithread (SMT) or to save power if no execution is needed, and the `LFENCE` instruction acts as a speculation barrier [15, 36].

Retpoline safety is based on the behavior of the predictor for the `RET` instruction. On Intel architectures before Skylake, speculation for `RET` instructions were always computed from the RSB [14]. On Skylake and after however, the contents of the BTB may be used if the RSB is empty, making these architectures vulnerable even if retpolines are used [31]. To prevent an attack which causes the underflow of the RSB, a technique known as RSB stuffing can be used on these architectures on events which could cause the RSB to be emptied [51]. However, a deep call stack may still result in unpredictable overflows, leaving these architectures vulnerable even with both RSB stuffing and retpolines enabled.

Measuring precise performance overheads of retpolines is difficult because they affect deep microarchitectural state such as the RSB, and may cause future mispredictions. Empirically, retpolines have been observed to result in as much as a 20% slowdown on some workloads, increasing the cost of an indirect branch from a worst-case cost of around 10 cycles [13] (indirect branch misprediction) to almost 70 cycles in the common case. The performance penalty Spectre imposes on indirect branches makes optimizing them much more important.

Hardware microcode mitigations. As a result of Spectre, microcode updates have been introduced which add functionality to control indirect branch predictions. These mechanisms include Indirect Branch Restricted Speculation (IBRS), Single Thread Indirect Branch Predictors (STIBP) and Indirect Branch Predictor Barrier (IBPB) [14]. IBRS works by defining four privilege levels: host and guest modes with corresponding user and supervisor modes. The processor guarantees that lower privilege modes and other logical processors cannot control the predictors of more privileged modes. STIBP and IBPB are used to protect VMs and processes across context switches by preventing predictions in one thread or context from affecting another thread or context.

These microcode mechanisms can replace retpolines. Unfortunately, the performance penalty of IBRS is quite high: Since it is implemented in microcode, it likely flushes the BTB on each privilege transition and requires a model-specific register (MSR) write whenever a privilege transition occurs. IBRS has an extremely high overhead compared to retpolines (observed to be as high as 25–53%+) [17, 47, 50].

IBRS is the only mechanism which completely protects Skylake and future processors, because the BTB may be used if the RSB underflows. However, due to concerns with complexity and performance, the Linux kernel has adopted the use of retpolines on all vulnerable architectures instead, using RSB stuffing to protect the RSB [51, 53].

Hardware mitigations. Finally, Intel has proposed mitigations for Spectre in new microarchitectures which require new microprocessors to be deployed. These mitigations cannot address Spectre in the billions of already deployed processors [37]. This includes technologies such as Enhanced Indirect Branch Restricted Speculation (Enhanced IBRS) [16] and control flow enforcement technology (CET) [14]. Enhanced IBRS eliminates the overhead of IBRS by removing the requirement to write to an MSR. CET restricts the speculations which the processor can make by requiring that indirect branches target only special `ENDBR` (end-branch) instructions.

Hardware mitigations will be much more performant than software or hardware microcode mitigation today, since future processors will be able to make deep changes to the microarchitecture to account for Spectre. Practically implementing these technologies on code which must run on both secure and vulnerable hardware remains an open question, especially

in the cloud where live migration between processors remains a real possibility [36,48].

2.2 Indirect Call Promotion

The cost of indirect calls have been historically observed to be high, even before the discovery of Spectre. The most common technique used to reduce the cost of indirect calls is known as *indirect call promotion*, where likely call targets are promoted to conditional direct calls, reducing the chance that the processor will mis-speculate an indirect call using a code fragment similar to that shown in Figure 2 [6,7].

Promoting indirect calls comes at a cost, however. Each promoted call increases code size, which significantly decreases performance if infrequently used targets are promoted. Code size also limits the number of targets that can be promoted. Indirect branches which call a large number of targets with equal likelihood are poor candidates for promotion.

Compilers can determine and promote likely targets at compile-time [9,23], through the use of profile-guided optimization or feedback-directed optimization (PGO/FDO) [10, 11,26,32,41,42]. Collection of targets in the Linux kernel, which is the focus of this paper, is complicated by several factors. First, branches collected through the use of profiling may not resemble the actual execution at runtime and incorrect learned targets may even result in regressions [40], particularly if the code is executed under diverse conditions. Previous work has shown that simply executing the Linux kernel under different workloads results in different profiles [54,55]. Second, mechanisms such as KASLR [45], JITed code (e.g., eBPF programs) and dynamically loaded modules, may make it impossible to learn targets until runtime. Finally, incorporating learned branch targets requires recompilation, which may mean having different binaries for each workload or a deployment infrastructure which adapts binaries over time [10,42]. This is incompatible with how kernels are provided in most OS distributions: as binary packages.

While binary translators [18, 27, 28] and JIT compilers [25, 33, 44] are capable of collecting branch targets at runtime, binary translators result in a significant overhead as they are designed to translate and instrument the entire binary, and may need to restrict the kernel's functionality for best performance [27]. JIT compilers cannot directly run the Linux kernel, although some progress has been made to leverage LLVM to run applications as complex as Linux [3].

2.3 Alternative Solutions

After we released parts of our code [4], several solutions that employ indirect call promotion have been proposed by Linux developers. Hellwig added a fast-path to code that invokes DMA operation based on the I/O memory management unit (IOMMU) that the system uses. This solution effectively performs indirect branch promotion of each call to a single static predetermined target: the functions that are used when no IOMMU is used. As a result, the solution does not provide any benefit when an IOMMU is used [21].

A similar solution was introduced by Abeni to reduce the overhead of indirect branches in the network stack [2]. This solution is also static, requiring the developer to determine at development time what the likely targets are of each call. In addition, this solution is not suitable for calls to functions in loadable modules, whose address is unknown at compilation time. The implementation, which requires changing function calls into C macros reduces code readability. As a result this solution is limited to certain use-cases.

Finally, Poimboeuf [43] proposed a mechanism that addresses indirect calls whose target rarely changes. The proposed solution uses direct calls, and when the target changes, performs binary rewriting to change the direct call target. As this mechanism does not have a fallback path, it is only useful in certain calls. In addition, it requires the programmer to explicitly invoke binary rewriting and the use of C macros negatively affects code readability.

```
1  call %rax  |        cmp ${likely},%eax
2             |        jnz miss
3             |        call {likely}
4             |        jmp done
5             |  miss: call %eax
6             |  done:
```

Figure 2: Indirect call promotion. Indirect branches on the left are replaced with a direct branch (line 3) which is called if the prediction is correct at runtime (lines 1, 2). Otherwise, a normal indirect call is made (line 5).

2.4 JumpSwitches

JumpSwitches are designed to mitigate Spectre by taking advantage of indirect call promotion and leveraging semantic information not available by compile-time. JumpSwitches are motivated by the following observations:

- Retpolines induce ≈70 cycles of overhead which can be leveraged by software to resolve indirect branches.
- Promoting indirect branches can be combined with ensuring the safety of speculative branch execution.
- Committing to specific optimizations at compile-time can limit performance and potentially risk safety (such as assuming Spectre-safe hardware).

Threat Model. JumpSwitches assume that only indirect branches and returns are vulnerable to Spectre variant 2, as stated by Intel [14] and the original Spectre disclosure [30,38]. It is also to important to note that while retpolines can serve as a defense against Spectre variant 1 ("Bounds Check Bypass") [30,39,49], JumpSwitches do not defend against Spec-

Mechanism	Overhead	Spectre-Safe	Learning
retpolines [49]	medium	yes	none
EIBRS [48]	low	yes	none
PGO/FDO [54]	low	w/retpoline	static
DBT/JIT [27]	high	w/retpoline	dynamic
JumpSwitches	low	dynamic	dynamic+semantic

Table 1: Comparison of various indirect call mechanisms, their relative overheads and if they are Spectre-safe.

tre variant 1. We assert that replacing retpolines with JumpSwitches does not make the Linux kernel vulnerable to Spectre variant 1, as retpolines are used solely as a Spectre variant 2 defense. In Linux, static analysis and selective masking/serialization is used to defend against Spectre v1 [12], since Spectre variant 1 defenses are still necessary even in "Spectre safe hardware", where retpolines are turned off for performance. Spectre variant 1 is not expected to be fixed in future hardware [46]. We assert that JumpSwitches are as safe as future "Spectre safe" processors currently on vendor roadmaps.

Compared to indirect call promotion implemented with a compiler, JumpSwitches are able to dynamically adapt to changing workloads and take advantage of semantic information only available at runtime, much as a JIT compiler may employ polymorphic inline caching [22]. Unlike binary translation, JumpSwitches are integrated in the kernel and designed for minimal overhead to only instrument indirect calls rather than the entire binary. Furthermore, JumpSwitches are able to take advantage of the rich semantic information available in the kernel source and lost in the binary. A summary of indirect call mechanisms can be found in Table 1.

Our work is focused on the Linux kernel since it fully supports retpolines and runs privileged code which must be protected against Spectre. We believe, however, that JumpSwitches can be applied as a general mechanism and be widely deployed as retpolines are today. The goals of JumpSwitches are to:

- Predict indirect branch targets while preserving safety.
- Require minimal programmer effort: leveraging JumpSwitches should not require source code changes.
- Be flexible: allow the programmer to provide additional semantic information when available.

3 JumpSwitch Architecture

JumpSwitches are code fragments which, like retpolines, serve as trampolines for indirect calls. Their purpose is to leverage indirect call promotion and use direct calls which have a much lower cost than indirect calls, especially in the era of Spectre. JumpSwitches are Spectre aware: if a JumpSwitch cannot promote an indirect call, a Spectre mitigated indirect call is made. In Spectre-vulnerable hardware, JumpSwitches fall back to retpolines, but future hardware may easily take advantage of technologies such as Enhanced IBRS.

We have developed five different types of JumpSwitches, each optimized for a different purpose. The simplest and default type of JumpSwitch is known as an *Inline JumpSwitch*, which is optimized for code size and covers the majority of use cases. The *Outline JumpSwitch* is used when we learn that an indirect branch has multiple targets. Inline and outline JumpSwitches are known as *generic JumpSwitches* and can be used on all indirect branches. We also provide three *semantic JumpSwitches* which support commonly encountered indirect branches where deeper semantic information is available from the programmer. *Search JumpSwitches* support a large number (hundreds) of targets. The *Registration JumpSwitch* covers the commonly used registration pattern used in callback lists. Finally, the *Instance JumpSwitch* covers the case where call targets are strongly correlated with an instance, such as an object or a process. Within the Linux kernel, the *JumpSwitch worker* learns about new branch targets and makes decisions on whether a JumpSwitch should be changed to a different type, outside the path of execution. To change the active JumpSwitch, the worker makes use of a multi-stage patching mechanism which atomically updates a JumpSwitch without risking safety.

JumpSwitches are integrated into the Linux build infrastructure through the use of a compiler plugin. Thanks to our integration with the Linux build system, taking advantage of inline JumpSwitches and outline JumpSwitches requires no source code changes. We also supply additional JumpSwitches which leverage semantic information available in the kernel provided by developers, enabling the search, registration and instance JumpSwitches.

In the next sections, we first describe each type of JumpSwitch. Then, we show how the JumpSwitch worker learns and adapts JumpSwitches during runtime. Finally, we show how we patch Linux with JumpSwitches as well as optimizations we made during integration.

3.1 JumpSwitch Types

Generic JumpSwitches can be used on all indirect calls, while semantic JumpSwitches cover common use cases. We enumerate the types of JumpSwitches below:

Inline JumpSwitch. These JumpSwitches serve as generic trampolines which replace an indirect call. They act as a basic building block for other JumpSwitches and enable dynamic learning of branch targets. Because they replace code, they must be short, otherwise they risk bloating code and increasing pressure on the instruction cache. At the same time, they must be upgradable by the JumpSwitch worker at runtime and support learning. In order to fulfill these three requirements, inline JumpSwitches are designed to be safe by default and easily patched. An example of an inline JumpSwitch and the indirect call it replaces is given in Figure 3.

```
1   call %eax        cmp ${likely},%eax
2                    jnz miss
3                    call {likely rel}
4                    jmp done
5              miss: call {slow rel}
6              done:
```

Figure 3: Inline JumpSwitch. Indirect branches on the left are replaced with a sequence that may promote a *likely* call to a direct call (lines 1–4), falling back to a *slow* path if the likely target was not in **%eax**.

```
1 cmp    ${ entry0 }, %eax
2 jz     { entry0 rel }
3 cmp    ${ entry1 }, %eax
4 jz     { entry1 rel }
5        ...
6 jmp    learning rel
```

Figure 4: Outline JumpSwitch. Multiple targets are supported, using `JZ` instructions to avoid the need for a function epilogue and falling back to learning if the target is not found.

The inline JumpSwitch may point to one of two targets: *likely* or *slow*. *Likely* represents a branch target that the JumpSwitch has learned to be likely and is promoted to avoid an indirect jump. *Slow* can represent one of three targets, depending on which mode the inline JumpSwitch is in:

- Learning mode, where *slow* points to learning code which updates a table of learned targets.
- Outline mode, where *slow* points to an outline JumpSwitch leading to more targets.
- Fallback mode, where *slow* points to either a retpoline or is a normal indirect call, depending on if the system is Spectre vulnerable.

When compiled, the inline JumpSwitch is set to fallback mode and both *likely* and *slow* point to a retpoline. At runtime, the JumpSwitch worker may patch *likely* and *slow* depending on which mode is required and what targets have been learned. When an inline JumpSwitch is executed, if *likely* matches the contents of the register holding the branch target (in this case, *eax*), the call on line 3 is executed. Otherwise, the call to *slow* is executed. It is important to note that while the value of *likely* is used by the `CMP` instruction represents a direct address, the target of the `CALL`s are relative, since there are no direct absolute jumps in x86-64.

Outline JumpSwitch. To support multiple targets dynamically without increasing code size in the common case where there is only a single learned target, outline JumpSwitches may be called by inline JumpSwitches. Unlike inline JumpSwitches, outline JumpSwitches are dynamically allocated and generated by the JumpSwitch worker as targets are learned. As an optimization, since outline JumpSwitches are called by inline JumpSwitches, we avoid the normal work of setting the frame pointer and returning by using jump instructions, as shown in Figure 4. As a result, each target uses two instructions: a `CMP` and a `JZ`. If the target is not in the outline JumpSwitch, we fall back to learning code, as in the inline JumpSwitch in learning mode.

While outline JumpSwitches support multiple targets, each target adds an additional conditional branch, which induces overhead. To avoid reducing performance due to excessive or unpredictable branch targets, we limit targets in an outline JumpSwitch to 6, for a total of 7 (1 in the inline JumpSwitch and 6 in the outline). To support more targets, a search JumpSwitch can be used.

In addition to the generic indirect branches targeted by inline and outline JumpSwitches, we also target common indirect branches when semantic information is available.

Registration JumpSwitch. The registration pattern occurs when a list of callbacks is registered for later use. Registration is used in the kernel for structures such as callback lists (e.g., notifiers such as `user_return_notifier` and `mmu_notifier`), or filter lists (e.g. `seccomp`).

In such cases, since the callbacks are called from a single call-site in a loop, learning targets would fail if the callback list length is greater than the maximum number of learning JumpSwitch targets. Instead, we use a registration JumpSwitch, which unrolls callback list invocation code, sets multiple call instructions to callbacks. When a function is added or removed callbacks from a callback list the registration JumpSwitch is explicitly invoked and patches the callback addresses into the call instructions.

Instance JumpSwitch. Another common pattern that JumpSwitches target are cases where the likely branch targets are strongly correlated with a process. For example, the running process may dictate which `seccomp` filters are running, or per-process `preemption_notifier` used. Instance JumpSwitches take advantage of semantic knowledge about the running workload, and contain one of the previous three JumpSwitch types, but on a per-instance basis.

To support instance JumpSwitches, a separate executable memory area is allocated for each process. This memory area contains the instance JumpSwitches. While each area is located in a different physical memory address, the instance JumpSwitch is always mapped in a fixed virtual address. This allows us to invoke process specific JumpSwitches by direct calls, as context switches between different processes also switch instance JumpSwitches to the process-specific ones. Learning and code modifications are then done on a per-process basis.

```
1  int syscall(int nr, regs_t *regs)
2  {
3    int direct_nr = private_nr[nr];
4
5    if (direct_nr == INVALID)
6          return call_table[nr](regs);
7
8    /* Hit; 4 entries per-process */
9    if (direct_nr < 2) {
10     if (direct_nr < 1)
11       return private_call_0(regs);
12     return private_call_1(regs);
13   }
14   if (direct_nr < 3)
15     return private_call_2(regs);
16   return private_call_3(regs);
17 }
```

Figure 5: Search JumpSwitch pseudo-code, similar to the one that is used to invoke system-calls. In this example there are 4 slots for the most common targets. If there is a miss, an indirect call is initiated (line 6). Otherwise, a direct branch is performed (lines 9-16). System-call indirection table and functions (prefixed with "private") are set per instance (i.e., process). They are located at a fixed virtual address, by mapped to different physical memory on each process.

Search JumpSwitch. Some indirect branches may have potentially hundreds of targets, such as in call tables (e.g., syscall, hypercalls) and event handlers (e.g., virtualization traps) and other jump tables commonly used to execute selection control, as commonly done by C "switch" statements. These constructs typically translate a key such a handler number to a function for that key, and can be compiled to machine code that use binary decision tree or to code that use jump-tables. In practice, compilers prefer jump-tables for densely packed case items, as they usually require fewer instructions and branches [8]. However, this behavior is based on the assumption that an indirect branches are inexpensive, an assumption which has changed and should be reevaluated in the era of Spectre, particularly when retpolines are required.

In these cases, the JumpSwitch may benefit from a search tree which may reduce the number of branches needed for an indirection lookup and support many more targets. However, in the Linux kernel, we experimented with the most commonly used table, the system call table, which is used to dispatch the function that handles system calls based on a well known ("magic") number. Linux implements this table manually and does not use a switch statement. In x86 Linux, there are over 300 system calls. When retpolines are enabled, we found both static jump tables and binary decision trees to be inefficient. Our experiments with static binary decision tree showed they easily degrade performance when more than very few system calls are used. Unfortunately, outline JumpSwitches do not perform well as all the slots quickly fill up and the learning mechanism disables the outline block to prevent excessive overhead and performance degradation.

To address this situation, search JumpSwitches use an adaptive binary decision tree that caches the most frequent call translations (in the case of a system call, from system call number to handler), and the jump-table is used as a fallback. We dynamically construct a binary decision tree and keep a bitmap, where each bit corresponds to the respective translation in the jump-table. When the translation is called, the search JumpSwitch checks and updates the bitmap if learning is enabled, then dispatches the request (Figure 5). The JumpSwitch worker periodically updates the decision tree based on the learned frequency data.

3.2 Learning and the JumpSwitch Worker

To learn new targets, JumpSwitches use a learning routine, which buffers learned targets in an optimized hash table, and the worker periodically updates JumpSwitches using multi-stage patching. Different routines are used for learning on generic (inline and outline JumpSwitches) and search JumpSwitches. Registration and instance JumpSwitches do not learn asynchronously and do not require the worker.

Generic Learning Routine. To learn new branch targets, we could have used hardware mechanisms such as Precise Event-Based Sampling (PEBS) [24], which is used by many PGO and FDO frameworks. However, PEBS has several limitations, such as not being able to selectively profile branches and cannot be run in most virtual environments. To ensure that JumpSwitches are hardware agnostic, we developed a lightweight software mechanism for learning branch targets.

Our software learning routine records branch targets in a small 256-entry per-core hash table. The branch source and destination instruction pointers are XOR'd and the low 8 bits are used as a key for the table. Each entry of the table saves the instruction pointer of the source and the destination (only the low 32-bits, as the top 32-bits are fixed), as well as a counter of number of invocations. We ignore hash collisions, which can potentially cause destinations that do not match the source to be recorded and wrong invocation count, as they only lead to suboptimal decisions in the worst case and do not affect correctness. This allows us to keep the learning routine simple and short (14 assembly instructions), which is important for keeping the overhead of learning low.

After the learning routine is done, fallback code is called, which may either be a retpoline if Spectre-vulnerable hardware is present or a normal indirect call.

Search Learning Routine. For search JumpSwitches, an alternate method is used. Search JumpSwitches are tracked

per process. Each thread holds a flag that indicates whether learning needs to be done. When learning is on, each thread records which calls have been performed in a per-core frequency table. Upon context-switch the frequencies are added to a per-process frequency table that sums them up, and the per-core table is cleared. When training is over, an interprocessor interrupt (IPI) is sent to cores that still run threads of the process to sum them up into the per-process table.

JumpSwitch Worker. The worker runs once every epoch (1 second default, configurable), or when a relearning event is triggered. The worker performs learning by reading the targets that were discovered by the learning routines and updating the JumpSwitch. The worker processes generic JumpSwitches and search JumpSwitches differently:

Generic JumpSwitch Updates. During each epoch, the JumpSwitch worker checks if new call targets were encountered by reading the hash tables on each core and summing the total calls for each source-destination pair on all cores. For each source, the worker sorts each destination by the number of hits and promotes those destinations. If the destinations have already been promoted, they are ignored, and if the maximum capacity of an outline JumpSwitch is reached, the inline JumpSwitch is put into fallback mode, which disables learning for the target. As a result, a worker run can result in the following changes to a JumpSwitch:

- Update an inline JumpSwitch's *likely* target.
- Switch an inline JumpSwitch from learning to outline.
- Create or add targets to an outline JumpSwitch.
- Switch an inline JumpSwitch to fallback mode.

Once the worker is done processing data, it clears all hash tables allowing calls with hash conflicts to save their data.

Generic Learning Policy. Learning imposes some overhead and should only be performed when a performance gain will likely result. To mitigate learning overheads, the worker holds generic JumpSwitches in three lists:

- Learning JumpSwitches, which are in learning mode. They do not improve performance, but track targets.
- Stable JumpSwitches, which have a single target. These JumpSwitches do not need to be disabled for relearning, as their fallback path jumps to the learning routine.
- Unstable JumpSwitches, which have more than a single target. These include JumpSwitches with an outlined block, and those that have too many targets, and were therefore set not to have an outlined block.

During each epoch, if no JumpSwitches were updated, the JumpSwitch worker picks a number of JumpSwitches (configurable, 16 default) from the unstable list and converts them into learning JumpSwitches, disabling them and setting the fallback to jump to the learning routine. To avoid being too aggressive, the worker does not switch a JumpSwitch into learning mode more than once every 60 seconds.

Search Learning Updates. For search JumpSwitches, the worker sums up per-cpu frequency tables, but instead of updating an inline JumpSwitch, a binary-search tree is updated, promoting frequent values and clearing the bitmap.

Search Learning Policy. Learning is turned on periodically per-process. For each process, we save whether learning is on and the last time it was performed. When a thread is scheduled to run, it checks if learning is on. If so, it caches the status in thread-local memory. If it is off, a check is performed to see whether a time interval passed since learning was last on (20 seconds default). If that time has elapsed, learning is turned back on, and the process is added into a list of learning processes. Learning is stopped on the next update.

3.3 Patching and Updating

To minimize the performance impact of patching inline JumpSwitches, the worker employs a multi-phase mechanism to ensure that JumpSwitches are safely updated as multiple instructions are patched live without locks or halting execution. We leverage the Linux `text_poke` infrastructure [29], designed for live patching of code.[2] Patching is a three phase process, outlined below, and line numbers refer to inline JumpSwitch shown on the right of figure 3.

1. A breakpoint is installed on line 1 by writing the single-byte breakpoint opcode onto the first byte of the instruction. If the breakpoint is hit, the handler emulates a call to the retpoline, as if it was executed on line 5. To simplify implementation, the handler does not perform the emulation directly, but instead moves the instruction pointer to a newly created chunk that pushes onto the stack the return address (line 6) and executes `JMP` branch to the retpoline chunk.
2. The patching mechanism waits for a quiescence period, to ensure no thread runs the instructions in lines 2–5. In the Linux kernel, this is performed by calling the `synchronize_sched` function. Afterwards, the instructions on lines 2, 3 and 5 are patched. The instruction on line 4 is not changed, to allow functions that return from the `CALL` in line 3 to succeed in completing the JumpSwitch.
3. The same breakpoint mechanism in phase 1 is used, this time restoring the `CMP` on line 1 with the new promoted target, re-enabling the JumpSwitch.

When a fully-preemptable kernel is used, we also check whether the JumpSwitch code was interrupted before the target function was called and rewind the saved instruction

[2] We have submitted upstream patches to Linux to further harden the security of this mechanism [5].

pointer to line 1. This ensures the code will be executed again when the thread is re-scheduled. To efficiently determine if JumpSwitch code was interrupted, a check is only performed only if instructions we use (cmp, jnz, jz, call and jmp) are interrupted.

3.4 Linux Integration

We implement and integrate JumpSwitches on Linux v4.18 through a gcc-plugin integrated into the Linux build system. The gcc-plugin is built during the kernel build and replaces call sites with our JumpSwitch code, allowing generic JumpSwitches to be seamlessly integrated into the Linux kernel without source code changes. We write the instruction pointer and the register used for the indirect call into a new ELF section. This information is read during boot to compose a list of calls, allowing the worker to easily realize which register is used in each JumpSwitch. It also serves as a security precaution to prevent intentional or malicious memory corruption of the JumpSwitch sampling data from causing the JumpSwitch worker from patching the wrong code. The use of JumpSwitches is configurable via a Kconfig `CONFIG` option.

Semantic JumpSwitches require slight changes to kernel source. To support instance JumpSwitches for processes, we mapped a per-process page in kernel space. We implemented both search and registration JumpSwitches to be placed in per-process instance JumpSwitches. We modified `seccomp` to use a registration JumpSwitch, which accounts for the fact that filters are per process by being placed in an instance JumpSwitch. We also patch system call dispatching to use a search JumpSwitch, to account for the large system call table which is used, and place it in an instance JumpSwitch. Overall, implementing our semantic JumpSwitches in the kernel required changing about 30 SLOC.

The JumpSwitch worker is integrated into the kernel in a similar manner to other periodic tasks in Linux which patch code such as the `static-keys`, `jump-label` and `alternatives` infrastructure in Linux.

3.5 Direct Kernel Entry

During our Linux integration, we observed that JumpSwitches did not provide the full speedup we expected. Further analysis revealed that this was due to the overhead of page-table isolation (PTI), which was introduced to mitigate against Meltdown, a different speculative execution vulnerability [1, 34]. PTI introduced a new trampoline used during system calls to switch between the user and kernel page tables. This trampoline is mapped to a different virtual address on each core so the trampoline can determine the correct per-core transitional kernel stack. The trampoline is part of a per-core data structure, and since this data-structure is large, it is located "far" (more than 2GB away from the kernel [19]), preventing a direct jump. Unfortunately, the resulting indirect jump must use a retpoline [52] on Spectre vulnerable hardware, resulting in lower than expected gains when we used JumpSwitches.

To eliminate the need for this retpoline, we split the per-core data structure into two data structures: a small one which includes the transitional kernel stack, TSS and trampoline code, which are all needed to transition into the kernel during a system call; and a second larger one that includes the other fields. This allowed us to move the small part of the trampoline back into the same 2GB in which the kernel code is mapped, and use a relative jump instead of a retpoline, resulting in a significant performance gain. Our solution requires replicating the trampoline page, which consumes a minimal amount of extra physical memory ($<$ 32MB for 8192 cores).

4 Evaluation

Our evaluation is guided by the following questions:

- How does the specialization of each JumpSwitch impact the performance of the kernel in isolation? (§4.1)
- How do JumpSwitches perform with real-world applications and benchmarks? (§4.2)
- How does learning impact JumpSwitches? (§4.3)
- How many targets are needed per indirect branch? (§4.4)
- Is JumpSwitch is useful after the recent security vulnerabilities are resolved in hardware? (§4.5)

Testbed. Our testbed consists of a Dell PowerEdge R630 server with Intel E5-2670 CPUs, a Seagate ST1200 disk, which runs Ubuntu 18.04. The benchmarks are run on guests with a 2-VCPUs and 16GB of RAM. Each measurement was performed at least 5 times and the average result and standard deviation are reported. All workloads were executed with a warm-up run prior to measurement.

Configurations. We run and report the speedup relative to the baseline system which uses retpolines as a mitigation against Spectre. We report the results of:

- **base**: The baseline system with retpolines enabled.
- **direct-entry**: direct jump kernel entry trampoline.
- **+inline**: *direct-entry* with inline JumpSwitches.
- **+outline**: *+inline* with outline JumpSwitches when there are multiple targets.
- **+registration**: *+outline* with per-process (instance) registration JumpSwitches for `seccomp`
- **+search**: *+registration* with per-process (instance) search JumpSwitches for system calls.
- **unsafe**: the baseline system with retpolines disabled.

4.1 Microbenchmarks

Given the diversity of JumpSwitches we implemented, we first wanted to evaluate how each type of JumpSwitch would

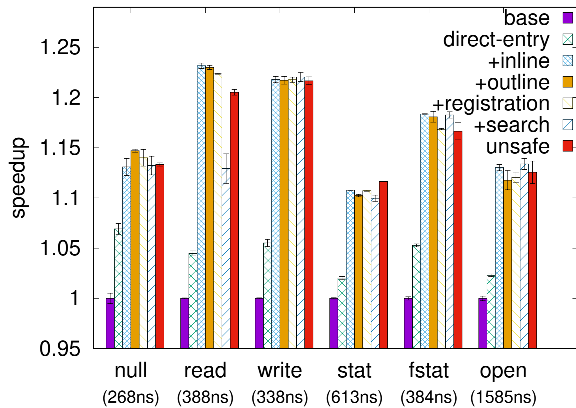

Figure 6: System call speedup relative to the baseline setup that uses retpolines. The runtime of the baseline system is reported in parentheses.

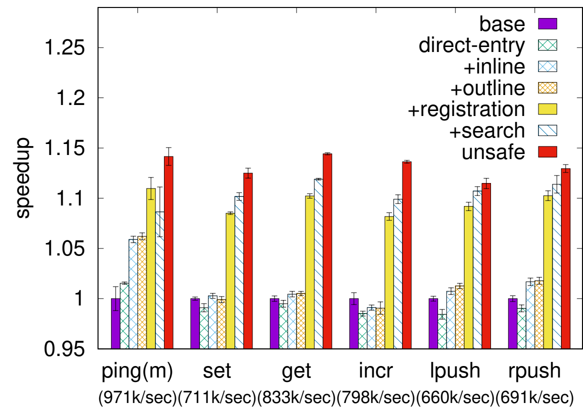

Figure 7: Relative speedup of Redis using JumpSwitch. The operations are are invoked and measured by redis-benchmark. The runtime of the baseline system is reported in parentheses.

improve the performance of the kernel in isolation. We evaluate system calls in a microbenchmark as they have shown to a particular source of slowdown as a result of both the Meltdown [1] and Spectre hardware vulnerabilities, as system calls stress user-kernel transitions, which must now be protected.

We measure the impact of JumpSwitch on the time it takes to run common system-calls using the `lmbench` tools for performance analysis [35]. Figure 6 shows the speedup relative to the baseline protected system. As shown, eliminating the indirect call in the entry trampoline provides a benefit of roughly 15ns which is more pronounced in short system calls. The inline JumpSwitch improves performance by up to 15%, making the system calls run as fast as they would without retpolines. It is noteworthy that this is due to the fact that the workload is very simple, which allows the training mechanism to inline call targets with very high precision.

This high precision is the reason that Outline JumpSwitches do not provide any benefit in this benchmark. Semantic JumpSwitches also offer little benefit here: `seccomp` filters are not installed and the same system call is called repeatedly.

To further understand the performance benefits of JumpSwitches, we some simple operations: Redis key-value store commands using redis-benchmark. Snapshotting is disabled to reduce variance. Each test runs the same command repeatedly, and the results are depicted in Figure 7. As seen, using registration JumpSwitches to avoid indirect calls when `seccomp` filters are invoked, provide up to 9%, performance improvement. This is due to the fact that `systemd`, software which acts as a system and service manager in Ubuntu, attaches 17 `seccomp` filters, which are executed upon each system call. Search JumpSwitches, whose benefit was not shown when the same system call was repeatedly executed, improve performance by up roughly 2%.

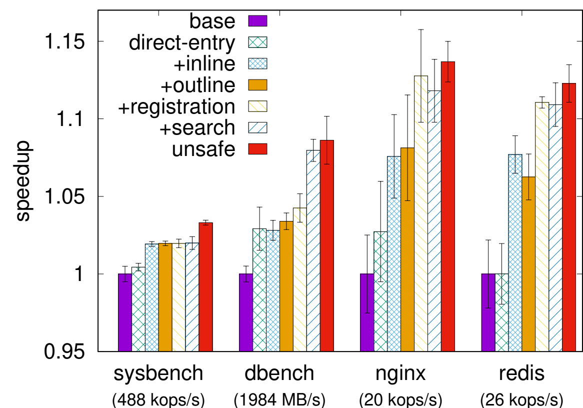

Figure 8: Relative speedup of macro-benchmarks using JumpSwitch. The baseline system is reported in parentheses.

4.2 Macrobenchmarks

Next, we want to see how JumpSwitches perform with real-world workloads which do not necessarily stress the userspace-kernel transition. We run the following benchmarks: *sysbench*, which runs a mixture of file read, write and flush operations, running on a temporary file-system (tmpfs); *dbench*, a disk benchmark that simulates file server workload, running on tmpfs; Nginx web-server, using ApacheBench workload generator to send 500k requests for a static webpage using with 10 concurrent requests at a time; and *Redis*, using Yahoo Cloud System Benchmark (YCSB) as a workload generator (running `workloadA`). In all cases we ensure the workload generator is not the bottleneck.

Figure 8 depicts the results. Eliminating the indirect branch from the entry trampoline provides a modest performance

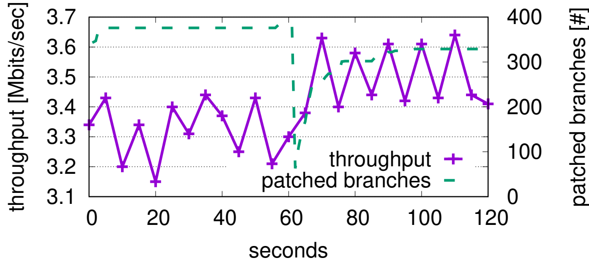

Figure 9: UDP throughput and the number of patched branches when the workload changes and learning is initiated after 60 seconds. A single inlined JumpSwitch is used.

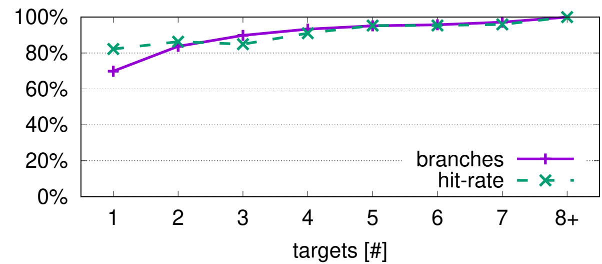

Figure 10: Hit-rate of the inlined and outlined JumpSwitch compared against a CDF of the number of targets that each indirect call-site holds while running Nginx.

improvement, which is most pronounced in dbench as it invokes many system calls. The inline JumpSwitch provides the major part of the performance gains, up to 8% improvement over the baseline system for the Redis benchmark. Like the Redis micro-benchmarks, the macro-benchmark shows a considerable gain (3%) from a registration JumpSwitch, due to the multiple (17) `seccomp` filters which are attached to it. Dbench shows a performance gain of up to 4% from the search JumpSwitch, as it repeatedly runs a small subset of system calls, which are quickly learned by the adaptive search tree. It appears that this mechanism also improves Redis performance, but due to the high standard deviation, it is hard to say so definitively. For the same reason it is hard to conclude whether the experienced performance degradation in nginx with some mechanisms is meaningful, especially since registration JumpSwitches have almost no effect on nginx, whose system calls do not go through `seccomp` filters.

Overall, the macro-benchmarks evaluation show that JumpSwitches can restore most of the performance loss due to retpolines, narrowing the difference between protected and non-protected systems to less than 3%.

4.3 Dynamic Learning

One of the main benefits of the runtime instrumentation of JumpSwitches over compile-time decisions is the ability to dynamically learn branch targets. To evaluate the value, effectiveness and performance of dynamic learning we create a scenario where the workload behavior changes. In this experiment we only enable inline JumpSwitches, emulating how compilers perform indirect branch prediction. To control learning, we disable the automatic learning mechanism and use a user-visible knob that initiates the relearning.

First, we run `iperf`—a network bandwidth measurement tool—to send and receive UDP packets using IPv6, and we set the kernel to learn and adapt the branches accordingly. Then we use iperf to measure the throughput of IPv4 UDP performance, by sending messages of a single byte. After 60 seconds, we restart the learning process.

Figure 9 shows the throughput (sampled every 5 seconds), and the number of adapted branches (sampled every second). As shown, restarting the learning process resets all the branches, dropping the number of patched branches to zero momentarily. Yet, within 5 seconds, over half of the branches that were patched prior to the benchmark execution are patched again with updated targets. The adaptation of the branches improves the overall throughput by ≈5%.

This demonstrates the value of dynamic learning over profile-based techniques, which "bake" in indirect branch promotions at compile time. Since learning is fast, it can be done periodically without degrading the overall performance of the system. Future work may apply a more advanced algorithm to do relearning, such as on a system event.

4.4 Branch Targets

The usefulness of inline and outline JumpSwitches depends on the number of branch targets and the distribution of the frequency in which they are used. To study this distribution, we used our system by modifying the number of branch target slots in each JumpSwitch and measuring the hit rate. In addition, we measured how many targets each branch has and created a cumulative distribution function to compare with the hit-rate. As shown in Figure 10, 71% of the function calls had a single target, and the inlined JumpSwitch by itself (only 1 allowed destination) achieved a hit-rate of 82%. As we increase the number of allowed destinations, the outline JumpSwitch further improves the hit-rate up to 96% when both outlined and inlined JumpSwitch are used.

This shows that inline JumpSwitches alone are able to handle a majority of cases, while outline JumpSwitches provide more complete coverage for branches with many targets. Only few branches require beyond 7 targets. In the small fraction of branches with 8 or more targets, outline JumpSwitches are disabled because the cost of the additional conditional branches outweigh the benefits of call promotion.

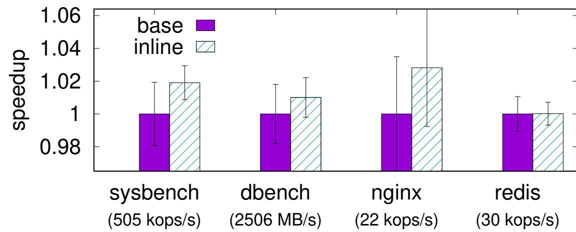

Figure 11: Benchmark speedup relative to the baseline when Spectre and Meltdown protections are disabled. The runtime of the baseline system is reported in parentheses.

4.5 Post-Spectre Benefits

Finally, we examine whether JumpSwitches are relevant when hardware solutions for Spectre and Meltdown mitigations are present, and retpolines are not longer needed. The benefit of JumpSwitches would be smaller, since the cost of an indirect branch becomes considerably lower. Some of our proposed mechanisms will become irrelevant. If Meltdown is resolved, the indirect branch in the trampoline page is not used. If Spectre is resolved, search and outline JumpSwitches become too costly relatively to the cost of an indirect branches. Registration JumpSwitches may improve performance, but our experiments indicate they require further micro-optimizations.

In contrast, inline JumpSwitches are potentially valuable even after the recent CPU bugs are fixed. Their performance benefit might be lower, making aggressive retraining of inline JumpSwitches inappropriate, yet retraining can still be done infrequently, based on user requests or in response to system events (e.g., CPU saturation). To evaluate the impact of JumpSwitches in such setups, we run the same macro-benchmarks while directing Linux to drop the protections against Meltdown (no page table isolation) and Spectre (no retpoline). We disable the automatic relearning mechanism and relearn manually when the workload is first invoked.

The results are shown in Figure 11. JumpSwitch can provide up to 2% performance improvement on systems which that are not vulnerable to Spectre and Meltdown. As shown on Redis, however, this benefit can be nullified in some cases.

5 Conclusion

The recent CPU vulnerabilities due to speculative execution revealed that the CPU cannot be regarded as a black-box that can be blindly relied on. Hardware bugs are hard to fix in existing systems, which necessitates the mitigation against the vulnerabilities using software techniques. JumpSwitch performs this task by extending compiler-optimization to make runtime decisions, while reducing the overhead of the current mitigation techniques. We have shown that JumpSwitches achieve our goal of leveraging speculative execution cycles to predict indirect branch targets while preserving safety, requiring minimal programmer effort while providing the flexibility for the programmer to add rich semantic information.

JumpSwitches show that software can efficiently perform hardware tasks such as branch prediction. Since proposed hardware mitigations against speculation will come with a cost in performance, a hardware-software solution would allow software to define in fine granularity which speculation is permitted and which needs to be blocked. JumpSwitches limit the allowed speculation using direct branches. Hardware mechanisms provide tools for software to perform this task more efficiently, for example, by providing raw interfaces to content addressable-memory. The benefit of combining both solutions is both in performance, by leveraging software knowledge, and in security, by allowing easier mitigation of potential hardware vulnerabilities.

Abstract

Modern high-speed devices (e.g., network adapters, storage, accelerators) use new host interfaces, which expose multiple software queues directly to the device. These *multi-queue* interfaces allow mutually distrusting applications to access the device without any cross-core interaction, enabling throughput in the order of millions of IOP/s on multicore systems. Unfortunately, while independent device access is scalable, it also introduces a new problem: unfairness. Mechanisms that were used to provide fairness for older devices are no longer tenable in the wake of multi-queue design, and straightforward attempts to re-introduce it would require cross-core synchronization that undermines the scalability for which multiple queues were designed.

To address these challenges, we present Multi-Queue Fair Queueing (MQFQ), the first fair, work-conserving scheduler suitable for multi-queue systems. Specifically, we (1) reformulate a classical fair queueing algorithm to accommodate multi-queue designs, and (2) describe a scalable implementation that bounds potential unfairness while minimizing synchronization overhead. Our implementation of MQFQ in Linux 4.15 demonstrates both fairness and high throughput. Evaluation with an NVMe over RDMA fabric (NVMf) device shows that MQFQ can reach up to 3.1 Million IOP/s on a single machine—20× higher than the state-of-the-art Linux Budget Fair Queueing. Compared to a system with no fairness, MQFQ reduces the slowdown caused by an antagonist from 3.78× to 1.33× for the FlashX workload and from 6.57× to 1.03× for the Aerospike workload (2× is considered "fair" slowdown).

1 Introduction

Recent years have seen the proliferation of very fast devices for I/O, networking, and computing acceleration. Commodity solid-state disks (e.g., Intel Optane DC P4800X [22] or Samsung PM1725a [38]) can perform at or near a million I/O operations per second. System-area networks (e.g., InfiniBand) can sustain several million remote operations per second over a single link [25]. RDMA delivers data across fabric within a few microseconds. GPUs and machine learning accelerators may offload computations that run just a few microseconds at a time [30]. At the same time, the proliferation of multicore processors has necessitated architectures tuned for independent I/O across multiple hardware threads [4, 36].

These technological changes have shifted performance bottlenecks from hardware resources to the software stacks that manage them. In response, it is now common to adopt a *multi-queue* architecture in which each hardware thread owns a dedicated I/O queue, directly exposed to the device, giving it an independent path over which to send and receive requests. Examples of this architecture include multi-queue SSDs [22, 38, 50] and NICs [42], and software like the Windows and Linux NVMe drivers, the Linux multi-queue block layer [5], SCSI multi-queue support [8], and data-plane OSes [4, 36]. A recent study [51] demonstrated up to 8× performance improvement for YCSB-on-Cassandra, using multi-queue NVMe instead of single-queue SATA.

To support the full bandwidth of modern devices, multi-queue I/O systems are designed to incur no cache-coherence traffic in the common case when sending and receiving requests. It's easy to see why: a device supporting millions of IOP/s sees each new request in a fraction of a microsecond—a time interval that allows for fewer than 10 cross-core cache coherence misses, and is comparable to the latency of a single inter-processor interrupt (IPI). Serializing requests at such high speeds is infeasible now, and will only become more so as device speeds continue to increase while single-core performance stays relatively flat. As a result, designers have concluded that conventional fair-share I/O schedulers, including fair queueing approaches [35, 40], which reorder requests in a single queue, are unsuited for modern fast devices.

Unfortunately, by cutting out the OS resource scheduler, direct multi-queue device access undermines the OS's traditional responsibility for fairness and performance isolation. While I/O devices (e.g., SSD firmware, NICs) may multiplex hardware queues, their support for fairness is hampered by their inability to reason in terms of system-level policies for resource principals (applications, virtual machines, or Linux

cgroups), or to manage an arbitrary number of flows. As a result, device-level scheduling tends to cycle naively among I/O queues in a round robin fashion [44]. Given such simple scheduling, a greedy application or virtual machine may gain unfair advantage by issuing I/O operations from many CPUs (so it can obtain resource shares from many queues). It may also gain advantage by "batching" its work into larger requests (so more of its work gets done in each round-robin turn). Even worse, a malicious application may launch a denial-of-service attack by submitting a large number of artificially created expensive requests (e.g., very large SSD writes) through many or all command queues.

As a separate issue, it is common for modern SSDs [9, 44] and accelerators [20, 32] to support parallel requests internally. Traditional resource scheduling algorithms, which assume underlying serial operation, are unsuitable for devices with a high degree of internal parallelism.

To overcome these problems, we present *Multi-Queue Fair Queueing (MQFQ)*—the first fair scheduler, to the best of our knowledge, capable of accommodating multi-queue devices with internal parallelism in a scalable fashion. As in classical *fair queueing* [13, 34], we ensure that each *flow* (e.g., an application, virtual machine, or Linux cgroup) receives its share of bandwidth. While classical fair queueing employs a single serializing request queue, we adapt the fair queueing principle to *multi-queue* systems, by efficiently tracking global resource utilization and arranging to *throttle* any queue that has exceeded its share by some bounded amount.

Accordingly, we introduce a *throttling threshold* T such that each core can dispatch, without coordinating with other cores, as long as the lead request in its queue is within T of the utilization of the slowest active queue, system-wide. This threshold creates a window within which request dispatches can *commute* [10], enabling scalable dispatch. We show mathematically that this relaxation has a bounded impact on fairness. When $T = 0$, the guarantees match those of classical fair queueing.

The principal obstacle to scalability in MQFQ is the need for cross-queue synchronization to track global resource utilization.We demonstrate that it is possible, by choosing appropriate data structures, to sustain millions of IOP/s while guaranteeing fairness. The key to our design is to *localize* synchronization (intra-core rather than inter-core; intra-socket rather than inter-socket) as much as possible. An instance of the *mindicator* of Liu et al. [29] allows us to track flows' shares without a global cache miss on every I/O request. A novel data structure we call the *token tree* allows us to track available internal device parallelism: an I/O completion frees up a slot that is preferentially reused by the local queue if possible; otherwise, our token tree allows fast reallocation to a nearby queue. Finally, a nonblocking variant of a timer wheel [43, 47] keeps track of queues whose head requests are too far ahead of the shares of their contributing flows: when resource utilization has advanced sufficiently, update of a single index suffices to turn the wheel and unblock the appropriate flows. MQFQ demonstrates that while scalable multi-queue I/O precludes serialization, it can tolerate infrequent, physically localized synchronization, allowing us to achieve both fairness and high performance.

Summarizing contributions:

- We present Multi-Queue Fair Queueing—to the best of our knowledge, the first scalable, fair scheduler for multi-queue devices.
- We demonstrate mathematically that adapting the fair queueing principle to multi-queue devices results in a bounded impact on fairness.
- We introduce the *token tree*, a novel data structure that tracks available dispatch slots in a multi-queue device with internal parallelism.
- We present a scalable implementation of MQFQ. Our implementation uses the token tree along with two other scalable data structures to localize synchronization as much as possible.

2 Background and Design

Fair queueing [13, 34] is a class of algorithms to schedule a network, processing, or I/O resource among competing flows. Each flow comprises a sequence of requests or packets arriving at the device. Each request has an associated cost, which reflects its resource usage (e.g., service time or bandwidth). Fair queueing then allocates resources in proportion to weights assigned to the competing flows.

A flow is said to be *active* if it has any requests in the system (either waiting to be dispatched to the device, or waiting to be completed *in* the device), and *backlogged* if it is active and has at least one outstanding request to be dispatched. Fair queueing algorithms are *work-conserving*: they schedule requests to consume surplus resources in proportion to the weights of the active flows. A flow whose requests arrive too slowly may become inactive and forfeit the unconsumed portion of its share.

Start-time Fair Queueing (SFQ) [18, 19] assigns a start and finish tag to each request when it arrives, and dispatches requests in increasing order of start tags; ties are broken arbitrarily. The tag values represent the point in the history of resource usage at which each request should start and complete according to a system notion of *virtual "time."* Virtual time always advances monotonically and is identical to real time if: (1) all flows are backlogged, (2) the device (server) completes work at a fixed ideal rate, (3) request costs are an accurate measure of service time, and (4) the weights sum to the service capacity. The start tag for a request is set to be the maximum of the virtual time at arrival and the last finish tag of the flow. The finish tag for a request is its start tag plus its cost, normalized to the weight of the flow.

When the server is busy, virtual time is defined to be equal to the start tag of the request in service, and when it is idle, maximum finish tag of any request that has been serviced by

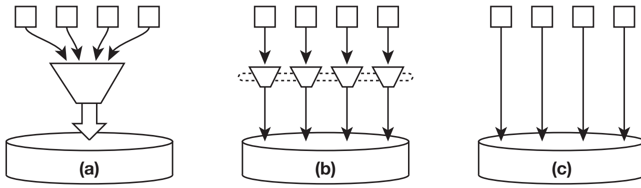

Figure 1: MQFQ (b) employs a set of per-CPU priority queues, rather than (a) a single central queue or (c) fully independent access. Queues coordinate through scalable data structures (suggested by the dotted line; described in Sec. 3) to maintain fairness.

that time. Note that this definition assumes at most a single request can be in service at any moment.

Parallel Dispatch A server with internal parallelism may service multiple requests simultaneously, so virtual time as defined in SFQ is not well-defined in this setting. Moreover, even an active flow may lag behind in resource utilization if it generates an insufficient number of concurrent requests to consume its assigned share.

SFQ(D) [23] works the same as SFQ but allows up to D in-service requests ($D = 1$ reduces to SFQ). Due to out-of-order completion, for the busy server case, virtual time is redefined to be the start tag of the last dispatched request. Note that this definition requires requests to be dispatched in increasing order of start tags, which precludes scalable implementation on multi-queue systems.

2.1 Multi-Queue Fair Queueing

The main obstacle in adapting fair queueing—or most other scheduling algorithms, for that matter—to a multi-queue I/O architecture is the need to dispatch requests in an order enforced by a central priority queue. Additional challenges include the need to dispatch multiple requests concurrently (to saturate an internally parallel device) and the inability to simply advance virtual "time" on dispatch or completion events, since these may occur out of order.

In MQFQ, we replace the traditional central priority queue (Fig. 1(a)) with a set of per-CPU priority queues (Fig. 1(b)), each of which serves to order local requests. To limit imbalance across queues, we suspend (*throttle*) any queue whose lead request is ahead of the slowest backlogged flow in the system (the one that determines the virtual time) by more than some predefined threshold T, allowing other queues to catch up. Setting $T = 0$, while limits scalability in practice, would effectively restore the semantics of a global priority queue. Setting $T > 0$ leads to relaxed semantics but lower synchronization overhead by utilizing the *Scalable Commutativity Rule* [10] to allow requests dispatches to be reordered, i.e., to commute. Specifically, it allows for windows of *conflict free* operations (i.e., no core writes a cache line that was read or written by another core) enabling scalable implementation. While short-term fluctuations of as much as T in the relative progress of flows is possible, it still preserves long-term shares. By adjusting T appropriately, we can find a design point that provides most of the fairness of traditional fair queueing with most of the performance of fully independent queues.

For an internally parallel device, in order to keep the device busy, we will often need to dispatch a new request before the previous one has finished. At the same time, since the device decides the order in which dispatched requests are served, we must generally avoid dispatching more requests than can actually be handled in parallel, thereby preserving our ability to order them. We therefore introduce a second parameter, D, which represents the maximum number of outstanding dispatched requests across all queues.

Recall that a *backlogged* flow is one that has requests ready to be dispatched, and an *active* flow is one that is either backlogged or has requests pending in the device. For any device that supports $D \geq 2$ concurrent requests, the distinction between backlogged and active is quite important: it is no longer the case that an active flow is using at least its fair share (i.e., the flow could be *non-saturating*). In a traditional fair queueing system, an active flow determines the progression of virtual time. With a parallel device, this convention would allow a non-saturating active flow to keep idle resources from being allotted to other flows, leading to underutilization. To fix this, a scheduler aware of internal parallelism needs to use backlogged (instead of active) flows to determine virtual time. We therefore define virtual time (and thus the start tag of a newly arriving request on a previously non-backlogged flow) to be the minimum start tag of all requests across all queues. In a multi-queue system, computing this global minimum without frequent cache misses is challenging. In Sec. 3.1 we show how we localize the misses using a mindicator [29].

The lack of a central priority queue, and our use of the throttling threshold T, raises the possibility not only that requests will complete out of order, but that they may be *dispatched* out of order.

We now define our notion of per-flow virtual time, in a way that accommodates the internal parallelism of the device while retaining the essential property that a *lagging* flow (i.e., a flow that is not backlogged) can never accumulate resources for future use. Recall that queues hold requests that have been submitted but not yet dispatched to the device. The flows that submitted these requests are backlogged by definition. For each such flow f, its virtual time is defined to be the start tag of f's first (oldest) backlogged (waiting to be dispatched) request. (Note that f may have backlogged requests in multiple queues.) Assuming f has multiple pending requests, dispatching this first request would increase f's virtual time by l/r, where r is f's weight (its allotted share of the device) and l is the length (size) of the request. (For certain devices we may also scale the "size" in accordance with operation type—e.g., to reflect the fact that writes are more expensive than reads on an SSD.)

We define global virtual time to be the minimum of per-flow virtual times across all backlogged flows. This is the same

as the minimum of the start tags of the lead requests across all queues, since requests in each queue are sorted by start tags. This equivalence allows us to ignore the maintenance of per-flow virtual times; instead, we directly maintain the global virtual time (hereafter, simply "virtual time") as the minimum start tag of the lead requests across all queues.

As soon as a flow becomes lagging, it stops contributing to the virtual time, which may advance irrespective of a lack of activity in the lagging flow. Request start tags from a lagging flow are still subject to the lower bound of current virtual time. MQFQ then ensures that no request is dispatched if its start tag exceeds the virtual time by more than T. To throttle a flow f that has advanced too far, it suffices to throttle any queues headed by f's requests: since requests in each queue are sorted by start tags, all other requests in such a queue are also guaranteed to be more than T ahead of virtual time.

High-level pseudocode for MQFQ appears in Fig. 2.

2.2 Fairness Analysis

If flows have equal weight, allocation of the device is fair if equal bandwidth is allocated to each (backlogged) flow in every time interval. With unequal weights, each backlogged flow should receive bandwidth proportional to its weight.

If we represent the weight of flow f as r_f and the service (in bytes) that it receives in the interval $[t_1,t_2]$ as $W_f(t_1,t_2)$, then an allocation is fair if for every time interval $[t_1,t_2]$, for every two backlogged flows f and m, we have:

$$\frac{W_f(t_1,t_2)}{r_f} - \frac{W_m(t_1,t_2)}{r_m} = 0$$

Clearly, this is possible only if the flows can be broken into infinitesimal units. For a packet- or block-based resource we want

$$\left|\frac{W_f(t_1,t_2)}{r_f} - \frac{W_m(t_1,t_2)}{r_m}\right| \leq H(f,m)$$

to be as close to 0 as possible. $H(f,m)$ is a function of the maximum request lengths, l_f^{max} and l_m^{max}, of flows f and m. Golestani [17] derives a lower bound on the fairness of any scheduler with single dispatch:

$$H(f,m) \geq \frac{1}{2}\left(\frac{l_f^{max}}{r_f} + \frac{l_m^{max}}{r_m}\right)$$

We similarly derive bounds on the fairness achieved by MQFQ. Our analysis builds on the fairness bounds for Start-time Fair Queueing (SFQ) [18] and SFQ(D) [23]. Goyal et al. [18] have previously shown in SFQ that in any interval for which flows f and m are backlogged during the entire interval, the difference of weighted services received by two flows at an SFQ server, given as:

$$\left|\frac{W_f(t_1,t_2)}{r_f} - \frac{W_m(t_1,t_2)}{r_m}\right| \leq \frac{l_f^{max}}{r_f} + \frac{l_m^{max}}{r_m}$$

is twice the lower bound. SFQ uses a single priority queue and serves one request at a time. Now consider an otherwise

```
global structures:
   VT mindicator
   wheel of throttled queues
   token tree of available slots
   set of ready queues (nonempty, unthrottled)

per-flow structures:
   end tag of last submitted request

per-CPU structures:
    local queue of not-yet-dispatched requests

on submission of request R:
   set R's start tag = MAX(VT, per-flow end tag)
   set R's end tag =
      R's start tag + R's service time
   update per-flow end tag
   insert R in local queue
   if R goes at the head
      update VT
   dispatch()

dispatch():
   if local queue is in throttling wheel
      remove it from wheel
   if local queue is in ready queues
      remove it from ready queues
   if local queue is empty
      return
   for lead request R from local queue
      if R's start tag is more than T ahead of VT
         add local queue to throttling wheel
         return
      attempt to obtain slot from token tree
      if unsuccessful
         add local queue to set of ready queues
         return
      remove R from local queue
      deliver R to device
      update VT
      if VT has advanced a bucket's worth
         turn the throttling wheel
         unblock any no-longer-throttled queues
            for which slots are readily available
         add the rest to the set of ready queues

on unblock:
   dispatch()

on request completion:
   choose nearest Q in ready queues (could be self)
   return slot to token tree w.r.t. Q
   unblock Q
```

Figure 2: High-level pseudocode for the MQFQ algorithm. Logic to mitigate races has been elided, as have certain optimizations (e.g., to avoid pairs of data structure changes that cancel one another out).

unchanged variant of SFQ in which the single priority queue is replaced by multiple priority queues with throttled dispatch. We service one request at a time, which can come from any of the queues so long as its start tag is less than or equal to the global minimum + T. We call this variant Multi-Queue Fair Queueing with single dispatch—MQFQ(1).

Theorem 1 *For any interval in which flows f and m are backlogged during the entire interval, the difference in weighted services received by two flows at an MQFQ(1) server with throttling threshold T is:*

$$\left|\frac{W_f(t_1,t_2)}{r_f} - \frac{W_m(t_1,t_2)}{r_m}\right| \leq 2T + \frac{l_f^{max}}{r_f} + \frac{l_m^{max}}{r_m}$$

We sketch a proof of Theorem 1 as follows.

Lemma 1 (Lower bound of service received by a flow): *If flow f is backlogged throughout the interval $[t_1, t_2]$, then in an MQFQ(1) server with throttling threshold T:*

$$W_f(t_1, t_2) \geq r_f \cdot (v_2 - T - v_1) - l_f^{max}$$

where v_1 is virtual time at t_1 and v_2 is virtual time at t_2.

Lemma 1 is true since at t_2 any backlogged flow has dispatched all requests whose start tag $\leq v_2 - T$. Only the last request may be outstanding at t_2—i.e., all but the last request must have completed. Since the last request's size is at most l_f^{max}, the finish tag of the last completed request must be at least $v_2 - T - l_f^{max}/r_f$. Therefore if we just count the completed requests in $[t_1, t_2]$, the minimum service received by backlogged flow f is at least $r_f \cdot (v_2 - T - v_1) - l_f^{max}$.

Lemma 2 (Upper bound of received service by a flow): *If flow f is backlogged throughout the internal $[t_1, t_2]$, then in an MQFQ(1) system with throttling threshold T:*

$$W_f(t_1, t_2) \leq r_f \cdot (v_2 + T - v_1) + l_f^{max}$$

Lemma 2 is true since at t_2 flow f may have, at most, dispatched all requests with start tag $\leq v_2 + T$. In the maximum case, the last completed request's finish tag will be no more than $v_2 + T$. In addition, one more request of size at most l_f^{max} may be outstanding and, in the maximum case, almost entirely serviced. Counting the completed requests and the outstanding request, the maximum service received by flow f is at most $r_f \cdot (v_2 + T - v_1) + l_f^{max}$.

Unfairness is maximized when one flow receives its upper bound of service while another flow receives its lower bound. Therefore, unfairness in MQFQ(1) with throttling threshold T is bounded by

$$\left| \frac{W_f(t_1, t_2)}{r_f} - \frac{W_m(t_1, t_2)}{r_m} \right| \leq 2T + \frac{l_f^{max}}{r_f} + \frac{l_m^{max}}{r_m}$$

This completes the proof of Theorem 1. ■

Note that when $T = 0$, MQFQ(1) provides the same fairness bound as SFQ. Therefore T represents a tradeoff between fairness and scalability in a multi-queue system.

If we allow $D > 1$ parallel dispatches in an MQFQ(D) server, the fairness bound changes as follows:

Theorem 2 *In any interval for which flows f and m are backlogged during the entire interval, the difference of weighted services received by the two flows at an MQFQ(D) server with throttling threshold T is given as:*

$$\left| \frac{W_f(t_1, t_2)}{r_f} - \frac{W_m(t_1, t_2)}{r_m} \right| \leq (D+1) \left(2T + \frac{l_f^{max}}{r_f} + \frac{l_m^{max}}{r_m} \right)$$

This is true based on a combination of Theorem 1 and the proved fairness bound for SFQ(D) [23]. We omit the detailed proof. When the throttling threshold $T = 0$, MQFQ(D) provides the same fairness bound as SFQ(D).

3 Scalability

MQFQ employs a separate priority queue for every CPU (hardware thread), to minimize coherence misses and maximize scalability. A certain amount of sharing and synchronization is required, however, to maintain fairness across queues. Specifically, we need to track (1) the progression of virtual time; (2) the number of available I/O slots and the queues that can use them; and (3) the state of queues (throttled or not) and when they should be unthrottled. Our guiding principle is to maximize locality wherever possible. So long as utilization and fairness goals are not violated, we prefer to dispatch from the local queue, queues on the same core, queues on the same socket, and queues on another socket, in that order.

3.1 Virtual Time

Virtual time in MQFQ reflects resource usage (e.g., bandwidth consumed), and not wall-clock time. When a flow transitions from lagging to backlogged, the request responsible for the transition is set to have its start tag equal to current virtual time. As long as the flow remains backlogged, its following requests get increasing start tags with respect to the flow's resource usage: the start tag of each new request is set to the end tag of the previous request. Virtual time, in turn, is the minimum start tag of any request across all queues.

Naively, one might imagine an array, indexed by queue, with each slot indicating the start tag of its queue's lead request (if any). We could then compute the global virtual time by scanning the array. Such a scan, however, is far too expensive to perform on a regular basis (see Sec. 4.3.1). Instead, we use an instance of Liu et al.'s *mindicator* structure [29], modified to preclude decreases in the global minimum. The mindicator is a tree-based structure reminiscent of a priority-queue heap. Each queue is assigned a leaf in the tree; each internal node indicates the minimum of its children's values. A flow whose virtual time changes updates its leaf and, if its previous value was the minimum among its siblings, propagates the update root-ward. Changes reach the root only when the global minimum changes. While this is not uncommon (time continues to advance, after all), many requests in a highly parallel device complete a little out of order, and the mindicator achieves a significant reduction in contention.

Within each flow, we must also track the largest finish tag across all threads. For this we currently employ a simple shared integer value, updated (with fetch-and-add) on each request dispatch. In future work, we plan to explore whether better performance might be obtained with a scalable monotonic counter [6, 14], at least for flows with many threads.

3.2 Available Slots

A queue in MQFQ is unable to dispatch either when it is too far ahead of virtual time or when the device is saturated. For the latter case, MQFQ must track the number of outstanding (dispatched but not yet completed) requests on the device. Ideally, we want to dispatch exactly as many requests as the

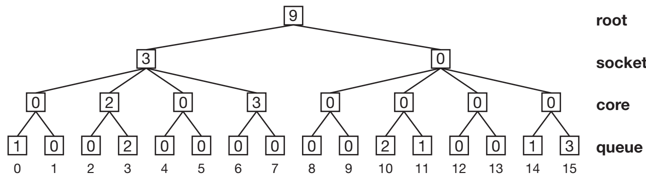

Figure 3: Example token tree for a 2-socket, 4-core-per, 2-thread-per machine. Values indicate currently unused device capacity. (If the device were fully subscribed [D outstanding requests], all values in the tree would be zero.) In the figure, there are 3 slots immediately available to queue 15. Queues 6 or 7 could use capacity allocated to their core; queues 4 or 5 could use capacity allocated to their socket; queues 8 or 9 would need to use capacity from the root.

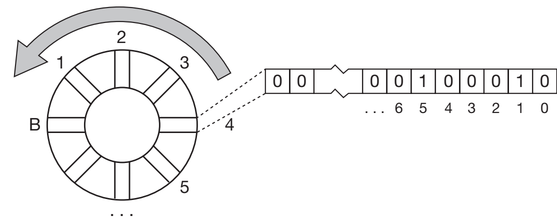

Figure 4: Timer wheel for throttled queues. If queue q is $k > T$ units ahead of global virtual time, it is placed in bucket $\min(\lceil k/b \rceil, B)$, where B is the number of buckets and b is a quantization parameter. In the figure, queues 1 and 5 are throttled in bucket 4.

device can handle in parallel, thereby avoiding any buildup in the device and preserving our ability to choose the ideal request to submit when an outstanding request completes.

We find (see Sec. 4.3.3) that a naive single shared cache line, atomically incremented and decremented upon dispatch and completion of requests, fails to scale when many queues are frequently trying to update its value. We therefore aim to improve locality by preferentially allocating available slots to physically nearby queues, in a manner reminiscent of cohort locks [15]. This approach meshes well with our notification mechanism, which prefers to unblock nearby queues.

As a compromise between locality and flexibility, we have implemented a structure we call the *token tree* (Fig. 3). Values in leaves represent unused capacity ("slots") currently allocated to a given local queue. Parent nodes represent additional capacity allocated to a given core, and so on up the tree. The values of all nodes together sum to the difference between D and the number of active requests on the device. When we need to dispatch a request, we try to acquire a slot from the leaf associated with the local queue. If the leaf is zero, we try to fetch from its parent, continuing upward until we reach the root. If nothing is available at that level, we suspend the queue. If there is unused capacity elsewhere in the tree, queues in that part of the tree will eventually be throttled. Capacity will then percolate upward, and ready queues will be awoken.

When releasing slots (in the completion interrupt handler, when the local queue is throttled or empty), we first choose a queue to awaken. We then release slots to the lowest common ancestor (LCA) of the local and the target CPUs in the token tree. Finally, we awaken the target CPU with an interprocessor interrupt (IPI). The strategy of picking nearby queues tends to keep capacity near the leaves of the token tree, minimizing contention at the higher levels, minimizing the cost of the IPI, and maximizing the likelihood that slots will be passed through a cache line in a higher level of the memory hierarchy. Experiments described in Sec. 4.3.2 confirm that IPIs significantly outperform an alternative based on polling.

3.3 Ready and Throttled Queues

The D parameter in MQFQ controls the number of outstanding requests and is a trade-off between utilization and fairness. While a larger D may better utilize the device, it can also impose looser fairness bounds and higher waiting time for incoming requests from a slower flow. Therefore, MQFQ will stop dispatching once there are D outstanding requests in the device. A queue in this case is likely to be both nonempty and unthrottled; such a queue is said to be *ready*.

As noted in Sec. 3.2, a completion handler whose local queue is empty or throttled will give away its released token. To do so, it looks for the closest queue (based on a pre-computed proximity matrix) that is flagged as ready and passes the token through the token tree.

Regardless of the number of outstanding requests, a queue will be throttled when its lead request is T ahead of global virtual time. When this happens, we need to be able to tell when virtual time has advanced enough that the queue can be unthrottled. To support this operation, we employ a simple variant of the classical timer wheel structure [43, 47] (Fig. 4). Each *bucket* of the wheel represents a b-unit interval of virtual time, and contains (as a bitmask) the set of queues that should be unthrottled at the beginning of that interval. Conceptually, we turn the wheel every b time units (in actuality, of course, we update an index that identifies bucket number 1), clear the bitmask in the old bucket 1, and unthrottle the queues that used to appear in that mask.

Given a finite number of buckets, B, a queue that needs to be throttled for longer than $B \times b$ will be placed in bucket B; this means that the wakeup handler for a queue must always double-check to make sure it doesn't have to throttle the queue again. Unlike a classical timing wheel, which contains a list of timer events in every bucket, our bitmask buckets can be manipulated with compare-and-swap, making the whole wheel trivially nonblocking.

As noted in Sec. 3.2, when slots become available in a completion handler, we choose queues from among the ready set, release the slots to the token tree, and send IPIs to the CPUs of the chosen queues. In a similar vein, if slots are available at the root of the token tree when the throttling wheel is turned, we likewise identify ready queues to which to send

IPIs. No fairness pathology arises in always choosing nearby queues: if some far-away queue lags too far behind, nearby queues will end up throttling, slots will percolate upward in the token tree, and the lagging queues will make progress.

3.4 Determining D and T in Practice

In practice, we use a hand-curated workload with varying degrees of concurrency and request sizes (with an approach similar to that of Chen et al. [9]) as a one-time setup step to discover the internal parallelism of a given multi-queue device which determines the parameter D. Any smaller value for D will not saturate the device, while larger Ds would lead to greater unfairness – specially for burstier workloads.

Unlike D which is determined solely by the degree of parallelism in the multi-queue device, the parameter T is affected by the characteristic of the workload – i.e., concurrency and request size. While a single-threaded workload can afford to have $T = 0$, a workload with small requests being submitted from multiple threads across multiple sockets require larger T value. To that end, once we have determined D, in a one-time setup step, we *over-provision* the parameter T for the worst-case workload so that the maximum throughput of the device can always be met.

4 Evaluation

We evaluate fairness and performance of MQFQ on two fast, multi-queue devices: NVMe over RDMA (NVMf, with multi-queue NICs) and multi-queue SSD (MQ-SSD). We also evaluate the scalability of each of our concurrent data structures.

In our NVMf setup, the host machine (where MQFQ runs) issues NVMe requests over RDMA to the target machine, which serves the requests directly from DRAM. We use the kernel host stack and SPDK [21] target stack. This setup can reach nearly 4 M IOP/s for 1KB requests. In our MQ-SSD setup, requests are fulfilled by a PCIe-attached Intel P3700 NVMe MQ-SSD. This setup provides nearly 0.5 M IOP/s for 4K requests.

We measured (with an approach similar to that of Chen et al. [9]) available internal parallelism to be 128 for the NVMf setup and 64 for the MQ-SSD setup. We chose T in each setup to be (roughly) the smallest value that didn't induce significant contention. We preconditioned the MQ-SSD with sequential writes to the whole address space followed by a series of random writes to reach steady state performance. We also disabled power management to ensure consistent results. We ran all experiments on a Linux 4.15 kernel in which KPTI [12] was disabled via boot parameter. For scalability experiments, thread affinities were configured to fill one hardware thread on each core of the first socket, then one on each core of the second socket before returning to populate the second hardware thread of each core. The CPU mask for fairness experiments was configured to partition the cores among competing tasks. Table 1 summarizes the experimental setup. In all of the experiments we use the length of requests in KB to advance virtual time—hence the unit for T is KB. Because the MQ-SSD setup has significantly lower bandwidth than the NVMf setup, we use it only for fairness experiments, not for scalability. The source code for our implementation is available at `http://github.com/hedayati/mqfq`.

4.1 Fairness and Efficiency

We compare MQFQ to two existing systems: (1) the recommended Linux setup for fast parallel devices, which performs no I/O scheduling (`nosched`) and is thus contention free, and (2) Budget Fair Queueing (BFQ) [46], a proportional share scheduler included for multi-queue stacks since Linux 4.12. For each of these, we consider three benchmarks: (a) the Flexible I/O Tester (FIO) [3], (b) the FlashX graph processing framework [52], and (c) the Aerospike key-value store [41].

FIO: FIO is a microbenchmark that allows flexible configuration of I/O patterns and scales quite well. We use FIO to generate workloads with known characteristics. Because FIO does so little processing per request, we also use it as an antagonist in multiprogrammed runs with FlashX and Aerospike. Each FIO workload has a name of the form αxβ (e.g., `2x4K`) where α indicates the number of threads (each on a dedicated queue) and β indicates the size of each request. For proportional sharing tests, we also indicate the weight of the flow in parentheses (e.g., `2x4K(3)`). The FIO queue depth (i.e., the number of submitted but not yet completed requests) is set to 128—large enough to maintain maximum throughput to the device.

To evaluate fairness and efficiency, we consider co-runs of FIO workloads where the internal device scheduler (if any) fails to provide fairness. We compare the slowdown of the flows relative to their time when running alone (in the absence of resource competition) as a measure of fairness as well as aggregated throughput as a measure of efficiency. We explore three cases in which competing flows differ in only one characteristic—request size, concurrency, or priority (weight). The results show that the underlying request processing, being oblivious to these characteristics, fails to provide fairness.

In Fig. 5 top-left and bottom-left, each of the flows uses an equal number of device queues. The device alternates between queues and guarantees the same number of processed requests from each. This results in flows sharing the device in proportion to request sizes rather than getting equal shares.

Fig. 5 top-middle and bottom-middle show two flows, one of which uses half the number of physical queues used by the other flow. With both flows submitting 4KB requests, the requests are processed in proportion to the number of utilized queues, causing unfairness.

Finally, Fig. 5 top-right and bottom-right show how MQFQ can be used to enforce shares in proportion to externally-specified per-flow weights (shown in parentheses).

In all of the above cases, the BFQ scheduler also guarantees fairness (as defined by flows' throughputs) but at a much higher cost compared to MQFQ.

Table 1: Experimental setup.

	MQ-SSD Setup	NVMf Setup
CPU & Mem.	Intel E5-2620 v3 (Haswell) @ 2.40GHz – 8GB	Intel E5-2630 v3 (Haswell) @ 2.40GHz – 64GB
Sockets×Cores	2×6 (24 hardware threads)	2×8 (32 hardware threads)
Target device	Intel P3700 NVMe MQ-SSD (800GB)	NVMe over RDMA Mellanox ConnectX-3 VPI Dual-Port 40Gbps
MQFQ parameters	$D = 64$, $T = 45$KB	$D = 128$, $T = 64$KB

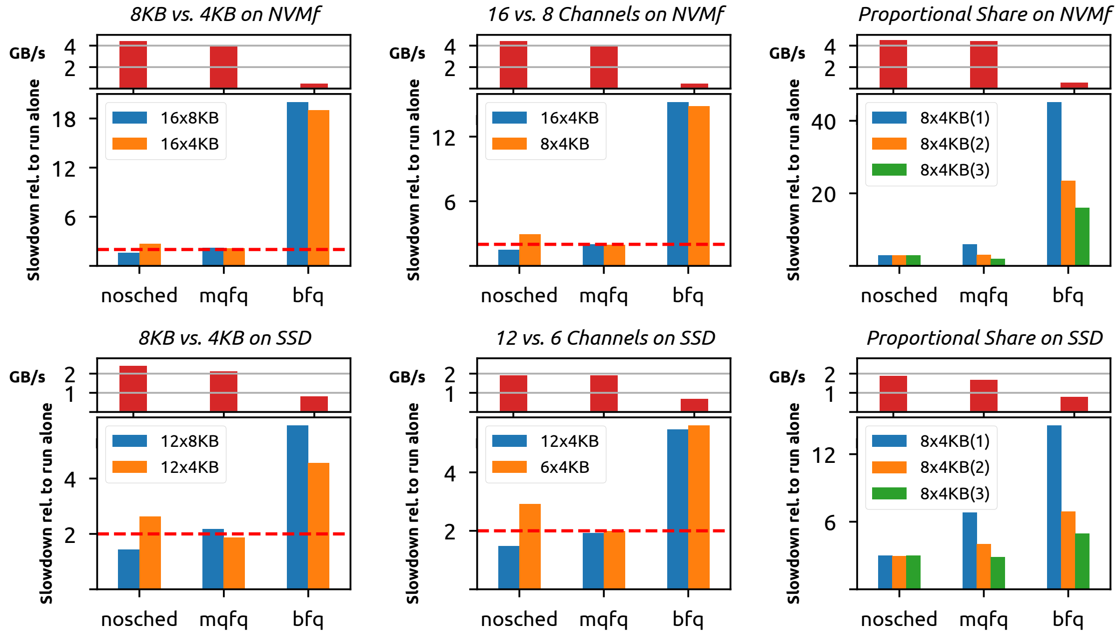

Figure 5: FIO fairness and efficiency. Round-robin (`nosched`) processing is unfair with respect to different request sizes (left), different numbers of queues (middle) and different proportional shares (right). Red dashed lines in the left and middle columns indicate proportional (ideal) slowdown. Aggregate bandwidth is shown above each graph.

FlashX: FlashX is a data analytics framework that utilizes SSDs to scale to large datasets. It can efficiently store and retrieve large graphs and matrices, and uses FlashR, an extended R programming framework, to process terabyte-scale datasets in parallel. We used FlashX to execute pagerank on the SOC-LiveJournal1 social network graph from SNAP [28]. The graph has 4.8M vertices and 68.9M edges and is stored on SSD or the NVMf target's DRAM for corresponding tests. We use FIO as an antagonist process to create contention with FlashX over the storage resource.

Fig. 6 shows the slowdown of co-runs of FlashX and FIO with different schedulers (or none—`nosched`). FlashX does not maintain a large queue depth; as a result, it can sustain only a fraction of the device's throughput. FIO, by contrast, is able to fully utilize the device given its large (I/O) parallelism. Running these together, MQFQ guarantees that FlashX gets its small share of I/O, while the rest is available to FIO, resulting in small (better than proportional) slowdowns (33% for FlashX and 14% for FIO on average between MQ-SSD and NVMf) — note that this is not unexpected since one of the flows, i.e., FlashX, is not saturating. While BFQ also reduces the slowdown for FlashX (from almost 4× to less than 2×), it slows down FIO due to its lack of support for I/O parallelism.

Aerospike: Aerospike is a flash-optimized key-value store. It uses direct I/O to a raw device in order to achieve high performance. Meta-data is kept in memory, but we configure our instance to make sure all requests will result in an I/O to the underlying device. We use the benchmark tool provided with Aerospike, running on a client machine, to drive a workload of small (512B) reads, ensuring that there will be no contention over the network for the NVMf setup. As in the FlashX experiments, we use FIO as a competitor workload.

Fig. 7 shows the slowdown of co-runs of Aerospike and FIO under BFQ, MQFQ, and `nosched`. For the NVMf setup, despite performing nearly 1 M transactions /sec., Aerospike fails to saturate the device before running out of CPUs. Therefore, as with FlashX, the co-run under MQFQ has negligible slowdown (3% for Aerospike and less than 20% for FIO). However, on the MQ-SSD setup Aerospike can fully utilize the

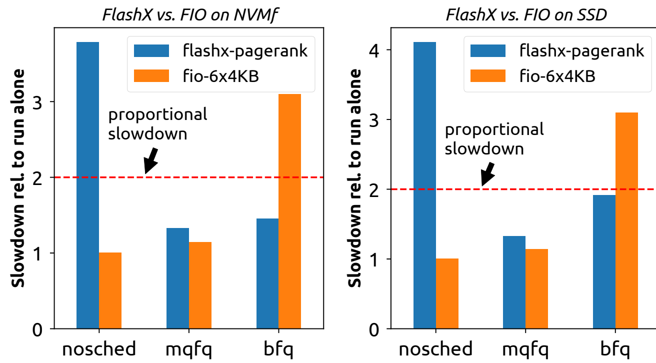

Figure 6: Fairness comparison for FlashX. MQFQ maintains fairness for FlashX, while allowing FIO to utilize the remaining bandwidth of the device.

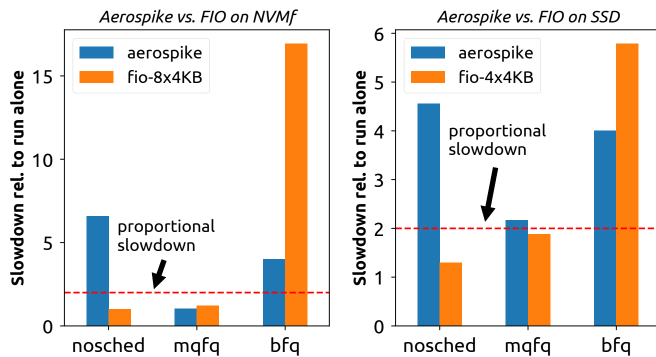

Figure 7: Fairness comparison for Aerospike. MQFQ maintains fairness (approximately at or below proportional slowdown). On the MQ-SSD (right), where Aerospike can utilize the full device, FIO is slowed down to half the available bandwidth.

device (with nearly 0.5 M transactions /sec.) and Aerospike and FIO end up getting half the available bandwidth each. BFQ's lack of support for parallel dispatch is evident on the faster NVMf device, where it results in 15× slowdown for FIO while giving only a modest improvement for Aerospike.

4.2 Scalability

We compare the scalability of MQFQ to that of an existing single-queue implementation of fair queueing—i.e., BFQ [46]. As noted in Sec. 1, Linux BFQ doesn't support concurrent dispatches and may not be able to fully utilize a device with internal parallelism. Other schedulers with support for parallel dispatch (e.g., FlashFQ [40]) have no multi-queue implementation. As a reasonable approximation of the missing strategy, we also compare MQFQ to a modified version of itself (MQFQ-serial) that serializes dispatches using a global lock. It differs from a real single-queue scheduler for a device with internal parallelism in that it maintains the requests in separate, per-CPU queues coordinated with our scalable data structures and the T and D parameters.

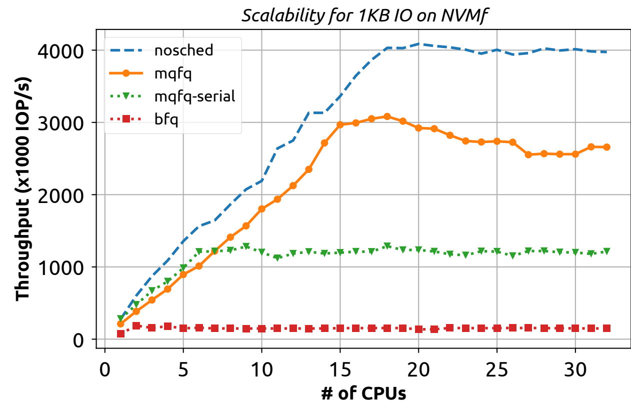

Figure 8: Overall scalability of unfair Linux multi-queue vs. MQFQ vs. MQFQ-serial vs. BFQ.

Our MQ-SSD setup at 460K IOP/s is not suitable for scalability experiments—the IOP/s limit, rather than the scheduler, becomes the scaling bottleneck. Some higher-IOP/s devices exist in the market and more will surely emerge in the future. Employing an array of SSDs can also enable over a million IOP/s. Alternatively, remote storage software solutions (e.g., ReFlex [26], NVMe over Fabric [33], FlashNet [45]) have the potential to yield more than a million IOP/s.

For this scalability evaluation, we therefore rely on the NVMf setup with 1KB requests. We chose 1KB because it yields the largest number of IOP/s (more request churn, leading to higher scheduler contention). In the `nosched` (no contention) case, this setup can reach 4 M IOP/s. We need multiple FIO threads to reach this maximum throughput.

Fig. 8 compares the throughput achieved with `nosched`, MQFQ, MQFQ-serial, and BFQ. With 15–19 active threads, MQFQ reaches more than 3 M IOP/s—2.6× better than MQFQ-serial and 20× better than BFQ. This constitutes 71% of the peak throughput of the in-memory NVMf device while providing the fairness properties needed for shared systems (as demonstrated in Sec. 4.1).

4.3 Design Decisions and Parameters

We assess the degree to which each of MQFQ's scalable data structures improves performance.

4.3.1 Virtual Time

We first evaluate the scalability of computing virtual time in MQFQ. As described in Sec. 3.1, our implementation uses a variant of the mindicator [29] to find the smallest start tag among queued requests across all queues. As in the token tree (Fig. 3), we structure the mindicator with successive levels for cores, sockets, and the full machine.

Fig. 9 shows how the mindicator scales with the number of queues. We are unaware of any existing data structure suitable as a replacement for the mindicator; we therefore implemented another lock-free alternative in which the minimum is

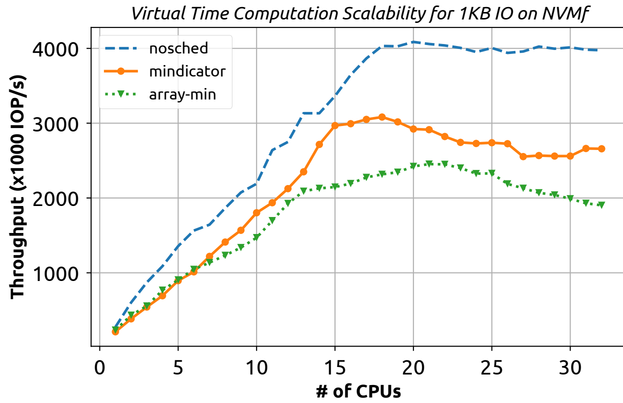

Figure 9: Throughput when maintaining virtual time with a mindicator vs. iterating over an array of queue minima.

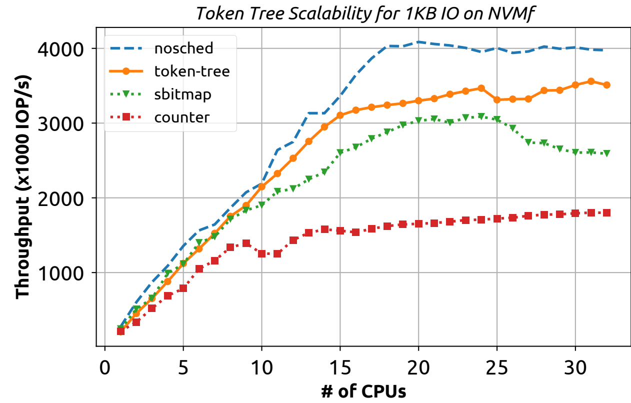

Figure 11: Scalability of token-tree vs. global counter vs. scalable bitmap in maintaining available dispatch slots.

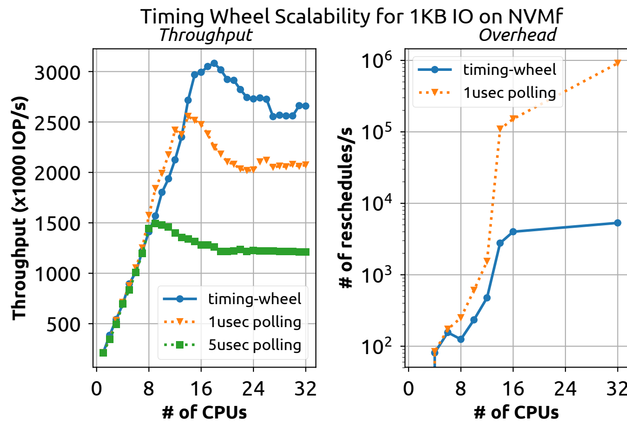

Figure 10: Scalability of unthrottling. Left: MQFQ throughput achieved using timing wheel vs. $1\mu s$ and $5\mu s$ polling. Right: polling causes spurious reschedules.

found by iterating over an array of queue-local minima after each request dispatch. (This could be thought as a one-level mindicator.) Our contention-localizing structure outperforms the array scan by nearly 40% at 32 threads.

4.3.2 Unthrottling

As discussed in Sec. 2, when a queue cannot dispatch it will be throttled. Once the situation changes (completion or progress of virtual-time) some throttled queues may need to be unthrottled. Any delay in doing so could leave the device underutilized. Our approach uses inter-processor interrupts to promptly notify appropriate CPUs that they can proceed when the unthrottling condition is met. We use a scalable timer wheel (Sec. 3.3) to support such notifications efficiently.

For comparison, arranging for each queue to poll the condition would be an easy but expensive way to implement unthrottling. We explore this option with a pinned, high resolution timer (hrtimer [11]), as it requires no communication between queues and can provide latency comparable to that of a cross-socket inter-processor interrupt. The timer is armed whenever the queue is throttled and upon firing, reschedules the dispatch routine. The effect is essentially polling for a change in virtual time, with a polling frequency determined by the value of the timer.

Fig. 10 (left) compares the throughput that MQFQ can achieve with the timing wheel vs. polling at $1\mu s$ or $5\mu s$ intervals. Results confirm that a delay in unthrottling leads to throughput degradation. Even extremely frequent ($1\mu s$) polling cannot achieve IOP/s performance comparable to that of our timer wheel approach. Less frequent polling leads to a dispatch delay that leaves the device underutilized.

In order to quantify the wasted CPU, we measure the number of reschedule operations caused by our timer wheel and by $1\mu s$ polling. The difference between the two shows how inefficient polling can be (the timer wheel incurs no spurious reschedules). Fig. 10 (right) shows the savings, in reschedules per second, achieved by using the timer wheel instead of a $1\mu s$ timer. With a few CPUs, roughly every queue is being signaled on every completion (so a carefully chosen frequency for polling that matches the rate of completion could be practical when the device is fully utilized), but the number of wasted cycles grows with the number of CPUs. With the timing wheel, on the other hand, unthrottling comes only as a result of completion, and therefore is upper-bounded by the device throughput.

4.3.3 Dispatch Slots

In order to keep a device with internal parallelism fully utilized, while also avoiding queue build-up in the device (which would adversely affect the fairness guarantee), MQFQ has to track the number of available dispatch slots. This number is modified by each queue as a result of a dispatch or a completion. Our scalable MQFQ design uses a novel token tree data structure for this purpose (presented in Sec. 3.2).

Kyber [39], a multi-queue I/O scheduler added since Linux 4.12, uses another data structure, called *sbitmap* (for Scalable

Bitmap), to throttle asynchronous I/O operations if the latency experienced by synchronous operations exceeds a threshold. The main idea in sbitmap is to distribute the tokens as bits in a number of cache lines (determined by expected contention over acquiring tokens). A thread tries to find the first clear bit in the cache line where the last successful acquire happened, falling back to iterating over all cache lines if all bits are set. This data structure reduces contention when the number of tokens is significantly larger than the number of threads. Yet another alternative to maintain a single global count of available dispatch slots using atomic increments and decrements.

Fig. 11 plots 1KB MQFQ IOP/s as a function of thread count using an atomic counter, a scalable bitmap, and a token tree to track the number of dispatched requests. To isolate the impact of these data structures, we disable virtual time computation in MQFQ. Using an atomic counter doesn't scale beyond the first socket. The scalable bitmap falls short when the number of waiting requests is significantly larger than device parallelism, resulting in local acquire and release of tokens. In comparison, the token tree paired with our throttling mechanism prefers interaction with local queues (based on a pre-computed proximity matrix) as long as they are no more than T ahead of virtual time, resulting in significantly better scalability (more than $2\times$ the throughput of the atomic counter and 36% more than the scalable bitmap).

5 Related Work

Fairness-oriented resource scheduling has been extensively studied in the past. Lottery scheduling [49] achieves probabilistic proportional-share resource allocation. Fairness can also be realized through per-task timeslices as in Linux CFQ [2] and BFQ [46], Argon [48], and FIOS [35]. Timeslice schedulers, however, are generally not *work-conserving*: they will sometimes leave the device unused when there are requests available in the system. The original fair queueing approaches, including Weighted Fair Queueing (WFQ) [13], Packet-by-Packet Generalized Processor Sharing (PGPS) [34], and Start-time Fair Queueing (SFQ) [18], employ virtual-time–controlled request ordering across per-flow request queues to maintain fairness.

Fair queueing approaches like SFQ(D) [23] and FlashFQ [40] have been tailored to manage I/O resources, allowing requests to be re-ordered and dispatched concurrently for better I/O efficiency in devices with internal parallelism. To maintain fairness in a multi-resource (e.g., CPU, memory and NIC) environment, DRFQ [16] adapted fair queueing by tracking usage of the respective dominant resource of each operation. Disengaged fair queueing [30] emulates the effect of fair queueing on GPUs while requiring only infrequent OS kernel involvement. It accomplishes its goal by monitoring and mitigating potential unfairness through occasional traps. All previous fair queueing schedulers assume a serializing scheduler over a single device queue, which does not scale well on modern multicores with fast multi-queue devices.

For multi-queue SSDs, Ahn et al. [1] supported I/O resource sharing by implementing a bandwidth throttler at the Linux cgroup layer (above the multi-queue device I/O paths). However, their time interval budget-based resource control is not work conserving: if one cgroup does not use its allotted resources in an interval, those resources are simply wasted. Lee et al. [27] improved read performance by isolating queues of multi-queue SSDs used for reads from those used for writes. Kyber [39] achieves better synchronous I/O latency by throttling asynchronous requests. However, neither approach is a full solution for fair I/O resource management. Stephens et al. [42] found that the internal round-robin scheduling of hardware queues in NICs leads to unfairness when the load is asymmetrically distributed across a NIC's multiple hardware queues. Their solution, Titan, requires programmable NICs to internally implement deficit round-robin and service queues in proportion to configured weights. FLIN [44] identifies major sources of interference in multi-queue SSDs and implements a scheduler in SSD controller firmware to protect against them. Unlike MQFQ, which is applicable to accelerators and multi-queue NICs, FLIN deals with the idiosyncrasies of Flash devices such as garbage collection and access patterns. In addition, FLIN considers any request originating from the same host-side I/O queue as belonging to the same "flow" and, being implemented in hardware, is unable to reason in terms of system-level resource principals (applications, virtual machines, or Linux cgroups).

For performance isolation and quality-of-service, ReFlex [26] employs a per-tenant token bucket mechanism to achieve latency objectives in a shared-storage environment. The token bucket mechanism and fair queueing resource allocation are complementary—the former performs admission control under a given resource allocation while the latter supports fair, work-conserving resource uses. Decibel [31] presents a system framework for resource isolation in rack-scale storage but it does not directly address the problem of resource scheduling. It uses two existing scheduling policies in its implementation—strict time sharing is not work-conserving; deficit round robin is work-conserving but requires a serializing scheduler queue that limits scalability.

Among multicore operating systems, Arrakis [36] and IX [4] support high-speed I/O by separating the control plane (managed by the OS) and the data plane (bypassing the OS) to achieve coherency-free execution. Their OS control planes enforce access control but not resource isolation or fair resource allocation. Zygos [37] suggests that sweeping simplification introduced by shared-nothing architectures like IX [4] leads to (1) not being work-conserving and (2) suffering from head-of-the-line blocking. They propose a work-stealing packet processing scheme that, while introducing cross-core interactions, eliminates head-of-the-line blocking and improves latency. Recent work has also built scalable data structures that localize synchronization in the multicore memory hierarchy (intra-core rather than inter-core; intra-socket rather

than inter-socket). Examples include the mindicator global minimum data structure [29], atomic broadcast trees [24], and NUMA-aware locks [15] and data structures [7]. For MQFQ, we introduce new scalable structures, including a timer wheel to track virtual time indexes and a token tree to track available device dispatch slots.

6 Conclusion

With the advent of fast devices that can complete a request every microsecond or less, it has become increasingly difficult for the operating system to fulfill its responsibility for fair resource allocation—enough so that some OS implementations have given up on fairness altogether for such devices. Our work demonstrates that surrender is not necessary: with judicious use of scalable data structures and a reformulation of the analytical bounds, we can maintain fairness in the long term and bound it in the short term, all without compromising throughput.

Our formalization of multi-queue fair queueing introduces a parameter, T, that bounds the amount of service that a flow can receive in excess of its share. Crucially, this bound does not grow with time. Moreover, our new definition of virtual time is provably equivalent to existing definitions when T is set to zero. Experiments with a modified Linux 4.15 kernel, a two-socket server, and a fast NVMe over RDMA device confirm that MQFQ can provide both fairness and very high throughput. Compared to running without a fairness algorithm on an NVMf device, our MQFQ algorithm reduces the slowdown caused by an antagonist from 3.78× to 1.33× for the FlashX workload and from 6.57× to 1.03× for the Aerospike workload. Its peak throughput reaches 3.1 Million IOP/s on a single machine, outperforming a serialized version of our own algorithm by 2.6× and Linux BFQ by 20×.

In future work, we plan to develop strategies for automatic tuning of the T and D parameters; extend our implementation to handle small computational kernels for GPUs and accelerators; and evaluate the extent to which fairness guarantees can continue to apply even to kernel-bypass systems, with dispatch queues in user space.

BRAVO – Biased Locking for Reader-Writer Locks

Dave Dice

alex.kogan@oracle.com

Abstract

Designers of modern reader-writer locks confront a difficult trade-off related to reader scalability. Locks that have a compact memory representation for active readers will typically suffer under high intensity read-dominated workloads when the "reader indicator" state is updated frequently by a diverse set of threads, causing cache invalidation and coherence traffic. Other designs use distributed reader indicators, one per NUMA node, per core or even per thread. This improves reader-reader scalability, but also increases the size of each lock instance and creates overhead for writers.

We propose a simple transformation, BRAVO, that augments any existing reader-writer lock, adding just two integer fields to the lock instance. Readers make their presence known to writers by hashing their thread's identity with the lock address, forming an index into a *visible readers table* and installing the lock address into the table. All locks and threads in an address space can share the same readers table. Crucially, readers of the same lock tend to write to different locations in the table, reducing coherence traffic. Therefore, BRAVO can augment a simple compact lock to provide scalable concurrent reading, but with only modest and constant increase in memory footprint.

We implemented BRAVO in user-space, as well as integrated it with the Linux kernel reader-writer semaphore (`rwsem`). Our evaluation with numerous benchmarks and real applications, both in user and kernel-space, demonstrate that BRAVO improves performance and scalability of underlying locks in read-heavy workloads while introducing virtually no overhead, including in workloads in which writes are frequent.

1 Introduction

A reader-writer lock, also known as a shared-exclusive lock, is a synchronization primitive for controlling access by multiple threads (or processes) to a shared resource (critical section). It allows shared access for read-only use of the resource, while write operations access the resource exclusively. Such locks are ubiquitous in modern systems, and can be found, for example, in database software, file systems, key-value stores and operating systems.

Reader-writer locks have to keep track of the presence of active readers before a writer can be granted the lock. In the common case, such presence is recorded in a shared counter, incremented and decremented with every acquisition and release of the lock in the read mode. This is the way reader-writer locks are implemented in the Linux kernel, POSIX pthread library and several other designs [3, 35, 42]. The use of a shared counter lends itself to a relatively simple implementation and has a compact memory representation for a lock. However, it suffers under high intensity read-dominated workloads when the "reader indicator" state is updated frequently by a diverse set of threads, causing cache invalidation and coherence traffic [7, 17, 20, 31].

Alternative designs for reader-writer locks use distributed reader indicators, for instance, one per NUMA (non-uniform memory access) node as in cohort locks [6], or even one lock per core as in the Linux kernel brlock [10] and other related ideas [26, 31, 39, 46]. This improves reader-reader scalability, but also considerably increases the size of each lock instance. Furthermore, the lock performance is hampered when writes are frequent, as multiple indicators have to be accessed and/or modified. Finally, such locks have to be instantiated dynamically, since the number of sockets or cores can be unknown until the runtime. As a result, designers of modern reader-writer locks confront a difficult trade-off related to the scalability of maintaining the indication of the readers' presence.

In this paper, we propose a simple transformation, called BRAVO, that augments any existing reader-writer lock, adding just two integer fields to the lock instance. When applied on top of a counter-based reader-writer lock, BRAVO allows us to achieve, and often beat, the performance levels of locks that use distributed reader indicators while maintaining a compact footprint of the underlying lock. With BRAVO, readers make their presence known to writers by hashing their

thread's identity with the lock address, forming an index into a *visible readers table*. Readers attempt to install the lock address into the element (slot) in the table identified by that index. If successful, readers can proceed with their critical section *without* modifying the shared state of the underlying lock. Otherwise, readers resort to the acquisition path of the underlying lock. Note that the visible readers table is shared by all locks and threads in an address space. Crucially, readers of the same lock tend to write to different locations in the table, reducing coherence traffic and thus resulting in a NUMA-friendly design. At the same time, a writer always uses the acquisition path of the underlying lock, but also scans the readers table and waits for all readers that acquired that lock through it. A simple mechanism is put in place to limit the overhead of scanning the table for workloads in which writes are frequent.

We implemented BRAVO and evaluated it on top of several locks, such as the POSIX pthread_rwlock lock and the PF-Q reader-writer lock by Brandenburg and Anderson [3]. For our evaluation, we used numerous microbenchmarks as well as `rocksdb` [40], a popular open-source key-value store. Furthermore, we integrated BRAVO with `rwsem`, a read-write semaphore in the Linux kernel. We evaluated the modified kernel through kernel microbenchmarks as well as several user-space applications (from the Metis suite [33]) that create contention on read-write semaphores in the kernel. All our experiments in user-space and in the kernel demonstrate that BRAVO is highly efficient in improving performance and scalability of underlying locks in read-heavy workloads while introducing virtually no overhead, even in workloads in which writes are frequent.

The rest of the paper is organized as following. The related work is surveyed in Section 2. We present the BRAVO algorithm in Section 3 and discuss how we apply BRAVO in the Linux kernel in Section 4. The performance evaluation in user-space and the Linux kernel is provided in Sections 5 and 6, respectively. We conclude the paper and elaborate on multiple directions for future work in Section 7.

2 Related Work

► **Reader-Indicator Design** Readers that are *active* – currently executing in a reader critical section – must be visible to potential writers. Writers must be able to detect active readers in order to resolve read-vs-write conflicts, and wait for active readers to depart. The mechanism through which readers make themselves visible is the *reader indicator*. Myriad designs have been described in the literature. At one end of the spectrum we find a centralized reader indicator implemented as an integer field within each reader-writer lock instance that reflects the number of active readers. Readers use atomic instructions (or a central lock) to safely increment and decrement this field. Classic examples of such locks can be found in the early work of Mellor-Crummey and Scott [35] and more recent work by Shirako et al. [42]. Another reader-writer lock algorithm having a compact centralized reader indicator is Brandenburg and Anderson's Phase-Fair Ticket lock, designated `PF-T` in [3], where the reader indicator is encoded in two central fields. Their Phase-Fair Queue-based lock, `PF-Q`, uses a centralized counter for active readers and an MCS-like central queue, with local spinning, for readers that must wait. We refer to this latter algorithm as "BA" throughout the remainder of this paper. Such approaches are compact, having a small per-lock footprint, and simple, but, because of coherence traffic, do not scale in the presence of concurrent readers that are arriving and departing frequently [7, 17, 20, 31].

To address this concern, many designs turn toward distributed reader indicators. Each cohort reader-writer lock [6], for instance, uses a per-NUMA node reader indicator. While distributed reader indicators improve scalability, they also significantly increase the footprint of a lock instance, with each reader indicator residing on its own private cache line or sector to reduce false sharing. In addition, the size of the lock is variable with the number of nodes, and not known at compile-time, precluding simple static preallocation of locks. Writers are also burdened with the overhead of checking multiple reader indicators. Kashyap et al. [27] attempt to address some of those issues by maintaining a dynamic list of per-socket structures and expand the lock instance on-demand. However, this only helps if a lock is accessed by threads running on a subset of nodes.

At the extreme end of the spectrum we find lock designs with reader indicators assigned per-CPU or per-thread [10, 26, 31, 39, 46]. These designs promote read-read scaling, but have a large variable-sized footprint. They also favor readers in that writers must traverse and examine all the reader-indicators to resolve read-vs-write conflicts, possibly imposing a performance burden on writers. We note that there are a number of varieties of such distributed locks: a set of reader-indicators coupled with a central mutual exclusion lock for writer permission, as found in cohort locks [6]; sets of mutexes where readers must acquire one mutex and writers must acquire all mutexes, as found in Linux kernel brlocks [10]; or sets of reader-writer locks where readers must acquire read permission on one lock, and writers must acquire write permission on all locks. To reduce the impact on writers, which must visit all reader indicators, some designs use a tree of distributed counters where the root element contains a sum of the indicators within the subtrees [30].

Dice et al. [19] devised *read-write byte-locks* for use in the *TLRW* software transactional memory infrastructure. Briefly, read-write byte-locks are reader-writer locks augmented with an array of bytes, serving as reader indicators, where indices in the array are assigned to favored threads that are frequent readers. These threads can simply set and clear these reader indicators with normal store operations. The motivation for read-write byte-locks was to avoid atomic read-modify-write

instructions, which were particularly expensive on the system under test. The design, as described, is not NUMA-friendly as the byte array occupies a single cache line.

In addition to distributing or dispersing the counters, individual counters can themselves be further split into constituent `ingress` and `egress` fields to further reduce write sharing. Arriving readers increment the ingress field and departing readers increment the egress field. Cohort reader-writer locks use this approach [6].

BRAVO takes a different approach, opportunistically representing active readers in the shared global visible readers table. The table (array) is fixed in size and shared over all threads and locks within an address space. Each BRAVO lock has, in addition to the underlying reader-writer lock, a boolean flag that indicates if reader bias is currently enabled for that lock. Publication of active readers in the array is strictly optional and best-effort. A reader can always fall back to acquiring read permission via the underlying reader-writer lock. BRAVO's benefit comes from reduced coherence traffic arising from reader arrival. Such coherence traffic is particularly costly on NUMA systems, consuming shared interconnect bandwidth and also exhibiting high latency. As such, BRAVO is naturally NUMA-friendly. However, unlike most other NUMA-aware reader-writer locks, it does not need to understand or otherwise query the system topology, further simplifying the design and reducing dependencies[1].

► **Optimistic Invisible Readers** Synchronization constructs such as *seqlocks* [9,23,29] allow concurrent readers, but forgo the need for readers to make themselves visible. Critically, readers do not write to synchronization data and thus do not induce coherence traffic. Instead, writers update state – typically a modification counter – to indicate that updates have occurred. Readers check that counter at the start and then again at the end of their critical section, and if writers were active or the counter changed, the readers self-abort and retry. An additional challenge for seqlocks is that readers can observe inconsistent state, and special care must be taken to constrain the effects and avoid errant behavior in readers. Often, non-trivial reader critical sections must be modified to safely tolerate optimistic execution. Various hybrid forms exist, such as the `StampedLock` [36] facility in `java.util.concurrent`, which consists of a reader-writer lock coupled with a seqlock, providing 3 modes: classic pessimistic write locking, classic pessimistic read locking, and optimistic reading.

To avoid the problem where optimistic readers might see inconsistent state, transactional lock elision [16,18,24,28,38] based on hardware transactional memory can be used. Readers are invisible and do not write to shared data. Such approaches can be helpful, but are still vulnerable to indefinite abort and progress failure. In addition, the hardware transactional memory facilities required to support lock elision are not available on all systems, and are usually best-effort, without any guaranteed progress, requiring some type of fallback to pessimistic mechanisms.

► **Biased Locking** BRAVO draws inspiration from *biased locking* [14,22,37,41,44]. Briefly, biased locking allows the same thread to repeatedly acquire and release a mutual exclusion lock without requiring atomic instructions, except on the initial acquisition. If another thread attempts to acquire the lock, then expensive *revocation* is required to wrest bias from the original thread. The lock would then revert to normal non-biased mode for some period before again becoming potentially eligible for bias. (Conceptually, we can think of the lock as just being left in the locked state until there is contention. Subsequent lock and unlock operations by the original thread are ignored – the unlock operation is deferred until contention arises). Biased locking was a response to the CPU-local latencies incurred by atomic instructions on early Intel and SPARC processors and to the fact that locks in Java were often dominated by a single thread. Subsequently, processor designers have addressed the latency concern, rendering biased locking less profitable.

Classic biased locking identifies a preferred thread, while BRAVO identifies a preferred access mode. That is, BRAVO biases toward a mode instead of thread identity. BRAVO is suitable for read-dominated workloads, allowing a fast-path for readers when reader bias is enabled for a lock. If a write request is issued against a reader-biased lock, reader bias is disabled and revocation (scanning of the visible readers table) is required, shifting some cost from readers to writers. Classic biased locking provides benefit by reducing the number of atomic operations and improving latency. It does not improve scalability. BRAVO reader-bias, however, can improve both latency and scalability by reducing coherence traffic on the reader indicators in the underlying reader-writer lock.

3 The BRAVO Algorithm

BRAVO transforms any existing reader-writer lock *A* into *BRAVO-A*, which provides scalable reader acquisition. We say *A* is the *underlying* lock in *BRAVO-A*. In typical circumstances *A* might be a simple compact lock that suffers under high levels of reader concurrency. *BRAVO-A* will also be compact, but is NUMA-friendly as it reduces coherence traffic and offers scalability in the presence of frequently arriving concurrent readers.

Listing 1 depicts a pseudo-code implementation of the BRAVO algorithm. BRAVO extends *A*'s structure with a new `RBias` boolean field (Line 2). Arriving readers first check the `RBias` field, and, if found set, then hash the address of the lock with a value reflecting the calling thread's identity to

[1] While BRAVO is topology oblivious, it does require high-resolution low-latency means of reading the system clock. We further expect that reading the clock is scalable, and that concurrent readers do not interfere with each other. On systems with modern Intel CPUs and Linux kernels the `RDTSCP` instruction or `clock_gettime(CLOCK_MONOTONIC)` fast system call suffice.

form an index into the visible readers table (Lines 12–13). (This readers table is shared by all locks and threads in an address space. In all our experiments we sized the table at 4096 entries. Each table element, or *slot*, is either `null` or a pointer to a reader-writer lock instance). The reader then uses an atomic compare-and-swap (CAS) operator to attempt to change the element at that index from `null` to the address of the lock, publishing its existence to potential writers (Line 14). If the CAS is successful then the reader rechecks the `RBias` field to ensure it remains set (Line 18). If so, the reader has successfully gained read permission and can enter the critical section (Line 19). Upon completing the critical section the reader executes the complementary operation to release read permission, simply storing `null` into that slot (Lines 29–31). We refer to this as the *fast-path*. The fast-path attempt prefix (Lines 11-23) runs in constant time. Our hash function is based on the *Mix32* operator found in [43].

If the recheck operation above happens to fail, as would be the case if a writer intervened and cleared `RBias` and the reader lost the race, then the reader simply clears the slot (Line 21) and reverts to the traditional *slow-path* where it acquires read permission via the underlying lock (Line 24). Similarly, if the initial check of `RBias` found the flag clear (Line 12), or the CAS failed because of collisions in the array (Line 14) – the slot was found to be populated – then control diverts to the traditional slow-path. After a slow-path reader acquires read permission from the underlying lock, it enters and executes the critical section, and then at unlock time releases read permission via the underlying lock (Line 33).

Arriving writers first acquire write permission on the underlying reader-writer lock (Line 36). Having done so, they then check the `RBias` flag (Line 37). If set, the writer must perform *revocation*, first clearing the `RBias` flag (Line 40) and then scanning all the elements of the visible readers table checking for conflicting fast-path readers (Lines 42–44). If any elements match the lock, the writer must wait for that fast-path reader to depart and clear the slot. If lock L has 2 fast-path active readers, for instance, then L will appear twice in the array. Scanning the array might appear to be onerous, but in practice the sequential scan is assisted by the automatic hardware prefetchers present in modern CPUs. We observe a scan rate of about 1.1 nanoseconds per element on our system-under-test (described later). Having checked `RBias` and performed revocation if necessary, the writer then enters the critical section (Line 50). At unlock-time, the writer simply releases write permission on the underlying reader-writer lock (Line 51). Therefore the only difference for writers under BRAVO is the requirement to check and potentially revoke reader bias if `RBias` was found set.

We note that writers only scan the visible reader table, and never write into it. Yet, this scan may pollute the writer's cache. One way to cope with it is to use non-temporal loads, however, exploring this idea is left for the future work. Note that revocation is only required on transitions from reading to

Listing 1: Simplified Python-like implementation of BRAVO

writing and only when `RBias` was previously set.

In summary, active readers can make their existence public in one of two ways : either via the visible readers table (fast-path), or via the traditional underlying reader-writer lock (slow-path). Our mechanism allows both slow-path and fast-path readers simultaneously. Absent hash collisions, concurrent fast-path readers will write to different locations in the visible readers table. Collisions are benign, and impact per-

formance but not correctness. Writers resolve read-vs-write conflicts against fast-path readers via the visible readers table and against slow-path readers via the underlying reader-writer lock.

One important remaining question is how to set `RBias`. In our early prototypes we set `RBias` in the reader slow-path based on a low-cost Bernoulli trial with probability $P = 1/100$ using a thread-local Marsgalia XOR-Shift [34] pseudo-random number generator. While this simplistic policy for enabling bias worked well in practice, we were concerned about situations where we might have enabled bias too eagerly, and incur frequent revocation to the point where *BRAVO-A* might be slower than *A*. Specifically, the worst-case scenario would be where slow readers repeatedly set `RBias`, only to have it revoked immediately by a writer.

The key additional cost in BRAVO is the revocation step, which executes under the underlying write lock and thus serializes operations associated with the lock[2]. As such, we measure the latency of revocation and multiply that period by N, a configurable parameter, and then inhibit the subsequent setting of bias in the reader slow-path for that period, bounding the worst-case expected slow-down from BRAVO for writers to $1/(N+1)$ (cf. Lines 41-49). Our specific performance goal is *primum non nocere* – first, do no harm, with *BRAVO-A* never underperforming *A* by any significant margin on any workload[3]. This tactic is simple and effective, but excessively conservative, taking into account only the worst-case performance penalty imposed by BRAVO, and not accounting for any potential benefit conferred by the BRAVO fast-path. Furthermore, measuring the revocation duration also incorporates the waiting time, as well as the scanning time, yielding a conservative over-estimate of the revocation scan cost and resulting in less aggressive use of reader bias. Despite these concerns, we find this policy yields good and predictable performance. For all benchmarks in this paper we used $N = 9$ yielding a worst-case writer slow-down bound of about 10%. Our policy required adding a second BRAVO-specific timestamp field `InhibitUntil` (Line 3), which reflects the earliest time at which slow readers should reenable bias[4]. We note that for safety, readers can only set `RBias` while they hold read permission on the underlying reader-writer lock, avoiding interactions with writers (cf. Lines 25–26).

In our implementations revoking waiters busy-wait for readers to depart. There can be at most one such busy-waiting thread for a given lock at any given time. We note, however, that it is trivial to shift to a waiting policy that uses blocking.

BRAVO acts as an accelerator layer, as readers can always fall back to the traditional underlying lock to gain read access. The benefit arises from avoiding coherence traffic on the centralized reader indicators in the underlying lock, and instead relying on updates to be diffused over the visible readers table. Fast-path readers write only into the visible readers table, and not the lock instance proper. This access pattern improves performance on NUMA systems, where write sharing is particularly expensive. We note that if the underlying lock algorithm *A* has reader preference or writer preference, then *BRAVO-A* will exhibit that same property. Write performance and the scalability of read-vs-write and write-vs-write behavior depends solely on the underlying lock. Under high write intensity, with write-vs-write and write-vs-read conflicts, the performance of BRAVO devolves to that of the underlying lock. BRAVO accelerates reads only. BRAVO fully supports the case where a thread holds multiple locks at the same time.

BRAVO supports *try-lock* operations as follows. For read *try-lock* attempts an implementation could try the BRAVO fast path and then fall back, if the fast path fails, to the slow path underling *try-lock*. An implementation can also opt to forgo the fast path attempt and simply call the underlying *try-lock* operator. We use the former approach when applying BRAVO in the Linux kernel as detailed in the next section. We note that if the underlying *try-lock* call is successful, one may set `RBias` if the BRAVO policy allows that (e.g., if the current time is larger than `InhibitUntil`). For write *try-lock* operators, an implementation will invoke the underlying *try-lock* operation. If successful, and bias is set, then revocation must be performed following the same procedure described in Lines 37–49.

As seen in Listing 1, the *slot* value must be passed from the read lock operator to the corresponding unlock. `null` indicates that the slow path was used to acquire read permission. To provide correct errno values in the POSIX pthread environment, a thread must be able to determine if it holds read, write, or no permission on a given lock. This is typically accomplished by using per-thread lists of locks currently held in read mode. We leverage those list elements to pass the slot. We note that the Cohort read-write lock implementation [6] passed the reader's NUMA node ID from lock to corresponding unlock in this exact fashion.

4 Applying BRAVO to the Linux Kernel `rwsem`

In this section, we describe prototype integration of BRAVO in the Linux kernel, where we apply it to `rwsem`. `Rwsem` is a read-write semaphore construct. Among many places inside the kernel, it is used to protect the access to the virtual memory area (VMA) structure of each process [11], which makes it a

[2]Additional costs associated with BRAVO include futile atomic operations from collisions, and sharing or false-sharing arising from near-collisions in the table. Our simplified cost model ignores these secondary factors. We note that the odds of collision are equivalent to those given by the "Birthday Paradox" [48] and that the general problem of deciding to set bias is equivalent to the classic "ski-rental" problem [47].

[3]Our approach conservatively forgoes the potential of better performance afforded by the aggressive use of reader bias in order to limit the possibility of worsened performance [49].

[4]We observe that it is trivial to collapse `RBias` and `InhibitUntil` into just a single field. For clarity, we did not do so in our implementation.

source of contention for data intensive applications [8, 11].

On a high level, rwsem consists of a counter and a waiting queue protected by a spin-lock. The counter keeps track of the number of active readers, as well as encodes the presence of a writer. To acquire the rwsem in the read mode, a reader atomically increments the counter and checks its value. If a (waiting or active) writer is not present, the read acquisition is successful; otherwise, the reader acquires the spin-lock protecting the waiting queue, joins the queue at the tail, releases the spin-lock and blocks, waiting for a wake-up signal from a writer. As a result, when there is no reader-writer contention, the read acquisition boils down to one atomic counter increment. On architectures that do not support an atomic increment instruction, this requires acquisition (and subsequent release) of the spin-lock. Even on architectures that have such an instruction (such as Intel x86), the read acquisition of rwsem creates contention over the cache line hosting the counter.

In our integration of BRAVO on top of rwsem, we make a simplifying assumption that the semaphore is always released by the same thread that acquired it for read. This is not guaranteed by the API of rwsem, however, this is a common way of using semaphores in the kernel. This assumption allows us to preserve the existing rwsem API and limits the scope of changes required, resulting in a patch of only three files and adding just a few dozens lines of code. We use this assumption when determining the slot into which a thread would store the semaphore address on the fast acquisition path, and clear that slot during the release operation[5].

While we have not observed any issue when running and evaluating the modified kernel, we note that our assumption can be easily eliminated by, for example, extending the API of rwsem to allow an additional pointer argument for read acquisition and release functions. In case the acquisition is made on the fast path, this pointer would be used to store the address of the corresponding slot; later, this pointer can be passed to a (different) releasing thread to specify the slot to be cleared. Alternatively, we can extend the API of rwsem to include a flag explicitly allowing the use of the fast path for read acquisition and release. This flag would be set only in call sites known for high read contention (such as in functions operating on VMAs), where a thread that releases the semaphore is known to be the one that acquired it. Other call sites for semaphore acquisition and release can be left untouched, letting them use the slow path only.

We note that the default configuration of the kernel enables a so-called spin-on-owner optimization of rwsem [32]. With this optimization, the rwsem structure includes an owner field that contains a pointer to the current struct of the owner task when rwsem is acquired for write. Using this field, a reader may check whether the writer is currently running on a CPU, and if so, spin rather than block [32]. While writers do not use this field to decide whether they have to spin (as there might be multiple readers), in the current rwsem implementation a reader updates the owner field regardless, storing there its current pointer along with a few control bits (that specify that the lock is owned by a reader). These writes by readers are for debugging purposes only, yet they create unnecessary contention on the owner field. We fix that by letting a reader set only the control bits in the owner field, and only if those bits were not set before, i.e., when the first reader acquires that rwsem instance after a writer. Note that all subsequent readers would read, but not update the owner field, until it is updated again by a writer.

[5]We determine the slot by hashing the task struct pointer (current) with the address of the semaphore.

5 User-space Evaluation

All user-space data was collected on an Oracle X5-2 system. The system has 2 sockets, each populated with an Intel Xeon E5-2699 v3 CPU running at 2.30GHz. Each socket has 18 cores, and each core is 2-way hyperthreaded, yielding 72 logical CPUs in total. The system was running Ubuntu 18.04 with a stock Linux version 4.15 kernel, and all software was compiled using the provided GCC version 7.3 toolchain at optimization level "-O3". 64-bit code was used for all experiments. Factory-provided system defaults were used in all cases, and *turbo mode* [45] was left enabled. In all cases default free-range unbound threads were used.

We implemented all locks within LD_PRELOAD interposition libraries that expose the standard POSIX pthread_rwlock_t programming interface. This allows us to change lock implementations by varying the LD_PRELOAD environment variable and without modifying the application code that uses reader-writer locks. This same framework was used to implement Cohort reader-writer locks [6].

In the following figures "BA" refers to the Brandenburg-Anderson PF-Q lock [3]; "Cohort-RW" refers to the C-RW-WP lock [6]; "Per-CPU" reflects a lock that consists of an array of BA locks, one for each CPU, where readers acquire read-permission on the sub-lock associated with their CPU, and writers acquire writer permission on all the sub-locks (this lock is similar to the Linux kernel brlock construct [10]); "pthread" is a default Linux POSIX "pthread_rwlock" read-write lock mechanism; "BRAVO-BA" reflects BRAVO implemented on top of BA and "BRAVO-pthread" is BRAVO implemented on top of pthread_rwlock.

We also experimented with several other reader-writer locks. In particular, we took data on the Brandenburg-Anderson PF-T lock and the BRAVO form thereof. PF-T implements the reader indicator via a central pair of counters, one incremented by arriving readers and the other incremented by departing readers. Waiting readers busy-wait on a dedicated *writer present* bit encoded in the reader arrival counter. In PF-Q active readers are tallied on a central pair of counters in the same fashion as PF-T, but waiting readers enqueue on an MCS-like queue. In both PF-T and PF-Q, arriving read-

ers update the central reader indicator state, generating more coherence traffic than would be the case for locks that use distributed reader indicators or BRAVO. Waiting readers in PF-T use global spinning, while waiting readers in PF-Q use local spinning on a thread-local field in the enqueued element. PF-T enjoys slightly shorter code paths but also suffers from lessened scalability because of the global spinning. We found that PF-T and PF-Q offer broadly similar performance, with PF-T having a slight advantage when the arrival rate is high, the number of waiting threads is low, and the waiting period is shorter. PF-T is slightly more compact having just 4 integer fields, while PF-Q has 2 such fields and 4 pointers. For brevity, we do not include PF-T results. We also found that "fair lock with local only spinning" by Mellor-Crummey and Scott [35] yielded performance similar to or slower than that of PF-Q.

We note that the default pthread read-write lock implementation found in our Linux distribution provides strong reader preference, and admits indefinite writer starvation[6]. The reader indicator is centralized and the lock has a footprint of 56 bytes for 64-bit programs. Waiting threads block immediately in the kernel without spinning. While this policy incurs overheads associated with voluntary context switching, it may also yield benefits by allowing "polite" waiting by enabling turbo mode for those threads making progress. Except where otherwise noted, we plot the number of concurrent threads on the X-axis, and aggregate throughput on the Y-axis, and report the median of 7 independent runs for each data point.

We use a 128 byte sector size on Intel processors for alignment to avoid false sharing. The unit of coherence is 64 bytes throughout the cache hierarchy, but 128 bytes is required because of the adjacent cache line prefetch facility where pairs of lines are automatically fetched together. BA requires just 128 bytes – 2 32-bit integer fields plus 4 pointers fields with the overall size rounded up to the next sector boundary. BRAVO-BA adds the 8-byte `InhibitUntil` field, which contains a timestamp, and the 4-byte `RBias` field. Rounding up to the sector size, this still yields a 128 byte lock instance. Per-CPU consists of one instance of BA for each logical CPU, yielding a lock size of 9216 bytes on our 72-way system. Cohort-RW consists of one reader indicator (128 bytes) per NUMA node, a central location for state (128 bytes) and a full cohort mutex [21] to provide writer exclusion. In turn, the cohort mutex requires one 128-byte sub-lock per NUMA node, and another 256 bytes for central state. Thus, the total size of the Cohort-RW lock on our dual-socket system is 896 bytes. (While our implementation did not do so, we note that a more space aggressive implementation of Cohort-RW could colocate the per-node reader indicators with the mutex sub-locks, and the central state for the read-write lock with its associated cohort mutex, yielding a size of 512 bytes).

[6] The pthread implementation allows writer preference to be selected via a non-portable API. Unfortunately this feature currently has bugs that result in lost wakeups and hangs: https://sourceware.org/bugzilla/show_bug.cgi?id=23861.

As noted above, the size of the pthread read-write lock is 56 bytes, and the BRAVO variant adds 12 bytes. The size of BA, BRAVO-BA, pthread, and BRAVO-pthread are fixed, and known at compile-time, while the size of Per-CPU varies with the number of logical CPUs, and the size of Cohort-RW varies with the number of NUMA nodes. Finally, we observe that BRAVO allows more relaxed approach toward the alignment and padding of the underlying lock. Since fast-path readers do not mutate the underlying lock fields, the designer can reasonably forgo alignment and padding on that lock, without trading off reader scalability.

The size of the lock can be important in concurrent data structures, such as linked lists or binary search trees, that use a lock per node or entry [4, 12, 25]. As Bronson at el. observe, when a scalable lock is striped across multiple cache lines to avoid contention in the coherence fabric, it is "prohibitively expensive to store a separate lock per node" [4].

BRAVO also requires the visible readers table. With 4096 entries on a system with 64-bit pointers, the additional footprint is 32KB. The table is aligned and sized to minimize the number of underlying pages (reducing TLB footprint) and to eliminate false sharing from variables that might be placed adjacent to the table. We selected a table size 4096 empirically but in general believe the size should be a function of the number of logical CPUs in the system. Similar tables in the linux kernel, such as the *futex* hash table, are sized in this fashion [5].

BRAVO yields a favorable performance trade-off between space and scalability, offering a viable alternative that resides on the design spectrum between classic centralized locks, such as BA, having small footprint and poor reader scalability, and the large locks with high reader scalability.

5.1 Sensitivity to Inter-Lock Interference

As the visible readers array is shared over all locks and threads within an address space, one potential concern is collisions that might arise when multiple threads are using a large set of locks. Near collisions are also of concern as they can cause false sharing within the array. To determine BRAVO's performance sensitivity to such effects, we implemented a microbenchmark program that spawns 64 concurrent threads. Each thread loops as follows: randomly pick a reader-writer lock from a pool of such locks; acquire that lock for read; advance a thread-local pseudo-random number generator 20 steps; release read permission on the lock; and finally advance that random number generator 100 steps. At the end of a 10 second measurement interval we report the number of lock acquisitions. No locks are ever acquired with write permission. Each data point is the median of 7 distinct runs. We report the results in Figure 1 where the X-axis reflects the number of locks in the pool (varying through powers-of-two between 1 and 8192) and the Y-axis is the number of acquisitions completed by BRAVO-BA divided by the number completed by a

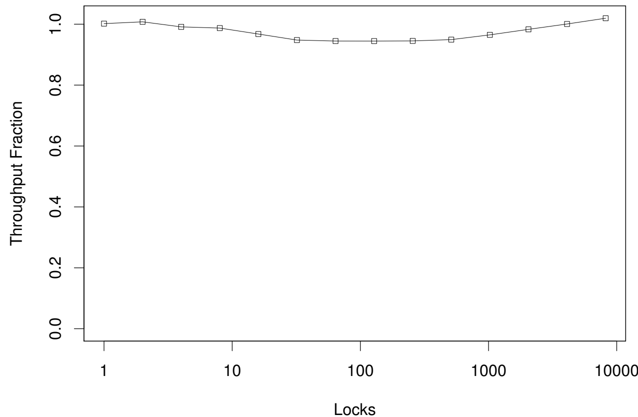

Figure 1: Inter-lock interference

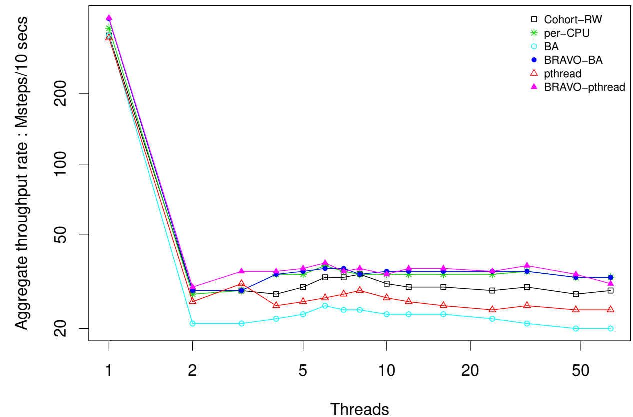

Figure 2: Alternator

specialized version of BRAVO-BA where each lock instance has a private array of 4096 elements. This fraction reflects the performance drop attributable to inter-lock conflicts and near conflicts in the shared array, where the modified form of BRAVO-BA can be seen as an idealized form that has a large per-instance footprint but which is immune to inter-lock conflicts[7]. The worst-case penalty arising from inter-lock interference (the lowest fraction value) is always under 6%.

5.2 Alternator

Figure 2 shows the results of our `alternator` benchmark. The benchmark spawns the specified number of concurrent threads, which organize themselves into a logical ring, each waiting for notification from its "left" sibling. Notification is accomplished via setting a thread-specific variable with a store instruction and waiting is via simple busy-waiting. Once notified, the thread acquires and then immediately releases read permission on a shared reader-writer lock. Next the thread notifies its "right" sibling and then again waits. There are no writers, and there is no concurrency between readers. At most one reader is active at any given moment. At the end of a 10 second measurement interval the program reports the number of notifications.

The BA lock suffers as the lines underlying the reader indicators "slosh" and migrate from cache to cache. In contrast BRAVO-BA readers touch different locations in the visible readers table as they acquire and release read permissions. BRAVO enables reader-bias early in the run, and it remains set for the duration of the measurement interval. All locks experience a significant performance drop between 1 and 2 threads due to the impact of coherent communication for notification. Crucially, we see that BRAVO-BA outperforms the underlying BA by a wide margin, and is competitive with the much larger Per-CPU lock. In addition, the performance of BA can be seen to degrade as we add threads, whereas the performance of BRAVO-BA remains stable. The same observations are true when considering BRAVO-pthread and pthread locks.

Since the hash function that associates a read locking request with an index is deterministic, threads repeatedly locking and unlocking a specific lock will enjoy temporal locality and reuse in the visible readers table.

5.3 test_rwlock

We next report results from the `test_rwlock` benchmark described by Desnoyers et al. [13][8]. The benchmark was designed to evaluate the performance and scalability of reader-writer locks against the RCU (Read-Copy Update) synchronization mechanism. We used the following command-line: `test_rwlock T 1 10 -c 10 -e 10 -d 1000`. The benchmark launches 1 fixed-role writer thread and T fixed-role reader threads for a 10 second measurement interval. The writer loops as follows: acquire a central reader-writer lock instance; execute 10 units of work, which entails counting down a local variable; release writer permission; execute a non-critical section for 1000 work units. Readers loop acquiring the central lock for reading, executing 10 steps of work in the critical section, and then release the lock. (The benchmark has no facilities to allow a non-trivial critical section for readers). At the end of the measurement interval the benchmark reports the sum of iterations completed by all the threads. As we can see in Figure 3, BRAVO-BA significantly outperforms BA, and even the Cohort-RW lock at higher thread counts. Since the workload is extremely read-dominated, the Per-CPU lock yields the best performance, albeit with a very

[7]We note that as we increase the number of locks, cache pressure constitutes a confounding factor for the specialized version of BRAVO-BA. For full discussion, see the extended version of this paper available at https://arxiv.org/abs/1810.01553.

[8]obtained from https://github.com/urcu/userspace-rcu/blob/master/tests/benchmark/test_rwlock.c and modified slightly to allow a fixed measurement interval.

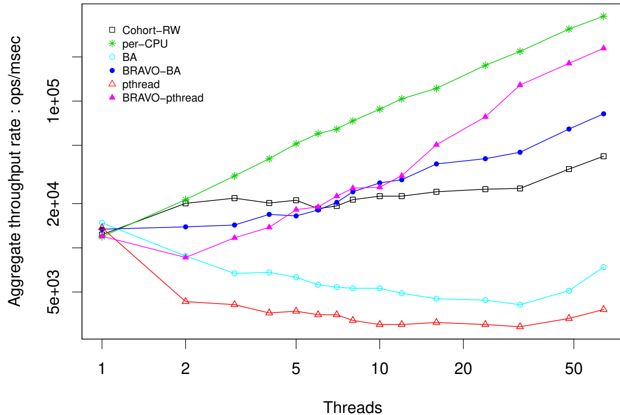

Figure 3: test_rwlock

large footprint and only because of the relatively low write rate. For that same reason, and due to its default reader preference, BRAVO-pthread easily beats pthread, and comes close to the performance level of Per-CPU.

5.4 RWBench

Using `RWBench` – modeled on a benchmark of the same name described by Calciu et al. [6] – we evaluated the reader-write lock algorithms over a variety of read-write ratios, ranging from write-intensive in Figure 4a (9 out of every 10 operations are writes) to read-intensive in Figure 4f (1 out of every 10000 operations are writes), demonstrating that BRAVO inflicts no harm for write-intensive workloads, but improves performance for more read-dominated workloads. `RWBench` launches T concurrent threads for a 10 second measurement interval. Each thread loops as follows: using a thread-local pseudo-random generator, decide to write with probability P via a Bernoulli trial; writers acquire a central reader-write lock for write permission and then execute 10 steps of a thread-local C++ `std::mt19937` random number generator and then release write permission, while readers do the same, but under read permission; execute a non-critical section of N steps of the same random-number generator where N is a random number uniformly distributed in $[0,200)$ with average and median of 100. At the end of the measurement interval the benchmark reports the total number of top-level loops completed.

In Figure 4a we see poor scalability over all the locks by virtue of the highly serialized write-heavy nature of the workload. Per-CPU fairs poorly as writes, which are common, need to scan the array of per-CPU sub-locks. Cohort-RW provides some benefit, while BRAVO-BA (BRAVO-pthread) tracks closely to BA (pthread, respectively), providing neither benefit nor harm. The same behavior plays out in Figure 4b ($P = 1/2$) and Figure 4c ($P = 1/10$), although in the latter we see some scaling from Cohort-RW. In Figure 4d ($P = 1/100$) we begin to see BRAVO-BA outperforming BA at higher thread counts. Figure 4e ($P = 1/1000$) and Figure 4f ($P = 1/10000$ – extremely read-dominated) are fairly similar, with BRAVO-BA and BRAVO-pthread yielding performance similar to that of Per-CPU, Cohort-RW yielding modest scalability, and BA and pthread yielding flat performance as the thread count increases.

5.5 `rocksdb` readwhilewriting

We next explore performance sensitivity to the reader-writer lock in the `rocksdb` database [40]. We observed high frequency reader traffic arising in the readwhilewriting benchmark from calls in `::Get()` to `GetLock()` defined in `db/memtable.cc`[9]. In Figure 5 we see the performance of BRAVO-BA and BRAVO-pthread tracks that of Per-CPU and always exceeds that of Cohort-RW and the respective underlying locks.

5.6 `rocksdb` hash_table_bench

`rocksdb` also provides a benchmark to stress the hash table used by their persistent cache[10]. The benchmark implements a central shared hash table as a C++ `std::unordered_map` protected by a reader-writer lock. The cache is pre-populated before the measurement interval. At the end of the 50 second measurement interval the benchmark reports the aggregate operation rate – reads, erases, insertions – per millisecond. A single dedicated thread loops, erasing random elements, and another dedicated thread loops inserting new elements with a random key. Both erase and insertion operations require write access. The benchmark launches T reader threads, which loop, running lookups on randomly selected keys. We vary T on the X-axis. All the threads execute operations back-to-back without a delay between operations. The benchmark makes frequent use of malloc-free operations in the `std::unordered_map`. The default malloc allocator fails to fully scale in this environment and masks any benefit conferred by improved reader-writer locks, so we instead used the index-aware allocator by Afek el al. [1].

The results are shown in Figure 6. Once again, BRAVO enhances the performance of underlying locks, and shows substantial speedup at high thread counts.

[9] We used `rocksdb` version 5.13.4 with the following command line: `db_bench -threads=T -benchmarks=readwhilewriting -memtablerep=cuckoo -duration=100 -inplace_update_support=1 -allow_concurrent_memtable_write=0 -num=10000 -inplace_update_num_locks=1 -histogram -stats_interval=10000000`

6 Linux Kernel Experiments

All kernel-space data was collected on an Oracle X5-4 system. The system has 4 sockets, each populated with an Intel Xeon CPU E7-8895 v3 running at 2.60GHz. Each socket has 18 cores, and each core is 2-way hyperthreaded, yielding 144 logical CPUs in total. The patch was applied on top of a recent Linux version 4.20.rc4 kernel, which we refer to as *stock*. We refer to the kernel version modified to use BRAVO simply as *BRAVO*.

Factory-provided system defaults were used in all cases. In particular, we compiled the kernel in the default configuration, which notably disables the lock performance data collection mechanism (aka `lockstat`[11]) built into the kernel for debugging lock performance. As we mention below, this mechanism was useful to gain insights into usage patterns of kernel locks in various applications. However, we kept it disabled during

[11] https://www.kernel.org/doc/Documentation/locking/lockstat.txt

performance measurements as it adds a probing effect by generating stores into shared variables, e.g., by keeping track of the last CPU on which a given lock instance, `rwsem` included, was acquired. These stores hamper the benefit of techniques like BRAVO that aim to reduce updates to the shared state during lock acquisition and release operations.

Each experiment is repeated 7 times, and the reported numbers are the average of the corresponding results. Unless noted, the reported results were relatively stable, with variance of less than 5% from the average in most cases.

6.1 will-it-scale

`will-it-scale` is an open-source collection of microbenchmarks[12] for stress-testing various kernel subsystems. `will-it-scale` runs in user-mode but is known to induce contention on kernel locks [15]. Each microbenchmark runs a given number of tasks (that can be either threads or processes), performing a series of specific system calls (such as opening and closing a file, mapping and unmapping memory pages, raising a signal, etc.). We experiment with a subset of microbenchmarks that access the VMA structure and create contention on `mmap_sem`, an instance of `rwsem` that protects the access to VMA [11]. In particular, the relevant microbenchmarks are `page_fault` and `mmap`. The former continuously maps a large (128M) chunk of memory, writes one word into every page in the chunk (causing a page fault for every write), and unmaps the memory. The latter simply maps and unmaps large chunks of memory. (Each of those benchmarks has several variants denoted as `page_fault1`, `page_fault2`, etc.)

Page faults require the acquisition of `mmap_sem` for read, while memory mapping and unmapping operations acquire `mmap_sems` for write [8]. Therefore, the access pattern for `mmap_sem` is expected to be read-heavy in the `page_fault` microbenchmark and more write-heavy in `mmap`. We confirmed that through `lockstat` statistics. We note that BRAVO is not expected to provide any benefit for `mmap`, yet we include it to evaluate any overhead BRAVO might introduce in write-heavy workloads.

Figure 7 presents the results of our experiments for `page_fault` and `mmap`, respectively. In `page_fault`, the BRAVO version performs similarly to stock as long as the latter scales. After 16 threads, however, the throughput of the stock version decreases while the BRAVO version continues to scale, albeit at a slower rate. At 142 threads, BRAVO outperforms stock by up to 93%. At the same time, `mmap` shows no significant difference in the performance of BRAVO vs. stock, suggesting that BRAVO does not introduce overhead in scenarios where it is not profitable.

6.2 Metis

Metis is an open-source MapReduce library [33] used in the past to assess the scalability of Linux kernel locks [2, 8, 27]. Metis is known for a relatively intense access to VMA through the mix of page-fault and mmap operations [27]. By collecting lock performance statistics with `lockstat`, however, we found that only few of Metis benchmarks have both a large number of `mmap_sem` acquisitions and a large portion of those acquisitions is for read. We note that like in all other kernel benchmarks, `lockstat` was disabled when measuring performance numbers reported below.

Tables 1 and 2 present the performance results, respectively, for `wc`, a map-reduce based word count, and `wrmem`, which allocates a large chunk of memory and fills it with random "words", which are fed into the map-reduce framework for inverted index calculation. The BRAVO version can achieve speedups of over 30%. We note that some of the data, particularly for `wc`, was noisy; we print values with variance larger than 5% from the mean in italics. (All values have variance of 19% or less). We also note that BRAVO did not create significant overhead for any other Metis benchmark, although some benchmarks produced noisy results similarly to `wc`.

7 Conclusion and Future Work

BRAVO easily composes with existing locks, preserving desirable properties of those underlying locks, and yielding a composite lock with improved read-read scalability. We specifically target read-dominated workloads with multiple concurrent threads that acquire and release read permission at a high rate. The approach is simple, effective, and yields improved performance for read-dominated workloads compared to commonly used compact locks. The key trade-off inherent in the design is the benefit accrued by reads against the potential slow-down imposed by revocation. Even in mixed or

Table 2: `wrmem` runtime (sec)

write-heavy workloads, we limit any slow-down stemming from revocation costs and bound harm, making the decision to use BRAVO simple. BRAVO incurs a very small footprint increase per lock instance, and also adds a shared table of fixed size that can be used by all threads and locks. BRAVO's key benefit arises from reducing coherence cost that would normally be incurred by locks having a central reader indicator. Write performance is left unchanged relative to the underlying lock. BRAVO provides read-read performance at, and often above, that of the best modern reader-writer locks that use distributed read indicators, but without the footprint or complexity of such locks. By reducing coherence traffic, BRAVO is implicitly NUMA-friendly.

► **Future directions** We identify a number of future directions for our investigation into BRAVO-based designs:

- Dynamic sizing of the visible readers table based on collisions. Large tables will have reduced collision rates, but larger scan revocation overheads.
- The reader fast-path currently probes just a single location and reverts to the slow-path after a collision. We plan on using a secondary hash to probe an alternative location. In that vein, we note that while we currently use a hash function to map a thread's identity and the lock address to an index in the table, there is no particular requirement that the function that associates a read request with an index be deterministic. We plan on exploring other functions, using time or random numbers to form indices. While this will be less beneficial in terms of cache locality for the reader, it might be helpful in case of temporal contention over specific slots.
- Accelerate the revocation scan operation via SIMD instructions such as AVX. The visible readers table is usually sparsely populated, making it amenable to such optimizations. As already noted, non-temporal non-polluting loads may also be helpful for the scan operation.
- As noted, our current policy to enable bias is conservative, and leaves untapped performance. We intend to explore more sophisticated adaptive policies based on recent behavior and to use a more faithful cost model.
- An interesting variation is to implement BRAVO on top of an underlying mutex instead of a reader-writer lock. Slow-path readers must acquire the mutex, and the sole source of read-read concurrency is via the fast path. We note that some applications might expect the reader-write lock implementation to be fully work conserving and *maximally admissive* – always allowing full read concurrency where available. For example, an active reader thread $T1$, understanding by virtue of application invariants that no writers are present, might signal another thread $T2$ and expect that $T2$ can enter a reader critical section while $T1$ remains within the critical section. This progress assumption would not necessarily hold if readers are forced through the slow path and read-read parallelism is denied.
- In our current implementation arriving readers are blocked while a revocation scan is in progress. This could be avoided by adding a mutex to each BRAVO-enhanced lock. Arriving writers immediately acquire this mutex, which resolves all write-write conflicts. They then perform revocation, if necessary; acquire the underlying reader-vs-write lock with write permission; execute the writer critical section; and finally release both the mutex and the underlying reader-writer lock. The underlying reader-writer lock resolves read-vs-write conflicts. The code used by readers remains unchanged. This optimization allows readers to make progress during revocation by diverting through the reader slow-path, mitigating the cost of revocation. This also reduces variance for the latency of read operations. We note that this general technique can be readily applied to other existing reader-writer locks that employ distributed reader indicators, such as Linux's brlock [10].

Acknowledgments

We thank Shady Issa for useful discussions about revocation and the cost model. We also thank the anonymous reviewers and our shepherd Yu Hua for providing insightful comments.

Mitigating Asymmetric Read and Write Costs in Cuckoo Hashing for Storage Systems

Yuanyuan Sun, Yu Hua*, Zhangyu Chen, Yuncheng Guo

Abstract

In storage systems, cuckoo hash tables have been widely used to support fast query services. For a read, the cuckoo hashing delivers real-time access with $O(1)$ lookup complexity via open-addressing approach. For a write, most concurrent cuckoo hash tables fail to efficiently address the problem of endless loops during item insertion due to the essential property of hash collisions. The asymmetric feature of cuckoo hashing exhibits fast-read-slow-write performance, which often becomes the bottleneck from single-thread writes. In order to address the problem of asymmetric performance and significantly improve the write/insert efficiency, we propose an optimized Concurrent Cuckoo hashing scheme, called CoCuckoo. To predetermine the occurrence of endless loops, CoCuckoo leverages a directed pseudoforest containing several subgraphs to leverage the cuckoo paths that represent the relationship among items. CoCuckoo exploits the observation that the insertion operations sharing a cuckoo path access the same subgraph, and hence a lock is needed for ensuring the correctness of concurrency control via allowing only one thread to access the shared path at a time; Insertion operations accessing different subgraphs are simultaneously executed without collisions. CoCuckoo improves the throughput performance by a graph-grained locking to support concurrent writes and reads. We have implemented all components of CoCuckoo and extensive experiments using the YCSB benchmark have demonstrated the efficiency and efficacy of our proposed scheme.

1 Introduction

Efficient query services are demanding and important to storage systems, which hold and process much more data than ever and the trend continues at an accelerated pace. The widespread use of mobile devices, such as phones and tablets, accelerates the generation of large amounts of data. There exist 1.49 billion mobile daily active users on Facebook in September 2018, with an increase of 9% year-over-year. In each minute, 300 new profiles are created and more than 208 thousand photos are uploaded to Facebook [5]. The explosion of data volume leads to nontrivial challenge on storage systems, especially on the support for query services [8, 12, 49]. Moreover, write-heavy workloads further exacerbate the storage performance. Much attention has been paid to alleviate the pressure on storage systems, which demands the support of low-latency and high-throughput queries, such as top-*k* query processing [30, 33], optimizing big data queries via automated program reasoning [42], offering practical private queries on public data [47], and optimizing search performance within memory hierarchy [9].

In order to improve the performance of query services for storage systems, efficient hash structures have been widely used. In general, each hash function maps each item to a unique bucket in a hash table, which needs to support constant-scale and real-time access. However, items may be hashed into the same bucket by hash functions, called **hash collisions**. Due to the use of efficient open-addressing design, cuckoo hashing [38] is able to mitigate hash collisions with amortized constant-time insertion overhead and lookup consumption to meet the throughput needs of real-world applications. Unlike conventional hashing schemes that offer only one bucket for each item, the cuckoo hashing provides multiple (usually two in practice [11, 19, 37, 40]) candidate positions for each item to reduce the probability of hash collisions. To perform a lookup operation, at most two positions are probed, and the worst-case time is constant-scale, thus delivering high performance especially in terms of low-latency read and lookup operations [10, 16, 18, 20, 25, 31, 44]. However, to insert an item, the cuckoo hashing has to probe the two candidate buckets for finding an empty position. If an empty slot does not exist, recursive replacement operations are needed to kick items out of their current positions until a vacant bucket is found, which forms a **cuckoo path**. There exists a certain probability of producing an **endless loop**, which occurs after a large number of step-by-step kick-out operations and turn out to be an insertion failure, thus resulting in slow-write performance. The property of asymmetric reads and writes in the cuckoo hashing becomes a potential performance bottlenecks for storage systems.

The endless loops not only lead to the slow-write operation, but also make storage systems unable to efficiently support **concurrent** operations on both reads and writes, which results in poor performance.

As the number of cores is increasing in modern processors, concurrent data structures are promising approaches to provide high performance for storage systems [13, 15, 21, 22, 43, 48, 50]. In general, locks are often utilized to ensure the consistency among multiple threads [4]. To mitigate the hash collisions for writes, most existing hash tables store items in a linked list with coarse-grained locks for entire tables [19], fine-grained locks for per bucket [2, 32] or Read-Copy-Update (RCU) mechanisms [35, 36, 46] for concurrency control. However, the coarse-grained locks for entire tables lead to poor scalability on multi-core CPUs due to the long lock time, and fine-grained per-bucket locks result in substantial resource consumption due to frequent locking and unlocking operations in a cuckoo path. RCU [34] works well for read-heavy workloads, but inefficiently for the workloads with more writes than reads. Moreover, the cuckoo hashing with per-bucket locks suffers from substantial performance degradations due to the occurrence of endless loops. The read operation has to wait for the write operation on the same bucket to complete and then release the lock before being executed. Hence, it is inefficient to frequently lock and unlock buckets during the long cuckoo paths of endless loops.

In order to offer a high-throughput and concurrency-friendly cuckoo hash table, we need to address two main challenges.

Poor Insertion Performance. Cuckoo hashing executes recursive replacing operations to kick items from their storage positions to the candidate positions for finding an empty bucket during an insertion procedure. Moreover, all efforts become useless when encountering an endless loop. To ensure the correctness of concurrency control, two continuous buckets in a path have to be locked for each kick-out operation. The frequent locking and unlocking on a cuckoo path will lead to high time overhead, which decreases the insertion performance.

Poor Scalability. The cuckoo path is possible to be very long in real-world applications. For example, the kick-out threshold is 500 in MemC3 [19], and thus the longest cuckoo path contains 500 buckets. All kick-out operations have to be completed in the buckets protected by the locks. Due to frequent use of locks to ensure consistency among multiple threads, the concurrent hash table results in poor scalability.

In fact, only insertion operations sharing the cuckoo path require locks for ensuring the consistency. Insertion operations through different cuckoo paths can be simultaneously executed. Based on this observation, we propose a lock-efficient concurrent cuckoo hashing scheme, named CoCuckoo. It leverages a directed pseudoforest containing several subgraphs to represent items' hashing relationship, which is further used to indicate the cuckoo paths of insertion operations. In the pseudoforest, each vertex corresponds to a bucket in the hash table, and each edge corresponds to an inserted item from its storage vertex to its backup vertex. In our CoCuckoo, the vertices corresponding to candidate positions of the path-overlapped items must be in the same subgraph. The path-overlapping can be interpreted that two or more cuckoo paths of items share the same nodes during insertion. In our design, each node only exists in a subgraph with a unique subgraph number. Hence, the operations on the path-overlapped nodes access the same subgraph. We leverage a graph-grained, rather than per-bucket, locking scheme to avoid potential contention. Once locking a subgraph number, all buckets with the same number cannot be accessed by different threads at the same time. If one thread intends to access a bucket, it first obtains the number of the subgraph to which the bucket belongs, to check if the subgraph number has been locked.

Specifically, we have the following contributions.

High Throughput. CoCuckoo not only retains cuckoo hashing's strength of supporting constant-scale lookups via open addressing, but also delivers high throughput by a graph-grained locking to support concurrent insertions.

Contention Mitigation. We optimize the graph-grained locking mechanism to pursue low lock overheads for different cases of insertions and release the locks as soon as possible to ease the contention. CoCuckoo is able to predetermine the insertion failures without the need of carrying out continuous kick-out operations, and thus avoids many unnecessary locking operations.

System Implementation. We have implemented all the components and algorithms of CoCuckoo. Moreover, we compared CoCuckoo with state-of-the-art and open-source scheme, *libcuckoo* [32], which offers multi-reader/multi-writer service.

2 Backgrounds

2.1 The Cuckoo Hashing

Cuckoo hashing [38] is an open-addressing technique with $O(1)$ amortized insertion and lookup time. In order to mitigate hash collisions, items can be stored in one of two buckets in a hash table. If one position is occupied, the item can be kicked out to the other [17, 26]. The frequent kick-out operations help items find empty positions for insertion with the costs of possible extra latency. On the other hand, we can definitely read the queried data in one of two hashed positions, thus obtaining constant-scale query time complexity.

Definition 1 ***Conventional Cuckoo Hashing.*** *Suppose that k is the number of hash functions, and S is a set of items. For the case of $k = 2$, conventional cuckoo hashing table H uses two independent and uniformly distributed hash functions h_1, h_2: $S \rightarrow \{0, \ldots, n-1\}$, where n is the size of the hash table. An item x can be stored in any of Buckets $h_1(x)$ and $h_2(x)$ in H, if being inserted successfully.*

The operation for inserting Item x proceeds by computing two hash values of Item x to find Buckets $h_1(x)$ and $h_2(x)$ that could be used to store the item. If either of the two buckets is empty, the item is then inserted into that bucket. Otherwise, an item is randomly chosen from the two candidate buckets and kicked out by Item x. The replaced item is then relocated to its own backup position, possibly replacing another item, until an empty bucket is found or a kick-out threshold is reached. The sequence of replaced items in an insertion operation is called a *cuckoo path*. For example, "$b \to k \to \phi$" is one cuckoo path to identify one bucket available to insert Item x as illustrated in Figure 1, which shows a standard cuckoo hash table with two hash functions. The start point of an edge (arrow) represents the actual storage position of an item, and the end point is the backup position. For instance, the bucket storing Item c is the backup position of Items a and n.

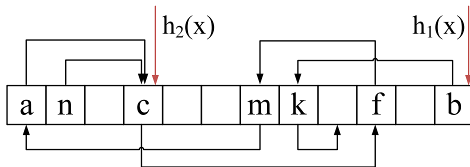

Figure 1: The conventional cuckoo hashing table.

A cuckoo graph is formed by considering each bucket in the hash table as a vertex and each item as an edge. The cuckoo graph can be transformed into a pseudoforest based on graph theory [29].

2.2 Pseudoforest Theory

A pseudoforest is an undirected graph where each vertex only corresponds to at most an edge, and each of maximally connected components, named **subgraphs**, has at most one cycle [7, 23]. The cycle formation starts from a vertex and returns to the vertex through connected edges. Namely, each subgraph in a pseudoforest has no more edges than vertices.

In order to clearly illustrate the direction of a cuckoo path in insertion operations, we extend the pseudoforest into a directed graph by adding the directions from storage positions of items to their backup positions. In the directed pseudoforest, each vertex corresponds to a bucket, and each edge corresponds to an inserted item from the storage vertex to its backup vertex. In the conventional cuckoo hash tables, each bucket stores at most one item, and thus each vertex in a directed pseudoforest has an outdegree of at most one. If the outdegree of a vertex is zero, the vertex corresponds to a vacant bucket, and the subgraph having the vertex contains no cycles, which is called **non-maximal subgraph**. Otherwise, if the outdegrees of all vertices are equal to one, the number of edges of the subgraph is equal to that of vertices, and thus the subgraph contains a cycle, which is a **maximal subgraph**. Any insertion into the subgraph containing a cycle leads to an endless loop [28]. Therefore, if the states of corresponding subgraphs are known before the item is inserted, the insertion result can be predetermined. Based on this property, we can accurately predetermine the occurrence of endless loops without the need of brute-force checking in a step-by-step way.

Figure 2a shows the corresponding pseudoforest of the cuckoo hash table before inserting Item x in Figure 1, which contains one maximal subgraph and one non-maximal subgraph. After inserting Item x, the two subgraphs are merged into a maximal subgraph, as shown in Figure 2b. In particular, after executing the kick-out operations during the insertion, the original vacant vertex becomes the storage position of Item k, and the vertex currently storing Item b becomes the backup position of Item k. The arrow between two vertices needs to be reversed.

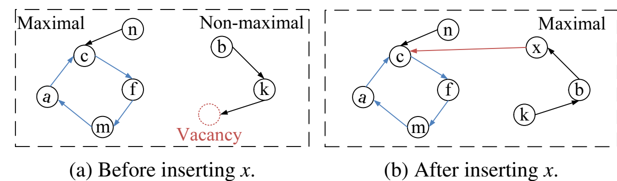

Figure 2: The directed pseudoforest.

In order to maintain the relationship of subgraphs in the pseudoforest, we assign a subgraph number to each bucket and its corresponding vertex, and hence the buckets with the same subgraph number belong to the same subgraph. However, as the subgraphs are merged during item insertion, the vertices with different subgraph numbers are merged into the same subgraph and need to be represented by the same subgraph number. Frequent updates to subgraph numbers of vertices cause severe insertion latency. In order to address this problem, we leverage **the disjoint-set data structure** [24] to maintain the relationship of subgraphs without updating the subgraph numbers.

2.3 The Disjoint-set Data Structure

In general, a disjoint-set data structure [24] is a tree-based structure that handles merging and lookup operations upon disjoint (non-overlapping) subsets, like our design goal. This structure offers near-constant-time complexity in adding new subsets, merging existing subsets, and determining if two or more elements exist in the same subset. Each element in the structure stores an *id*, and a parent pointer. If an element's parent pointer does not point to any other elements, this element is called the root of the tree and becomes the representative member of its subset. A subset may contain only one element. However, if the element has a parent, the element is part of the subset that is identified by uptracking the parents' chain until a representative element (without a parent) is found at the root of the tree.

Three operations can be performed efficiently on the disjoint-set data structure:

MakeSet(x) creates a subset of a new element x, which has a unique *id*, and a parent pointer to itself. The parent

pointer to itself indicates that the element is the representative member of its own subset. The *MakeSet* operation has $O(1)$ time complexity.

Find(x) follows the chain of parent pointers from a leaf element x up to the tree until it reaches the representative member of the tree to which x belongs. In order to make *Find* operations time-efficient, **path compression** operation is used to flatten the tree-based structure by allowing each element to point to the root whenever *Find* is performed. This is valid because each element accessed on the way to the root is part of the same subset. The resulting flatter tree not only speeds up the future operations on these elements, but also accelerates the operations that reference them.

Union(x,y) uses **Find(x)** and **Find(y)** to determine the roots of x and y. If the roots are distinct, the two corresponding trees are combined by attaching the root of one to that of the other, e.g., the root of the tree with fewer elements to the root of the tree having more elements.

The unique number of each subgraph in the directed pseudoforest is viewed as an element in the disjoint-set data structure. When a new subgraph with a unique number is generated, the *MakeSet* operation is called to generate a new corresponding subset. The *Find* operation is performed when we want to know if the subgraphs of two vertices belong to the same subgraph. Moreover, the *Union* operation is triggered when subgraphs are merged.

3 The CoCuckoo Design

The cost-efficient CoCuckoo improves throughput performance via a graph-grained locking to support concurrent insertions and lookups. CoCuckoo leverages a directed pseudoforest containing several subgraphs to represent items' hashing relationship, which is used to indicate the cuckoo paths in insertion operations. A subgraph consists of the vertices corresponding to buckets, as well as the edges corresponding to the inserted items from their storage positions to their backup positions. The disjoint-set data structure is used to maintain the relationship among subgraphs and stored in memory. Meanwhile, the pseudoforest is just a variant of the cuckoo hash table and is not stored. Figure 3 shows the framework of CoCuckoo. A key and its corresponding metadata are stored in each bucket of the hash table (**H_Table**). The metadata per bucket include the position of the value corresponding to the key (*v_pos*), and the subgraph number of the subgraph to which the bucket belongs (*sub_id*). The *sub_id*s are initialized to -1. Moreover, the disjoint-set data structure called **UF_Array** is described in Section 3.3.2.

Each candidate bucket of an item to be inserted into the hash table possibly corresponds to a vertex in the pseudoforest. If a bucket in the hash table does not correspond to any vertices in the pseudoforest, it means that this bucket has not been visited before and is not a candidate bucket for any inserted items. In general, this bucket corresponds to an *EMPTY* subgraph, and its *sub_id* is -1. Hence, an item

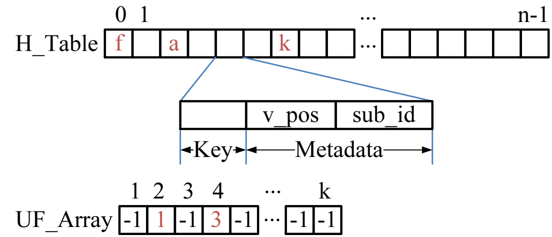

Figure 3: The CoCuckoo framework.

can be directly inserted into a bucket corresponding to an *EMPTY* subgraph. There are at most two *EMPTY* subgraphs for each item insertion due to the existence of two candidate positions. According to the number of corresponding *EMPTY* subgraphs, we classify item insertions into three cases, namely, *TwoEmpty*, *OneEmpty*, and *ZeroEmpty*, respectively showing 2, 1, and 0 *EMPTY* subgraphs.

Moreover, only insertion operations sharing the same cuckoo path require the locks for guaranteeing the correctness of concurrent insertions. Insertion operations through different cuckoo paths access different subgraphs, which can be simultaneously executed and have no lock contention. Based on this observation, CoCuckoo allows the vertices, which correspond to candidate positions of the path-overlapped items, to exist in the same subgraph. We leverage graph-grained locking to avoid potential collisions. These threads won't conflict as long as they manipulate different subgraphs. Most subgraphs are small enough as demonstrated in Figure 6, and hence only a few vertices are constrained at a time.

3.1 Intra-thread Operation

Items inserted into cuckoo hashing form a *cuckoo graph*, which is represented as a directed pseudoforest in our CoCuckoo. Each vertex in the pseudoforest corresponds to a bucket of the hash table and each edge corresponds to an item. An inserted item generates an edge from its actual storage position to its backup position. The pseudoforest reveals cuckoo paths of kick-out operations for item insertion. Hence, the directed pseudoforest can be used to track and exhibit path overlapping of items in advance to avoid potential collisions by a graph-grained locking.

3.1.1 The Case of *TwoEmpty*

When two candidate positions of an item have not yet been used and represented by any vertices in subgraphs of the pseudoforest, i.e., two *EMPTY* subgraphs, the item can be directly inserted into one bucket (the position hashed by the first function by default). Hence, the insertion needs to create a new subgraph, which is non-maximal and ends up with an empty vertex, as shown in Figure 4a to insert Items a, f, and k, respectively. To clearly show these cases, we leverage two hash tables in the following examples. Items hashed by the second function is inserted into the second hash table.

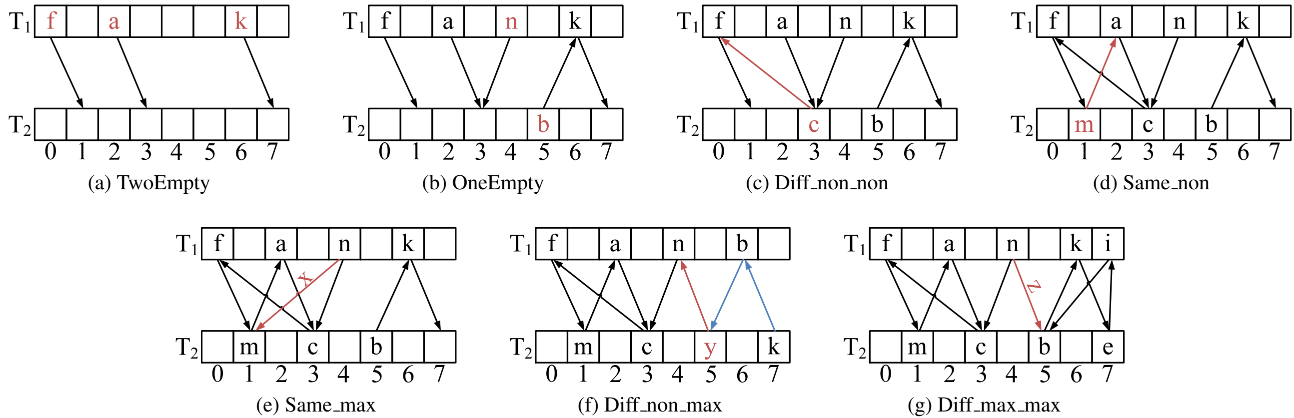

Figure 4: The cases of item insertions.

3.1.2 The Case of *OneEmpty*

One of two candidate buckets of an item corresponds to an existing vertex in the pseudoforest, and the other corresponds to an *EMPTY* subgraph, which will become a new vertex after inserting the item. As shown in Figure 4b, Items b and n can be directly inserted into Buckets $T_2[5]$ and $T_1[4]$ respectively due to available vacancy.

3.1.3 The Case of *ZeroEmpty*

Two candidate positions of an item correspond to two existing vertices in the pseudoforest, which exist either in the same subgraph or both subgraphs. Moreover, each subgraph is either maximal or non-maximal. According to the states and number of subgraphs, we classify the case of *ZeroEmpty* into four subcases.

Diff_non_non: If the vertices corresponding to two candidate positions of an item exist in two non-maximal subgraphs, the item can be successfully inserted into the hash table due to the existence of vacancies. The two subgraphs will be further merged, i.e., inserting Item c into Bucket $T_2[3]$, as shown in Figure 4c.

Same_non: When the two vertices are in the same non-maximal subgraph, there exists a vacant bucket for the item. It will be inserted into the hash table and the corresponding subgraph becomes maximal. For example, Item m is inserted into the hash table and we add an edge from Bucket $T_2[1]$ to Bucket $T_1[2]$. Hence the corresponding subgraph forms a loop, as shown in Figure 4d.

Max: If the two vertices exist in one maximal directed subgraph (named **Same_max**, e.g., Item x in Figure 4e), or two maximal subgraphs (named **Diff_max_max**, e.g., Item z in Figure 4g), no vacancies are available for the new item. The insertion fails even if executing many kick-out operations within a loop. Unlike it, CoCuckoo predetermines the failure in advance and store the item in temporary space (e.g., a stash) [16, 26].

Diff_non_max: One vertex exists in a maximal subgraph and the other is in a non-maximal subgraph in this case. There exists a vacant bucket for the item. The insertion will be successful after several kick-out operations. For example, as shown in Figure 4f, the cuckoo path is "$b \rightarrow k \rightarrow \phi$" when inserting Item y. The two subgraphs are further merged into a new maximal directed subgraph after the insertion.

3.2 Inter-thread Synchronization Optimization

Each thread gets a request from its own task queue each time. Only insertion operations sharing the same cuckoo path require locks for guaranteeing the correctness of concurrent insertions. If two or more insertion requests are path-overlapped, the corresponding threads access to the same subgraph. Hence, the threads that visit the same subgraph have to wait for locks due to guaranteeing the correctness, and the threads that visit different subgraphs can be executed concurrently. To further alleviate the lock contention and overheads, we optimize the operations on different cases of insertions to release locks as soon as possible.

Algorithm 1 shows the steps involved in the insertion of Item x. First, we predetermine the insertion failure if the case is *MAX*, and then lock the subgraphs as shown in Algorithm 2. Second, we determine the case of item insertion and execute corresponding insertion operations.

3.2.1 The Case of *TwoEmpty*

The corresponding thread allocates a new subgraph number, which is locked and assigned to the two *EMPTY* subgraphs. The subgraph number is used to identify a unique subgraph. Since the buckets of *EMPTY* subgraphs can be accessed without acquiring locks, other threads may occupy these buckets before the thread assigns a subgraph number to them. We utilize two atomic subgraph number assignment operations (based on *Compare-And-Swap* instructions) for consistency. If both atomic operations are successful, the two *EMPTY* subgraphs are assigned the same subgraph number. The item can be inserted directly into one of its candidate buckets without kick-out operations. Finally, a non-maximal subgraph is produced. Once the two *EMPTY* subgraphs are

Algorithm 1 Insert(Item x, Hash a, Hash b)

```
1: /*a and b are two indexes of Item x's candidate positions*/
2: if SG_a is maximal && SG_b is maximal then
3:     Return; /*Failure predetermination*/
4: end if
5: LockGraphs(a,b);
6: Result ← False;
7: if SG_a and SG_b are EMPTY then
8:     Result ← InsertTwoEmpty(x,a,b);
9: else if SG_a is EMPTY || SG_b is EMPTY then
10:    if SG_a is EMPTY then
11:        Result ← InsertOneEmpty(x,a,b);
12:    else
13:        Result ← InsertOneEmpty(x,b,a);
14:    end if
15: else
16:    if SG_a is maximal && SG_b is maximal then
17:        Result ← InsertMax(x,a,b);
18:    else if SG_a is non-maximal && SG_b is non-maximal then
19:        if SG_a == SG_b then
20:            Result ← InsertSameNon(x,a,b);
21:        else
22:            Result ← InsertDiffNonNon(x,a,b);
23:        end if
24:    else if SG_a is non-maximal then
25:        Result ← InsertDiffNonMax(x,a,b);
26:    else
27:        Result ← InsertDiffNonMax(x,b,a);
28:    end if
29: end if
30: if Result == False then
31:    Goto 2;
32: end if
```

Algorithm 2 LockGraphs(Int a, Int b)

```
1: while True do
2:     if SG_b < SG_a then
3:         SWAP(SG_a,SG_b);
4:     end if
5:     if SG_a is EMPTY then
6:         Return;
7:     else
8:         /*Lock subgraphs in order to avoid deadlocks*/
9:         LOCK(SG_a);
10:        if SG_a ≠ SG_b then
11:            LOCK(SG_b);
12:        end if
13:    end if
14:    if SG'_a == SG_a&&SG'_b == SG_b then
15:        /*SG'_a and SG'_b are subgraph numbers after locking*/
16:        break;/*Double check*/
17:    else
18:        UNLOCK(SG_a);
19:        if SG_a ≠ SG_b then
20:            UNLOCK(SG_b);
21:        end if
22:    end if
23: end while
```

found with different subgraph numbers, the atomic operations fail, and the *Insert* operation has to be re-executed as shown in Algorithm 3.

Algorithm 3 InsertTwoEmpty(Item x, Hash a, Hash b)

```
1: LOCK(SG); /*The corresponding subgraph number*/
2: if AtomicAssign(&SG_a,SG)&&AtomicAssign(&SG_b,SG) then
3:     DirectInsert(x,Bucket[a]);/*Insert directly into B[a]*/
4:     Tag[SG] ← NON_MAX_MARK;
5:     UNLOCK(SG);
6:     Return True;
7: else
8:     UNLOCK(SG);
9:     Return False;
10: end if
```

3.2.2 The Case of *OneEmpty*

One candidate bucket of the item to be inserted corresponds to an *EMPTY* subgraph, which is vacant. The other candidate bucket of the item corresponds to an existing vertex of a subgraph. The item can be directly inserted into the *EMPTY* subgraph, no matter what the state of another subgraph is. Hence, we utilize two atomic operations without locks to execute the insertion operation. The *Insert* operation atomically assigns the number of the existing subgraph to the new vertex, and inserts the item into the new vertex by an atomic write operation as shown in Algorithm 4. Moreover, the state of the final merged subgraph depends on the pre-merged subgraph without changes. If the vertex has been already occupied by another item, the subsequent atomic write operation of insertion fails, which means that the original *EMPTY* subgraph has been merged with another subgraph and becomes not empty. The *Insert* operation has to be restarted, and the insertion case becomes *ZeroEmpty*. Hence, the insertion protocol ensures forward progress and doesn't produce repeated atomic operation failures.

Algorithm 4 InsertOneEmpty(Item x, Hash a, Hash b)

```
1: if AtomicAssign(&SG_a,SG_b) then
2:     if AtomicInsert(x,Bucket[a]) then
3:         Return True;
4:     else
5:         Return False;
6:     end if
7: else
8:     Return False;
9: end if
```

3.2.3 The Case of *ZeroEmpty*

Diff_non_non: The *Insert* operation locks the two corresponding non-maximal subgraphs, inserts the item after several kick-out operations, and then releases the lock after the

two subgraphs have been merged as shown in Figure 5. The merged subgraph is non-maximal, which has a vacant bucket for another item to be inserted.

Algorithm 5 InsertDiffNonNon(Item x, Hash a, Hash b)

1: $Kick\text{-}out(x, Bucket[a])$; /*Enter from $B[a]$*/
2: $Union(SG_a, SG_b)$;
3: $UNLOCK(SG_a)$;
4: $UNLOCK(SG_b)$;
5: Return $True$;

Same_non: The merged subgraph is maximal after the item is inserted, and no vacancies are available for other items to be inserted. Hence, to ease the lock contention, our optimization is to lock the corresponding subgraph and mark it to be maximal, and unlock the subgraph before executing kick-out operations of the insertion, as shown in Algorithm 6.

Algorithm 6 InsertSameNon(Item x, Hash a, Hash b)

1: $Tag[SG] \leftarrow MAX_MARK$;
2: $UNLOCK(SG)$;
3: $Kick\text{-}out(x, Bucket[a])$;/*Enter from $B[a]$*/
4: Return $True$;

Max: No vacancies are available in the corresponding subgraphs for items in this case, and the *Insert* operation will always walk into a loop and be predetermined to a failure. We just unlock the corresponding subgraph(s) without any other operations, as shown in Algorithm 7.

Algorithm 7 InsertMax(Item x, Hash a, Hash b)

1: $UNLOCK(SG_a)$;
2: **if** $SG_a \neq SG_b$ **then**
3: $\quad UNLOCK(SG_b)$;
4: **end if**
5: Return $True$;

Diff_non_max: There exists only one vacancy for an item, and the state of the merged subgraph is predetermined to be maximal after the item is inserted in the case. Other threads accessing the subgraph first obtain the subgraph state and will not insert items when the subgraph is maximal. For the *Insert* operation, the corresponding thread obtains the lock of the non-maximal subgraph and marks it to be maximal, and then releases the lock immediately. The insertion with several kick-out operations and the merging operation of two subgraphs complete outside the lock, as shown in Algorithm 8.

Algorithm 8 InsertDiffNonMax(Item x, Hash a, Hash b)

1: $Tag[SG_a] \leftarrow MAX_MARK$;
2: $UNLOCK(SG_a)$;
3: $UNLOCK(SG_b)$;
4: $Kick\text{-}out(x, Bucket[a])$;/*Enter from $B[a]$*/
5: $Union(SG_a, SG_b)$;
6: Return $True$;

3.3 Subgraph Management

3.3.1 Subgraph Number Allocation

We allocate each newly created subgraph a new number for identification. Each subgraph number represents a unique subgraph, and each vertex of the subgraph records the number of its corresponding bucket. All threads allocate subgraph numbers concurrently. When a thread requests a subgraph number, we lock the number generator. Other threads have to wait for unlocking, thus increasing the response time of requests and possibly becoming performance bottleneck. Moreover, we only need to confirm that the subgraph numbers are unique without the need of continuity. In order to decrease the response time without locks and ensure consistency of subgraph number allocation, we leverage a simple modular function to compute the subgraph numbers for all threads. In the modular function, the modulus is the total number of threads p, and the remainder is the number of each thread r. Hence, the subgraph number allocated by each thread is $n = kp + r$, while the parameter k is an accumulator. A subgraph number generator serves for a thread. For example, in the 8-thread CoCuckoo, the subgraph numbers allocated by $Thread$ 2 is 2, 10, 18, and so on. Hence, we allocate subgraph numbers for each thread in order, and then add one to the accumulator k after creating a new subgraph.

3.3.2 Subgraph Merging

When vertices corresponding to two candidate positions of an inserted item exist in two subgraphs, they are merged after item insertion. To avoid exhaustively searching for all vertex members of corresponding subgraphs and updating their subgraph numbers (sub_ids in metadata) when subgraphs are merged, a tree-based data structure called **disjoint-set data structure** is utilized to maintain the relationship between subgraphs. Each node in the tree stores a subgraph number and a parent pointer. In order to avoid deadlocks, we always merge the subgraphs with bigger numbers into that with smaller numbers. After subgraphs are merged, the parent pointer of the node with bigger number points to the node with smaller number, which becomes the representative of the tree. The newly merged subgraph is possible to be merged again with others. Finally, the subgraph number of the tree's root represents the number of the subgraph merged from all prior subgraphs.

The $Union$ operation is called when merging subgraphs is needed. $Union(sub_id1, sub_id2)$ uses $Find(sub_id1)$ and $Find(sub_id2)$ to determine the roots of the nodes with sub_id1 and sub_id2. If the roots are distinct, the trees are combined by attaching the tree whose root has the bigger subgraph number to the root of the smaller one. Furthermore,

$Find(sub_id)$ follows the chain of parent pointers from a leaf node with sub_id1 up to the tree until it reaches a root node, whose parent is itself. The subgraph number stored in the root node is the actual subgraph number of all nodes in the chain.

An array **UF_Array** is used to implement the disjoint-set data structure. The length of the array is the number of subgraphs, and the indexes of the array indicate the subgraph numbers. The values of elements are initialized to -1, and updated to the indexes of their parents after merging. Specifically, there are two cases for the value of an element in the array: (1) If the value of an element is equal to -1, the subgraph number represented by the index is a root node; (2) If the value of an element is larger than 0, the subgraph number corresponding to the value is the parent node of the subgraph number represented by the index. As shown in Figure 3, $UF_Array[1] = -1$ means that the subgraph number 1 is the root node; $UF_Array[2] = 1$ means that the subgraph number 1 is the parent node of the subgraph number 2. Therefore, all buckets with subgraph number 2 have the actual subgraph number of 1.

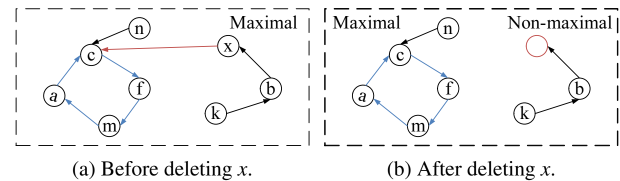
3.3.3 Item Deletion and Subgraph Splitting

For an item, when the vertex of the storage position is not on a cycle, the corresponding subgraph is split into two subgraphs when deleting the item [6]. To avoid reconstructing the hash table and updating *sub_ids* of all buckets, the *re_edge* information in metadata per bucket is added to record the related edges of the bucket in the corresponding subgraph. When deleting Item *x*, we first compute the two corresponding buckets of Item *x*, i.e., determine the storage and backup positions. Item *x* is deleted from the storage bucket in the hash table, and the corresponding edge is deleted from the *re_edge* in two buckets. All related edges and buckets are then recursively searched from the *re_edge* in the candidate buckets. Finally, all searched buckets are updated with a new *sub_id*. In order to optimize the delete operation after splitting subgraphs, all buckets in the subgraph containing the storage position of Item *x* do not need to update their *sub_ids*. Their actual *sub_ids* can be searched by UF_Array. The thread that performed the delete operation acquires the lock of the corresponding subgraph until the operation completes. Figure 5 shows an example of splitting subgraph when deleting Item *x*. The backup position of Item *x* (namely, the storage position of Item *c*) is found by hash computation, and all related nodes in the left subgraph are iteratively searched by the *re_edge* information in the metadata of related buckets. We then update all *sub_id*s of searched related buckets in hash tables.

4 Performance Evaluation

4.1 Experimental Setup

The server used in our experiments is equipped with an Intel 2.4GHz 16-core CPU, 24GB DDR3 RAM, and 2TB hard disk. The L1 and L2 caches of the CPU are 32KB and 256KB, respectively. The programming language of all functional components of CoCuckoo scheme is C/C++. Moreover, multi-threading is implemented by the *pthread* via a *pthread.h* header and a thread library.



(a) Before deleting *x*. (b) After deleting *x*.

Figure 5: An example of splitting subgraph.

Workloads: The widely-used industry standard in evaluating the performance of key-value stores is the *Yahoo! Cloud Serving Benchmark* (YCSB) [14]. We use this benchmark to generate five workloads, each with different proportions of *Insert* and *Lookup* queries to represent real-world scenarios, as shown in Table 1. Especially, the INS workload is the worst case for cuckoo hashing (resulting in a nearly full table), and the remaining four workloads are common cases with *Lookup* operations. Moreover, each workload has two million key-value pairs. Each key in workloads is 16 bytes and each value is 32 bytes for most experiments (except in Section 4.2.4 that uses various sizes for evaluating the effect of size on throughput). The default cuckoo hash table has $2^{21} = 2,097,152$ slots, which consumes about 96MB memory in total.

Table 1: Distributions of different queries in each workload.

Workload	Insert	Lookup
Insert-only (INS)	100%	0%
Insert-heavy (IH)	75%	25%
Insert-lookup balance (ILB)	50%	50%
Lookup-heavy (LH)	25%	75%
Lookup-only (LO)	0%	100%

Threads: In our experiments, there are five settings for the number of threads, including a single thread, 4, 8, 12, and 16 threads, to evaluate the concurrency performance.

Comparisons: We compare our proposed CoCuckoo with open-source *libcuckoo* [3, 32], which is optimized to offer multi-reader/multi-writer service through spin_locks based on concurrent multi-reader/single-writer cuckoo hashing used in *MemC3* [19]. Since *libcuckoo* has multiple slots per bucket to mitigate collisions [19,39,41,51], we also evaluate the performance of 2-, 4-, 8- and 16-way *libcuckoo*. We follow the default configuration of *libcuckoo* in the original paper [32] and only adjust the numbers of threads and slots to facilitate fair comparisons in concurrency. The results of CoCuckoo and *libcuckoo* come from in the same experimental environment.

We focus on the performance improvements from our design in the context of workloads with concurrent insertions and lookups by measuring the throughput and latency of

multiple threads accessing the same hash table. In general, the request response on the cuckoo hashing table becomes slower as the load factor increases, since more items have to be moved [32]. Hence, we measure the throughput and latency for certain load factor intervals (from 0 to 80%), and average throughput and latency.

4.2 Results and Analysis

4.2.1 Lock Granularity

A graph-grained lock is used for concurrency control in our CoCuckoo. Since most subgraphs are small, the granularity of graph-grained locks is acceptable, which only constrain a very small number of buckets. We have measured the number of subgraphs in each size interval with Insert-only workload. Figure 6 demonstrates that most subgraphs are small. For example, 44.25% subgraphs contain only 3 vertices, and about 99% subgraphs contain no more than 10 vertices. Very few buckets are constrained once for ensuring the correctness of concurrency control of the multi-thread hash tables. We obtained identical experimental results under single-threaded and multi-thread conditions. The reason is that for given hash functions, the hash location of each item is determined. Based on hashed locations, the cuckoo subgraphs are also determined, except the difference of the order in which the vertices are added into subgraphs due to the concurrency of threads.

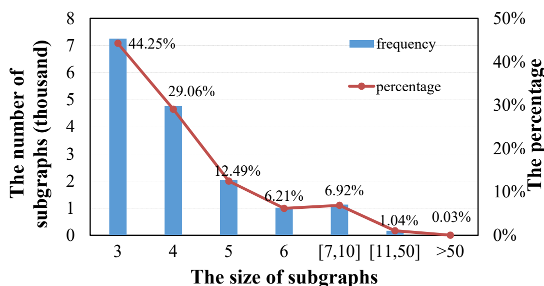


Figure 6: The number of subgraphs in each size interval.

4.2.2 Throughput

This subsection evaluates the average throughput under an increasing number of threads with five workloads and throughput at different table occupancies with Insert-only workload. The throughput is the average number of requests completed per second.

Figure 7 shows the average throughput under an increasing number of threads with five different workloads. The average throughput increases with the increasing number of threads in all cuckoo hashing tables, due to the multi-thread acceleration. In *libcuckoo*, the lower associativity improves the throughput, because each lookup checks fewer slots in order to find the key, and each insertion needs to probe fewer slots in a bucket for an empty slot. In 4-way *libcuckoo*, each *Lookup* requires at most two cache-line reads to find the key and one more cache-line read to obtain the value. Furthermore, in 16-way *libcuckoo*, each *Lookup* requires at most eight cache-line reads to find the key and one more cache-line read to obtain the value. With the increasing number of threads, we observe that CoCuckoo significantly increases the average throughput over *libcuckoo* by 50% to 130% as shown in Figure 7f. In particular, the growth rate is defined as the throughput growth ratio of CoCuckoo relative to 2-way *libcuckoo*.

Figure 8a illustrates that the impact of load factors on 16-thread cuckoo hashing throughput for Insert-only workload. With the increase of load factors, the throughput decreases, since each *Insert* operation has to probe more buckets for finding an empty slot, and requires more item replacements to insert the new item. The *libcuckoo* utilizes *Breadth-First Search* (BFS) to find an empty slot for item insertion, and the path threshold is 5 in open-source implementation [3]. In 1-way *libcuckoo*, the threshold is reached at lower load factor, and expensive rehashing operations are executed, which results in poor performance. However, a higher load factor (more than 0.65) results in performance decrease in terms of throughputs of CoCuckoo. We argue that as the load factor increases, the subgraph merge operations become more frequent, thus leading to the decreasing number of subgraphs and the increasing number of vertices included in a single subgraph. Hence, more vertices are constrained by one thread that handles the *Insert* operation due to the graph-grained locking. Compared with *libcuckoo*, the proposed CoCuckoo obtains significant performance improvements in terms of throughputs.

4.2.3 Predetermination for Insertion

Table 2 shows the fractions of all cases with different workloads of containing *Insert* operations in 16 threads. In each workload, the two cases of *TwoEmpty* and *OneEmpty* account for a large proportion, which means that most insertion operations probe new and empty buckets, and add new vertices into corresponding subgraphs in the pseudoforest. Hence, with executing these insertion operations, the threads leverage short-term (*TwoEmpty*) or no (*OneEmpty*) locks the shared buckets, which alleviates the lock contention and further improves the throughput of CoCuckoo. The *Max* case occurs in INS and IH workloads, which means the proposed CoCuckoo predetermines insertion failures and releases locks without any kick-out operations to ease the contention.

4.2.4 Different Key Sizes

All prior experiments used the workloads with 16-byte keys and 32-byte values. We further evaluate the average throughput of cuckoo hash tables with different key sizes at the load factor of 0.8, as shown in Figure 8b- 8f.

In each figure, we show the average throughput, as the key size increases from 8 bytes to 64 bytes with Insert-only workload. The throughput decreases, as the key size increases due to the increased *String_copy* and *String_comp* overheads, as well as memory bandwidth overhead. More-

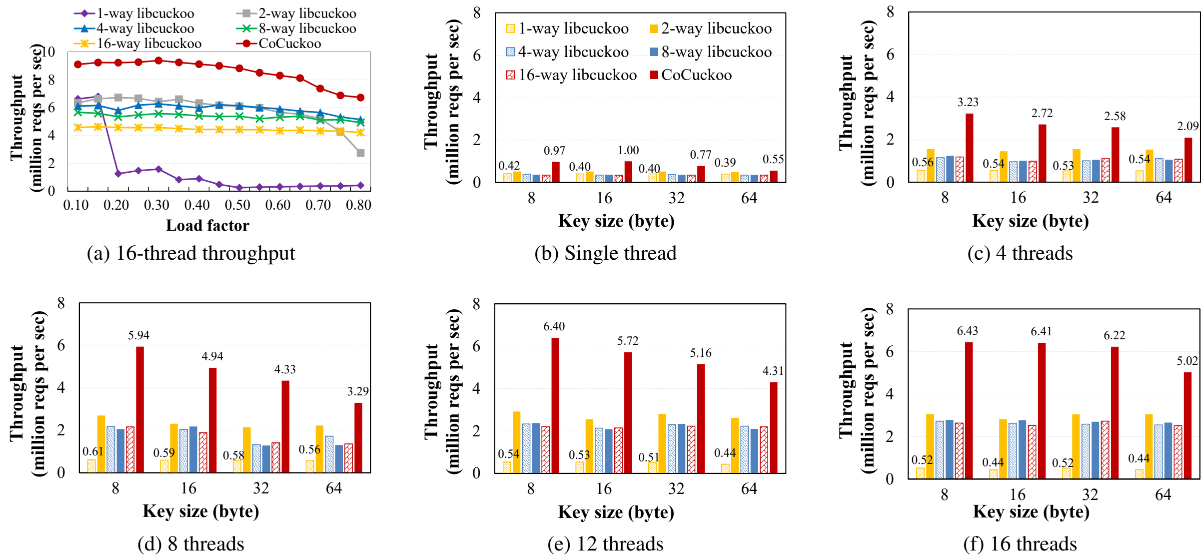
Workloads	TwoEmpty	OneEmpty	Same_non	Max	Diff_non_non	Diff_non_max
Insert-only	25.673%	37.9628%	0.0003%	13.9802%	13.1447%	9.239%
Insert-heavy	32.9343%	40.4907%	0.0004%	3.5921%	16.7513%	6.2312%
Insert-lookup balance	44.675%	39.6011%	0.0002%	0%	15.7235%	0.0002%
Lookup-heavy	64.4448%	30.1658%	0%	0%	5.3894%	0%



(a) 16-thread throughput (b) Single thread (c) 4 threads

(d) 8 threads (e) 12 threads (f) 16 threads

Figure 8: The throughput in different table occupancies and sizes of keys with Insert-only workload.

over, our concurrent cuckoo hashing becomes much less effective with large keys. For example, in the case of 16 threads, the throughput of CoCuckoo is 6.43 million requests per second with 8-byte keys, which is 135% higher than 4-way *libcuckoo*. The throughput of CoCuckoo is only 95% higher than 4-way *libcuckoo* with 64-byte keys. Similarly, hyperthreading also becomes much less effective with larger keys. For example, with 64-byte keys, the 4-thread throughput of CoCuckoo is 2.09 million requests per second, 8-thread throughput is more than 57% higher than 4-thread throughput, but 16-thread throughput is only 50% higher than 8-thread throughput. In order to support large-size keys, the full keys and values can be stored outside the table and referenced by a pointer, which possibly damages lookup performance. A null pointer indicates that the bucket is unoccupied.

4.2.5 Extra Space Overhead and Impact

Extra space overhead comes from the auxiliary structure of CoCuckoo, which includes two parts. One is the UF_Array to maintain the relationship among subgraphs. The other is the *sub_id* (subgraph number) stored in each bucket of the cuckoo hash table. Specifically, the UF_Array length is the number of subgraphs, and the indexes of the array indicate the subgraph numbers. The maximum number of subgraphs is equal to that of buckets in hash tables. The subgraph number is an *Int* type data in our implementation, which is usually 4 bytes in currently compilers (e.g., GCC). For subgraph numbers, the *sub_id* is stored in each bucket as metadata.

The default cuckoo hash table has 2^{21} slots. Therefore, the extra space overhead is totally $2^{21} * (4+4)B = 16MB$, which is deterministic and very small, compared with current memory capacity. Moreover, the pseudoforest is the theoretical transformation form of the cuckoo hash table, which is not stored in memory. In essence, we leverage acceptable space overhead to obtain significant performance improvements, which is a suitable trade-off. Moreover, in order to examine its impact upon system performance, we evaluate the throughput with the extra space through the Insert-only workload. To facilitate fair comparisons, we define the identical space available for both *libcuckoo* and CoCuckoo. As shown in Figure 9, we observe that CoCuckoo increases the throughput over 2-way *libcuckoo* by 73% to 159%, which is comparable to 75%-150% in Figure 7a in Section 4.2.2, thus exhibiting little impact.

We also evaluate the average execution time per request. As shown in Figure 10, the average time per request in 16-thread CoCuckoo is $1.66\mu s$, which is much shorter than $16.37\mu s$ in *libcuckoo*. Frequent rehash operations occur during the item insertion of 1-way *libcuckoo*, resulting in longer insertion time.

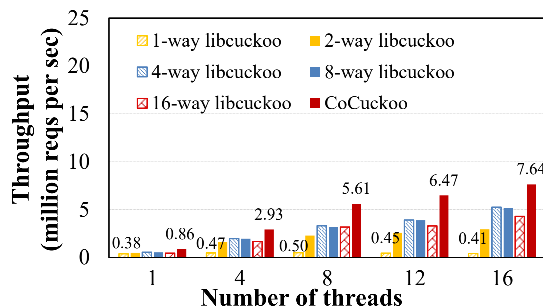


Figure 9: The average throughput with the same space overhead at the load factor of 0.8.

4.2.6 Deletion Latency

The *re_edge* information in metadata per bucket is included for supporting deletion. We evaluate the impact of deletion on performance by measuring request latency. The latency is defined as the time required to be executed in the concurrent program operation per request except the time in a serial program operation. Specifically, for a request, the latency is equal to the execution time of a thread in a concurrent program minus the time it consumes in a serial program. We use the YCSB benchmark to generate two workloads: (1) 5% *Delete*: 95% *Insert* and 5% *Delete* requests; (2) 10% *Delete*: 90% *Insert* and 10% *Delete* requests, each with one million key-value pairs with deletion.

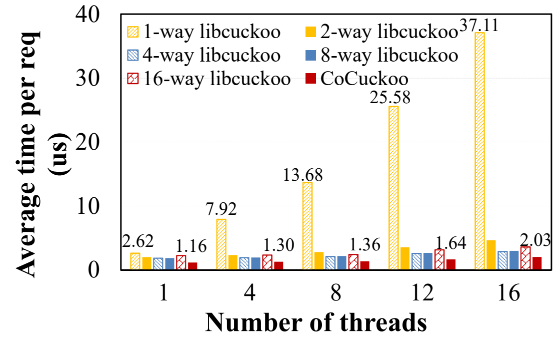

Figure 10: The average time per request with the same space overhead.

Figure 11 shows the average request latency of CoCuckoo with six workloads containing *Insert* and *Delete* operations. With the increasing number of threads, the average latency increases due to more intense lock contentions. The time waiting for locks increases with the increasing number of threads. For example, with Insert-only workload, the single-thread latency is $1.16\mu s$ per request, 8-thread latency is 2.6% longer than single-thread latency, and 16-thread latency is 50.0% longer than 8-thread latency. However, with the same number of threads, the average latency of different workloads incurs slight changes. Deletions are generally executed within locks, which exacerbates lock contentions. The latency of *Delete* is similar to that of *Insert* and larger than that of *Lookup*.

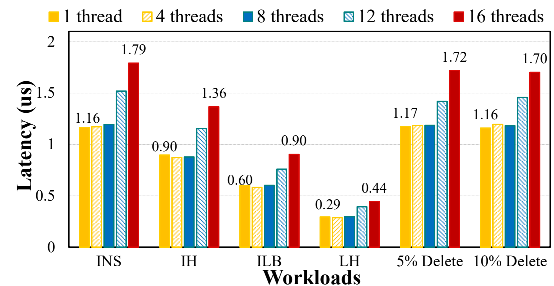

Figure 11: Average latency in different workloads.

Figure 12 illustrates the impact of load factors on latency performance of CoCuckoo with 5% *Delete*. As the load factor increases, there is a slight decrease in latency. Due to our optimization in Section 3.2.2, the average latency of Case *OneEmpty* is smaller than that of Case *TwoEmpty*. The proportion of Case *OneEmpty* increases while the proportion of Case *TwoEmpty* significantly decreases as the load factor increases. Hence, the overall latency decreases. In the meantime, due to appropriate load factors, the decrease of request latency is slow. For example, 16-thread latency is $1.73\mu s$ at

a load factor of 0.10 for the hash table, and 1.68μs at a load factor of nearly 0.50, which is only 2.9% smaller than that at a load factor of 0.10.

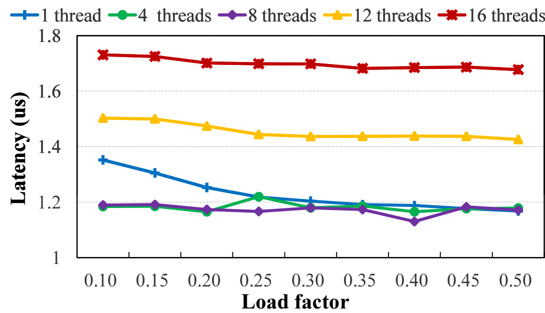

Figure 12: The latency at different table occupancies with 5% *Delete*.

5 Related Work

Performance-constrained single-thread hash tables. The Google's *dense_hash_map*, which is available in the Google SparseHash [1] library, supports fast lookup services. The dense hash uses open addressing with internal quadratic probing and achieves space efficiency for extremely high speeds. Moreover, this table stores items in a single large array and maintains a maximum 0.5 load factor by default.

Horton table [11] is an enhanced bucketized cuckoo hash table for reducing the number of CPU cache lines that are accessed in each lookup, thus achieving higher throughput. Most items are hashed by only a single function and therefore are retrieved by accessing a single bucket, namely, a single cache line. For negative lookups, item remapping enables low access costs to access one cache line.

SmartCuckoo [45] is a cost-efficient cuckoo hash table for accurately predetermining the status of cuckoo operations and the occurrence of endless loops. A directed pseudoforest representing the hashing relationship is utilized to track item placements in the hash table, and further avoid walking into an endless loop.

However, the performance of these hash tables does not scale with the number of cores in the processor, due to only a single thread permitted in execution, which suffer from the performance bottleneck of slow writes in storage systems. Unlike them, the design goal of our CoCuckoo is to efficiently support concurrent operations and deliver high performance in storage systems via concurrency-friendly hash tables.

High-performance concurrent hash tables. *Relativistic hash table* [46] is the data structure that supports shrinking and expanding while allowing concurrent, wait-free and linearly scalable lookups. The proposed resize algorithms reclaim memory as the number of items decreases, and enable Read-Copy Update (RCU) [34–36, 46] hash tables to maintain constant-scale performance as the number of item increases, without delaying or disrupting readers.

MemC3 [19] is designed to provide caching for read-mostly workloads and leverages the optimistic cuckoo hashing, which supports multiple readers without locks and a single writer. Instead of moving "items" forward along the cuckoo path, the cuckoo hashing used in *MemC3* moves "vacancies" backwards along the cuckoo path. The backward method ensures that an item can always be found by a reader.

The *libcuckoo* [32] redesigns *MemC3* to minimize the size of the hash table's critical sections and allow for significantly increased parallelism, which supports two concurrency control mechanisms, i.e., fine-grained locking and hardware transactional memory.

These schemes are dedicated to improve lookup performance and however fail to work well for tables with more insertion than lookup operations due to the occurrence of hash collisions and endless loops. Our proposed CoCuckoo focuses on write-heavy workloads for supporting concurrent insertions and lookups.

Moreover, CoCuckoo currently addresses the performance bottleneck for cuckoo hashing with two hash functions. The setting of more than two hash functions would significantly increase operation complexity [16,52], which can be reduced to two using techniques such as double hashing [27].

6 Conclusion

Most existing concurrent cuckoo hash tables are used for read-intensive workloads and fail to address the potential problem of endless loops during item insertion. We proposed CoCuckoo, an optimized concurrent cuckoo hashing scheme, which represents cuckoo paths as a directed pseudoforest containing multiple subgraphs to indicate items' hashing relationship. Insertion operations sharing the same cuckoo path need to access the same subgraph, and hence a lock is needed for ensuring the correctness of concurrent operations. Insertion operations accessing different subgraphs enable simultaneous execution. CoCuckoo classifies item insertions into three cases and leverages a graph-grained locking mechanism to support concurrent insertions and lookups. We further optimize the mechanism and release locks as soon as possible to mitigate the contention for pursuing low lock overheads. Extensive experiments using the YCSB benchmark demonstrate that the proposed CoCuckoo achieves higher throughput performance than state-of-the-work scheme, i.e., *libcuckoo*.

Abstract

With rising network rates, cloud vendors increasingly deploy FPGA-based SmartNICs (F-NICs), leveraging their *inline* processing capabilities to offload hypervisor networking infrastructure. However, the use of F-NICs for *accelerating general-purpose server applications in clouds* has been limited.

NICA is a hardware-software co-designed framework for inline acceleration of the application data plane on F-NICs in multi-tenant systems. A new *ikernel* programming abstraction, tightly integrated with the network stack, enables application control of F-NIC computations that process *application* network traffic, with minimal code changes. In addition, NICA's virtualization architecture supports fine-grain time-sharing of F-NIC logic and provides I/O path virtualization. Together these features enable cost-effective sharing of F-NICs across virtual machines with strict performance guarantees.

We prototype NICA on Mellanox F-NICs and integrate ikernels with the high-performance VMA network stack and the KVM hypervisor. We demonstrate significant acceleration of real-world applications in both bare-metal and virtualized environments, while requiring only minor code modifications to accelerate them on F-NICs. For example, a transparent key-value store cache ikernel added to the stock `memcached` server reaches 40 Gbps server throughput (99% line-rate) at 6 µs 99th-percentile latency for 16-byte key-value pairs, which is 21× the throughput of a 6-core CPU with a kernel-bypass network stack. The throughput scales linearly for up to 6 VMs running independent instances of `memcached`.

1 Introduction

SmartNICs with integrated FPGAs (*F-NICs*) [19, 68, 89, 119] are an appealing platform for accelerating I/O intensive network applications. They have been increasingly deployed in data centers and public clouds [33, 66], e.g., in each MS Azure server, enabling line-rate throughput and low, predictable latency at high power efficiency [33]. Many hardware vendors, including Intel, have already announced F-NICs in their future offerings [98].

Data-center F-NICs are used mainly to accelerate infrastructure tasks, such as network functions [61, 72, 80, 119] and software-defined networking [33, 66]. These tasks leverage the F-NIC's *inline processing* capabilities, where data is processed while being transferred between the host and the network, without CPU involvement. In addition, F-NICs are often repurposed as standalone FPGAs running complete applications, e.g., search or deep learning [20, 24, 60, 86].

This paper explores new acceleration opportunities emerging from the growing deployment of F-NICs in clouds, beyond infrastructure tasks and monolithic applications. We seek to leverage F-NICs for inline acceleration of data plane processing in network-intensive applications. For example, F-NICs may run datacenter tax tasks, such as deserialization, hashing, and authentication, which reportedly consume over a quarter of the CPU cycles in data centers [48]. An F-NIC may serve as an extra caching layer for key-value stores, responding directly in case of a hit and eliminating the CPU involvement. We show, for example, that this architecture achieves near line-rate throughput (40 Gbps) for stock `memcached` (§6.2.1). Promising results for application-specific traffic steering, packet transformation, and network stack offloading have been reported in prior work [50, 83]. We discuss these and other applications in §3.

Unfortunately, building such F-NIC-accelerated applications today is hard. First, there are **no adequate operating system abstractions** for inline acceleration of general-purpose applications on F-NICs. Such abstractions should associate F-NIC tasks with the application process, and they should provide well-defined execution boundaries and isolated per-task state while supporting easy integration of F-NIC functionality with the application logic. OpenCL and CUDA provide general lookaside acceleration support, but they are a poor match for F-NICs because they require explicit kernel invocation and data transfers that are irrelevant for the inline processing scenario. Floem [83] provides language-level constructs to accelerate applications on SmartNICs, but it targets CPU-based rather than FPGA-based SmartNIC architectures, and requires application refactoring to use its data

flow model, complicating acceleration of legacy workloads. SmartNIC-accelerated networking frameworks such as AccelNet, eBPF-XDP, and DPDK rte_security [33, 39, 84] are domain specific and lack application-level abstractions. Systems for data plane acceleration, e.g. P4 and FlexNIC [13, 50], expose packet-level match-action rules for F-NIC management, but lack abstractions for application-level semantics.

Second, F-NICs provide **no virtualization support**, preventing their sharing among cloud tenants. Existing virtualization mechanisms for FPGAs [18, 23, 34, 51, 101, 118] and GPUs [49, 73] rely on space partitioning or coarse-grain time sharing of the compute fabric. The former, however, results in hardware underutilization [51, 112, 116], whereas the latter may affect processing latency due to slow context switching and FPGA reconfiguration times [49, 51, 73, 91], making it unsuitable for latency-sensitive tasks. More fundamentally, F-NICs lack *I/O path virtualization* to isolate and protect per-application I/O across shared buses between the network, the FPGA and the host CPU. Thus, current F-NICs cannot guarantee performance isolation for co-located applications.

We introduce **NICA**, a system for FPGA-based **NIC** Server **A**cceleration. NICA introduces new software abstractions and co-designed F-NIC hardware runtime for application acceleration in cloud systems. NICA manages one or more *Accelerator Functional Units (AFUs)* [42, 101] – application-specific hardware accelerators hosted on an F-NIC. Such AFUs can be developed by users, or provided by cloud vendors and deployed on-demand.

OS abstraction. We introduce a novel *ikernel* (inline kernel) abstraction, which represents an AFU in a user program. An application dynamically *attaches* the ikernel to one or more transport layer sockets, activating the respective AFU. Subsequently, all traffic sent and received via these sockets is processed by the AFU without CPU invocation. To communicate via the sockets, the CPU may use standard POSIX sockets API calls, or a high-performance zero-copy interface for application-level messages. The ikernel abstraction is private to a process and provides protection for the AFU application and network state. We discuss the ikernel abstraction, its network stack integration, and FPGA runtime support in §4.1.

AFU virtualization. NICA supports sharing of AFUs among multiple virtual machines (VMs) while guaranteeing state protection and quality of service (QoS). We address two primary requirements: (1) *AFU I/O channel virtualization*, including host and network traffic, by adding anti-spoofing, classification, and packet schedulers for the I/O sent and received by AFUs; and (2) *fine-grain AFU time-sharing*, which uses a hardware task scheduler that switches contexts at a fine granularity, thus allowing better hardware utilization for latency-sensitive applications. We describe AFU virtualization in §4.2 and show how it enables performance isolation in §6.

NICA provides necessary on-FPGA services for accelerating applications on F-NICs in a multi-tenant setting, including an FPGA-resident network transport layer, compute and I/O scheduling blocks, and AFU state isolation. However, the development of high-throughput network-focused AFUs on FPGAs is beyond the scope of this paper. Fortunately, some promising solutions are emerging, such as template libraries with optimized building blocks for network processing [32]. In addition, we believe that cloud providers will increasingly offer AFUs using an "app marketplace" deployment model [4, 17, 40], with a variety of AFUs ready to be used on their infrastructure (see §3).

We prototype NICA[1] on Mellanox Innova F-NICs [68] with a Xilinx FPGA and 2GB of onboard memory. We implement the ikernel API, integrate it with the VMA kernel-bypass network stack [69], and implement the AFU virtualization support in the KVM hypervisor. We also co-design the FPGA hardware support for the software abstractions and AFU virtualization, and we integrate full UDP and partial TCP layer implementation in FPGA.

We evaluate the system with microbenchmarks and accelerate two real-world applications: a `memcached` server and a Node.js-based IoT monitoring server, by implementing the respective AFUs on the F-NIC. Enabling F-NIC acceleration required minimal software changes: 107 additional lines of C and 20 additional lines of JavaScript respectively.

A transparent hot-item cache AFU integrated with `memcached` serves GET hits at 6 µs 99th-percentile latency and 40.3 Mtps throughput for 16B keys/values, 99% of the 40 Gbps line rate and 21.6× faster than the 6-core CPU baseline. For a Zipf(0.99)-distributed workload with 0.2% SETs, NICA acceleration results in a 4.6× speedup.

NICA allows sharing of an F-NIC among multiple VMs while providing significant performance gains. It introduces negligible throughput and latency overheads while maintaining a fair bandwidth allocation, controllable by the hypervisor.

In summary, we make the following contributions:

- We introduce an ikernel OS abstraction for inline acceleration of applications on F-NICs.
- We design an F-NIC virtualization framework that supports I/O QoS and low-latency time sharing of compute resources.
- We implement NICA for Mellanox F-NICs, analyze its performance, and demonstrate the development simplicity and performance benefits for accelerating `memcached` and a Node.js-based IoT server.

2 Background

We describe the F-NIC architecture and survey FPGA programming principles and sharing mechanisms.

2.1 F-NIC architecture

We describe bump-in-the-wire F-NICs, focusing on Mellanox Innova, but others [19, 80, 89] are similar.

[1] https://github.com/acsl-technion/nica

Figure 1: A bump-in-the-wire F-NIC

Bump-in-the-wire. A typical F-NIC (Figure 1) combines a commodity network ASIC (e.g., ConnectX-4 Lx NIC) with an FPGA and local DRAM. The FPGA is located *between* the ASIC and the network port, interposing on all Ethernet traffic in and out of the NIC. The FPGA and the ASIC communicate directly via an internal bus (e.g., 40 Gbps Ethernet), and a PCIe bus connects the ASIC to the host.

The bump-in-the-wire design reuses the existing data and control planes between the CPU and the NIC ASIC, with its QoS management, and virtualization support (SR-IOV), mature DMA engines, and software stack.

F-NIC programming. The development of an F-NIC-accelerated application involves both hardware logic on FPGA and associated software on the CPU. F-NIC vendors provide a lightweight *shell IP*: a set of low-level hardware interfaces for basic operations, including link-layer packet exchange with the network and the host, onboard DRAM access, and control register access. However, the vendor SDK leaves it to customers to implement higher level features such as FPGA network stack processing or virtualization support.

2.2 FPGA concepts

Field Programmable Gate Arrays (FPGAs) are "a sea" of logic, arithmetic, and memory elements, which users can configure to implement custom compute circuits. FPGA compute capacity is determined by the *area* available for the circuits.

FPGA development. FPGAs can be seen as "software-defined" hardware. The software definition, *a design*, is implemented using register transfer languages (RTL) such as Verilog. Additionally, designers can use high-level synthesis (HLS) tools to generate RTL, e.g., from a restricted version of C++ [67]. However, HLS C++ programs are different from CPU programs, and must follow certain rules, including explicit exposure of fine-grain pipeline- and task- parallelism to achieve high performance. Implementation tools then compile the design into an *FPGA image* targeting specific hardware.

Finally, users can load the image onto an FPGA (slow, up to a few seconds), entirely replacing the previous design. Some FPGAs support *partial reconfiguration* to replace only a subset of the entire FPGA, a much faster process (milliseconds), which unfortunately incurs significant area overheads [51].

FPGA sharing. There are three ways to share an FPGA: space partitioning, coarse-grain, and fine-grain time sharing.

Space partitioning divides FPGA resources into disjoint sets used by different AFUs [18, 20, 51]. If shared I/O interfaces (memory, PCIe bus) are securely isolated and multiplexed, this method enables low-overhead FPGA sharing among mutually distrustful AFUs but requires larger FPGAs to fit them all. *Coarse-grain time sharing* dynamically switches AFUs via full or partial reconfiguration [20, 51]. It incurs high switching latency and thus is not suitable for F-NICs' latency-sensitive applications. *Fine-grain time sharing* allows multiple CPU applications to use the same AFU [44]. The AFU implements the context switch internally, in hardware. Packet processing applications such as AccelNet [33] use this approach to process each packet in the context of its associated flow. Such AFUs oversee switching between the contexts; therefore this type of sharing requires AFUs to be *trusted* to ensure fair use and state isolation between their users.

NICA combines both space sharing for untrusted AFUs, and fine-grain time sharing for trusted AFUs, to achieve maximum utilization under area constraints of F-NICs.

3 Motivation

We consider emerging opportunities for application acceleration by using F-NICs in clouds.

3.1 F-NICs in data centers

Microsoft has been among the first to deploy F-NICs at large scale, having installed the Catapult F-NICs in over a million Azure servers. Their recent work [33] analyzes the cost, power, and performance trade-offs of F-NICs in data centers and decisively shows their benefits. Following Azure, other data centers, such as China Mobile [115], Tencent [66], Huawei [88], and Selectel [94], are deploying F-NICs, and leading hardware vendors are adding F-NICs to their offerings [98]. These technology trends suggest that F-NICs will become a commodity, motivating our goal to broaden the scope of their applications.

3.2 Use cases for F-NIC acceleration

What sets F-NICs apart from stand-alone FPGAs is their ability to *interpose and process the network traffic* to and from the host with low overhead. For application acceleration, the application data plane can be partitioned between the F-NIC and the CPU, even for latency-sensitive fine-grain tasks.

We identify several common task categories in the server data plane that benefit from F-NIC acceleration.

Filtering. F-NICs may execute compute-intensive processing, such as per-message stateless authentication (e.g., JSON web token validation [47]), and filter invalid requests before reaching the CPU. We evaluate this example in §6.2.2.

Such filtering patterns arise in many server applications. For example, F-NICs may implement high-performance, simplified versions of popular services to accelerate common behavior (fast path), falling back to the CPU for corner cases (slow path). We show in §6.2.1 how an F-NIC-hosted key-value store cache reduces server load.

Transformation. F-NICs may convert data formats, perform (de)serialization, compression, encryption, or similar datacenter tax tasks [48]. They can change data layout, e.g., transpose matrices [35], sample, or realign data [2, 38] for efficient CPU/GPU processing or storage. As F-NICs may run a (potentially limited) network transport layer, they may speed up CPU transport layer processing [50], as we show in §6.

Transformation is often combined with filtering. For example, to accelerate the log-structured merge (LSM)-trees [22, 79], the F-NIC may store the tree's first level in its local memory, executing updates without interrupting the CPU, batching and sorting them before sending them to the host.

Steering. F-NICs may improve server performance using application-specific packet steering and inter-core load balancing [50, 89], processing complex steering policies at line-rate, e.g., using heavy-hitter approximation sketches [62].

Generation. Applications may offload the transmission of outgoing messages to multiple destinations. Examples include data replication and erasure coding in storage systems [38, 53, 77], and the shuffle stage in distributed analytics engines.

3.3 AFUs in the cloud

AFUs are custom accelerators that can be instantiated on any compatible FPGA and used via a companion software library. There are two deployment models for cloud AFUs: in the FPGA-as-a-Service (FaaS) model, tenants use their own AFUs on cloud infrastructure [3, 5, 41], whereas with the *app marketplace* model, cloud providers offer common AFUs for on-demand deployment [40].

For example, while Amazon provides FaaS, its Marketplace offers third-party AFUs [4]. Similarly, Microsoft deploys its own cloud hardware microservices [17, 24, 33]. The marketplace model opens more opportunities for better F-NIC utilization. As cloud providers develop or audit these AFUs, they can trust them to allow fine-grain sharing. By co-locating tenants that request the same AFU, cloud providers may increase their infrastructure utilization, thereby increasing power efficiency [108] and reducing costs. Pre-designed AFUs are less flexible than customer-provided AFUs, but vendors can offer them at a lower cost due to the more aggressive sharing.

NICA's design supports both deployment models.

4 Design

NICA overview. Figure 2 shows the main NICA components with a single physical AFU. NICA comprises three layers: application-visible OS abstractions and services inside a VM integrated with the network stack (§4.1); the hypervisor layer for managing F-NIC resources and QoS (§4.2); the hardware layer which includes the support for OS abstractions, physical AFU logic (pAFU), a virtualization framework exposing virtual AFUs (vAFUs), and a hardware runtime with network I/O services for application-level message processing on AFUs.

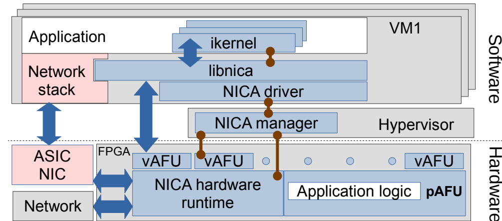

Figure 2: NICA overview. Light blue shapes are NICA components. Blue and brown lines are the data and control path respectively. vAFU: virtual AFU, pAFU: physical AFU.

4.1 Abstractions for inline acceleration

Among our primary goals is to simplify the use of inline accelerators in existing applications with minimal changes. Our abstractions thus provide a general interface for AFU management, which is compatible with standard network I/O interfaces. They allow application control of AFU execution and efficient communication between the host and the AFU.

4.1.1 The ikernel abstraction

An *ikernel* is an OS object that represents an AFU in a user program. An owner process creates an ikernel and controls it exclusively. Essentially, the ikernel extends the process abstraction into the AFU, and NICA protects the ikernel state from other CPU processes and ikernels.

To invoke an AFU, it must be associated with an active network flow. Thus, applications activate the AFU by *attaching* one or more sockets to its ikernel, thereby rerouting the associated traffic through the AFU. The ikernel stops processing the socket's traffic when the application detaches or closes the socket, keeping the AFU state intact for later invocations. Dynamic attachment adds flexibility by enabling software involvement in connection establishment and session preparation, thereby allowing applications to activate an ikernel only for specific clients or request types, for example.

The attachment semantics depends on the protocol. For a UDP socket, the ikernel receives all incoming packets destined to the socket's listening port. For TCP sockets, the effect of attachment depends on the socket state. Attaching a *connected* TCP socket migrates its state to the AFU hardware network layer. After a process attaches a listening TCP socket to an ikernel, the AFU handles new connection requests, as applications with a high connection rate may benefit from accelerating the connection establishment process. Nevertheless, NICA notifies the host network stack about new connections, off the critical path, to provide application control over these connections from the host.

A process may create several shared-nothing ikernels of the same AFU, e.g., to keep different cryptographic contexts for a crypto-AFU, but our intended usage is one ikernel per AFU per process. Multiple threads of a process may attach

Function	Purpose
`ikernel* ik_create(uuid_t, int dram_size)`	Allocate an ikernel
`void ik_destroy(ikernel*)`	Deallocate an ikernel
`int ik_attach(ikernel*, int sock)`	Attach ikernel and socket
`int ik_detach(ikernel*, int sock)`	Detach ikernel and socket
`int ik_command(ikernel*, cmd* desc)`	Invoke RPC command
`cr* ik_create_cr(ikernel*)`	Allocate a ring
`void ik_destroy_cr(cr*)`	Deallocate a ring
`int cr_post_recv/send(cr*, buf*)`	Pass buffers to the ikernel
`int cr_poll(cr*, wc*, int n)`	Poll ring for completion

Table 1: Control (top) and data plane (bottom) ikernel API.

their sockets to the same ikernel, thereby sharing the AFU state among them.

For now, a socket can be attached only to a single ikernel, but we plan to enable ikernel chaining in the future (§4.4).

Alternatives. We choose the ikernel abstraction because it captures the intuitive application-level semantics of inline network processing. We also considered using match-action rules, as in FlexNIC [50] and DPDK [84]. These are not associated with sockets, but rather with packet header rules, e.g., selecting packets of a specific five-tuple. Such an interface suits packet processing but is too low-level for application logic offloading. The ikernel socket-level abstraction hides the details of the hardware-resident network stack and allows simpler integration with existing applications.

4.1.2 Control plane

The control APIs (Table 1) allow initialization, teardown, and access to the AFU-resident application state. Under the hood, they interact with the network stack on the host and on the F-NIC to coordinate resource allocation and AFU processing.

Initialization and attachment. An `ik_create` call initializes an ikernel given an AFU's UUID. When the ikernel attaches to a socket it updates the F-NIC network stack. Once the ikernel is attached, the NICA driver tracks the socket state, detaching the flow when the socket is closed. The application may also detach an ikernel before the connection terminates.

The `ik_create` call may initialize a pre-loaded AFU or load it at runtime using partial reconfiguration. The ikernel abstraction hides the AFU hardware initialization details from the user, leaving the OS in charge of manipulating the FPGA-AFU allocation, similarly to AmorphOS [51].

Application state. Applications may access the ikernel state in the AFU. The hardware could expose the state in two ways: (1) as shared memory between the host and the F-NIC; or (2) using remote procedure calls (RPC) from the CPU to the AFU that retrieve/set the state. Shared memory might not be efficient, however. First, FPGA logic can keep frequently-accessed data in private memory, such as registers or block RAM, for efficiency. This memory is not exposed to the CPU. Further, access to the shared state requires explicit synchronization, which is costly over PCIe. Therefore, we chose the RPC model, which allows the AFU to implement arbitrary atomic transactions, including e.g., getting a snapshot of its state. Internally, NICA also uses the same mechanism to control transport layer and QoS parameters.

Error handling. An AFU that encounters an error exposes it to an ikernel runtime which periodically checks for errors via the RPC mechanism. In addition, the ikernel may abort the connection or detach itself from the respective sockets and forward packets without offloading.

4.1.3 Data plane

NICA provides two ways to perform network I/O with inline acceleration: POSIX API and *custom rings*.

POSIX networking API. After attaching an ikernel to a socket, the application may use standard I/O calls, e.g., `send`, `recv`, and `epoll_wait`, while the AFU transparently processes the data in-flight. We currently support the POSIX APIs only for UDP sockets.

Custom rings. POSIX I/O interfaces incur the overhead of extra data copies into user buffers [81] and host-side network stack processing. On the other hand, an AFU may need to exchange *application-level* messages with the host application. For example, a deserialization AFU may send ready-to-use data objects to the application. Furthermore, an AFU may need to steer the processed messages to different CPU cores, i.e., for application-aware load balancing.

NICA introduces a *custom ring*[2] (CR) abstraction that provides a zero-copy API for sending/receiving *application messages*, bypassing the host network stack. Each ikernel may create multiple associated CRs to enable message steering for multi-core systems.

The CR interfaces are similar to VIA/RDMA verbs [30] (Table 1). Specifically, each CR comprises a queue pair (QP) and a completion queue (CQ). The application allocates its communication memory buffers and registers them with the CR. It then posts the send/receive requests to the respective queue in the QP. The request completions show up in the CQ.

Custom rings vs. random access. FPGA acceleration frameworks [37, 43, 101] and some I/O intensive AFUs [29, 38, 60] allow random access to CPU memory from the AFU, which is useful for fine-grain sharing of data-structures between the CPU and the AFU. NICA currently focuses on the AFU tasks that communicate with the CPU via a streaming I/O pattern, which is much easier to implement using a producer-consumer CR interface. We leave support for random host memory access for future work.

Synchronization. In the most common application scenarios, networking or custom ring operations implicitly synchronize the CPU application and the AFU processing. In more complex cases, when the AFU accumulates the application state (e.g., for network I/O monitoring or consensus), the ikernel

[2] The hardware uses a descriptor *ring* buffer just like a regular NIC, but the buffer contents are application messages rather than raw packets.

RPC interface allows AFU developers to provide application-specific mechanisms to safely access ikernel state.

4.1.4 Usability

We expect adding ikernels to existing applications to require relatively small design or code changes. In case of filtering (see §3.2), an application may still use POSIX sockets as before, while receiving only the filtered data. For example, `memcached` requires no changes to its data processing to use the KVS cache AFU (§6). Data transformation tasks, such as deserialization, may use custom rings to obtain or send back the data in an application-friendly form. Steering applications may use per-core custom rings to get the contents directly to the correct application thread or a GPU. A generation application, e.g., replication, may send only one data copy via the custom ring, while the AFU will distribute it to pre-configured destinations.

4.2 Virtualization

To support fine-grain sharing of AFUs, as required for low latency applications, we introduce the notion of a *virtual AFU, vAFU*, which represents a single isolated hardware entity on the F-NIC. Each vAFU provides state protection and performance isolation across all the shared resources on the F-NIC. To clarify, a vAFU is a hardware entity, whereas an ikernel is an OS object that belongs to a process. Connecting multiple ikernels to the same vAFU might be possible, i.e., allowing in-VM resource allocation policy enforcement, yet we do not support it in our prototype.

One F-NIC may host multiple physical AFUs via space sharing, whereas each such AFU may support multiple vAFUs via fine-grain time sharing, as explained below. For example, our key-value-store cache AFU supports 64 vAFUs, allowing concurrent acceleration of up to 64 different `memcached` servers on the same F-NIC (§6).

Fine-grain AFU sharing. Supporting multiple vAFUs on a single physical AFU requires low-overhead hardware context switching mechanism. The vAFU context includes the ikernel state in DRAM and registers and the contexts of the sockets connected via that vAFU. Each received packet may belong to a different vAFU so slow context switch would not only increase application latency but also increase the required NICA internal buffer space.

To support fine-grain sharing, we store the vAFU context by reserving fast memory for each vAFU rather than evict/reload it to/from slow DRAM memory. Specifically, the AFU registers are replicated to store data for all concurrently active vAFU contexts. Each vAFU is associated with a hypervisor-chosen tag. The AFU switches to the context requested by the scheduler by updating the active tag register. Such a context switch can be extremely fast, e.g., up to 3 clock cycles in our prototype.

However, the number of vAFUs that can be supported is constrained due to the limited size of fast memory on the FPGA. For more vAFUs, AFUs may use DRAM to store the contexts and use latency hiding techniques, i.e., increased concurrency. Our current prototype uses fast memory, yet it is enough to host up to 64 vAFUs for the evaluated applications.

4.2.1 State protection

NICA protects the vAFU state in DRAM, fast memory, and hardware registers. For the DRAM, we use a segment-based MMU for simplicity. Similarly, we protect the control registers of the RPC interface by including a vAFU tag.

Additionally, NICA ensures correct steering of network traffic to and from the vAFU via its on-NIC network stack (§5.3). In particular, it guarantees that a vAFU will not perform network spoofing attacks toward the host and will receive only the packets destined to that vAFU. These two aspects are essential for supporting untrusted AFUs in NICA.

4.2.2 Performance isolation

NICA supports isolation of I/O channels and compute resources. The compute scheduling is necessary only among the vAFUs of the same physical AFU. The FPGA loads different physical AFUs into different partitions, and thus they do not share FPGA compute resources. DRAM bandwidth partitioning is left for future work.

I/O bandwidth sharing. The bandwidth allocation between tenants is often implemented inside a virtual switch or in the NIC internal switch. However, in a bump-in-the-wire architecture the F-NIC sends vAFU-generated messages directly to the network, bypassing these policies. Therefore, NICA provides its own bandwidth allocation mechanisms, similar to the traffic class (TC) mechanisms used in NICs [10].

To control the vAFU egress bandwidth, both towards the CPU and towards the network, we add a set of TC queues (see Figure 3). Packets are classified to these queues and scheduled. We use a work-conserving deficit round robin (DRR) scheduler [95] to allocate bandwidth, but more complex policies can be used. NICA's bandwidth scheduler is trusted and used by all the vAFUs on the F-NIC.

The vAFU recognizes when the TC queues are full and may drop the packets or propagate the contention if possible. For example, it may slow down the host by using custom ring flow control or slow down the sender through explicit congestion notification (ECN).

NICA does not manage the ingress bandwidth into the vAFU from the network or the host, as the sender (TOR or host virtual switch) already shapes ingress traffic.

AFU compute sharing. An AFU must determine which vAFU to activate at any given time, and which packets to serve first. We considered two design options: a general compute scheduler for all AFUs (similar to the I/O scheduler)

or an internal AFU-specific scheduler for each AFU. These two options represent an inherent trade-off between FPGA resource consumption and design generality.

A generic scheduler in front of the vAFUs could reorder packets according to a global policy, simplifying the AFU design. However, such a scheduler requires deep input queues, therefore increasing consumption of F-NIC fast memory. Further, the need for queuing is protocol-dependent. For example, TCP has its own input queues to receive out-of-order packets, so extra scheduling queues would be wasteful. Moreover, AFUs may customize queue contents to save resources, e.g. by keeping parsed requests instead of full packets.

We thus decided to implement a custom, application-specific scheduler in each AFU.

4.3 AFU development

AFUs implement hardware interfaces to receive/transmit transport layer and custom ring data, configuration and control interfaces for RPC, and, optionally, provide vAFU scheduling and virtualization.

All the packets passing through an AFU are tagged with metadata that identifies the associated ikernel and flow, which can be used by the AFU for ikernel state isolation. The AFU receives per-TC usage levels and CR flow control (see §5.2).

While designing such FPGA hardware can be difficult, we try to simplify the development by using high-level synthesis to design our AFUs in C++, and use the `ntl` class library [32] to implement common modules such as AFU schedulers and control-plane interfaces. In addition, the NICA hardware runtime handles some common tasks such as transport processing and egress scheduling, thus simplifying AFU development.

4.4 Discussion

F-NIC transport layer. An inline AFU requires transport layer services to process data at the application layer; it may terminate flows or generate and send new messages. Our current design uses a full implementation of UDP and TCP logic in hardware. With this solution, the F-NIC effectively runs its own complete network stack.

A complete TCP/IP stack in hardware simplifies AFU development but increases F-NIC resource consumption and maintenance difficulty [75]. To eliminate NIC transmission buffers, an AFU could generate retransmissions on-demand or use host memory [85, 97]. If packet reordering is rare, an AFU may process received data only in-order, deferring out-of-order packets to the CPU [85]. A resource-efficient TCP design for inline AFUs warrants further research, so we choose a simple solution to evaluate the ikernel abstraction compatibility with TCP.

Virtual switch offloading. F-NICs intercept the inbound network traffic *before* it reaches the CPU. As a result, it becomes difficult to handle hypervisor policy and virtual networking rules, e.g., as in Open vSwitch, because they are typically handled by the hypervisor's virtual switch software running on CPU. This issue is not unique to NICA and exists with standard SR-IOV NICs [33]. Typical solutions pass the first packet to software and offload per-flow policy to hardware match-action rules [33, 59, 78]. While this may take significant area of the F-NIC's FPGA [33], future F-NIC designs may be able to harden this functionality [20, 31].

Multi-AFU support and services. Our design provides all the necessary mechanisms to run multiple AFUs on the F-NIC: packet schedulers, steering, RPC and MMU isolation modules. Currently, a single socket may only be attached to a single AFU. However, there are use cases for chaining several AFUs in a single application to accelerate various aspects of the server's traffic [16, 56, 117]. Multi-AFU chaining requires extensions to resource isolation mechanisms and software interfaces, which we plan to explore in the future.

5 Implementation

We implement NICA for the Mellanox Innova F-NIC and integrate it with the KVM/QEMU hypervisor and VMA user-space networking library [69].

5.1 AFU virtualization

NICA implements hardware virtualization of the physical AFUs, exposing virtual AFUs (vAFUs in Figure 2) to VMs. Currently, the hypervisor allocates one vAFU for each requested ikernel. NICA isolates the vAFU I/O channels in hardware and requires no software mediation.

We utilize the NIC's SR-IOV functionality to virtualize the data path (both POSIX and custom rings). SR-IOV enables unmediated overhead-free access from the guest to the NIC hardware. In general, implementing SR-IOV in custom accelerators is quite challenging, but the bump-in-the-wire architecture of our F-NIC allows reusing the existing NIC hardware SR-IOV mechanism. For the control plane, which is less sensitive to performance, NICA uses para-virtualization.

5.2 Software

We implement the NICA API in the `libnica` library. It integrates with the VMA user-space networking library, providing the POSIX socket API with kernel bypass and direct hardware access. We modify VMA to support the ikernel abstraction.

The NICA VM driver mediates between `libnica` and the hypervisor's NICA manager daemon, using a para-virtual device (virtio-serial). The NICA manager runs in the hypervisor and controls AFU hardware through the F-NIC kernel driver. NICA software stack is about 2,200 LOC.

Custom ring using RoCE. We use the F-NIC's RoCE support [105] to implement the CR, employing the ASIC NIC

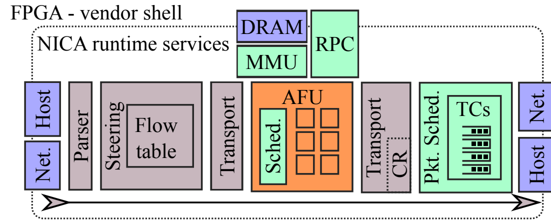

Figure 3: NICA hardware runtime (only ingress is shown, 1 AFU). Isolation modules are green. Each AFU supports multiple vAFUs. Sched.=Scheduler.

hardware and software layers using the bump-in-the-wire architecture. The implementation associates CRs with RoCE unreliable connected (UC) queue pairs (QPs). To send to a specific CR, NICA's transport layer generates RoCE packets to the host, targeting the appropriate QP. The ASIC RoCE engine writes the data directly to the application buffers, providing address translation, DMA, and completion notifications.

In our bump-in-the-wire F-NIC, the FPGA logic does not have a direct end-to-end flow control mechanism with the host, and UC does not provide such a mechanism either. Therefore, NICA adds a credit-based flow control mechanism between the AFU and the CPU application. The custom ring APIs transparently invoke this mechanism.

5.3 Hardware runtime

Figure 3 shows our FPGA processing pipeline. For clarity, we describe ingress (from network to host) only. The FPGA runtime provides the hardware support for inline programming abstractions and the essential services for inline acceleration. These include: (1) the custom rings and RPC mechanism to support efficient data and control plane primitives for ikernels; (2) a memory management unit (MMU) for memory isolation; (3) a network processing stack to support application-level processing in the AFU, which includes the parser, flow steering, and the transport layer; and (4) a virtualization layer, implementing AFU and packet schedulers.

We develop NICA and the evaluated AFUs in HLS [114] and Verilog. Table 2 shows the FPGA resources and number of code lines. NICA operates the FPGA at 216.25 MHz.

TCP/IP implementation. Our prototype includes full support for UDP and partial support for TCP. The UDP/IP service splits/combines the header and the payload. As the CR utilizes RoCE over UDP, it also uses the UDP/IP service.

The TCP implementation builds on an existing 10 Gbps FPGA TCP/IP stack [96]. Its integration with NICA is incomplete, as it lacks virtualization and socket migration support (though existing techniques apply [8, 27]). It is included primarily to validate how NICA abstractions hold with TCP.

Table 2: FPGA utilization and lines of code. LUTs: lookup tables, FFs: flip-flops, RAMB18: block RAM units.

	Module	Area (% of total) LUTs	FFs	RAMB18	LOC HLS	Verilog
System	NICA	13%	9%	13%	6643	1736
	TCP stack	6%	4%	13%	15303	1110
	Vendor shell	51%	32%	7%		
Apps	NICA-KVcache	5%	2%	2%	975	
	IoT server	10%	7%	8%	646	1627

5.4 Limitations

Our prototype may run only two physical AFUs, where one is a minimal AFU that passes through unmodified traffic. This is not a design limitation but stems from the FPGA area constraints (see Table 2). Further, NICA does not yet support virtual switch offloading, and our current CR implementation does not transmit, only receives. In addition, our F-NIC does not support partial reconfiguration. We hope the next generation of the F-NIC [31] will resolve these limitations, as it is expected to have a larger FPGA with more space and hardened network virtualization support.

NICA performance drops dramatically when crossing NUMA links. We are investigating a potential hardware bug.

6 Evaluation

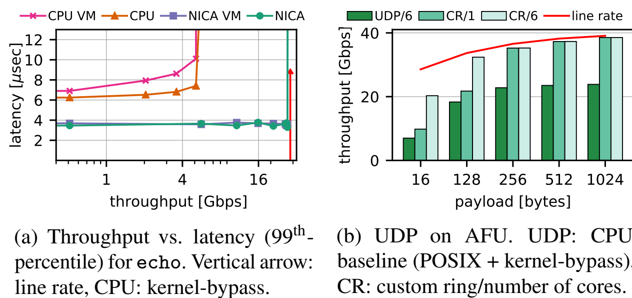
Hardware setup. We use four machines with Intel® Xeon® E5-2620 v2 2.1 GHz CPUs, connected via a Mellanox SN2100 40 Gbps switch. Three (clients) use Mellanox ConnectX®-4 Lx EN NIC, and one (server) uses a 40 Gbps Mellanox® Innova™ Flex 4 Lx EN (1st gen.) F-NIC, equipped with a Xilinx XCKU060 FPGA. The server is a dual socket NUMA machine with 64 GB RAM. Hyper-threading and power saving settings are disabled.

CPU baseline. We use VMA [69] user-level network stack with kernel bypass, optimized by Mellanox and broadly used for high-performance networking [33]. We use commodity NICs with the same ASIC as our F-NIC but without the FPGA. Due to the NUMA performance issue of the current prototype (§5.4), to allow a fair comparison, we constrain our experiments to the NUMA node closer to the NIC.

F-NIC maximum power consumption. The F-NIC consumes up to 30 W [68] vs. 14.2 W [70] for the client NICs.

Performance measurement. We use `sockperf` [71], a benchmarking tool optimized for VMA. To reliably measure performance, we use performance counters on NICA's FPGA runtime, the NIC, and the switch. We run each experiment 5 times, each 60 second long.

NICA configuration. We set a max. of 4 TCs, 64 ikernels, VMs, and custom rings, 1K UDP ports, and 10K TCP flows.



(a) Throughput vs. latency (99th-percentile) for `echo`. Vertical arrow: line rate, CPU: kernel-bypass.

(b) UDP on AFU. UDP: CPU baseline (POSIX + kernel-bypass), CR: custom ring/number of cores.

Figure 4: Microbenchmarks

6.1 Microbenchmarks

We use several microbenchmarks to evaluate the benefits of NICA acceleration through filtering and transport layer acceleration and to estimate virtualization overheads.

Experiment 1: Virtualization performance. Figure 4a shows the throughput-latency comparison of bare-metal and virtualized echo server AFU vs. the CPU baseline for 64-byte packets. We measure no overheads of the AFU virtualization.

At 5 Gbps, the latency of the virtualized AFU is 2×/2.8× lower than bare-metal/in-VM CPU server respectively. At 6.7 Gbps, the baseline latency spikes to 38 µs, while the AFU achieves up to 27.6 Gbps at 4 µs latency, above which we see packet drops. The stable low latency at high throughput is a valuable property of F-NIC accelerators.

Experiment 2: UDP performance. We run a pass-through AFU that receives UDP packets and transfers them to the host via CRs, saving the host UDP processing. The CPU baseline uses VMA for POSIX API kernel bypass, with 6 CPU cores. Figure 4b shows the throughput for different packet sizes. Offloading UDP processing to the AFU boosts the throughput from 2.9× and 1.7× for small and large packets respectively. For larger packets, a single-core CR outperforms 6-core UDP.

Experiment 3: TCP performance. We evaluate NICA's preliminary TCP support by accelerating a monitoring server microbenchmark. The server receives integers as 18-byte messages (4-byte integers with a 14-byte sockperf header) and computes their average, alerting the user when the received values are above a given threshold. With NICA, the AFU maintains the average and sends only the messages above the threshold via the custom ring (bypassing the host TCP stack).

For 6 flows from 6 clients, the AFU consumes 34.8M messages/sec, 3× faster than the baseline's 11.5M messages/sec (single core). The AFU benefits diminish as the portion of the messages sent to the host increases, down to a modest 11% throughput improvement. This indicates that *the F-NIC transport layer processing contributes much less than filtering to the overall performance benefits*.

Experiment 4: I/O isolation overheads. We evaluate the egress scheduler when using two AFUs: a traffic generator AFU and a pass-through AFU. The former generates messages to the network at maximum throughput. The latter transfers messages between the host and the network. These AFUs share the network egress I/O channel and are assigned to separate traffic classes. We set the scheduler quantum to 1 KB.

We measure the latency of a few 64-byte packets sent via the pass-through AFU while the generator AFU sends 1514-byte packets. At 38.4 Gbps load, the low-latency pass-through packets suffer a 1 µs overhead to 99th-percentile latency compared to an empty system. This result demonstrates that the *I/O isolation mechanism achieves low overhead even under heavy contention*.

6.2 Application benchmarks

We accelerate two large applications: `memcached` and a Node.js-based IoT server. We build a transparent cache AFU for the former and an authentication AFU for the latter, integrating both into the CPU software.

6.2.1 Transparent `memcached` cache

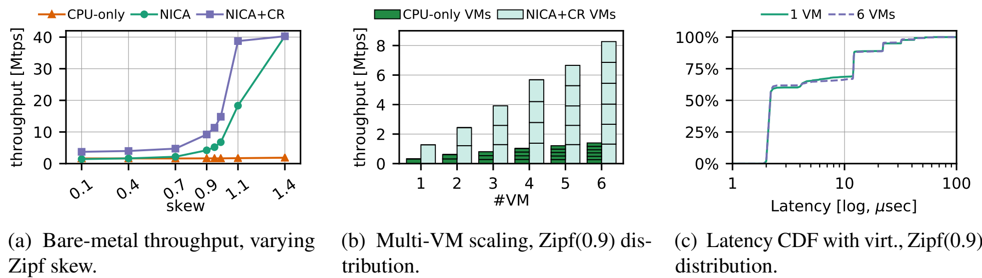
We prototype a transparent look-through cache for `memcached`, called NICA-KVcache. The AFU parses `memcached`'s ASCII UDP protocol and serves GETs directly from its F-NIC DRAM-resident cache. The AFU passes GET misses and other update requests to the host. Upon update, the AFU *invalidates* the respective cache entry. The AFU populates the cache by intercepting GET *responses* from the host, ensuring coherence even if the host drops the updates due to overload. The AFU caches keys/values of up to 16-byte and uses a direct-mapped cache for simplicity.

We implement two designs: one with POSIX API and another with CRs. The former requires changing `memcached` to instantiate the ikernel and attach sockets. The latter introduces CR polling to the `memcached` worker thread event loop. Adding the F-NIC acceleration support required 107 and 135 LOC for the POSIX API and CR versions respectively.

Workload. We initialize the CPU server with 32 M 16-byte keys and values (4 GB with overheads) and set the AFU cache to store 2 M keys per-ikernel (128 MB RAM). The CPU baseline uses an unmodified `memcached` with the VMA network stack. Clients generate a YCSB-like [25] workload with varying skew using `sockperf`.

Bare-metal performance. Figure 5a shows that for lower skews (high miss rate), the CPU (6 cores) is the bottleneck. With Zipf(0.99) distribution (YCSB's default), NICA+CR achieves 9× speedup. For 100% hit-rate, the AFU becomes network-bound (99% of 40 Gbps line-rate), resulting in 21× higher throughput than the baseline.

The cache hit-rate also dictates the latency distribution (not shown). We observe a mixture of two distributions: cache hits and cache misses. With Zipf(0.99) distribution and 1 Mtps load, the F-NIC serves cache hits at a stable 2.1 µs. Misses, served by the host, are 6 µs at the 99th-percentile, versus



(a) Bare-metal throughput, varying Zipf skew.

(b) Multi-VM scaling, Zipf(0.9) distribution.

(c) Latency CDF with virt., Zipf(0.9) distribution.

Figure 5: NICA-KVcache results, CPU+VMA (kernel-bypass) vs. NICA with/without a custom ring (CR).

Table 3: NICA-KVcache throughput [Mtps] with 0.2% SETs.

Skew	0.90	0.95	0.99	1.10
Baseline (CPU-only with kernel-bypass)	1.55	1.55	1.55	1.55
NICA with custom ring	5.98	6.51	7.10	8.28

10.5 µs in the baseline. *The latency improvement is due to the reduced CPU load as a result of filtering.*

Table 3 shows the throughput with 0.2% SETs (common in Facebook [15]). At Zipf(0.99), NICA is 4.6× faster than the baseline. With 10% SETs (not shown), CPU throughput dominates, thus NICA shows no performance improvement.

Other KVS implementations. NICA-KVcache offers significant advantages even when used with highly optimized CPU-only KVS implementations, such as MICA [63], which achieve line-rate throughput using CPU cores alone. In this case, NICA-KVcache reduces the required number of CPU cores by filtering all the cache hits and leaving only the misses to the CPU, thereby improving the overall system efficiency. More specifically, for a given hit rate in the NICA-KVcache, achieving line-rate requires the CPU throughput to be $line_rate \cdot (1 - hit_rate)$ transactions per second.

For example, MICA [63] reaches 5 Mtps on a single CPU core with 100% GETs for 32 M 16-byte keys and values (1GB of data) with a Zipf(0.99) distribution. Optimistically assuming perfect scaling, MICA would reach line-rate (59.5 Mtps) with 12 cores, without NICA-KVcache acceleration. In contrast, with NICA-KVcache of size 128MB, running the same Zipf(0.99) key distribution results in 75% hit-rate, thus the CPU only handles 14.9 Mtps, utilizing just 3 CPU cores.

This result demonstrates that the use of NICA for accelerating key-value stores is cost-effective, considering that a single CPU core is reportedly more expensive than a SmartNIC [33].

Accelerated KVS. Floem [83] implemented a similar key-value store cache on a Cavium SmartNIC and reported a 3.6× performance improvement with 100% hit-rate with write-back, and no benefits for 10% SETs write-through, as in NICA. Rather than `memcached`, Floem required a custom KVS server, however. KV-Direct [60] with small requests achieves comparable performance to NICA (with 100% hits) but reaches 180 Mtps using client-side batching. Unlike NICA-KVcache, its data-plane is fully implemented in hardware, and it only uses the host for slab allocation.

Contribution of network-stack processing. Figure 5a shows that using CR for low cache hit rates results in 2.2× speedup over the CPU baseline. In this case, the use of CR eliminates the network stack processing on the host but keeps the application processing on the CPU. Naturally, higher hit rates result in a higher portion of the requests handled by the AFU, and much higher speedups. This experiment suggests that *the network stack offloading alone is not enough to reach the full performance potential of the F-NIC acceleration*.

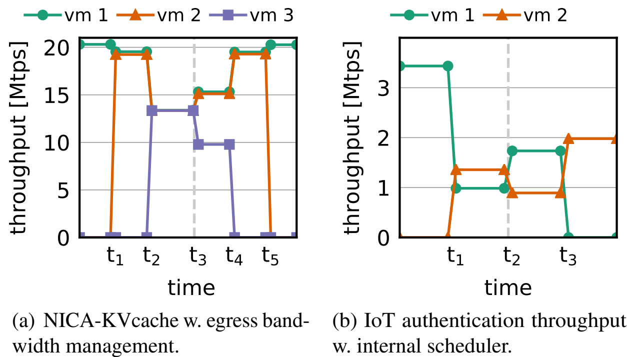
Virtualization performance. We evaluate the performance with a varying number of VMs. Each VM uses 5 GB of server RAM, 1 dedicated CPU core, a vAFU, and 2 M keys worth of vAFU cache. For Zipf(0.9), Figure 5b shows near-linear scaling, consistently achieving a 5.6× speedup over the CPU. Further, we observe no measurable negative impact of virtualization on vAFU latency. The system achieves similar results with 64 M keys per VM, utilizing most of the 64 GB RAM of our machine.

Figure 5c shows the latency distribution of a single VM and 6 VMs executions under 1.3 Mtps load, for a Zipf(0.90) workload. The latency increases for the top 40% of the requests, which matches the expected hit-rate. We observe that the VM CPU latency is much higher than the bare-metal latency reported above, but cache hits are served at the same latency with and without virtualization.

This experiment confirms that *AFU fine-grain sharing is feasible and effective*.

Network bandwidth isolation. We use 3 VMs, associated with 3 TCs, and initially configure them to share the egress bandwidth equally. We use a Zipf(1.4) distribution (99.9% hit-rate), and a 20 Mtps load on each VM, to stress the scheduler.

Figure 6a shows the throughput of each VM over time. At first, only VM 1 is active, using the whole AFU. When VM 2's clients start, the combined egress throughput is barely above the AFU's maximum (39 Mtps), and the clients process 19 Mtps each. When VM 3's clients start, the combined throughput surpasses the maximum, and the scheduler divides the bandwidth equally (13 Mtps per VM). At t_3, we change the bandwidth allocation to 40%/40%/20% and observe an asym-



(a) NICA-KVcache w. egress bandwidth management.

(b) IoT authentication throughput w. internal scheduler.

Figure 6: QoS experiments

Table 4: Node.js goodput (valid req. received) under DoS.

Valid packet ratio	40%	60%	80%	100%
Baseline (req/sec)	1489	2294	3131	3960
NICA (req/sec)	5165 (3.4×)	5165 (2.3×)	5231 (1.6×)	5181 (1.3×)

metric allocation. This confirms the *NICA egress isolation is successful in allocating bandwidth among the tenants*.

6.2.2 IoT authentication

We prototype an IoT monitoring server using Node.js with JSON web token (JWT) stateless authentication. The JavaScript-based server exposes an endpoint to which IoT devices publish their measurement using the CoAP protocol [12], similarly to the SAMSUNG Artik IoT cloud API [92]. The payload of each request contains an authentication token, which includes the device ID and a timestamp, and signed using HMAC-SHA256. Invalid requests are discarded.

Our prototype authentication AFU parses received packets, extracts the token, verifies the signatures (using a SHA-256 accelerator [99]) and drops requests with invalid tokens. Valid requests are passed to the CPU and only undergo token expiration check there.

We evaluate our IoT authentication accelerator against a software-only Node.js server. Adding NICA support using POSIX APIs required 20 JavaScript LOC and 34 lines for the libnica generic Node.js module, demonstrating *the simplicity of integrating the ikernel abstraction with complex software*.

In this experiment, we simulate a Denial of Service (DoS) attack by sending a varying number of invalid tokens with incorrect signatures in the input stream. Table 4 shows the goodput, in requests/sec, as a function of the valid packet ratio. While the baseline degrades linearly, NICA maintains a constant goodput by filtering the invalid packets.

One may wonder whether optimizing the Node.js server (e.g., rewriting it in C) would diminish the AFU acceleration benefits. We argue that this is not the case. The AFU hardware achieves the throughput of 3.5 Mtps, about 3 orders of magnitude higher than the software throughput. As long as the rest of the CPU processing pipeline remains the bottleneck, the AFU remains effective. Additionally, compute acceleration alone results in only 30% speedup. The remaining speedup is due to filtering invalid packets, which would be helpful in the CPU-optimized version too.

AFU compute sharing. The AFU's throughput can be bounded by its SHA-256 hashing units and depends on the input JWT token sizes. To fairly share the hashing units among vAFUs, we introduce a custom DRR scheduler (§4.2.2)) that controls the per-VM utilization of the AFU hashing units.

We use 2 VMs to demonstrate the performance isolation. Clients send 10 Mtps of invalid requests to each VM, but VM 2 receives requests with 40% larger tokens. We start the experiment with the scheduler disabled and enable it mid-run.

Figure 6b shows the throughput of each VM over time. At first, only VM 1 clients are active, allowing the AFU to process at max speed (3.5 Mtps). When VM 2 begins receiving at t_1, VM 1 processes only 28% of the requests, which is below its fair share. With the scheduler enabled, at t_2, both VMs receive half of their respective maximum throughput. We observe that *NICA's compute performance isolation is essential to allow sharing of compute-bound AFUs*.

7 Related work

NIC-based acceleration. Commodity NICs have been offering network stack offloads ranging from checksum calculations, segmentation, and receive-side-scaling (RSS) to RDMA [9, 82, 87, 105, 110] and TCP offload engines [75]. Such offloads are limited to network and transport layer processing, while NICA focuses on the application layer.

Our work builds upon previous attempts to accelerate general purpose applications through inline processing in SmartNICs. Early work on Network Processing Units (NPUs) [1, 113] programming abstractions [16, 56] has shown the potential of customizing the I/O path for applications. More recently, FlexNIC [50] has proposed an RMT-based [14] NIC for inline acceleration of application packet processing, showing how to leverage RMT hardware for application acceleration. Floem [83] aids design of NPU accelerated applications. sPIN [38] offers inline acceleration of high-performance computing (HPC) tasks such as tag-matching, data transformation, or replication, but the Portals 4 host abstraction is unsuitable for socket applications.

While we also consider inline acceleration, our goals, design, platform, and evaluation methodology are different. FlexNIC focuses on applications of SmartNIC RMT acceleration, whereas NICA offers convenient OS abstractions for integrating inline accelerators into user applications. FlexNIC targets RMT SmartNICs with constrained functionality, whereas NICA targets more flexible bump-in-the-wire FPGAs. These may run large parts of application logic, necessitating more expressive interfaces for state and execution management, such as host-NIC network stack interaction. As RMT devices

are designed to work at line-rate, performance isolation of concurrent application pipelines is unnecessary; conversely, we show that QoS support is essential to expose F-NICs in cloud systems.

Packet processing frameworks such as DPDK and eBPF-XDP [39] include inline acceleration mechanisms, e.g., for cryptographic protocols such as IPSec [84] or offloading eBPF programs to SmartNICs [52]. However, these target system-wide packet processing tasks, so they lack a transport layer, network stack integration, and multiple application support.

Linux also supports attaching eBPF programs to sockets [26], similarly to ikernels, to perform inline packet processing. However, such programs cannot process transmitted packets or generate new ones, and use a POSIX API data-path, whereas ikernels enable zero-copy application messaging.

C-CORE [56] proposes the stream handlers abstraction for inline processing, but unlike ikernels, they provide no virtualization mechanisms. Streamline [16] is an OS subsystem for tailoring application I/O path that uses UNIX pipes as an abstraction, but it does not allow dynamic attachment and configuration of filters.

Some F-NIC vendors have proprietary APIs for inline application development. Solarflare AOE allows low latency TCP transmission [97] from an F-NIC. Unlike NICA, it only offloads transmissions. Maxeler MPC-N supports inline UDP/TCP application acceleration [7]. All the above lack virtualization support, and their proprietary host application abstractions are too hardware specific.

SmartNIC applications. Eden [6] and AccelNet [33] accelerate network functions on data-center end-nodes with SmartNICs. However, these are loosely coupled with host applications, whereas NICA's model couples the AFU logic with the host server logic.

Hardware accelerators for Network Function Virtualization (NFV) [18, 34, 117] target the NFV domain and hence do not provide abstractions for general purpose applications, lack host-accelerator network stack integration provided by ikernels, and provide no I/O path virtualization to/from the accelerator.

Several works have accelerated specific applications on F-NICs [24, 57, 60, 64, 106, 107]. NICA provides an infrastructure for building such AFUs in the clouds.

Languages for SmartNIC AFU development. P4 [13] is a DSL for implementing network functions with implementations for FPGAs [100, 111]. The Click [55] router has been ported to F-NICs [61, 90]. Emu [102] enables the development of network functions on NetFPGA using HLS. These can be used to simplify AFU development for NICA, but do not provide application-level abstractions.

Floem [83] is a DSL for NPU-accelerated applications. However, it requires refactoring applications to its DSL, while ikernel abstraction is less intrusive.

FPGA virtualization and sharing. AmorphOS [51] improves FPGA utilization by sharing an FPGA among multiple AFUs, and dynamically switching AFUs. Its hull isolates different AFUs used by different applications. We apply similar mechanisms to F-NIC. However, AmorphOS does not isolate FPGA network interfaces, and its context switching mechanism is not suitable for latency-sensitive networking applications.

Multes [44] shares an FPGA among tenants using a single pipeline. AccelNet [33] allows flow-context switching on a packet-by-packet basis. NICA's fine-grained time-sharing design is similar, but its goal is to virtualize inline accelerators for application layer, rather than a standalone FPGA application or cloud network/transport layers.

Remote/distributed FPGA frameworks [7, 19, 104] share FPGAs over the network with a remote CPU. Other have virtualized local look-aside accelerators [23, 36, 101, 118]. In contrast, NICA virtualizes local inline networking AFUs.

Standalone FPGAs, GPUs, or switches. Our choice of FPGA-based SmartNICs has been motivated by prior works on accelerating networking applications [11, 21, 45, 76, 103, 109]. Unlike NICA, they focus on standalone FPGAs.

Other inline acceleration techniques let GPU kernels control communication using GPU-centric networking abstractions [28, 54, 58, 74], or process data in transit on programmable switches or network accelerators [46, 62, 65, 93]. Conversely, NICA provides tighter integration of server software and AFUs. This simplifies integration with legacy programs and makes acceleration transparent for clients.

8 Conclusion and future work

As F-NICs are becoming common in data centers, new use cases for application layer inline acceleration are starting to emerge. NICA provides the ikernel OS abstraction to easily integrate F-NIC-based accelerators into applications and introduces virtualization mechanisms to share them securely and fairly in cloud systems. NICA's real-world prototype demonstrates the significant performance potential for inline acceleration of virtualized server systems, with minimal software development effort.

We believe NICA's inline abstractions are suitable beyond F-NICs and plan to investigate their use in CPU-FPGA systems and non-FPGA SmartNICs. NICA raises a range of research topics, such as distributed heterogeneous architectures, accelerator chaining, and reliable transport offloading, which we will explore in the future.

Abstract

We investigate the use of SmartNIC-accelerated servers to execute microservice-based applications in the data center. By offloading suitable microservices to the SmartNIC's low-power processor, we can improve server energy-efficiency without latency loss. However, as a heterogeneous computing substrate in the data path of the host, SmartNICs bring several challenges to a microservice platform: network traffic routing and load balancing, microservice placement on heterogeneous hardware, and contention on shared SmartNIC resources.

We present E3, a microservice execution platform for SmartNIC-accelerated servers. E3 follows the design philosophies of the Azure Service Fabric microservice platform and extends key system components to a SmartNIC to address the above-mentioned challenges. E3 employs three key techniques: ECMP-based load balancing via SmartNICs to the host, network topology-aware microservice placement, and a data-plane orchestrator that can detect SmartNIC overload. Our E3 prototype using Cavium LiquidIO SmartNICs shows that SmartNIC offload can improve cluster energy-efficiency up to 3× and cost efficiency up to 1.9× at up to 4% latency cost for common microservices, including real-time analytics, an IoT hub, and virtual network functions.

1 Introduction

Energy-efficiency has become a major factor in data center design [80]. U.S. data centers consume an estimated 70 billion kilowatt-hours of energy per year (about 2% of total U.S. energy consumption) and as much as 57% of this energy is used by servers [22, 74]. Improving server energy-efficiency is thus imperative [17]. A recent option is the integration of low-power processors in server network interface cards (NICs). Examples are the Netronome Agilio-CX [59], Mellanox BlueField [51], Broadcom Stingray [13], and Cavium LiquidIO [15], which rely on ARM/MIPS-based processors and on-board memory. These SmartNICs can process microsecond-scale client requests but consume much less energy than server CPUs. By sharing idle power and the chassis with host servers, SmartNICs also promise to be more energy and cost efficient than other heterogeneous or low-power clusters. However, SmartNICs are not powerful enough to run large, monolithic cloud applications, preventing their offload.

Today, cloud applications are increasingly built as microservices, prompting us to revisit SmartNIC offload in the cloud. A microservice-based workload comprises loosely coupled processes, whose interaction is described via a dataflow graph. Microservices often have a small enough memory footprint for SmartNIC offload and their programming model efficiently supports transparent execution on heterogeneous platforms. Microservices are deployed via a microservice platform [3–5, 40] on shared datacenter infrastructure. These platforms abstract and allocate physical datacenter computing nodes, provide a reliable and available execution environment, and interact with deployed microservices through a set of common runtime APIs. Large-scale web services already use microservices on hundreds of thousands of servers [40, 41].

In this paper, we investigate efficient microservice execution on SmartNIC-accelerated servers. Specifically, we are exploring how to integrate multiple SmartNICs per server into a microservice platform with the goal of achieving better energy efficiency at minimum latency cost. However, transparently integrating SmartNICs into microservice platforms is non-trivial. Unlike traditional heterogeneous clusters, SmartNICs are collocated with their host servers, raising a number of issues. First, SmartNICs and hosts share the same MAC address. We require an efficient mechanism to route and load-balance traffic to hosts and SmartNICs. Second, SmartNICs sit in the host's data path and microservices running on a SmartNIC can interfere with microservices on the host. Microservices need to be appropriately placed to balance network-to-compute bandwidth. Finally, microservices can contend on shared SmartNIC resources, causing overload. We need to efficiently detect and prevent such situations.

We present E3, a microservice execution platform for SmartNIC-accelerated servers that addresses these issues. E3

*The author is now at Google.

follows the design philosophies of the Azure Service Fabric microservice platform [40] and extends key system components to allow transparent offload of microservices to a SmartNIC. To balance network request traffic among SmartNICs and the host, E3 employs equal-cost multipath (ECMP) load balancing at the top-of-rack (ToR) switch and provides high-performance PCIe communication mechanisms between host and SmartNICs. To balance computation demands, we introduce *HCM*, a hierarchical, communication-aware microservice placement algorithm, combined with a data-plane orchestrator that can detect and eliminate SmartNIC overload via microservice migration. This allows E3 to optimize server energy efficiency with minimal impact on client request latency.

We make the following contributions:

- We show why SmartNICs can improve energy efficiency over other forms of heterogeneous computation and how they should be integrated with data center servers and microservice platforms to provide efficient and transparent microservice execution (§2).
- We present the design of E3 (§3), a microservice runtime on SmartNIC-accelerated server systems. We present its implementation within a cluster of Xeon-based servers with up to 4 Cavium LiquidIO-based SmartNICs per server (§4).
- We evaluate energy and cost-efficiency, as well as client-observed request latency and throughput for common microservices, such as a real-time analytics framework, an IoT hub, and various virtual network functions, across various homogeneous and heterogeneous cluster configurations (§5). Our results show that offload of microservices to multiple SmartNICs per server with E3 improves cluster energy-efficiency up to 3× and cost efficiency up to 1.9× at up to 4% client-observed latency cost versus all other cluster configurations.

2 Background

Microservices simplify distributed application development and are a good match for low-power SmartNIC offload. Together, they are a promising avenue for improving server energy efficiency. We discuss this rationale, quantify the potential benefits, and outline the challenges of microservice offload to SmartNICs in this section.

2.1 Microservices

Microservices have become a critical component of today's data center infrastructure with a considerable and diverse workload footprint. Microsoft reports running microservices 24/7 on over 160K machines across the globe, including Azure SQL DB, Skype, Cortana, and IoT suite [40]. Google reports that Google Search, Ads, Gmail, video processing, flight search, and more, are deployed as microservices [41]. These microservices include large and small data and code footprints, long and short running times, billed by run-time

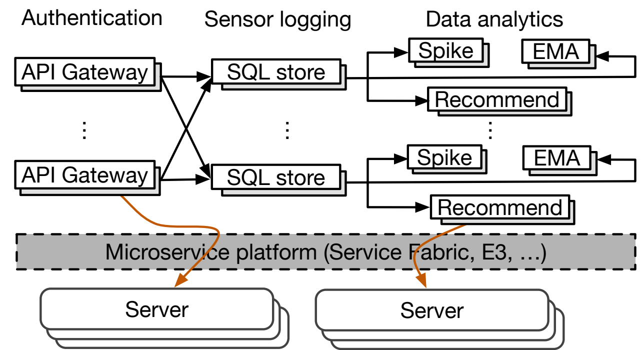

Figure 1: Thermostat analytics as DAG of microservices. The platform maps each DAG node to a physical computing node.

and by remote procedure call (RPC) [28]. What unifies these services is their software engineering philosophy.

Microservices use a modular design pattern, which simplifies distributed application design and deployment. Microservices are loosely-coupled, communicating through a set of common APIs, invoked via RPCs [86], and maintain state via *reliable collections* [40]. As a result, developers can take advantage of languages and libraries of their choice, while not having to worry about microservice placement, communication mechanisms, fault tolerance, or availability.

Microservices are also attractive to datacenter operators as they provide a way to improve server utilization. Microservices execute as light-weight processes that are easier to scale and migrate compared with a monolithic development approach. They can be activated upon incoming client requests, execute to request completion, and then swapped out.

A microservice platform, such as Azure Service Fabric [40], Amazon Lambda [3], Google Application Engine [4], or Nirmata [5], is a distributed system manager that enables isolated microservice execution on shared datacenter infrastructure. To do so, microservice platforms include the following components (cf. [40]): 1. *federation subsystem*, abstracting and grouping servers into a unified cluster that holds deployed applications; 2. *resource manager*, allocating computation resources to individual microservices based on their execution requirements; 3. *orchestrator*, dynamically scheduling and migrating microservices within the cluster based on node health information, microservice execution statistics, and service-level agreements (SLAs); 4. *transport subsystem*, providing (secure) point-to-point communication among various microservices; 5. *failover manager*, guaranteeing high availability/reliability through replication; 6. troubleshooting utilities, which assist developers with performance profiling/debugging and understanding microservice co-execution interference.

A microservice platform usually provides a number of programming models [10] that developers adhere to, like dataflow and actor-based. The models capture the execution requirements and describe the communication relationship among microservices. For example, the data-flow model (e.g. Amazon Datapipe [6], Google Cloudflow [29], Azure Data

Factory [55]) requires programmers to assemble microservices into a directed acyclic graph (DAG): nodes contain microservices that are interconnected via flow-controlled, lossless dataflow channels. These models bring attractive benefits for a heterogeneous platform since they explicitly express concurrency and communication, enabling the platform to transparently map it to the available hardware [68, 70]. Figure 1 shows an IoT thermostat analytics application [54] consisting of microservices arranged in 3 stages: 1. Thermostat sensor updates are authenticated by the API gateway; 2. Updates are logged into a SQL store sharded by a thermostat identifier; 3. SQL store updates trigger data analytic tasks (e.g, spike detection, moving average, and recommendation) based on thresholds. The dataflow programming model allows the SQL store sharding factor to be dynamically adjusted to scale the application with the number of thermostats reporting. Reliable collections ensure state consistency when re-sharding and the microservice platform automatically migrates and deploys DAG nodes to available hardware resources.

A microservice can be stateful or stateless. Stateless microservices have no persistent storage and only keep state within request context. They are easy to scale, migrate, and replicate, and they usually rely on other microservices for stateful tasks (e.g., a database engine). Stateful microservices use platform APIs to access durable state, allowing the platform full control over data placement. For example, Service Fabric provides reliable collections [40], a collection of data structures that automatically persist mutations. Durable storage is typically disaggregated for microservices and accessed over the network. The use of platform APIs to maintain state allows for fast service migration compared with traditional virtual machine migration [19], as the stateful working set is directly observed by the platform. All microservices in Figure 1 are stateful. We describe further microservices in §4.

2.2 SmartNICs

SmartNICs have appeared on the market [15, 51, 59] and in the datacenter [25]. SmartNICs include computing units, memory, traffic managers, DMA engines, TX/RX ports, and several hardware accelerators for packet processing, such as cryptography and pattern matching engines. Unlike traditional accelerators, SmartNICs integrate the accelerator with the NIC. This allows them to process network requests in-line, at much lower latency than other types of accelerators.

Two kinds of SmartNIC exist: (1) *general-purpose*, which allows transparent microservice offload and is the architecture we consider. For example, Mellanox BlueField [51] has 16 ARMv8 A72 cores with 2×100GE ports and Cavium LiquidIO [15] has 12 cnMIPS cores with 2×10GE ports. These SmartNICs are able to run full operating systems, but also ship with lightweight runtime systems that can provide kernel-bypass access to the NIC's IO engines. (2) FPGA and ASIC based SmartNICs target highly specialized applications. Examples include match-and-action processing [25, 43] for network dataplanes, NPUs [26], and TPUs [39] for deep neural network inference acceleration. FPGAs and ASICs do not support transparent microservice offload. However, they can be combined with general-purpose SmartNICs.

A SmartNIC-accelerated server is a commodity server with one or more SmartNICs. Host and SmartNIC processors do not share thermal, memory, or cache coherence domains, and communicate via DMA engines over PCIe. This allows them to operate as independent, heterogeneous computers, while sharing a power domain and its idle power.

SmartNICs hold promise for improving server energy-efficiency when compared to other heterogeneous computing approaches. For example, racks populated with low-power servers [8] or a heterogeneous mix of servers, suffer from high idle energy draw, as each server requires energy to power its chassis, including fans and devices, and its own ToR switch port. System-on-chip designs with asymmetric performance, such as ARM's big.LITTLE [38] and DynamIQ [2] architectures, and AMD's heterogeneous system architecture (HSA) [7], which combines a GPU with a CPU on the same die, have scalability limits due to the shared thermal design point (TDP). These architectures presently scale to a maximum of 8 cores, making them more applicable to mobile than to server applications. GPGPUs and single instruction multiple threads (SIMT) architectures, such as Intel's Xeon Phi [36] and HP Moonshot [34], are optimized for computational throughput and the extra interconnect hop prevents these accelerators from running latency-sensitive microservices efficiently [57]. SmartNICs are not encumbered by these problems and can thus be used to balance the power draw of latency-sensitive services efficiently.

2.3 Benefits of SmartNIC Offload

We quantify the potential benefit of using SmartNICs for microservices on energy efficiency and request latency. To do so, we choose two identical commodity servers and equip one with a traditional 10GbE Intel X710 NIC and the other with a 10GbE Cavium LiquidIO SmartNIC. Then we evaluate 16 different microservices (detailed in §4) on these two servers with synthetic benchmarks of random 512B requests. We measure request throughput, wall power consumed at peak throughput (defined as the knee of the latency-throughput graph, where queueing delay is minimal) and when idle, as well as client-observed, average/tail request latency in a closed loop. We use host cores on the traditional server and SmartNIC cores on the SmartNIC server for microservice execution. We use as many identical microservice instances, CPUs, and client machines as necessary to attain peak throughput and put unused CPUs to their deepest sleep state. The SmartNIC does not support per-core low power states and always keeps all 12 cores active, diminishing SmartNIC energy efficiency results somewhat. The SmartNIC microservice runtime system uses a kernel-

Microservice	Host (Linux)						Host (DPDK)							SmartNIC

Table 1: Microservice comparison among host (Linux and DPDK) and SmartNIC. RPS = Throughput (requests/s), W = Active power (W), C = Number of active cores, L = Average latency (ms), 99% = 99th percentile latency, RPJ = Energy efficiency (requests/Joule).

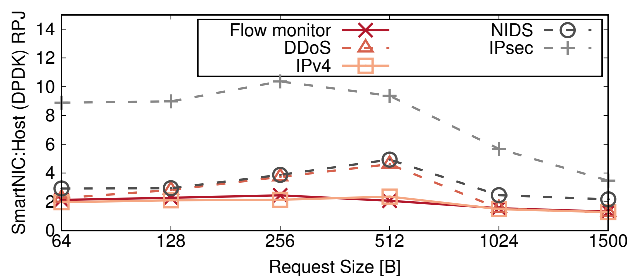

Figure 2: Request size impact on SmartNIC RPJ benefits.

bypass network stack (cf. §4). To break out kernel overheads from the host experiments, we run all microservices on the host in two configurations: 1. Linux kernel network stack; 2. kernel-bypass network stack [63], based on Intel's DPDK [1].

Table 1 presents measured peak request throughput, active power (wall power at peak throughput minus idle wall power), number of active cores, (tail-)latency, and energy efficiency, averaged over 3 runs. Active power allows a direct comparison of host to SmartNIC processor power draw. Energy efficiency equals throughput divided by active power.

Kernel overhead. We first analyze the overhead of in-kernel networking on the host (Linux versus DPDK). As expected, the kernel-bypass networking stack performs better than the in-kernel one. On average, it improves energy efficiency by 21% (% column in Table 1) and reduces tail latency by 16%. Energy efficiency improves because (1) DPDK achieves similar throughput with fewer cores; (2) at peak server CPU utilization, DPDK delivers higher throughput.

SmartNIC performance. SmartNIC execution improves the energy efficiency of 12 of the measured microservices by a geometric mean of 6.5× compared with host execution using kernel bypass (× column in Table 1). The SmartNIC consumes at most 24.7W active power to execute these microservices while the host processor consumes up to 113W. IPSec, BM25, Recommend, and NIDS particularly benefit from various SmartNIC hardware accelerators (crypto coprocessor, fetch-and-add atomic units, floating point engines, and pattern matching units). NATv4, Count, EMA, KVS, Flow monitor, and DDoS can take advantage of the computational bandwidth and fast memory interconnect of the SmartNIC. In these cases, the energy efficiency comes not just from the lower power consumed by the SmartNIC, but also from peak throughput improvements versus the host processor. KNN and Spike attain lower throughput on the SmartNIC. However, since the SmartNIC consumes less power, the overall energy efficiency is still better than the host. For all of these microservices, the SmartNIC also improves client-observed latency. This is due to the hardware accelerated packet buffers and the elimination of PCIe bus traversals. SmartNICs can reduce average and tail latency by a geometric mean of 45.3% and 45.4% versus host execution, respectively.

The host outperforms the SmartNIC for Top ranker, Bayes classifier, SQL, and API gateway by a geometric mean of 4.1× in energy efficiency, 41.2% and 30.0% in average and tail latency reduction. These microservices are branch-heavy with large working sets that are not handled well by the simpler cache hierarchy of the SmartNIC. Moreover, the API gateway uses double floating point numbers for the rate limiter implementation, which the SmartNIC emulates in software.

Request size impact. SmartNIC performance depends also on request size. To demonstrate this, we vary the request size of our synthetic workload and evaluate SmartNIC energy efficiency benefits of 5 microservices versus host execution. Figure 2 shows that with small (≤128B) requests, SmartNIC benefit of IPSec, NIDS, and DDoS is smaller. Small requests are more computation intensive and we are limited by the SmartNIC's wimpy cores. SmartNIC offload hits a sweet-spot at 256–512B request size, where the benefit almost doubles. Here, network and compute bandwidth utilization are balanced for the SmartNIC. At larger request sizes, we are network bandwidth limited, allowing us to put host CPUs to sleep and SmartNIC benefits again diminish. This can be seen in particular for IPsec, which outperforms on the SmartNIC due

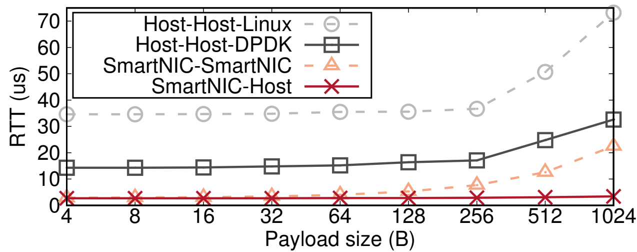

Figure 3: Average RTT (3 runs) of different communication mechanisms in a SmartNIC-accelerated server.

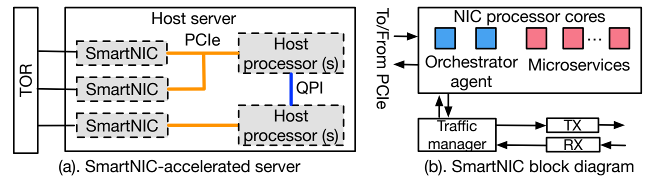

Figure 4: Hardware and software architecture of E3.

to hardware cryptography acceleration, but still diminishes with larger request sizes. We conclude that request size has a major impact on the benefit of SmartNIC offload. Measuring it is necessary to make good offload choices.

We conclude that SmartNIC offload can provide large energy efficiency and latency benefits for many microservices. However, it is not a panacea. Computation and memory intensive microservices are more suitable to run on the host processor. We need an efficient method to define and monitor critical SmartNIC offload criteria for microservices.

2.4 Challenges of SmartNIC Offload

While there are quantifiable benefits, offloading microservices to SmartNICs brings a number of additional challenges:

- SmartNICs share the same Ethernet MAC address with the host server. Layer 2 switching is not enough to route traffic between SmartNICs and host servers. We require a different switching scheme that can balance traffic and provide fault tolerance when a server equips multiple SmartNICs.
- Microservice platforms assume uniform communication performance among all computing nodes. However, Figure 3 shows that SmartNIC-Host (via PCIe) and SmartNIC-SmartNIC (via ToR switch) communication round-trip-time (RTT) is up to 83.3% and 86.2% lower than host-host (via ToR switch) kernel-bypass communication. We have to consider this topology effect to achieve good performance.
- Microservices share SmartNIC resources and contend with SmartNIC firmware for cache and memory bandwidth. This can create a head-of-line blocking problem for network packet exchange with both SmartNIC and host. Prolonged head-of-line blocking can result in denial of service to unrelated microservices and is more severe than transient sources of interference, such as network congestion. We need to sufficiently isolate SmartNIC-offloaded microservices from firmware to guarantee quality of service.

3 E3 Microservice Platform

We present the E3 microservice platform for SmartNIC-accelerated servers. Our goal is to maximize microservice energy efficiency at scale. Energy efficiency is the ratio of microservice throughput and cluster power draw. Power draw is determined by our choice of SmartNIC-acceleration, while E3 focuses on maximizing microservice throughput on this heterogeneous architecture. We describe how we support microservice offload to a SmartNIC and address the request routing, microservice placement, and scheduling challenges.

E3 overview. E3 is a distributed microservice execution platform. We follow the design philosophies of Azure Service Fabric [40] but add energy efficiency as a design requirement. Figure 4 shows the hardware and software architecture of E3. E3 runs in a typical datacenter, where servers are grouped into racks, with a ToR switch per rack. Each server is equipped with one or more SmartNICs, and each SmartNIC is connected to the ToR. This creates a new topology where host processors are reachable via any of the SmartNICs (Figure 4-a). SmartNICs within the same server also have multiple communication options—via the ToR or PCIe (§3.1).

Programming model. E3 uses a dataflow programming model. Programmers assemble microservices into a DAG of microservice nodes interconnected via channels in the direction of RPC flow (cf. Figure 1). A channel provides lossless data communication between nodes. A DAG in E3 describes all RPC and execution paths of a single microservice application, but multiple DAGs may coexist and execute concurrently. E3 is responsible for mapping DAGs to computational nodes.

Software stack. E3 employs a central, replicated cluster resource controller [40] and a microservice runtime on each host and SmartNIC. The resource controller includes four components: (1) traffic control, responsible for routing and load balancing requests between different microservices; (2) control-plane manager, placing microservice instances on cluster nodes; (3) data-plane orchestrator, dynamically migrates microservices across cluster nodes; (4) failover/replication manager, providing failover and node membership management using consistent hashing [75]. The microservice runtime includes an execution engine, an orchestrator agent, and a communication subsystem, described next.

Execution engine. E3 executes each microservice as a multi-threaded process, either on the SmartNIC or on the host. The host runs Linux. The SmartNIC runs a lightweight firmware. Microservices interact only via microservice APIs,

allowing E3 to abstract from the OS. SmartNIC and host support hardware virtual memory for microservice confinement. E3 is work-conserving and runs requests to completion. It leverages a round-robin policy for steering incoming requests to cores, context switching cores if needed.

Orchestrator agent. Each node runs an orchestrator agent to periodically monitor and report runtime execution characteristics to the resource controller. The information is used by (1) the failover manager to determine cluster health and (2) the data-plane orchestrator to monitor the execution performance of each microservice and make migration decisions. On the host, the agent runs as a separate process. On the SmartNIC, the agent runs on dedicated cores (blue in Figure 4-b) and a traffic manager hardware block exchanges packets between the NIC MAC ports and the agent. For each packet, the agent determines the destination (network, host, or SmartNIC core).

3.1 Communication Subsystem

E3 leverages various communication mechanisms, depending on where communicating microservices are located.

Remote communication. When communicating among host cores across different servers, E3 uses the Linux network stack. SmartNIC remote communication uses a user-level network stack [63].

Local SmartNIC-host communication. SmartNIC and host cores on the same server communicate via PCIe. Prior work has extensively explored communication channels via PCIe [47, 48, 60], and we adopt their design. High-throughput messaging for PCIe interconnects requires leveraging multiple DMA engines in parallel. E3 takes advantage of the eight DMA engines on the LiquidIO, which can concurrently issue scatter/gather requests.

Local SmartNIC-SmartNIC communication. SmartNICs in the same host can use three methods for communication. 1. Using the host to relay requests, involving two data transfers over PCIe and pointer manipulation on the host, increasing latency. 2. PCIe peer-to-peer [23], which is supported on most SmartNICs [15, 51, 59]. However, the bandwidth of peer-to-peer PCIe communication is capped in a NUMA system when the communication passes between sockets [57]. 3. ToR switch. We take the third approach and our experiments show that this approach incurs lower latency and achieves higher bandwidth than the first two.

3.2 Addressing and Routing

Since SmartNICs and their host servers share Ethernet MAC addresses, we have to use an addressing/routing scheme to distinguish between these entities and load balance across them. For illustration, assume we have a server with two SmartNICs; each NIC has one MAC port. If remote microservices communicate with this server, there will be two possible paths and each might be congested.

We use equal-cost multi-path (ECMP) [84] routing on the ToR switch to route and balance load among these ports. We assign each SmartNIC and the host its own IP. We then configure the ToR switch to route to SmartNICs directly via the attached ToR switch port and an ECMP route to the host IP via any of the ports. The E3 communication subsystem on each SmartNIC differentiates by destination IP address whether an incoming packet is for the SmartNIC or the host. On the host, we take advantage of NIC teaming [56] (also know as port trunking) to bond all related SmartNIC ports into a single logical interface, and then apply the dynamic link aggregation policy (supporting IEEE 802.3ad protocol). ECMP automatically balances connections to the host over all available ports. If a link or SmartNIC fails, ECMP will automatically rebalance new connections via the remaining links, improving host availability.

3.3 Control-plane Manager

The control-plane manager is responsible for energy-efficient microservice placement. This is a computing intensive operation due to the large search space with myriad constraints. Hence, it is done on the control plane. Service Fabric uses simulated annealing, a well-known approximate algorithm, to solve microservice placement. It considers three types of constraints: (1) currently available resources of each computing node (memory, disk, CPU, network bandwidth); (2) computing node runtime statistics (aggregate outstanding microservice requests); (3) individual microservice execution behavior (average request size, request execution time and frequency, diurnal variation, etc.). Service Fabric ignores network topology and favors spreading load over multiple nodes.

E3 extends this algorithm to support bump-in-the-wire SmartNICs, considering network topology. We categorize *computing nodes* (host or SmartNIC processors) into different levels of communication distance and perform a search from the closest to the furthest. We present the HCM algorithm (Algorithm 1). HCM takes as input the microservice DAG G and source nodes V_{src}, as well as the cluster topology T, including runtime statistics for each computing node (as collected). HCM performs a breadth-first traversal of G to map microservices to cluster computing nodes (*MS_DAG_TRAVERSE*).

If not already deployed (*get_deployed_node*), HCM (via *MS_DAG_TRAVERSE*) assigns a microservice V to a computing node N via the *find_first_fit* function (lines 9-11) and deploys it via *set_deployed_node*. *find_first_fit* is a greedy algorithm that returns the first computing node that satisfies the microservice constraints (via its resource and runtime statistics) without considering communication cost. If no such node is found, it returns a node closest to the constraints. Next,

Algorithm 1 HCM microservice placement algorithm

```
1:  G : microservice DAG graph
2:  V_src : source microservice node(s) of the DAG
3:  T : server cluster topology graph
4:  procedure MS_DAG_TRAVERSE(G, V_src, T)
5:      Q.enqueue(V_src)                                ▷ Let Q be a queue
6:      while Q is not empty do
7:          V ← Q.dequeue()
8:          N ← get_deployed_node(V)
9:          if N is NULL then
10:             N ← find_first_fit(V, T)
11:             set_deployed_node(V, N)
12:         for W in all direct descendants of V in G do
13:             N_W ← MS_PLACE(W, N, T)
14:             set_deployed_node(W, N_W)
15:             Q.enqueue(W)
16:
17: V : microservice to place
18: N : computational node of V's ancestor
19: T : server cluster topology graph
20: procedure MS_PLACE(V, N, T)
21:     Topo ← get_hierarchical_topo(N, T)
22:     for L in all Topo.Levels do
23:         N ← find_best_fit(V, Topo.node_list(L))
24:         if N is not NULL then
25:             return N
26:     return find_first_fit(V, T)                     ▷ Ignore topology
```

for the descendant microservices of a node V (lines 12-15), HCM assigns them to computing nodes based on their communication distance to V (*MS_PLACE*). To do so, HCM first computes the *hierarchical topology representation* of computing node N via *get_hierarchical_topo*. Each level in the hierarchical topology includes computing nodes that require a similar communication mechanism, starting with the closest. For example, in a single rack there are four levels in this order: 1. The same computing node as V; 2. An adjacent computing node on the same server; 3. A SmartNIC computing node on an adjacent server; 4. A host computing node on an adjacent server. If there are multiple nodes in the same level, HCM uses *find_best_fit* to find the best fit, according to resource constraints. If no node in the hierarchical topology fits the constraints, we fall back to *find_first_fit*.

3.4 Data-plane Orchestrator

The data-plane orchestrator is responsible for detecting load changes and migrating microservices in response to these changes among computational nodes at run-time. To do so, we piggypack several measurements onto the periodic node health reports made by orchestrator agents to the resource controller: This approach is lightweight and integrates well with runtime execution. We believe that our proposed methods can also be used in other microservice schedulers [33, 62, 66].

In this section, we introduce the additional techniques implemented in our data-plane orchestrator to mitigate issues of SmartNIC overload caused by compute-intensive microservices. These can interfere with the SmartNIC's traffic manager, starving the host of network packets. They can also simply execute too slowly on the SmartNIC to be able to catch up with the incoming request rate.

Host starvation. This issue is caused by head-of-line blocking of network traffic due to microservice interference with firmware on SmartNIC memory/cache. It is typically caused by a single compute-intensive microservice overloading the SmartNIC. To alleviate this problem, we monitor the incoming/outgoing network throughput and packet queue depth at the traffic manager. If network bandwidth is under-utilized, but there is a standing queue at the traffic manager, the SmartNIC is overloaded, and we need to migrate microservices.

Microservice overload. This issue is caused by microservices in aggregate requiring more computational bandwidth than the SmartNIC can offer, typically because too many microservices are placed on the same SmartNIC. To detect this problem, we periodically monitor the execution time of each microservice and compare to its exponential moving average. When the difference is negative and larger than 20%, we assume a microservice overload and trigger microservice migration. The threshold was determined empirically.

Microservice migration. For either issue, the orchestrator will migrate the microservice with the highest CPU utilization to the host. To do so, it uses a cold migration approach, similar to other microservice platforms. Specifically, when the orchestrator makes a migration decision, it will first push the microservice binary to the new destination, and then notify the runtime of the old node to (1) remove the microservice instance from the execution engine; (2) clean up and free any local resources; (3) migrate the working state, as represented by reliable collections [40], to the destination. After the orchestrator receives a confirmation from the original node, it will update connections and restart the microservice execution on the new node.

3.5 Failover/Replication Manager

Since SmartNICs share the same power supply as their host server, our failover manager treats all SmartNICs and the host to be in the same fault domain [40], avoiding replica placement within the same. Replication for fault tolerance is typically done across different racks of the same datacenter or across datacenters, and there is no impact from placing SmartNICs in the same failure domain as hosts.

Microservice	S	Description
IPsec		Authenticates (SHA-1) & encrypts (AES-CBC-128) NATv4 [42]
BM25		Search engine ranking function [85], e.g., ElasticSearch
NATv4		IPv4 network address translation using DIR-24-8-BASIC [32]
NIDS		Network intrusion detection w/ aho-corasick parallel match [81]
Count	✓	Item frequency counting based on a bitmap [42]
EMA	✓	Exponential moving average (EMA) for data streams [83]
KVS	✓	Hashtable-based in-memory key-value store [24]
Flow mon.	✓	Flow monitoring system using count-min sketch [42]
DDoS	✓	Entropy-based DDoS detection [58]
Recommend	✓	Recommendation system using collaborative filtering [82]
KNN		Classifier using the K-nearest neighbours algorithm [87]
Spike	✓	Spike detector from a data stream using Z-score [72]
Bayes		Naive Bayes classifier based on *maximum a posteriori* [49]
API gw	✓	API rate limiter and authentication gateway [9]
Top Ranker	✓	Top-K ranker using quicksort [78]
SQL	✓	In-memory SQL database [52]

Table 2: 16 microservices implemented on E3. S = Stateful.

Application	Description	N	Microservices
NFV-FIN	Flow monitoring [42, 64]	72	Flow mon., IPsec, NIDS
NFV-DIN	Intrusion detection [64, 88]	60	DDoS, NATv4, NIDS
NFV-IFID	IPsec gateway [42, 88]	84	NATv4, Flow mon., IPsec, DDoS
RTA-PTC	Twitter analytics [78]	60	Count, Top Ranker, KNN
RTA-SF	Spam filter [35]	96	Spike, Count, KVS, Bayes
RTA-SHM	Server health mon. [37]	84	Count, EMA, SQL, BM25
IOT-DH	IoT data hub [77]	108	API gw, Count, KNN, KVS, SQL
IOT-TS	Thermostat [54]	108	API,EMA,Spike,Recommend,SQL

Table 3: 8 microservice applications. N = # of DAG nodes.

4 Implementation

Host software stack. The E3 resource controller and host runtime are implemented in 1,287 and 3,617 lines of C (LOC), respectively, on Ubuntu 16.04. Communication among co-located microservices uses per-core, multi-producer, single-consumer FIFO queues in shared memory. Our prototype uses UDP for all network communication.

SmartNIC runtime. The E3 SmartNIC runtime is built in 3,885 LOC on top of the Cavium CDK [16], with a user-level network stack. Each microservice runs on a set of non-preemptive hardware threads. Our implementation takes advantage of a number of hardware accelerator libraries. We use (1) a hardware managed memory manager to store the state of each microsevice, (2) the hardware traffic controller for Ethernet MAC packet management, and (3) atomic fetch-and-add units to gather performance statistics. We use page protection of the cnMIPS architecture to confine microservices.

Microservices. We implemented 16 popular microservices on E3, as shown in Table 2, in an aggregate 6,966 LOC. Six of the services are stateless or use read-only state that is modified only via the cluster control plane. The remaining services are stateful and use reliable collections to maintain their state. When running on the SmartNIC, IPsec and API gateway can use the crypto coprocessor (105 LOC), while Recommend and NIDS can take advantage of the deterministic finite automata unit (65 LOC). For Count, EMA, KVS, and Flow monitor, our compiler automatically uses the dedicated atomic fetch-and-add units on the SmartNIC. When performing single-precision floating-point computations (EMA, KNN, Spike, Bayes), our compiler generates FPU code on the SmartNIC. Double-precision floating-point calculations (API gateway) are software emulated. E3 reliable collections currently only support hashtables and arrays, preventing us from migrating the SQL engine. We thus constrain the control-plane manager to pin SQL instances to host processors.

System/Cluster	Cost [$]	BC	WC	Mem	Idle	Peak	Bw
Beefy	4,500	12	0	64	83	201	20
Wimpy	2,209	0	32	2	79	95	20
Type1-SmartNIC	4,650	12	12	68	98	222	20
Type2-SmartNIC	6,750	16	48	144	145	252	40
SuperBeefy	12,550	24	0	192	77	256	80
4×Beefy	18,000	48	0	256	332	804	80
4×Wimpy	8,836	0	128	8	316	380	80
2×B.+2×W.	13,018	24	64	132	324	592	80
2×Type2-SmartNIC	13,500	32	96	288	290	504	80
1×SuperBeefy	12,550	24	0	192	77	256	80

Table 4: Evaluated systems and clusters. BC = Beefy cores, WC = Wimpy cores, Mem = Memory (GB), Idle and Peak power (W), Bw = Network bandwidth (Gb/s).

Applications. Based on these microservices, we develop eight applications across three application domains: (1) Distributed real-time analytics (RTA), such as Apache Storm [78], implemented as a dataflow processing graph of workers that pass data tuples in real time to trigger computations; (2) Network function (NF) virtualization (NFV) [61], which is used to build cloud-scale network middleboxes, software switches, and enterprise IT networks, by chaining NFs; (3) An IoT hub (IOT) [53], which gathers sensor data from edge devices and generates events for further processing (e.g., spike detection, classifier) [?, 77]. To maximize throughput, applications may shard and replicate microservices, resulting in a DAG node count larger than the involved microservice types. Table 3 presents the microservice types involved in each application, the deployed DAG node count, and references the workloads used for evaluation. The workloads are trace-based and synthetic benchmarks, validated against realistic scenarios. The average and maximum node fanouts among our applications are 6 and 12, respectively. Figure1 shows IOT-TS as an example. IOT-TS is sharded into 6×API, 12×SQL, 12×EMA, 12×Spike, and 12×recommend and each microservice has one backup replica.

5 Evaluation

Our evaluation aims to answer the following questions:

1. What is the energy efficiency benefit of microservice SmartNIC-offload? Is it proportional to client load? What is the latency cost? (§5.1)
2. Does E3 overcome the challenges of SmartNIC-offload? (§5.2, §5.3, §5.4)
3. Do SmartNIC-accelerated servers provide better total cost of ownership than other cluster architectures? (§5.5)
4. How does E3 perform at scale? (§5.6)

Experimental setup. Our experiments run on a set of clusters (Table 4 presents the server and cluster configurations), attached to an Arista DCS-7050S ToR switch. Beefy is a Supermicro 1U server, with a 12-core E5-2680 v3 processor at 2.5GHz, and a dual-port 10Gbps Intel X710 NIC. Wimpy is ThunderX-like, with a CN6880 processor (32 cnMIPS64 cores running at 1.2GHz), and a dual-port 10Gbps NIC. SuperBeefy is a Supermicro 2U machine, with a 24-core Xeon Platinum 8160 CPU at 2.1GHz, and a dual-port 40Gbps Intel XL710 NIC. Our SmartNIC is the Cavium LiquidIOII [15], with one OCTEON processor with 12 cnMIPS64 cores at 1.2GHz, 4GB memory, and two 10Gbps ports. Based on this, we build two SmartNIC servers: Type1 is Beefy, but swaps the X710 10Gbps NIC with the Cavium LiquidIOII; Type2 is a 2U server with two 8-core Intel E5-2620 processors at 2.1GHz, 128GB memory, and 4 SmartNICs. All servers have a Seagate HDD. We build the clusters such that each has the same amount of aggregate network bandwidth. This allows us to compare energy efficiency based on the compute bandwidth of the clusters, without varying network bandwidth. We also exclude the switch from our cost and energy evaluations, as each cluster uses an identical number of switch ports.

We measure server power consumption using the servers' IPMI data center management interface (DCMI), cross-checked by a Watts Up wall power meter. Throughput and average/tail latency across 3 runs are measured from clients (Beefy machines), of which we provide as many as necessary. We enable hyper-threading and use the `Intel_pstate` governor for power management. All benchmarks in this section report energy efficiency as throughput over server/cluster **wall power** (not just active power).

5.1 Benefit and Cost of SmartNIC-Offload

Peak utilization. We evaluate the latency and energy efficiency of using SmartNICs for microservice applications, compared to homogeneous clusters. We compare 3×Beefy to 3×Type1-SmartNIC, to ensure that microservices also communicate remotely. We focus first on peak utilization, which is desirable for energy efficiency, as it amortizes idle power draw. To do so, we deploy as many instances of each application and apply as much client load as necessary to maximize request throughput without overloading the cluster, as determined by the knee of the latency-throughput curve.

Figure 5 shows that Type1-SmartNIC achieves an average 2.5×, 1.3×, and 1.3× better energy efficiency across the NFV, RTA, and IOT application classes, respectively. This goes along with 43.3%, 92.3%, and 80.4% average latency savings and 35.5%, 90.4%, 88.6% 99th percentile latency savings, respectively. NFV-FIN gains the most—3× better energy efficiency—because E3 is able to run all microservices on the SmartNICs. RTA-PTC benefits the least—12% energy efficiency improvement at 4% average and tail latency cost—as E3 only places the Count microservice on the SmartNIC and migrates the rest to the host.

Power proportionality. This experiment evaluates the power proportionality of E3 (energy efficiency at lower than peak utilization). Using 3×Type1-SmartNIC, we choose an application from each class (NFV-FIN, RTA-SHM, and IOT-TS) and vary the offered request load between idle and peak via a client side request limiter. Figure 8 shows that RTA-SHM and IOT-TS are power proportional. NFV-FIN is not power proportional but also draws negligible power. NFV-FIN runs all microservices on the SmartNICs, which have low active power, but the cnMIPS architecture has no per-core sleep states.

We conclude that applications can benefit from E3's microservice offload to SmartNICs, in particular at peak cluster utilization. Peak cluster utilization is desirable for energy efficiency and microservices make it more common due to light-weight migration. However, transient periods of low load can occur and E3 draws power proportional to request load. We can apply insights from Prekas, et al. [65] to reduce polling overheads and improve power proportionality further.

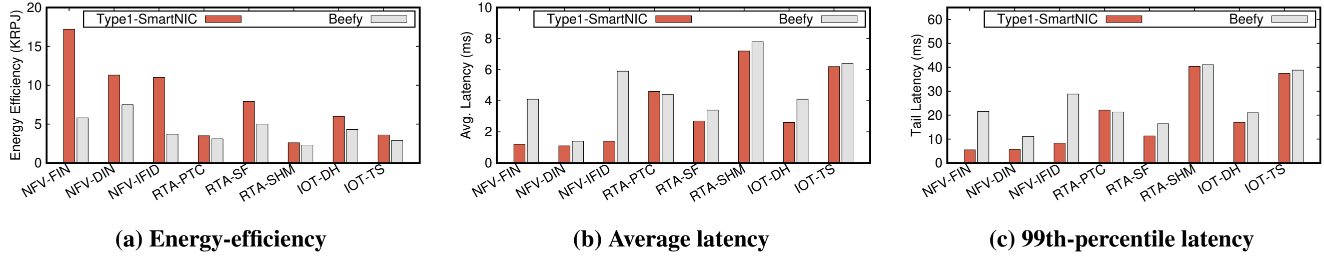
5.2 Avoiding Host Starvation

We show that E3's data-plane orchestrator prevents host starvation by identifying head-of-line blocking of network traffic. To do so, we use 3×Type1-SmartNIC and place as many microservices on the SmartNIC as fit in memory. E3 identifies the microservices that cause interference (Top Ranker in RTA-PTC, Spike in RTA-SF, API gateway in IOT-DH and IOT-TS) and migrates them to the host. As shown in Figure 7, our approach achieves up to 29× better energy efficiency and up to 89% latency reduction across RTA-PTC, RTS-SF, IOT-DH, and IOT-TS. For the other applications, our traffic engine has little effect because the initial microservice assignment already put the memory intensive microservices on the host.

5.3 Sharing SmartNIC and Host Bandwidth

This experiment evaluates the benefits of sharing SmartNIC network bandwidth with the host. We compare two Type2-SmartNIC configurations: 1. Sharing aggregate network bandwidth among host and SmartNICs, using ECMP to balance host traffic over SmartNIC ports; 2. Replacing one SmartNIC with an Intel X710 NIC used exclusively to route traffic to the host. To emphasize the load balancing benefits, we always place the client-facing microservices on the host server. Note that SmartNIC-offloaded microservices still exchange network traffic (when communicating remotely or among SmartNICs) and interfere with host traffic.

Figure 9 shows that load balancing improves application throughput up to 2.9× and cluster energy efficiency up to 2.7× (NFV-FIN). Available host network bandwidth when sharing SmartNICs can be up to 4× that of the dedicated



(a) Energy-efficiency **(b) Average latency** **(c) 99th-percentile latency**

Figure 5: Energy-efficiency, average/tail latency comparison between Type1-SmartNIC and Beefy at peak utilization.

Cluster	NFV-FIN	RTA-SHM	IOT-TS
4×Beefy	5.1	1.9	2.7
4×Wimpy	29.9	0.4	0.1
2×B.+2×W.	8.2	1.4	1.9
2×Type2-SmartNIC	29.0	4.5	6.1
1×SuperBeefy	8.8	2.9	5.0

Table 5: Energy efficiency across five clusters (KRPJ).

NIC, which balances better with the host compute bandwidth. With a dedicated NIC, host processors can starve for network bandwidth. IOT-TS is compute-bound and thus benefits the least from sharing. In terms of latency, all cases behave the same since the request execution flows are the same.

5.4 Communication-aware Placement

To show the effectiveness of communication-aware microservice placement, we evaluate HCM on E3 without data-plane orchestrator. In this case, all microservices are stationary after placement. We avoid host starvation and microservice overload by constraining problematic microservices to the host.

Using 3×Type1-SmartNIC and all placement constraints of Service Fabric [40] (described in §3.3), we compare HCM with both simulated annealing and an integer linear program (ILP). HCM places the highest importance on minimizing microservice communication latency. Simulated annealing and ILP use a cost function with the highest weight on minimizing co-execution interference. Hence, HCM tries to co-schedule communicating microservices on proximate resources, while the others will spread them out. ILP attempts to find the best configuration, while simulated annealing approximates. Figure 6 shows that compared to simulated annealing and ILP, HCM improves energy efficiency by up to 35.2% and 22.0%, and reduces latency by up to 24.0% and 18.6%, respectively. HCM's short communication latency benefits outweigh interference from co-execution.

5.5 Energy Efficiency = Cost Efficiency

While SmartNICs benefit energy efficiency and thus potentially bring cost savings, can they compete with other forms of heterogeneous clusters, especially when factoring in the capital expense to acquire the hardware? In this experiment, we evaluate the cost efficiency, in terms of request throughput over total cost and time of ownership, of using SmartNICs for microservices, compared with four other clusters (see Table 4). Assuming that clusters are usually at peak utilization, we use the cost efficiency metric $\frac{Throughput \times T}{CAPEX + (Power \times T \times Electricity)}$, where $Throughput$ is the measured average throughput at peak utilization for each application, as executed by E3 on each cluster, T is elapsed time, $CAPEX$ is the capital expense to purchase the cluster including all hardware components ($), $Power$ is the elapsed peak power draw of the cluster (Watts), and $Electricity$ is the price of electricity ($/Watts). The cluster cost and power data is shown in Table 4 and we use the average U.S. electricity price [31] of $0.0733/kWh. Figure 10 reports results for three applications of very different points in the workload space, extrapolated over time of ownership by our cost efficiency metric.

We make three observations. First, in the long term (>1 year of ownership), cost efficiency is increasingly dominated by energy efficiency. This highlights the importance of energy efficiency for data center design, where servers are typically replaced after several years to balance CAPEX [12]. Second, when all microservices are able to run on a low power platform (NFV-FIN), both 4×Wimpy and 2×Type2-SmartNIC clusters are the most cost efficient. After 5 years, 4×Wimpy is 14.1% more cost efficient than 2×Type2-SmartNIC because of the lower power draw. Third, when a microservice application contains both compute and IO-intensive microservices (RTA-SHM, IOT-TS), the 2×Type2-SmartNIC cluster is up to 1.9× more cost efficient after 5 years of ownership than the next best cluster configuration (4×Beefy in both cases).

Table 5 presents the measured energy-efficiency, which shows cost efficiency in the limit (over very long time of ownership). We can see that 4×Wimpy is only 3% more energy efficient (but has lower CAPEX) than 2×Type2-SmartNIC for NFV-FIN. 2×Type2-SmartNIC is on average 2.37× more energy-efficient (but has higher CAPEX) than 1×SuperBeefy, which is the second-best cluster in terms of energy-efficiency.

5.6 Performance at Scale

We evaluate and discuss the scalability of E3 along three axes: 1. Mechanism performance scalability; 2. Tail-latency; 3. Energy-efficiency.

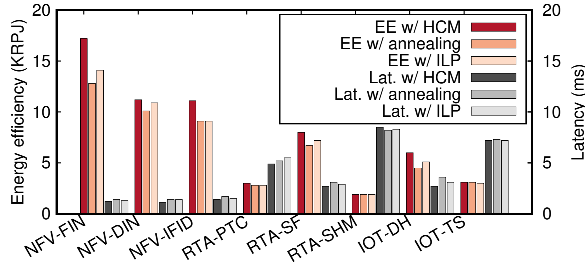


Figure 6: Communication-aware microservice placement.

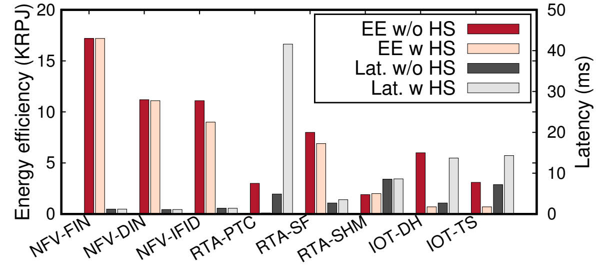

Figure 7: Avoiding host starvation (HS).

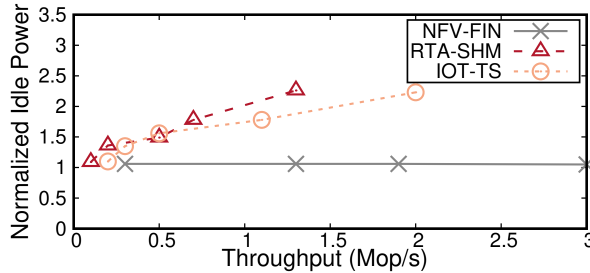

Figure 8: Power draw of 3 applications normalized to idle power of 3×Type1-SmartNIC, varying request load.

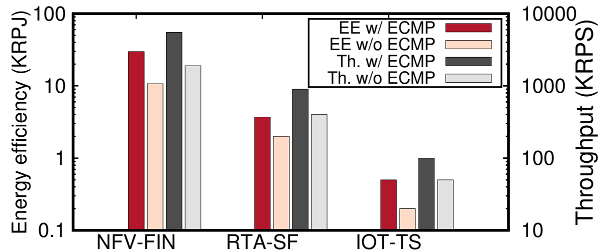

Figure 9: ECMP-based SmartNIC sharing (log y scale).

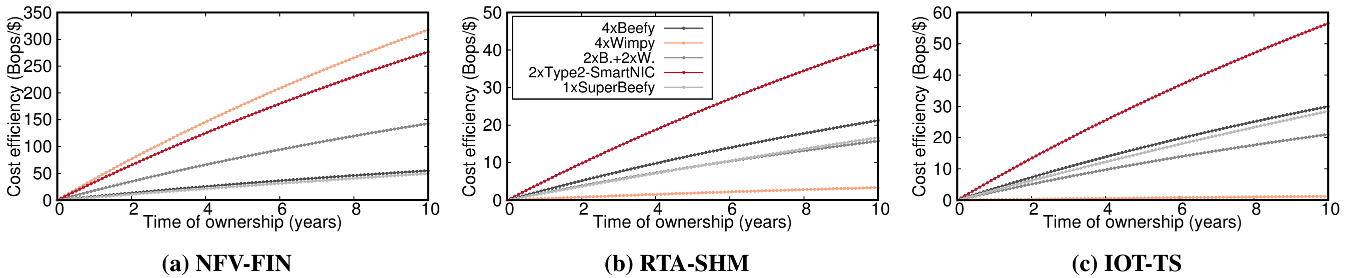

(a) NFV-FIN (b) RTA-SHM (c) IOT-TS

Figure 10: Cost efficiency of 3 applications across the cluster configurations from Table 4.

Servers →	100	200	400	600	800	1,000
HCM	4.85	8.31	19.83	34.32	74.39	263.46
Annealing	3.15	4.73	7.43	15.64	23.50	61.42
ILP	7.64	19.43	84.83	361.85	$\gg 1s$	$\gg 1s$

Table 6: Per-microservice deployment time (ms) scalability.

Mechanism scalability. At scale, pressure on the control-plane manager and data-plane orchestrator increases. We evaluate the performance scalability of both mechanisms with an increasing number of Type2-SmartNIC servers in a simulated FatTree [30] topology with 40 servers per rack. To avoid host starvation and microservice overload, E3's data-plane orchestrator receives one heartbeat message (16B) every 50ms from each SmartNIC that reports the queue length of the traffic manager and the SmartNIC's microservice execution times. The orchestrator parses the heartbeat message and makes a migration decision (§3.4). Figure 11 shows that the time taken to transmit the message and make a decision with a large number of servers stays well below the time taken to migrate the service (on the order of 10s-100s of ms) and is negligibly impacted by the number of deployed microservices. This is because the heartbeat message contributes only 1Kbps of traffic, even with 50K servers.

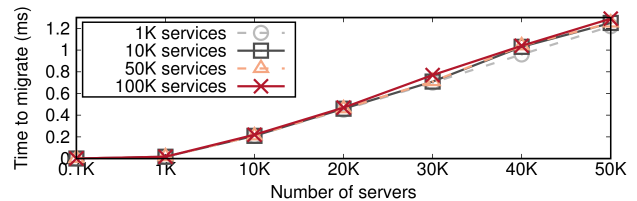

Figure 11: Orchestrator migration decision time scalability.

E3 uses HCM in the control-plane manager. We compare it to simulated annealing and ILP, deploying 10K microservices on an increasing number of servers. Table 6 shows that while HCM does not scale as well as simulated annealing, it can deploy new microservices in a reasonable time span (<<1s) at scale. ILP fails to deliver acceptable performance.

Tail latencies. At scale, tail latencies dominate [20]. While SmartNICs can introduce high tail latency for some microservices (§2.3), E3 places these microservices on the host to ensure that application-level tail-latency inflation is minimized

(§5.1). The tail-latency impact of SmartNIC offload is reduced at scale, as baseline communication latency increases with increasing inter-rack distance.

Energy-efficiency and power budgets. E3's energy efficiency benefits are constant regardless of deployment size and power budgets. At scale, there is additional energy cost for core and spine switches, but these are negligible compared to racks (ToRs and servers). Within a rack, ToR switch energy consumption stays constant, as all compared systems use the same number of switch ports. Our results show that E3 achieves up to 1.9x more throughput under the same power budget. Conversely, operators can save 48% of power, offering the same bandwidth.

6 Related Work

Architecture studies for microservices. Prior work has explored the architectural implications of running microservices [21, 27, 79]. It shows that wimpy servers hold potential for microservices under low loads, as they have less cache utilization and network virtualization overhead compared with traditional monolithic cloud workloads. FAWN [8] explored using only low-power processor architecture for data-intensive workloads as an energy and cost-effective alternative to server multiprocessors. However, FAWN assumed that I/O speeds are much lower than CPU speeds and so CPUs would be left idle for data-intensive applications. With the advent of fast network technologies, server CPUs are still required. Motivated by these studies, we focus on using SmartNIC-accelerated servers for energy efficiency.

Heterogeneous scheduling. A set of schedulers for performance-asymmetric architectures have been proposed. For example, Kumar et al. [44, 45] use instructions per cycle to determine relative speedup of each thread on different types of cores. HASS [73] introduces the architectural signature concept as a scheduling indicator, which contains information about memory-boundedness, available instruction-level parallelism, etc. CAMP [71] combines both efficiency and thread-level parallelism specialization and proposes a lightweight technique to discover which threads could use fast cores more efficiently. PTask [69] provides a data-flow programming model for programmers to manage computation for GPUs. It enables sharing GPUs among multiple processes, parallelizes multiple tasks, and eliminates unnecessary data movements. These approaches target long-running computations, mostly on cache coherent architectures, rather than microsecond-scale, request-based workloads over compute nodes that do not share memory and are hence not applicable.

Microservice scheduling. Wisp [76] enforces end-to-end performance objectives by globally adapting rate limiters and request schedulers based on operator policies under varying system conditions. This work is not concerned with SmartNIC heterogeneity. UNO [46] is an NFV framework that can systematically place NFs across SmartNIC and host with a resource-aware algorithm on the control plane. E3 is a microservice platform and thus goes several steps further: (1) E3 uses a data-plane orchestrator to detect node load and migrates microservices if necessary; (2) HCM considers communication distance during the placement. With the advent of SmartNICs and programmable switches, researchers have identified the potential performance benefits of applying request processing across the communication path [14]. E3 is such a system designed for the programmable cloud and explores the energy efficiency benefits of running microservices.

Power proportionality. Power proportional systems can vary energy use with the presented workload [50]. For example, Prekas, et al. propose an energy-proportional system management policy for memcached [65]. While E3 can provide energy proportionality, we are primarily interested in energy-efficiency. Geoffrey et al. [18] propose a heterogeneous power-proportional system. By carefully selecting component ensembles, it can provide an energy-efficient solution for a particular task. However, due to the high cost of ensemble transitions, we believe that this architecture is not fit for high bandwidth I/O systems. Rivoire, et al. propose a more balanced system design (for example, a low-power, mobile processor with numerous laptop disks connected via PCIe) and show that it achieves better energy efficiency for sorting large data volumes [67]. Pelican [11] presents a software storage stack on under-provisioned hardware targeted at cold storage workloads. Our proposal could be viewed as a balanced-energy approach for low-latency query-intensive server applications, rather than cold, throughput intensive ones.

7 Conclusion

We present E3, a microservice execution platform on SmartNIC-accelerated servers. E3 extends key system components (programming model, execution engine, communication subsystem, scheduling) of the Azure Service Fabric microservice platform to a SmartNIC. E3 demonstrates that SmartNIC offload can improve cluster energy-efficiency up to 3× and cost efficiency up to 1.9× at up to 4% latency cost for common microservices.

INSIDER: Designing In-Storage Computing System for Emerging High-Performance Drive

Zhenyuan Ruan* Tong He Jason Cong
University of California, Los Angeles

Abstract

We present INSIDER, a full-stack redesigned storage system to help users fully utilize the performance of emerging storage drives with moderate programming efforts. On the hardware side, INSIDER introduces an FPGA-based reconfigurable drive controller as the in-storage computing (ISC) unit; it is able to saturate the high drive performance while retaining enough programmability. On the software side, INSIDER integrates with the existing system stack and provides effective abstractions. For the host programmer, we introduce virtual file abstraction to abstract ISC as file operations; this hides the existence of the drive processing unit and minimizes the host code modification to leverage the drive computing capability. By separating out the drive processing unit to the data plane, we expose a clear drive-side interface so that drive programmers can focus on describing the computation logic; the details of data movement between different system components are hidden. With the software/hardware co-design, INSIDER runtime provides crucial system support. It not only transparently enforces the isolation and scheduling among offloaded programs, but it also protects the drive data from being accessed by unwarranted programs.

We build an INSIDER drive prototype and implement its corresponding software stack. The evaluation shows that INSIDER achieves an average 12X performance improvement and 31X accelerator cost efficiency when compared to the existing ARM-based ISC system. Additionally, it requires much less effort when implementing applications. INSIDER is open-sourced [5], and we have adapted it to the AWS F1 instance for public access.

1 Introduction

In the era of big data, computer systems are experiencing an unprecedented scale of data volume. Large corporations like Facebook have stored over 300 PB of data at their warehouse, with an incoming daily data rate of 600 TB [62] in 2014. A recent warehouse-scale profiling [42] shows that data analytics has become a major workload in the datacenter. Operating on such a data scale is a huge challenge for system designers. Thus, designing an efficient system for massive data analytics has increasingly become a topic of major importance [23, 27].

The drive I/O speed plays an important role in the overall data processing efficiency—even for the in-memory computing framework [68]. Meanwhile, for decades the improvement of storage technology has been continuously pushing forward the drive speed. The two-level hierarchy (i.e., channel and bank) of the modern storage drive provides a scalable way to increase the drive bandwidth [41]. Recently, we witnessed great progress in emerging byte-addressable non-volatile memory technologies which have the potential to achieve near-memory performance. However, along with the advancements in storage technologies, the system bottleneck is shifting from the storage drive to the host/drive interconnection [34] and host I/O stacks [31, 32]. The advent of such a "data movement wall" prevents the high performance of the emerging storage from being delivered to end users—which puts forward a new challenge to system designers.

Rather than moving data from drive to host, one natural idea is to move computation from host to drive, thereby avoiding the aforementioned bottlenecks. Guided by this, existing work tries to leverage drive-embedded ARM cores [33, 57, 63] or ASIC [38, 40, 47] for task offloading. However, these approaches face several system challenges which make them less usable: 1) **Limited performance or flexibility**. Drive-embedded cores are originally designed to execute the drive firmware; they are generally too weak for *in-storage computing (ISC)*. ASIC, brings high performance due to hardware customization; however, it only targets the specific workload. Thus, it is not flexible enough for general ISC. 2) **High programming efforts.** First, on the host side, existing systems develop their own customized API for ISC, which is not compatible with an existing system interface like POSIX. This requires considerable host code modification to leverage the drive ISC capability. Second, on the drive side, in order to access the drive file data, the offloaded drive program has to understand the in-drive file system metadata. Even worse, the developer has to explicitly maintain the metadata consistency between host and drive. This approach requires a significant programming effort and is not portable across different file systems. 3) **Lack of crucial system support.** In practice, the drive is shared among multiple processes. Unfortunately, existing work assumes a monopolized scenario; the isolation and resource scheduling between different ISC tasks are not explored. Additionally, data protection is an important concern; without it, offloaded programs can issue arbitrary R/W requests to operate on unwarranted data.

To overcome these problems, we present INSIDER, a full-stack redesigned storage system which achieves the following design goals.

*Corresponding author.

Saturate high drive rate. INSIDER introduces the FPGA-based reconfigurable controller as the ISC unit which is able to process the drive data at the line speed while retaining programmability (§3.1). The data reduction or the amplification pattern from the legacy code are extracted into a drive program which could be dynamically loaded into the drive controller on demand (§3.2.2). To increase the end-to-end throughput, INSIDER transparently constructs a system-level pipeline which overlaps drive access time, drive computing time, bus data transferring time and host computing time (§3.5).

Provide effective abstractions. INSIDER aims to provide effective abstractions to lower the barrier for users to leverage the benefits of ISC. On the host side, we provide virtual file abstraction which abstracts ISC as file operations to hide the existence of the underlying ISC unit (§3.3). On the drive side, we provide a compute-only abstraction for the offloaded task so that drive programmers can focus on describing the computation logic; the details of underlying data movement between different system components are hidden (§3.4).

Provide necessary system support. INSIDER separates the control and data planes (§3.2.1). The control plane is trusted and not user-programmable. It takes the responsibilities of issuing drive access requests. By performing the safety check in the control plane, we *protect* the data from being accessed by unwarranted drive programs. The ISC unit, which sits on the data plane, only intercepts and processes the data between the drive DMA unit and storage chips. This compute-only interface provides an *isolated* environment for drive programs whose execution will not harm other system components in the control plane. The execution of different drive programs is hardware-isolated into different portions of FPGA resources. INSIDER provides an *adaptive drive bandwidth scheduler* which monitors the data processing rates of different programs and provides this feedback to the control plane to adjust the issuing rates of drive requests accordingly (§3.6).

High cost efficiency. We define cost efficiency as the effective data processing rate per dollar. INSIDER introduces a new hardware component into the drive. Thus, it is critical to validate the motivation by showing that INSIDER can achieve not only better performance, but also better cost efficiency when compared to the existing work.

We build an INSIDER drive prototype (§4.1), and implement its corresponding software stack, including compiler, host-side runtime library and Linux kernel drivers (§4.2). We could mount the PCIe-based INSIDER drive as a normal storage device in Linux and install any file system upon it. We use a set of widely used workloads in the end-to-end system evaluation. The experiment results can be highlighted as follows: 1) INSIDER greatly alleviates the system interconnection bottleneck. It achieves 7X∼11X performance compared with the host-only traditional system (§5.2.1). In most cases, it achieves the optimal performance (§5.2.2). 2) INSIDER achieves 1X∼58X (12X on average) performance and 2X∼150X (31X on average) cost efficiency compared to the ARM-based ISC system (§5.5). 3) INSIDER only requires moderate programming efforts to implement applications (§5.2.3). 4) INSIDER simultaneously supports multiple offloaded tasks, and it can enforce resource scheduling adaptively and transparently (§5.3).

2 Background and Related Work

2.1 Emerging Storage Devices: Opportunities and Challenges

Traditionally, drives are regarded as a slow device for the secondary persistent storage, which has the significantly higher access latency (in ms scale) and lower bandwidth (in hundreds of MB per second) compared to DRAM. Based on this, the classical architecture for storage data processing presented in Fig. 3a has met users' performance requirements for decades. The underlying assumptions of this architecture are: 1) The interconnection performance is higher than the drive performance. 2) The execution speeds of host-side I/O stacks, including the block device driver, I/O scheduler, generic block layer and file system, are much faster than the drive access. While these were true in the era of the hard-disk drive, the landscape has totally changed in recent years. The bandwidth and latency of storage drives have improved significantly within the past decade (see Fig. 1 and Fig. 2). However, meanwhile, the evolution of the interconnection bus remains stagnant: there have been only two updates between 2007 and 2017.[1]

For the state-of-the-art platform, PCIe Gen3 is adopted as the interconnection [66], which is at 1 GB/s bidirectional transmission speed per link. Due to the storage density[2] and due to cost constraints, the four-lane link is most commonly used (e.g., commercial drive products from Intel [7] and Samsung [14]), which implies the 4 GB/s duplex interconnection bandwidth. However, this could be easily transcended by the internal bandwidth of the modern drive [24, 33, 34]. Their internal storage units are composed of multiple channels, and each channel equips multiple banks. Different from the serial external interconnection, this two-level architecture is able to provide scalable internal drive bandwidth—a sixteen-channel, single-bank SSD (which is fairly common now) can easily reach 6.4 GB/s bandwidth [46]. The growing mismatch between the internal and external bandwidth prevents us from fully utilizing the drive performance. The mismatch gets worse with the advent of 3D-stacked NVM-based storage which can deliver comparable bandwidth with DRAM [35, 54]. On the other hand, the end of Dennard scaling slows down the performance improvement of CPU, making it unable to catch the ever-increasing drive speed. The long-established block layer is now reported to be a major

[1] Although the specification of PCIe Gen 4 was finalized at the end of 2017, there is usually a two-year waiting period for the corresponding motherboard to be available in the market. Currently there is no motherboard supporting PCIe 4.0, and we do not include it in the figure.

[2] CPU has limited PCIe slots (e.g., 40 lanes for an Xeon CPU) exposed due to the pin constraint. Using more lanes per drive leads to low storage density. In practice, a data center node equips 10 or even more storage drives.

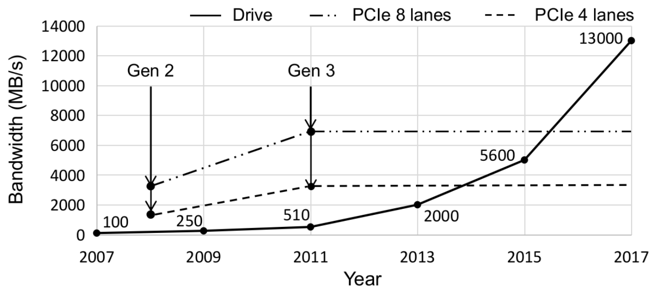

Figure 1: The bandwidth evolution of storage drives. Data are taken from [18] [4] [1] [8] [13] [16] in chronological order. This figure also presents the bandwidth evolution of PCIe (in 4 lanes and 8 lanes).

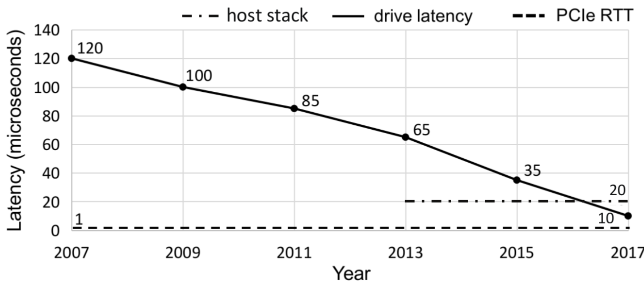

Figure 2: The latency evolution of storage drives. Data are taken from [15] [3] [9] [8] [10] [11] in chronological order. Meanwhile the latency of the host storage stack is about 20 μs [32], and the PCIe RTT (which includes the latency of bus and controller) is about 1 μs [50].

bottleneck of the storage system [28], and less than half raw drive speed is delivered to the end user [31, 56].

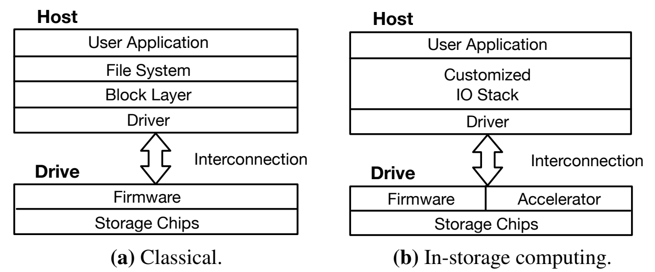
On the latency side, the state-of-the-art SSD delivers R/W latency below 10 μs [14], and the future NVM-based storage can potentially deliver sub-microsecond latency [30]. Meanwhile, the round-trip latency of PCIe still remains at about 1 μs [50], and the host-side I/O stack latency is even more than 20 μs [31, 32]. This implies that the latencies of host-side I/O stack are going to dominate the end-to-end latency.

In summary, the emerging storage devices bring hope—along with great challenges—to system designers. Unless the "data movement wall" is surpassed, high storage performance will not be delivered to end users.

2.2 Review of In-Storage Computing

In order to address the above system bottlenecks, the *in-storage computing (ISC)* architecture is proposed [48, 61], shown in Fig. 3b. In ISC, the host partially offloads tasks into the *in-storage accelerator* which can take advantage of the higher internal drive performance but is relatively less powerful compared to the full-fledged host CPU. For tasks that contain computation patterns like filtering or reduction, the output data volume of the accelerator, which will be transferred back to host via interconnection, is greatly reduced so that bottlenecks of interconnection and host I/O stacks are alleviated [33, 57, 63]. With customized IO stacks, the system bypasses the traditional OS storage stacks to achieve lower latency. With ISC, considerable performance and energy gains are achieved [25].

Historically, the idea of ISC was proposed two decades



(a) Classical. **(b)** In-storage computing.

Figure 3: Drive data processing architecture.

ago [43, 59], but did not become popular at that time. The reasons are twofold: 1) For the technology at that time, it was too expensive to integrate computing unit with storage drive; 2) More importantly, the drive performance was much lower than the performance of the host/drive bus, so in-storage computing could only bring limited performance benefits.

However, with the great improvement of VLSI technology in the past two decades, integration expense is greatly reduced. In fact, currently, every high-end SSD equips one or even multiple embedded CPUs. Meanwhile, the drive performance consistently increases, and goes beyond the performance of host/drive interconnection (see Fig. 1 and Fig. 2). This gap validates the motivation of ISC. Therefore, in recent years, we witness the revival of in-storage computing [49]. Most of the recent work focuses on offloading user-defined tasks to drive-embedded CPUs, which are originally designed to execute the firmware code, e.g., flash translation layer (FTL). However, this approach faces the following limitations.

Limited computing capability. Drive-embedded CPUs are usually fairly weak ARM cores which can be up to 100X slower compared to the host-side CPU (Table 3 in [63]). Based on this, offloading tasks to drive may lead to a decreased data processing speed by a factor of tens [33]. A recent work [48] proposes a dynamic workload scheduler to partition tasks between host and drive ARM processor. However, the optimal point they found is very close to the case in which all the tasks are executed at the host; this emphasizes that embedded cores are too feeble to provide a distinguishable speedup.

No effective programming abstractions. Existing work does not provide effective abstractions for programmers. On the host side, they develop their own customized API for ISC which is not compatible with an existing system interface like POSIX. This requires considerable host code modification to leverage the drive ISC capability. On the drive side, the drive program either manages the drive as a bare block device without a file system (FS), e.g., [48], or has to carefully cooperate with the host FS to access the correct file data, e.g., [32]. This distracts drive programmers from describing the computing logic and may not be portable across different FSes. It is important to provide effective abstractions to lower the barrier for users to leverage the benefits of ISC [26].

Lack of crucial system support. Naturally, the drive is shared among multiple processes, which implies the scenario of concurrently executing multiple ISC applications. This is

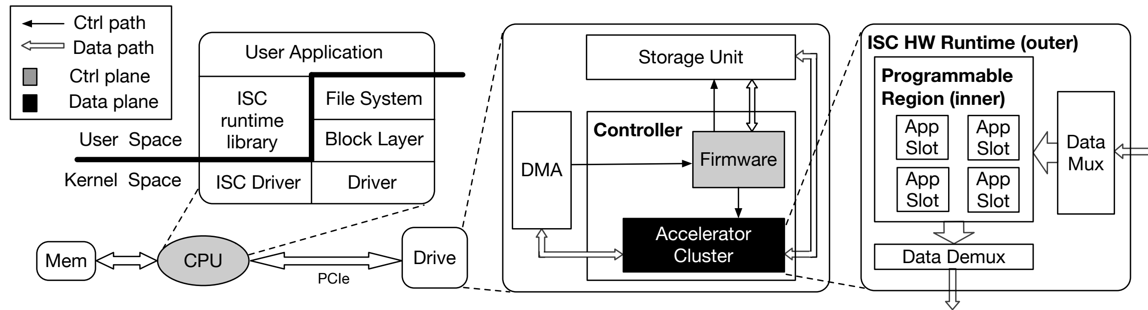


Figure 4: System architecture of INSIDER. INSIDER separates the control plane and the data plane; accelerator cluster sits on the data plane (black box) while the host-side library and drive-side firmware sit on the control plane (gray box).

especially important for the emerging storage drive since a single application may not fully saturate the high drive speed. It is crucial to provide support for protection, isolation and bandwidth scheduling. Without data protection, the malicious or erroneous ISC task may operate on unwarranted data; without isolation, the execution of one ISC task may harm the execution of other ISC tasks, or even the firmware execution; without bandwidth scheduling, some ISC tasks may forcibly occupy the drive, hampering fairness and liveness. However, existing work, e.g., [33, 34, 48], does not respond to these issues by assuming a monopolized execution environment.

Finally, another line of research equips the drive with an ASIC, which is the customized hardware chip designed for specific workloads. For instance, YourSQL [40] and Biscuit [38] equip a hardware IP with a key-based pattern matcher; work in [47] adopts a special hardware for database join and scan operations, etc. While ASIC-based solutions can achieve even much better performance compared to the high-end host CPU in their targeting applications, they are too specific to support other tasks. It requires the design of N chips to support N different applications; this introduces N times manufacturing, area size and energy cost. Thus, ASIC solutions are too inflexible to support general ISC.

3 INSIDER System Design

To overcome the problems above, we redesign the storage system across all layers, from the user layer down to the hardware layer. The design of INSIDER is introduced below.

3.1 FPGA-Based ISC Unit

The scenario of ISC puts forth several requirements to the in-drive processing unit.

High reconfigurability. As mentioned earlier, ASIC-based solutions can only target specific workloads. We wish the processing unit to be flexible enough to support general ISC.

Support massive parallelism. We analyze the computation patterns of data analytic workloads (§5.2) that are suitable for ISC. These applications expose abundant pipeline-level and data-level parallelism. The processing unit should have a proper architecture to capture those inherent parallelisms.

High energy efficiency. The storage drive is an energy-efficient device whose power consumption is just about 10 W [14]. The processing unit should not significantly compromise the energy efficiency of the drive.

	GPU	ARM	X86	ASIC	FPGA
Programmability	Good	Good	Good	No	Good
Data-level parallelism	Good	Poor	Fair	Best	Good
Pipeline-level parallelism	No	No	No	Best	Good
Energy efficiency	Fair	Fair	Poor	Best	Good

Table 1: Evaluating five candidates of ISC unit.

Given those requirements, we evaluate several candidates of ISC unit (see Table 1). FPGA comes out to be the best fit in our scenario. First, FPGA is generally reconfigurable and can form customized architectures for the targeted workloads. Second, through customization, FPGA can efficiently capture the inherent parallelism of applications. The data-level parallelism can be seized by replicating the processing elements to construct SIMD units [69]; the pipeline-level parallelism can be leveraged by constructing a deep hardware pipeline [60]. Finally, FPGA could achieve high energy efficiency between microprocessors and ASICs [58].

3.2 Drive Architecture

Fig. 4 presents the system architecture of INSIDER. We focus on introducing the drive-side design in this subsection.

3.2.1 Separating Control and Data Planes

The INSIDER drive controller consists of two decoupled components: the firmware logic and the accelerator cluster (i.e., the FPGA-based ISC unit). The firmware cooperates with the host-side ISC runtime and the ISC driver to enforce the *control plane* execution (marked in Fig. 4). It receives the incoming drive access requests from host, converts their logical block addresses into physical block addresses, and finally issues the requests to the storage unit. The accelerator cluster is separated out into the *data plane*. It does not worry about where to read (write) data from (to) the storage chip. Instead, it **intercepts and processes** the data between the DMA controller and the storage chip.

By separating control and data plane, we expose a *compute-only* abstraction for the in-drive accelerator. It does not proactively initiate the drive accessing request. Instead, it only passively processes the intercepted data from other components. The control plane takes the responsibilities of conducting file permission check at host and issuing drive accessing requests;

it prevents the drive data from being accessed by unwarranted drive programs. In addition, the compute-only abstraction brings an *isolated* environment for the accelerator cluster; its execution will not harm the execution of other system components in the control plane. The execution of different offloaded tasks in the accelerator cluster is further *hardware-isolated* into different portions of FPGA resources.

3.2.2 Accelerator Cluster

As shown in the rightmost portion of Fig. 4, the accelerator cluster is divided into two layers. The inner layer is a programmable region which consists of multiple application slots. Each slot can accommodate a user-defined application accelerator. Different than the multi-threading in CPU, which is time multiplexing, different slots occupy different portions of hardware resources simultaneously, thus sharing FPGA in spatial multiplexing. By leveraging partial reconfiguration [44], host users can dynamically load a new accelerator to the specified slot. The number of slots and slot sizes are chosen by the administrator to meet the application requirements, i.e., number of applications executing simultaneously and the resource consumption of applications. The outer layer is the hardware runtime which is responsible for performing flow control (§3.5) and dispatching data to the corresponding slots (§3.6). The outer layer is set to be user-unprogrammable to avoid safety issues.

3.3 The Host-Side Programming Model

In this section we introduce *virtual file abstraction* which is the host-side programming model of INSIDER. A virtual file is fictitious, but pretends to be a real file from the perspective of the host programmer—it can be accessed via a subset of the POSIX-like file I/O APIs shown in Table 2. The access to virtual file will transparently trigger the underlying system data movement and the corresponding ISC, creating an illusion that this file does really exist. By exposing the familiar file interface, the effort of rewriting the traditional code into the INSIDER host code is negligible.

We would like to point out that INSIDER neither implements the full set of POSIX IO operations nor provides the full POSIX semantics, e.g., crash consistency. The argument here is similar to the GFS [37] and Chubby [29] papers: files provide a familiar interface for host programmers, and exposing a file-based interface for ISC can greatly alleviate the programming overheads. Being fully POSIX-compliant is not only expensive but also unnecessary in most use cases.

3.3.1 Virtual File Read

Listing 1 shows a snippet of the host code that performs virtual file read. We will introduce the design of virtual file read based on the code order. Fig. 5 shows the corresponding diagram.

System startup During the system startup stage, INSIDER creates a hidden mapping file *.USERNAME.insider* in the host file system for every user. The file is used to store the virtual file mappings (which will be discussed soon). For security concerns, INSIDER sets the owner of the mapping file to the corresponding user and sets the file permission to 0640.

```
// register a virtual file
string virt = reg_virt_file(real_path,acc_id);
// open the virtual file
int fd = vopen(virt.c_str(),O_RDONLY);
if (fd != -1) {
  // send drive program parameters (if there are any)
  send_params(fd, param_buf, param_buf_len);
  int rd_bytes = 0;
  // read virtual file
  while (rd_bytes = vread(fd, buf, buf_size)) {
    // user processes the read data
    process(buf, rd_bytes);
  }
  // close virtual file, release resources
  vclose(fd);
}
```

Listing 1: Host-side code of performing virtual file read.

1). int vopen(const char *path, int flags)
2). ssize_t vread(int fd, void *buf, size_t count)
3). ssize_t vwrite(int fd, void *buf, size_t count)
4). int vsync(int fd)
5). int vclose(int fd)
6). int vclose(int fd, size_t *rfile_written_bytes)
7). string reg_virt_file(string file_path, string acc_id)
8). string reg_virt_file(tuple<string, uint, uint> file_sg_list, string acc_id)
9). bool send_params(int fd, void *buf, size_t count)

Table 2: INSIDER host-side APIs. *vwrite, vsync* will be discussed in §3.3.2 while others will be discussed in §3.3.1.

Registration. The host program determines the file data to be read by the in-drive accelerator by invoking *reg_virt_file* (method 7 in Table 2); it takes the path of a real file plus an application accelerator ID, and then maps them into a virtual file. Alternatively, *reg_virt_file* (method 8) accepts a vector of <file name, offset, length> tuples to support the gather-read pattern.[3] This allows us to create the virtual file based on discrete data from multiple real files. During the registration phase, the mapping information will be recorded into the corresponding mapping file, and the specified accelerator will be programmed into an available slot of the in-drive reconfigurable controller. INSIDER currently enforces a simple scheduling policy: it blocks when all current slots are busy.

File open. After registration, the virtual file can be opened via *vopen*. The INSIDER runtime will first read the mapping file to know the positions of the mapped real file(s). Next, the runtime issues the query to the host file system to retrieve the accessing permission(s) and the ownership(s) of the real file(s). Then, the runtime performs the file-level permission check to find out whether the *vopen* caller has the correct access permission(s); in INSIDER, we regard the host file system and INSIDER runtime as trusted components, while the user programs are treated as non-trusted components. If it is an unauthorized access, *vopen* will return an invalid file descriptor. Otherwise, the correct descriptor will be returned, and the corresponding accelerator slot index (used in §3.6) will be

[3] Currently INSIDER operates drive data at the granularity of 64 B, therefore the offset and length fields have to be multiples of 64 B. It is a limitation of our current implementation rather than the design.

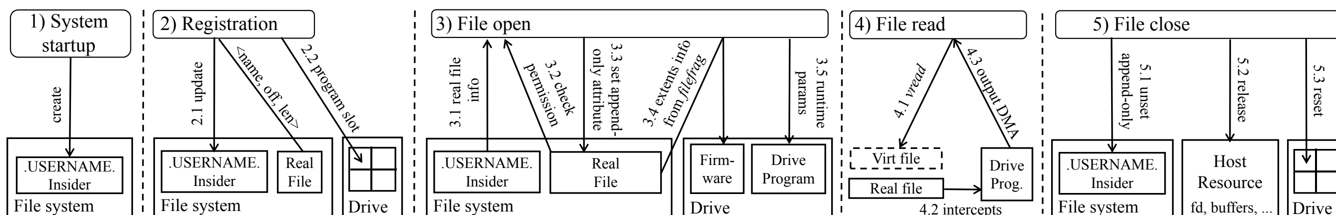

Figure 5: The system diagram of performing virtual file read. Only major steps are shown in this figure, see the text description in §3.3.1 for details.

sent to the INSIDER drive. After that, the INSIDER runtime asks the INSIDER kernel module to set the append-only attribute (if it is not already set by users before) on the mapped real file(s); this is used to guarantee that the current blocks of the real file(s) will not be released or replaced during the virtual file read.[4] Later on, INSIDER retrieves the locations of real file extents via the *filefrag* tool and transfers them to the drive. Finally, the host program sends runtime parameters of the accelerator program (discussed in §3.4), if there are any, via *send_params* to the drive.

File read. Now the host program can sequentially read the virtual file via *vread*. It first triggers the INSIDER drive to read the corresponding real file extents. The accelerator *intercepts* the results from the storage chips and invokes the corresponding data processing. Its output will be transferred back to the host via DMA, creating an illusion that the host is reading a normal file (which actually turns out to be a virtual file). The whole process is deeply pipelined without stalling. The detailed design of pipelining is discussed in §3.5. It seems to be meaningless to read the ISC results randomly, thus we do not implement a *vseek* interface.

File close. Finally, the virtual file is closed via *vclose*. In this step, the INSIDER runtime will contact the INSIDER kernel module to clear the append-only attribute if it was previously set in *vopen*. The host-side resource (e.g., file descriptor, the host-side buffer for DMA, etc.) will be released. Finally, the runtime sends the command to the INSIDER drive to reset the application accelerator to its initial state.

Virtual file read helps us to alleviate the bandwidth bottleneck in the drive → host direction. For example, for the feature selection application [64], the user registers a virtual file based on the preselected training data and the corresponding accelerator. The postselected result could be automatically read via *vread* without transferring the large preselected file from drive to host. Thus, the host program can simply use the virtual file as the input file to run the ML training algorithm.

3.3.2 Virtual File Write

Virtual file write works mostly in the same way but reverses the data path direction. We focus on describing the difference.

Registration. Virtual write requires users to preallocate enough space for the real file(s) to store the write output. If users leverage the *fallocate* system call to preallocate the file, they have to make sure to clear the *unwritten* flag on the file extents.[5] Otherwise, later updates on the real file may only be perceived via the INSIDER interface but not the OS interface.

File open. Besides the steps in §3.3.1, INSIDER runtime invokes $fsync$ to flush dirty pages of the real file(s) to drive if there are any. This guarantees the correct order between previous host-initiated write requests and the upcoming INSIDER drive-initiated write requests.

File write. In the file write stage, users invoke *vwrite* to write data to the virtual file. The written data is transferred to INSIDER drive through DMA, and then will be *intercepted and processed* by the accelerator. The output data will be written into the corresponding real file blocks. INSIDER also provides *vsync* (method 4 in Table 2), which can be used by users to flush in-core *vwrite* data to the INSIDER drive.

File close. Besides the steps in §3.3.1, INSIDER runtime will drop the read cache of the real file(s), if there are any, to guarantee that the newly drive-written data can be perceived by the host. This is conducted via calling *posix_fadvise* with *POSIX_FADV_DONTNEED*. Via invoking a variant of *vclose* (method 6 in Table 2), users can know the number of bytes written to the real file(s) by the underlying INSIDER drive. Based on the returned value, users may further invoke *ftruncate* to truncate the real file(s).

Virtual file write helps us alleviate the bandwidth bottleneck in the host → drive direction, since less data needs to be transferred through the bus (they then gets amplified in drive). For example, the user can register a virtual file based on a compressed real file and a decompression drive program. In this scenario, only compressed data needs to be transferred through the bus, and the drive performs in-storage decompression to materialize the decompressed file.

Since the virtual file write is mostly symmetric to the virtual file read, in the following we will introduce other system designs based on **the direction of read** to save space.

3.3.3 Concurrency Control

In INSIDER, a race condition might happen in the following cases: 1) Simultaneously a single real file is being *vwrite* and *vread*; 2) Simultaneously a real file is being *vwrite* by different processes; 3) A single real file is being *vread*, and meanwhile it is being written by a host program. In these cases, the users may encounter non-determinate results.

[4] With the append-only attribute, *ftruncate* will fail to release blocks, and the file defragmentation tool, e.g., *xfs_fsr* will ignore these blocks [21].

[5] In Linux, some file systems, e.g., ext4, will put the *unwritten* flag over the file extents preallocated by *fallocate*. Any following read over the extents will simply return zero(s) without actually querying the underlying drive; this is designed for security considerations since the preallocated blocks may contain the data from other users.

```
1  struct APP_Data {
2   char bytes[64]; // 64-byte width data interface.
3   unsigned short len; // Number of valid bytes.
4   bool eop; // Mark the end of the file.
5  };
6
7  // The ISC filter kernel.
8  void filter(Queue<APP_Data> &app_input_data,
9              Queue<APP_Data> &app_output_data,
10             Queue<unsigned int> &app_input_params) {
11  int lower_bound, upper_bound;
12  bool valid_lower_bound = false;
13  bool valid_upper_bound = false;
14  while (1) {
15   if (!valid_lower_bound) { // Read lower bound.
16    app_input_params.read(lower_bound);
17    valid_lower_bound = true;
18   } else if (!valid_upper_bound) { // Read upper bound.
19    app_input_params.read(upper_bound);
20    valid_upper_bound = true;
21   } else { // Do filtering
22    APP_Data record;
23    app_input_data.read(record);
24    // Call a macro (omitted in code) to transform the
25    // first 4B of input bytes into int.
26    int key = EXTRACT_KEY(record.bytes);
27    // Check the filtering condition.
28    if (lower_bound <= key && key <= upper_bound) {
29     // Write the matched record into the output queue.
30     APP_Data filtered_record;
31     // All 64 bytes data are valid.
32     filtered_record.len = 64;
33     // Set the EOP accordingly.
34     filtered_record.eop = record.eop;
35     // Copy the input record data.
36     for (int i = 0; i < 64; i ++) {
37      filtered_record.bytes[i] = record.bytes[i];
38     }
39     app_output_data.write(filtered_record);
40    } else if (record.eop) {
41     // Mark the EOP of the output when hitting input EOP.
42     filtered_record.len = 0;
43     filtered_record.eop = true;
44     app_output_data.write(filtered_record);
45    }
46   }
47  }
48 }
```

Figure 6: A simple example of the INSIDER drive accelerator code.

The problem also applies to Linux file systems: for example, different host processes may write to a same file. Linux file systems do not automatically enforce the user-level file concurrency control and leave the options to users. INSIDER makes the same decision here. When it is necessary, users can reuse the Linux file lock API to enforce the concurrency control by putting the R/W lock to the mapped real file.

3.4 The Drive-Side Programming Model

In this section we introduce the drive-side programming model. INSIDER defines a clear interface to hide all details of data movements between the accelerator program and other system components so that the device programmer *only* needs to focus on describing the computation logic. INSIDER provides a drive-side compiler which allows users to program in-drive accelerators with C++ (see Fig. 6 for a sample program). Additionally, the INSIDER compiler also supports the traditional RTL (e.g., Verilog) for experienced FPGA programmers. As we will see in §5.2, only C++ is used in the evaluation, and it can already achieve near-optimal performance in our scenario (§5.2.2).

Drive program interface consists of three FIFOs—data input FIFO, data output FIFO and parameter FIFO, as shown in the sample code. Input FIFO stores the intercepted data which is used for the accelerator processing. The output data of the accelerator, which will be sent back to host and acquired by *vread*, is stored into output FIFO. The host-sent runtime parameters are stored in parameter FIFO. The input and the output data are wrapped into a sequence of flits, i.e., *struct APP_Data* (see Fig. 6). The concept of flit is similar to the "word size" in host programs. Each flit contains a 64-byte payload, and the *eop* bit is used for marking the end of the input/output data. The length of data may not be multiples of 64 bytes, the *len* field is used to indicate the length of the last flit. For example, 130-byte data is composed by three flits; the last flit has *eop* = true and *len* = 2.

The sample program first reads two parameters, upper bound and lower bound, from the parameter FIFO. After that, in each iteration, the program reads the input record from the input FIFO. Then the program checks the filtering condition and writes the matched record into the output FIFO. Users can define stateful variables which are alive across iterations, e.g., line 11 - line 13 in Fig. 6, and stateless variables as well, e.g., line 22. These variables will be matched into FPGA registers or block RAMs (BRAMs) according to their sizes. The current implementation does not allow placing variables into FPGA DRAM, but it is trivial to extend.

INSIDER supports **modularity**. The user can define multiple sub-programs chained together with FIFOs to form a complete program, as long as it exposes the same drive accelerator interface shown above. Chained sub-programs will be compiled as separate hardware modules by the INSIDER compiler, and they will be executed in parallel. This is very similar to the dataflow architecture in the streaming system, and we can build a map-reduce pipeline in drive with chained sub-programs. In fact, most applications evaluated in §5.2 are implemented in this way. Stateful variables across sub-programs could also be passed through the FIFO interface.

3.5 System-Level Pipelining

Logically, in INSIDER, *vread* triggers the drive controller to fetch storage data, perform data processing, and transfer the output back to host. After that, the host program can finally start the host-side computation to consume the data. A naive design leads to the execution time $t = t_{drive_read} + t_{drive_comp.} + t_{output_trans.} + t_{host_comp}$. As we will see in §5.2, this leads to a limited performance.

INSIDER constructs a deep system-level pipeline which includes all system components involved in the end-to-end processing. It happens **transparently** for users; they simply use the programming interface introduced in §3.3 and §3.4. With pipelining, the execution time is decreased to $max(t_{drive_read}, t_{drive_comp.}, t_{output_trans.}, t_{host_comp})$.

Overlap $\mathbf{t_{drive_read}}$ with $\mathbf{t_{drive_comp.}}$ We carefully design the INSIDER hardware logic to ensure that it is fully pipelined, so that the storage read stage, computation stage and output DMA stage overlap one another.

Overlap drive, bus and host time We achieve this by ① Pre-issuing the file access requests during *vopen* which would trigger the drive to perform the precomputation; ② Allocating the host memory in the INSIDER runtime to buffer the drive precomputed results. With ①, the drive has all the position information of the mapped real file, and it can perform computation at its own pace. Thus, the host-side operation is decoupled from the drive-side computation. ② further decouples the bus data transferring from the drive-side computation. Now, each time that the host invokes *vread*, it simply pops the precomputed result from host buffers. To prevent the

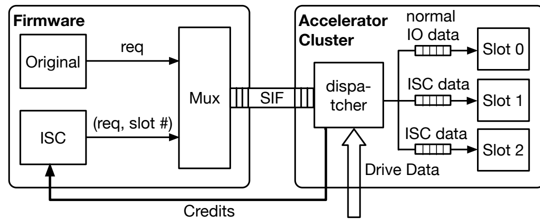

Figure 7: The drive architecture for supporting simultaneous multiple tasks.

drive from overflowing host buffers when host lags behind, INSIDER enforces credit-based flow control for each opened virtual file.

3.6 Adaptive Bandwidth Scheduler

Naturally, the drive is shared among multiple processes, which implies the scenario of parallel execution of multiple applications. For example, a single application may not fully saturate the high internal drive bandwidth so that the remaining bandwidth can be leveraged by others to improve the drive utilization. There are two concerns that should be addressed to support simultaneous multiple applications: 1) Given the fact that the drive is multiplexed among accelerators, we need a mechanism to dispatch drive data to the corresponding accelerator correctly. 2) Different accelerators have different data processing rates which can change dynamically. We need to implement a dynamic weighted fair queueing policy to schedule the drive bandwidth among accelerators adaptively.

Multiplexing. We develop a moderate extension to the original drive firmware (i.e., the one that does not support simultaneous multiple applications) to support multiplexing: we add an ISC unit and a multiplexer, see Fig. 7. The original firmware is used for handling the normal drive I/O requests as usual, while the ISC unit is used for handling the ISC-related drive requests. The ISC unit receives the file logical block addresses and the accelerator slot index from the INSIDER host runtime. The multiplexer will receive the request from both the ISC unit and the original firmware. The received request will be forwarded to the storage unit (not drawn in the figure), and its slot index will be pushed into the *Slots Index FIFO (SIF)*. The slot 0 is always locked for the pass-through logic, which is used for the normal drive read request since it does not need any in-storage processing. Thus, for the request issued by the original firmware, the MUX will push number 0 into SIF. After receiving the drive read data, the dispatcher of the accelerator cluster will pop a slot index from SIF and dispatch the data to the application FIFO connected to the corresponding application slot.

Adaptive Scheduling. The ISC unit maintains a set of *credit registers* (initialized to R) for all offloaded applications. The ISC unit will check registers of applications that have pending drive access requests, in a round-robin fashion. If the register of an application is greater than 0, the ISC unit will issue a drive access request in size C with its slot index, and then decrement its credit register. For the application with a higher data processing rate, its available FIFO size is going to be decreased more quickly, which brings us feedback information for performing the adaptive drive bandwidth scheduling. Each time data is dispatched to the application FIFO, the dispatcher will check the available space of that FIFO. If it is greater than C, the dispatcher will release one credit to the corresponding credit register in the ISC unit.

In practice, we choose the drive access request size C to be the minimal burst size that is able to saturate the drive bandwidth, and choose R to be large enough to hide the drive access latency. Ideally, we could solve an optimization problem to minimize the FPGA buffer size which equals to $R \cdot C$. We leave out the details here.

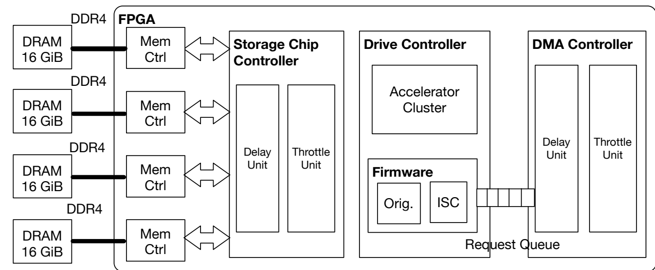

Figure 8: The diagram of the INSIDER drive prototype.

4 Implementation

The implementation of INSIDER contains 10K lines of C/C++ code (including the traditional host code and the FPGA HLS code), 2K lines of Verilog code and 2K lines of script code. The FPGA-side implementation is done based on the ST-Accel framework [60]. We have already adapted both the drive prototype and the software stack to the AWS F1 (FPGA) instance for public access, see [5].

4.1 The INSIDER Drive Prototype

So far there is no such a drive device on the market yet. We build an INSIDER drive prototype ourselves based on an FPGA board, see Fig. 8. The drive is PCIe-based and its implementation contains three parts: storage chip controller, drive controller and DMA controller. We implement a simple firmware logic in the drive controller; it is responsible for handling host-sent drive access commands, and the functionalities of performing wear-leveling and garbage collection have not been implemented yet. The remaining FPGA resource is used to accommodate the logics of drive programs. To emulate the performance of an emerging storage drive, our prototype should connect to multiple flash chips. However, there is no FPGA board in the market that has enough U.2 or M.2 flash connectors to meet our requirements. Therefore, in our prototype, we use four DRAM chips to emulate the storage chips. We add a set of delay and throttle units into the storage chip controller and DMA controller; they are configurable via our host-side API, therefore we could dynamically configure them to change the performance metrics (*i.e.,* bandwidth and latency) of our emulated storage chips and interconnection bus.

Application	Description	Comment	Data Size (GiB)	Parameter	Devel.Time (Person-Day)	LoC[6]	
						Host	Drive
Grep [38]	String matching.	Fully offloaded. Virtual file read.	60	983040 rows, 65536-byte row. 32-byte search string.	3	51	193
KNN [59]	K-nearest neighbors.	Offload the distance calculation into drive, and put K-partial sort in host. Virtual file read.	56.875	K = 32, 14680064 training cases, 4096 dims, 1-byte weight.	2	77	72
Bitmap file decompression	Decompress the bitmap file.	Offload run-length decoding into drive. Other preparation steps like header parsing and format checking are put in host. Virtual file write.	3.3	Compression ratio is about 7, width = 187577, height = 129000, planes = 1, depth = 8.	4	94	145
Statistics [55, 63]	Statistical calculation per input row.	Offload the row-level data reduction operations into drive, and put the computation over the reduced row data in host. Virtual file read.	48	65536 rows, 196608 numbers per row, 4-byte number.	3	65	170
SQL query [40, 65]	A query consists of select, sum, where, group by, and order by.	Offload data filtering into drive, and put sorting and grouping in host. Virtual file read.	60	2013265920 records 32-byte record.	5	97	256
Integration [48]	Combine data from different sources.	Fully offloaded. Virtual file read.	61	1006632960 records, 64-byte record, 32-byte query.	5	41	307
Feature Selection [64]	Relief algorithm to prune features.	Fully offloaded. Virtual file read.	61	15728640 hit records, 15728640 miss records, 256 dims.	9	50	632

Table 3: A descriptions of applications used in the evaluation. We present the experimental data sizes and application parameters. Additionally, we show the developing effort by listing the lines of code and the development time.

4.2 The INSIDER Software Stack

This section briefly introduces the software stack of INSIDER. We have omitted the details due to space constraints.

Compiler. INSIDER provides compilers for both host and drive. The host-side compiler is simply a standard *g++* which, by default, links to the INSIDER runtime. The front-end of the drive-side compiler is implemented on LLVM, while its back-end is implemented on Xilinx Vivado HLS [22] and a self-built RTL code transformer.

Software Simulator. FPGA program compilation takes hours, which greatly limits the iteration speed of the program development. INSIDER provides a system-level simulator which supports both the C++-level and RTL-level simulation. The simulator reduces the iteration time from hours into (tens of) minutes.

Host-side runtime library. The runtime library bypasses the OS storage stack and is at the user space. When necessary, it will use the POSIX I/O interface to interact with the host file system. Its implementation contains the drive parameter configuring API plus all methods in Table 2. Additionally, the runtime library cooperates with the drive hardware to support the system-level pipelining and the credit-based flow control.

Linux kernel drivers. INSIDER implements two kernel drivers. The first driver registers the INSIDER drive as a block device in Linux so that it could be accessed as a normal storage drive. The second driver is ISC related: it manages the DMA buffer for virtual file operations and is responsible for setting/unsetting the append-only attribute to the real file(s) in *vopen*/*vclose*.

5 Evaluation

5.1 Experiment Setup

We refer to the performance metrics of the current high-end SSDs to determine the drive performance used in our evaluation. On the latency side, the current 3D XPoint SSD already achieves latency less than 10 μs [6, 39]. On the throughput side, the high-end SSD announced in 2017 [17] could achieve

Host	Operating System	Linux LTS 4.4.169
	RAM	128 GB
	CPU	2*Intel Xeon E5-2686 v4
	File System	XFS
Drive	FPGA	Xilinx Virtex XCVU9P
	Capacity	64 GB
	Latency	5 μs
	Sequential R/W	16 GB/s (i.e., 14.9 GiB/s)
	Random 4K R/W	1200 KOPS
	Host/Drive Int. Speed	PCIe Gen3 x8 *or* x16
	Number of Slots	3

Table 4: Experiment setup.

13.0 / 9.0 GB/s sequential R/W performance. We project these numbers (according to the trend in Fig. 1, 2) to represent the performance of the next-generation high-performance drive. Table 4 provides details of our experiment setup. We use 32 CPU cores in the evaluation.

5.2 Applications

We choose applications used in the existing work to evaluate the INSIDER system (see Table 3). We implement them by ourselves. All drive programs are implemented in C++.

5.2.1 Speedup and Its Breakdown

See Fig. 9 for the performance comparison of seven applications. We choose the traditional host-only implementation which uses the POSIX interface as the baseline. It uses OpenMP to parallelize the computation to take advantage of 32 CPU cores. The first optimization is to replace the POSIX interface with the ISC interface to bypass overheads of the host I/O stack. This is conducted by registering the virtual file based on the real file and the pass-through (PT) program. The PT program simply returns all the inputs it receives as outputs. Thus, by invoking *vread* over the virtual file, we acquire the data of the real file. In Fig. 9, *Host-bypass* is the abbreviation for this version, while the suffix x8 and x16 stand for using PCIe Gen3 x8 and x16 as the interconnection, respectively. With the host-side code refactoring, we can conduct pipelining to overlap the computation time and the file access time;

[6]It does not include empty lines, comments, logging, timer, etc.

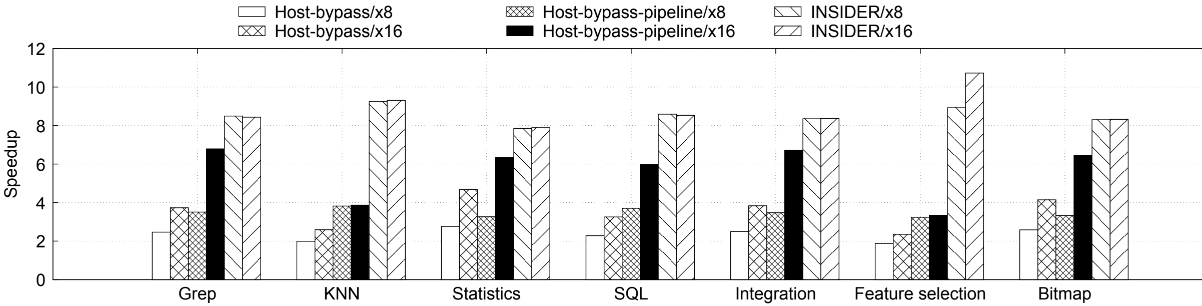

Figure 9: Speedup of optimized host-only versions and INSIDER version compared to the host-only baseline (§5.2.1).

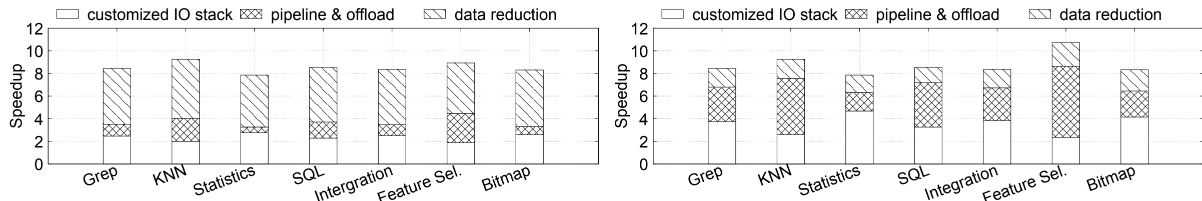

(a) INSIDER/*x8* (*i.e,* the bus-limited case).

(b) INSIDER/*x16* (*i.e,* the bus-ample case).

Figure 10: The breakdown of the speedup achieved by INSIDER compared with the host-only baseline (§5.2.1).

this corresponds to *Host-bypass-pipeline* in Fig. 9. Finally, we leverage the ISC capability to offload computing tasks to the drive. For this version we largely reuse code from the baseline version since the virtual file abstraction allows us to stay at the traditional file accessing interface (§3.3) and INSIDER transparently constructs the system-level pipeline (§3.5). This corresponds to INSIDER in Fig. 9.

Note that the end-to-end execution time here includes the overheads of INSIDER APIs like *vopen, vclose*, but it does not include the overhead of reconfiguring FPGA, which is in the order of hundreds of milliseconds and is proportional to the region size [67]. We envision that in practice the application execution has time locality so that the overheads of reconfiguring will be amortized by multiple following calls.

The speedup of version INSIDER is derived from three aspects: 1) customized I/O stack (§4.2), 2) task offloading (§3.4) and system-level pipelining (§3.5), and 3) reduced data volume (which leads to lower bus time). See Fig. 10 for the speedup breakdown in these three parts. In the x8 setting, which has lower bus bandwidth, data reduction is the major source of the overall speedup. By switching from x8 to x16, the benefit of data reduction decreases, which makes sense since now we use a faster interconnection bus. Nevertheless, it still accounts for a considerable speedup. Meanwhile, pipelining and offloading contribute to a major part of the speedup.

As we discussed in §2.1, four-lane (the most common) and eight-lane links are used in real life because of storage density and cost constraints. INSIDER/*x16* does not represent a practical scenario at this point. The motivation for showing both the results of x8 and x16 is to compare the benefits of data reduction in both bus-limited and bus-ample cases.

5.2.2 Optimality and Bottleneck Analysis

Table 5 shows the performance bottleneck of different execution schemes for seven applications. For *Host-bypass*, limited PCIe bandwidth is the major bottleneck for the overall performance. In contrast, after enabling the in-storage processing, even in the PCIe x8 setting, there is only one case in which PCIe becomes the bottleneck (see INSIDER/*x8*). For most cases in INSIDER, the overall performance is bounded by the internal drive speed, which indicates that the **optimal performance** has been achieved. For some cases, like KNN and feature selection, host-side computation is the performance bottleneck for *Host-bypass*. This is alleviated in INSIDER since FPGA has better computing capabilities for the offloaded tasks. For INSIDER, *SQL query* is still bottlenecked by the host-side computation of the non-offloaded part.

	Host-bypass/x8	*Host-bypass/x16*	INSIDER/*x8*	INSIDER/*x16*
Grep	PCIe	PCIe	Drive	Drive
KNN	PCIe	Comp.	Drive	Drive
Statistics	PCIe	PCIe	Drive	Drive
SQL query	PCIe	Comp.	Comp.	Comp.
Integration	PCIe	PCIe	Drive	Drive
Feature selection	Comp.	Comp.	PCIe	Drive
Bitmap decompression	PCIe	PCIe	Drive	Drive

Table 5: The end-to-end performance bottleneck of different executing schemes over seven different applications. Here *PCIe, Drive and Comp.* indicate that the bottleneck is PCIe performance, drive chip performance and the host-side computation performance, respectively (§5.2.2).

5.2.3 Development Efforts

Table 3 also presents the developing efforts of implementing these applications in terms of lines of code (column *LoC*) and the developing time (column *Devel. Time*). With virtual file abstraction, all host programs here only require less than half an hour to be ported to the INSIDER; The main development time is spent on implementing the drive accelerator which requires drive programmers to tune the performance. This time is expected to be reduced in the future with continuous improvements on the FPGA programming toolchain. Addi-

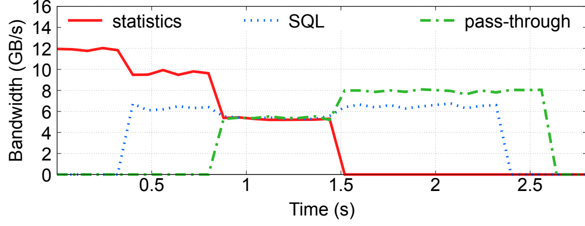

Figure 11: Data rates of accelerators that are executed simultaneously in drive. The drive bandwidth is 16 GB/s, and the bandwidth requested by *statistics*, *SQL* and *pass-through* are 12 GB/s, 6.4 GB/s and 8 GB/s, respectively. *statistics* starts before time 0 s and ends at about time 1.5 s. *SQL* starts at about time 0.4 s and ends at about time 2.4 s. *Pass-through* starts at about time 0.8 s and ends at about time 2.6 s.

	LUT	FF	BRAM	DSP
Grep	34416	24108	1	0
KNN	9534	11975	0.5	0
Statistics	14698	15966	0	0
SQL query	9684	14044	1	0
Integration	40112	6497	14	0
Feature selection	41322	44981	24	48
Bitmap decompression	60837	13676	0	0
INSIDER framework	68981	120451	309	0
DRAM and DMA IP cores	210819	245067	345.5	12
XCVU9P [19]	1181768	2363536	2160	6840
XC7A200T [2]	215360	269200	365	740

Table 6: The top half shows the FPGA resource consumption in our experiments. Generally, an FPGA chip contains four types of resources: look-up tables (LUTs), flip-flops (FFs), block RAMs (BRAMs, which are SRAM-based), digital signal processors (DSPs). The bottom half shows the initial available resource in FPGA XCVU9P and XC7A200T.

tionally, since INSIDER provides a clear interface to separate the responsibilities between host and drive, drive programs could be implemented as a *library* by experienced FPGA developers. This can greatly lower the barrier for host users when it comes to realizing the benefits of the INSIDER drive.

Still, the end-to-end developing time is much less compared to an existing work. Table 1 in work [61] shows that WILLOW requires thousands of LoC and one-month development time to implement some basic drive applications like simple drive I/O (1500 LoC, 1 month) and file appending (1588 LoC, 1 month). WILLOW is definitely an excellent work, and here the main reason is that WILLOW was designed at a lower layer to extend the semantics of the storage drive, while INSIDER focuses on supporting ISC by exposing a compute-only interface at drive and file APIs at host.

5.3 Simultaneous Multiprocessing

In this section we focus on evaluating the effectiveness of the design in §3.6. We choose *statistics, SQL query, and pass-through* as our offloaded applications. On the drive accelerator side, we throttle their computing speeds below the drive internal bandwidth so that each of them cannot fully saturate the high drive rate: $BW_{drive} = 16$ GB/s, $BW_{stat} = 12$ GB/s, $BW_{SQL} = 6.4$ GB/s, $BW_{PT} = 8$ GB/s. The host-side task scheduling has already been enforced by the host OS, and our goal here is to evaluate the effectiveness of the drive-side bandwidth scheduling. Hence, we modify the host programs so that they only invoke INSIDER APIs without doing the host-side computation. In this case, the application execution time is a close approximation of the drive-side accelerator execution time. Therefore, the data processing rate for each accelerator can be calculated as $rate = \Delta size(data)/\Delta time$.

Fig. 11 presents the runtime data rate of three accelerators that execute simultaneously in drive. As we can see, INSIDER will try best to accommodate the bandwidth requests of offloaded applications. When it is not possible to do so, i.e., the sum of total requested bandwidth is higher than the drive bandwidth, INSIDER will schedule bandwidth for applications in a fair fashion.

5.4 Analysis of the Resource Utilization

Table 6 presents the FPGA resource consumption in our experiments. The end-to-end resource usage consists of three parts: ① User application logic. Row *Grep* to row *Bitmap decompression* correspond to this part. ② INSIDER framework. Row INSIDER *framework* corresponds to this part. ③ I/O IP cores. This part mainly comprises the resource for the DRAM controller and the DMA controller. Row *DRAM and DMA IP cores* correspond to this part.

We note that ③ takes the major part of the overall resource consumption. However, these components actually already exist (in the form of ASIC hard IP) in modern storage drives [33], which also have a built-in DRAM controller and need to interact with host via DMA. Thus, ③ only reflects the resource use that would only occur in our prototype due to our limited evaluation environment. The final resource consumption should be measured as ①+②. Row *XCVU9P* [19] and row *XC7A200T* show the available resource of a high-end FPGA (which is used in our evaluation) and a low-end FPGA [7], respectively. We notice that in the best case, the low-end FPGA is able to simultaneously accommodate five resource-light applications (*grep, KNN, statistics, SQL, integration*). The key insight here is that, for the ISC purpose, we *only* need to offload code snippet involving data reduction (related to the virtual file read) or data amplification (related to the virtual file write), therefore the drive programs are frugal in the resource usage.

5.5 Comparing with the ARM-Based System

Methodology. We assume that only the FPGA-based ISC unit is replaced by the ARM CPU, and all other designs remain unchanged. We extract the computing programs from the traditional host-only implementation used in §5.2. Since we assume the system-level pipelining (§3.5) is also deployed here, the final end-to-end time of the ARM-based platform could be calculated as $T_{e2e} = max(T_{host}, T_{trans}, T_{ARM})$, where T_{host} denotes the host-side processing time and T_{trans} denotes the host/drive data transferring time. Here, T_{host} and T_{trans} are taken from the measured data of INSIDER at §5.2. We target Cortex-A72 (using parameters in [12]), which is a high-end quad-core three-way superscalar ARM processor. We conduct runtime profilings over an ARM machine to extract

[7] We do not directly use XC7A200T in the evaluation since we cannot find a low-end FPGA board with large DRAM, which forces us to use XCVU9P.

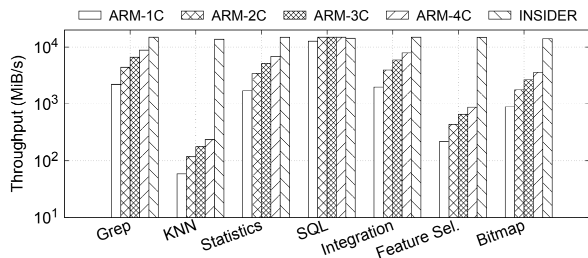

Figure 12: End-to-end data processing rates of INSIDER and the ARM-based platforms. ARM-*N*C means to use *N* core(s).

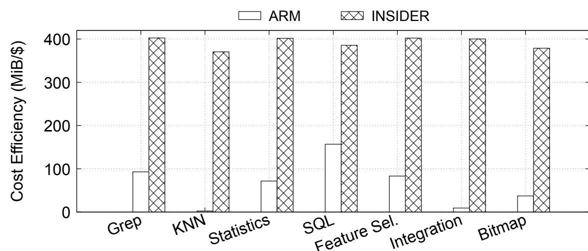

Figure 13: Cost efficiency (defined as data processing rates per dollar) of INSIDER and the ARM-based platforms. We do not include the cost of storage drive, whose price varies significantly across configurations.

the number of program instructions. The program execution time is then calculated *optimistically* by assuming that it has *perfect IPC* and *perfect parallelism* over multiple cores.

Fig. 12 (in log scale) shows the end-to-end data processing rates of INSIDER and the ARM-based platform. The speedup of INSIDER is highly related to the computation intensity of examined applications, but on average, INSIDER could achieve 12X speedup. For *KNN*, which is the most compute-intensive case, INSIDER could achieve 58X speedup; while for *SQL query*, which has the least computation intensity, the ARM-based platform could achieve the same performance.

We further present the cost efficiency of the ARM and INSIDER platforms, which is defined as the data processing rate per dollar. As discussed in §5.4, FPGA XC7A200T is already able to meet our resource demand; thus we use it in this evaluation. The wholesale price of FPGA is much less compared to its retail price according to the experience of Microsoft [36]. For a fair comparison, we use the wholesale prices of FPGA XC7A200T ($37 [20]) and ARM cortex-A72 ($95 [12]). We did not include the cost of storage drive in this comparison. Fig. 13 shows the cost efficiency results. Compared with the ARM-based platform, INSIDER achieves 31X cost efficiency on average. Specifically, it ranges from 2X (in *SQL query*) to 150X (in *KNN*).

6 Future Work

In-storage computing is still in its infancy. INSIDER is our initial effort to marry this architectural concept with a practical system design. There is a rich set of interesting future work, as we summarize in the following.

Extending INSIDER for a broader scenario. First, from the workload perspective, an extended programming model is desired to better support the data-dependent applications like key-value store. The current programming model forces host to initiate the drive access request, thus it cannot bypass the interconnection latency.

Second, from the system perspective, it would be useful to integrate INSIDER with other networked systems to reduce the data movement overheads. Compared to PCIe, performance of the network is further constrained, which creates yet another scenario for INSIDER [45]. The design of INSIDER is mostly agnostic to the underlying interconnection. By changing the DMA part into RDMA (or Ethernet), INSIDER can support the storage disaggregation case, helping cloud users to cross the "network wall" and take advantage of the fast remote drive. Other interesting use cases include offloading computation to HDFS servers and NFS servers.

Data-centric system architecture. Traditionally, the computer system is designed to be computing-centric, in which the data from IO devices are transferred and then processed by CPU. However, the traditional system is facing two main challenges. First, the data movement between IO devices and CPU has proved to be very expensive [53], which can no longer be ignored in the big data era. Second, due to the end of Dennard Scaling, general CPUs can no longer catch up with the ever-increasing speed of IO devices. Our long-term vision is to refactor the computer system into being data-centric. In the new architecture, CPU is only responsible for control plane processing, and it offloads data plane processing directly into the customized accelerator inside of IO devices, including storage drives, NICs [50, 52], memory [51], etc.

7 Conclusion

To unleash the performance of emerging storage drives, we present INSIDER, a full-stack redesigned storage system. On the performance side, INSIDER successfully crosses the "data movement wall" and fully utilizes the high drive performance. On the programming side, INSIDER provides simple but effective abstractions for programmers and offers necessary system support which enables a shared executing environment.
