Abstract

Data analysis and retrieval is a widely-used component in existing artificial intelligence systems. However, each request has to go through each layer across the I/O stack, which moves tremendous irrelevant data between secondary storage, DRAM, and the on-chip cache. This leads to high response latency and rising energy consumption. To address this issue, we propose Cognitive SSD, an energy-efficient engine for deep learning based unstructured data retrieval. In Cognitive SSD, a flash-accessing accelerator named DLG-x is placed by the side of flash memory to achieve near-data deep learning and graph search. Such functions of in-SSD deep learning and graph search are exposed to the users as library APIs via NVMe command extension. Experimental results on the FPGA-based prototype reveal that the proposed Cognitive SSD reduces latency by 69.9% on average in comparison with CPU based solutions on conventional SSDs, and it reduces the overall system power consumption by up to 34.4% and 63.0% respectively when compared to CPU and GPU based solutions that deliver comparable performance.

1 Introduction

Unstructured data, especially unlabeled videos and images, etc., have grown explosively in recent years. It is reported that the unstructured data occupies up to 80% of storage capacity in commercial datacenters [10]. Once being stored and managed in the cloud machines, the massive amount of unstructured data leads to intensive retrieval requests issued by users, which pose significant challenge to the processing throughput and power consumption of a datacenter [19]. Consequently, it is critical to support fast and energy-efficient data retrieval in the cloud service infrastructure to reduce the total cost of ownership (TCO) of datacenters.

Unfortunately, conventional content-based multimedia data retrieval systems suffer from the issues of inaccuracy, power inefficiency, and high cost especially for large-scale unstructured data. Fig. 1(a) briefly depicts a typical content-based

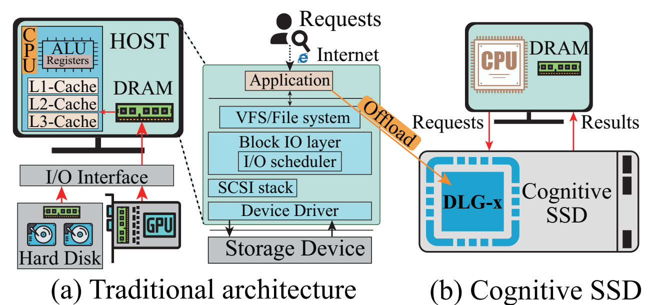

Fig. 1. Traditional architecture (a) vs. Cognitive SSD (b).

data retrieval system composed of CPU/GPU and conventional storage devices based on a compute-centric architecture [14]. When a data retrieval request arrives from the internet or the central server, the CPU has to reload massive potential data from disk into the temporary DRAM [14] and match the features of the query with those of the loaded unstructured data to find the relevant targets. This compute-centric architecture is confronted with several critical sources of overhead and inefficiency. (1) The current I/O software stack significantly burdens the data retrieval system when it simply fetches data from the storage devices on retrieval requests [60], as shown in Fig. 1(a). The situation is even worse since it is reported the performance bottleneck has migrated from hardware (75∼50us [11]) to software (60.8us [48]) as traditional HDDs are replaced by non-volatile memory [41,48]. (2) Massive data movement incurs energy and latency overhead in the conventional memory hierarchy. This issue becomes severe as the scale of data under query increases because the relevant data at the low-level storage must travel across a slow I/O interface (e.g., SATA), main memory and multi-level caches before reaching the compute units of CPU or GPUs [24], which is depicted in Fig. 1(a).

To address these issues, as shown in Fig. 1(b), this work aims to tailor a unified data storing and retrieval system within the compact storage device, and eliminate the major IO and data moving bottleneck. In this system, retrieval requests are directly sent to the storage devices, and the target data analysis and indexing are completely performed where the unstruc-

[1]Corresponding authors are Ying Wang and Huawei Li.

tured data resides. Building such a data retrieval system based on the proposed Cognitive SSD bears the following design goals: (1) providing a high accuracy, low latency, and energy efficient query mechanism affordable in a compact SSD, (2) exploiting the internal bandwidth of flash devices in an SSD for energy-efficient deep learning based data processing, and (3) enabling developers to customize the data retrieval system for different dataset. These points are stated in detail below.

First, instead of relying on the general-purpose CPU or GPU devices in Fig. 1(a), we must have a highly computation-efficient yet accurate data retrieval architecture in consideration of the SSD form factor and cost. A conventional data retrieval framework is inaccurate or too computationally expensive to be implemented within a resource-constrained SSD. In this work, we are the first to propose a holistic data retrieval mechanism by combining the deep learning and graph search algorithm (DLG), where the former could extract the semantic features of unstructured data and the latter could improve database search efficiency. The DLG solution achieves much higher data retrieval accuracy and enables user-definable computation complexity through deep learning model customization, making it possible to implement a flexible and efficient end-to-end unstructured data retrieval system in the SSD.

Second, although DLG is a simple and flexible end-to-end data retrieval solution, embedding it into SSDs still takes considerable effort. We designed a specific hardware accelerator that supports deep hashing and graph search simultaneously, DLG-x, to construct the target Cognitive SSD without using power-unsustainable CPU or GPU solutions. However, the limited DRAM inside an SSD is mostly used to cache the metadata for flash management, leaving no free space for the deep learning applications. Fortunately, we have proved that the bandwidth of internal flash interface surpasses that of external IO interface in a typical SSD, which matches the bandwidth demand of the DLG-x with proper data layout mapping. By rebuilding the data path in the SSD and deliberately optimizing the data-layout related to deep learning models and graphs on NAND flash, the DLG-x could fully exploit internal parallelism and directly access data from NAND flash bypassing the on-board DRAM.

Finally, as we introduce deep learning technology into the SSD, we must expose the software abstraction of Cognitive SSD to users and developers to process different data structures with different deep learning models. Thus, we abstract the underlying deep learning mechanism, feature analysis, and data structure indexing mechanism as user-visible calls by utilizing the NVMe protocol [6] for command extension. Not only can users' requests trigger the DLG-x accelerator to search the target dataset for query-relevant structures, but also system developers can freely configure the deep hashing architecture with different representation power and overhead for different dataset and performance requirement. In contrast to conventional ad-hoc solutions, Cognitive SSD allows system developers to adjust the retrieval accuracy as well as the real-time performance of the data retrieval service through provided APIs. Meanwhile, Cognitive SSD also supports the flexible combination of special commands to achieve different data retrieval related tasks, like in-storage data categorization and hashing-only functions. In summary, we make the following novel contributions:

1. We propose Cognitive SSD, to enable within-SSD deep learning and graph search by integrating a specialized deep learning and graph search accelerator (DLG-x). The DLG-x directly accesses data from NAND flash without crossing multiple memory hierarchies to decrease data movement path and power consumption. To the best of our knowledge, this work is the first to combine the deep learning and graph search methods for fast and accurate data retrieval in SSD.
2. We employ Cognitive SSD to build a serverless data retrieval system, which completely abandons the conventional data query mechanism in orthodox compute-centric systems. It can independently respond to data retrieval requests at real-time speed and low energy cost. It can also scale to a multi-SSD system and significantly reduces the hardware and power overhead of large-scale storage nodes in data centers.
3. We build a prototype of Cognitive SSD on the Cosmos plus OpenSSD platform [7] and use it to implement a data retrieval system. Our evaluation results demonstrate that Cognitive SSD is more energy-efficient than a multimedia retrieval system implemented on CPU and GPU, and reduces latency by 69.9% on average compared to the implementation with CPU. We also show that it outperforms conventional computing and storage node used in the data center when Cognitive SSD scales out to form smart lightweight storage nodes that include connected Cognitive SSD array.

2 Background and Preliminaries

2.1 Unstructured Data Retrieval System

Content-based unstructured data retrieval systems aim to search for certain data entries from the large-scale dataset by analyzing their visual or audio content. Fig. 2 depicts a typical content-based retrieval procedure consists of two main stages: feature extraction, and database indexing. Feature extraction generates the feature vector for the query data, and database indexing searches for similar data structures in storage with that feature vector encoded in a semantic space.

Feature Extraction and Deep Learning. The rise of deep learning transfers the focus of researches to deep convolution neural network (DCNN) [38] based features [61], as it provides better mid-level representations [37,40]. Fig. 2 depicts a typical DCNN that contains four key types of network layers: (1) convolution layer, which extracts visual feature from input by moving and convolving multidimensional filters across the input data organized into 3D tensors, (2) activation, the

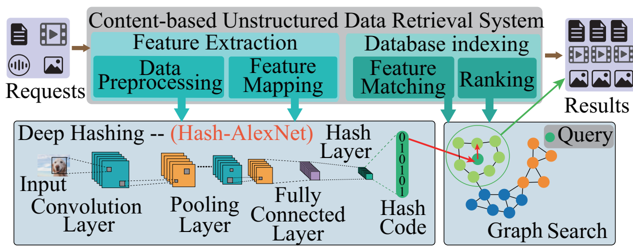

Fig. 2. Content-based multimedia data retrieval system.

nonlinear transformation that we do over the input signal, (3) pooling layers, which down-sample the input channels for scale and other types of invariance, and (4) fully connected (FC) layer, which performs linear operations between the features and the learned weights to predict the categorization or other high level characteristics of input data. Such a neural network is flexible and can be designed to have different hyper-parameters, like the number of the convolution and pooling layers stacked together and the dimension and number of convolution filters. Changing these parameters will impact the generalization ability and also computational overhead of neural networks, which are usually customizable for different dataset or application scenarios [47]. Some prior work directly employs the high-dimension output vector of the FC layer for data retrieval and is thought too expensive in terms of memory footprint and computation complexity [39]. Thus, we adopt deep hashing [38] to achieve effective yet condensed data representation. Fig. 2 exemplifies a deep hashing architecture, Hash-AlexNet, where a hash layer follows the last layer of AlexNet [35] to project the data feature learned from AlexNet into the hash space, and the generated hash code can be directly used to index the relevant data structures and get rid of the complex data preprocessing stage.

Database indexing: Graph-based approximate nearest neighbor search(ANNS) methods named NSG [27], a complement to deep hashing, achieves both accurate and fast data retrieval results, as was proved in previous work [17, 26]. The main idea of NSG is mapping the query hash code into a graph. The vertex of the graph represents an instance, and the edge stands for the similarities between entities, where the value of the edge represents the strength of similarity. On top of that, NSG can iteratively check neighbors' neighbors in the graph to find the true neighbors of the query based on the neighbor of a neighbor is also likely to be a neighbor concept. In this manner, the NSG could avoid unnecessary data checking to reduce retrieval latency.

In summary, deep hashing followed by graph search can perform low-latency and high-precision retrieval performance compared to traditional solutions using brute-force search or hash algorithms. Meanwhile, it also makes the retrieval framework more compact and efficient because of the similar compute patterns and data stream, so that they can fit into compact and power-limited SSDs.

2.2 Near data processing & deep learning accelerator

For hardware-software co-design, there are two directions in SSD research: open-channel SSD and near-data processing (NDP). While open-channel SSD enables direct flash memory access via system software [15, 42, 44, 59], near-data processing (NDP) moves computation from the system's main processors into memory or storage devices [16, 18, 25, 46, 50, 51, 56].

In NDP, Morpheus [52] provides a framework for moving computation to the general-purpose embedded processors on NVMe SSD. FAWN [13] uses low-power processors and flash to handle data processing and focuses on a key-value storage system. SmartSSD [34] introduces the Smart SSD model, which pairs in-device processing with a powerful host system capable of handling data-oriented tasks without modifying the operating system. [53] supports fundamental database operations including sort, scan, and list intersection by utilizing Samsung SmartSSD. [23] investigates by simulation the possibility of employing the embedded ARM processor in SSDs to run SGDs, which is a key components of neural network training. However, none of them can handle deep learning processing due to the performance limit of the embedded processor. Thereby, [22] presents intelligent solid-state drives (iSSDs) that embed stream processors into the flash memory controllers to handle linear regression and k-means workloads. [43] integrates programmable logics into SSDs to achieve energy-efficiency computation for web-scale data analysis. Meanwhile, [32] also uses FPGAs to construct BlueDBM that uses flash storage and in-store processing for cost-effective analytics of large datasets, such as graph traversal and string search. GraFBoost [33] focuses on the acceleration of graph algorithms on an in-flash computing platform instead of deep learning algorithms as this work.

Cognitive SSD Prior active disks are integrating either general purpose processors incapable of handling high-throughput data or specialized accelerators with only the support of simple functions like scanning and sorting. These in-disk computation engines are unable to fulfill the requirement of high-throughput deep neural network (DNN) inference because computation-intensive DNNs generally rely on power-consuming CPU or GPUs in the case of data analysis and query tasks. To enable energy-efficient DNN, prior work proposes a variety of energy-efficient deep learning accelerators. For example, Diannao and C-Brain map large DNNs onto a vectorized processing array and employ a data tiling policy to exploit locality in neural parameters [20, 49]. Eyeriss applies the classic systolic array architecture to the inference of CNN, and outperforms CPU and GPU in energy efficiency dramatically [21]. However, these researches focus on optimizing the internal structure of accelerator and relied on large-capacity SRAM or DRAM instead of external non-volatile memory. In contrast to these works and prior active SSD designs, we propose **Cognitive SSD**, the first work that enables the storage device to employ deep learning to conduct

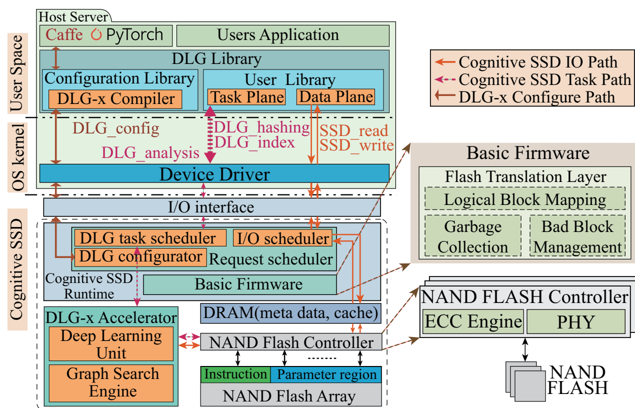

Fig. 3. Overview of the Cognitive SSD system.

in-storage data query and analysis. It is designed to replace the conventional data retrieval system and contains a flash-accessing accelerator (DLG-x) for deep learning and graph search. The DLG-x is deliberately reshaped to take advantage of the large flash capacity and high internal bandwidth, and it is also re-architected to enable graph search to target indexing.

3 Cognitive SSD System

Target Workload. As shown in Fig. 2, this work combines the strengths of deep hashing and graph search technique (DLG) to reduce the complexity of retrieval systems on the premise of high accuracy, which makes it possible to offload retrieval task from CPU/GPU into the resource-constraint Cognitive SSD. Based on that, we build an end-to-end data retrieval system that supports multimedia data retrieval such as audio, video and text. For example, audio can be processed by recurrent or convolutional neural network models on Cognitive SSD to generate hash codes, which act as an index for retrieving relevant audio data inside the SSD. In this paper, image retrieval is used as a showcase. As shown in Fig. 3, Cognitive SSD is designed to support the major components in the framework of DLG, allowing developers to customize and implement data retrieval solutions. Such a near-data retrieval system consists of two major components: the DLG library running in lightweight server that manages user requests, and the Cognitive SSD is plugged into the host server via the PCIe interface. As shown in Table 1, as the interface of Cognitive SSD system, the DLG library is established by leveraging the *Vendor Specific Commands* in the I/O command set of the *NVMe* protocol. It contains a *configuration library* and a *user library*. The configuration library enables the administrator to choose and deploy different deep learning models on the Cognitive SSD quickly according to application demand. After the feature-extracting deep hashing model has been deployed on the Cognitive SSD, a data processing request arriving at the host server could send and establish a query session to it by invoking the APIs provided by the user library. Then, the runtime system on the embedded processor of the Cognitive SSD receives and parses the request to activate the corresponding DLG-x module, which is associated with the user-created session. Next, we elaborate on the software and hardware design details of Cognitive SSD.

3.1 The Cognitive SSD Software: DLG Library

3.1.1 Configuration Library

Update Deep Learning Models: Because the choice of deep learning models significantly impacts the data retrieval system performance, the system administrator must be able to customize a specific deep hashing model according to the complexity and volume of database, and the quality of service measured by response latency or request throughput. Thereby, the configuration library provides a DLG-x compiler compatible with popular deep learning frameworks (i.e., Caffe) to allow the administrator to train the new deep learning model and generate corresponding DLG-x instructions offline. Then, the administrator can update the learning model running on the Cognitive SSD by updating the DLG-x instructions. The updated instructions are sent to the instruction area allocated in the NAND flash and stay there until a model change command (*DLG_config* in Fig. 3) is issued. Meanwhile, the DLG-x compiler also reorganizes the data layout of the DLG algorithm to fully utilize the internal flash bandwidth according to the structures of neural network model and graph, before the parameters of deep learning model and graphs are written to the NAND flash. The physical address of weight and graph structure information is recorded in the DLG-x instruction. In this manner, the DLG-x obtains the physical address of required data directly at runtime, instead of adopting the address translation or look-up operations that incur additional overhead. More details about the data reorganization scheme are introduced in § 4.

3.1.2 User Library

Data Plane: The data plane provides *SSD_read* and *SSD_write* APIs for users to control data transmission between the host server and the Cognitive SSD. These two commands operate directly on the physical address bypassing the flash translation layer. Users can invoke these APIs to inject data sent from users to the data cache region or the NAND flash on the Cognitive SSD based on the parameter of data address and data size. Afterwards, users can use those addresses to direct the operands in other APIs.

Task Plane: To improve the scalability of the DLG-x accelerator that supports deep hashing neural networks and graph search algorithms, we abstract the function of the DLG-x into three APIs in the task plane of user library: *DLG_hashing*, *DLG_index*, and *DLG_analysis*. These APIs are established using the ***C0h***, ***C1h***, and ***C2h*** commands of NVMe I/O protocol, respectively. All of them possess two basic parameters carried by NVMe protocol ***DWord***s: the *data address* indicating the data location in Cognitive SSD, and the *data size* in bytes.

First, the *DLG_hashing* API is designed to extract the condensed feature of input data and map it into the hash or seman-

Table 1: **DLG Library APIs for Cognitive SSD**

	-	API	NVMe command	DWord10	DWord11	DWord12	Description
Configuration Library	-	*DLG_config*	0xC3	address	size	Instruction/model	Update instruction and model on DLG-x
User Library	Task Plane	*DLG_hashing*	0xC0	data address	data size	Hashcode length	Extract the hashing feature of input data
		DLG_index	0xC1	data address	data size	T	Fast database indexing
		DLG_analysis	0xC2	data address	data size	User-defined	Analysis of input data
	Data Plane	*SSD_read*	0xC4	data address	data size	–	Physical Address Read
		SSD_write	0xC5	data address	data size	–	Physical Address Write

tic space, which is fundamental in a data retrieval system and useful for other analysis functions like image classification or categorization. This command contains an extended parameter: *hashcode length*, which determines the capacity of the carried information. For example, compared to the database with 500 objects types, the database with 1000 objects needs a longer hash code to avoid information loss. Second, the *DLG_index* API is abstracted from the graph search function of the DLG-x. It also includes an extended parameters: *T*, represents the number of search results configured by users based on the applications scenarios. Finally, the *DLG_analysis* API allows users to analyze the input data using the data analysis and processing ability of deep neural networks and it also possesses a reserved field for user-defined functions. These task APIs are the abstraction of the key near-data processing kernels provided by Cognitive SSD, and they can be invoked independently or combinedly to develop different in-SSD data processing functions. For instance, users could combine the *DLG_hashing* and *DLG_index* APIs to accomplish data retrieval on a large-scale database, where *DLG_hashing* maps the features of query data to a hash code and *DLG_index* uses it to search for the top-*T* similar instances.

3.1.3 Cognitive SSD Runtime The Cognitive SSD runtime deployed on the embedded processor inside the Cognitive SSD is responsible for managing the incoming extended I/O command via PCIe interface. It also converts the API-related commands into machine instructions for the DLG-x accelerator, as well as handles basic operations for NAND flash. It includes a request scheduler and the basic firmware. The request scheduler contains three modules: the ***DLG task scheduler***, the ***I/O scheduler***, and the ***DLG configurator***. The *DLG configurator* receives *DLG_config* commands from the host and updates the instructions generated by the compiler and parameters of the specified deep learning model for Cognitive SSD. The *DLG task scheduler* responds to users requests as supported in the task plane and initiates the corresponding task session in Cognitive SSD. The I/O scheduler dispatches I/O requests to the basic firmware or the DLG-x. The basic firmware includes the flash translation layer, for logical block mapping, garbage collection, bad block management functions, and communicates with the NAND flash controller for general I/O requests.

Note that the DLG-x accelerator occupies a noticeable portion of the flash bandwidth once activated, which perhaps degrades the performance of normal I/O requests. To alleviate this problem, instead of letting the task or I/O scheduler wait until the request is completed (denoted as Method A), the *DLG task scheduler* receives the NVMe command sent from host with doorbell mechanism and actively polls the completion status of the DLG-x periodically (denoted as Method B) to decide if the next request is dispatchable. We tested the normal read/write bandwidth of Cognitive SSD prototype described in § 5.1 with the Flexible IO Tester (fio) benchmark [4], under the worst-case influence where the DLG-x accelerator operations occupied all the Cognitive SSD channels. Experiments (Table 2) demonstrate that adopting Method B only causes a drop of 27%-44% in the normal I/O bandwidth whilst using Method A decreases almost 91% of the read/write bandwidth averagely when the DLG-x accelerator is busy dealing with the over-committed retrieval tasks.

Table 2: The I/O Bandwidth of Cognitive SSD.

-	I/O Bandwidth (MB/s) (I/O size = 128KB)			
-	Write	Random Write	Read	Random Read
Method-A	79.79	76.19	72.30	81.13
Method-B	524.86	421.23	654.31	698.98
Peak-Bandwidth	886.58	761.90	903.79	901.41

3.2 Hardware Architecture: Cognitive SSD

Fig. 3 depicts the hardware architecture of Cognitive SSD. It is composed of an embedded processor running the Cognitive SSD runtime, a DLG-x accelerator and NAND flash controllers connected to flash chips. Each NAND flash controller connects one channel of NAND flash module and uses an ECC engine for error correction. When the devices in each channel operate in lock-step and are accessed in parallel, the internal bandwidth surpasses the I/O interface. More importantly, though SSDs often have compact DRAM to cache data or metadata, the internal DRAM capacity can hardly satisfy the demand of the deep learning, which is notorious for its numerous neural network parameters. Worse still, the basic firmware like FTL and other components also occupy major memory resources. Therefore, the NAND flash controller is exposed to the DLG-x accelerator, which enables the DLG-x to read and write the related working data directly from NAND flash, bypassing the internal DRAM.

3.3 The Procedure of data retrieval in Cognitive SSD

Fig. 3 also depicts the overall process of Cognitive SSD when users perform unstructured data retrieval task. First, assume that the hardware instruction and parameters of Hash-AlexNet

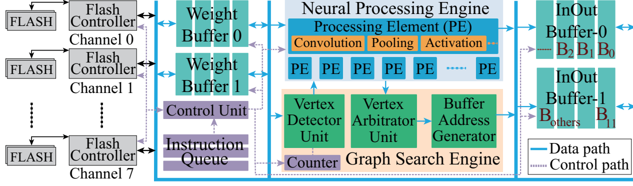

Fig. 4. The Architecture of DLG-x accelerator.

model have been generated and written to the corresponding region by leveraging the DLG-x compiler and the *DLG_config* command shown in Fig. 3. The Hash-AlexNet is the developer designated neural network for feature extraction of input data. Then, when the host DLG library captures a retrieval request, it packages and writes the user input data from the designated host memory space to Cognitive SSD through the *SSD_write* API. Meanwhile, the *DLG_hashing* command carrying the address of input data is sent to Cognitive SSD for hash code generation. Receiving the command, the request scheduler of the cognitive runtime parses it and notifies the DLG-x accelerator to start a hashing feature extraction session. Then, the DLG-x automatically fetches input query data from the command-specified data address and then loads deep learning parameters from NAND flash. Meanwhile, the other command, *DLG_index*, is sent and queued by the task scheduler. After the hash code is produced, the *DLG_index* is dispatched to invoke the graph search function in the DLG-x and uses the hash result to search the data graphs for relevant data entries. In this case, the DLG-x keeps fetching graph data from the NAND flash and sends the final retrieval results to the host memory once the task is finished.

4 DLG-x Accelerator

4.1 Architecture: Direct Flash Accessing

In contrast to a traditional hardware accelerator [20], the DLG-x accelerator is designed to directly obtain the majority of the working-set data from NAND flash. Fig. 4 illustrates the high-level diagram. The DLG-x accelerator has two activation buffers (InOut Buffer) and double-banked weight buffers. The intermediate results of each neural network layers are temporarily stored in the activation buffers, while the weight buffers act as a bridge buffer between the Neural Processing Engine (NPE) and the flash, which stream out the large quantity of neural parameters to the NPE. The NPE comprises a set of processing engines (PEs), which can perform fixed-point convolutions, pooling, and activation function operations. The Graph Search Engine (GSE) cooperates with the NPE and is responsible for graph search with the hash code generated by NPE. Both the NPE and GSE are managed by the control unit that fetches instructions from memory. Considering the I/O operation granularity of NAND flash, we reorganize the data layout of neural networks including both the static parameters and the intermediate feature data, to exploit the high internal flash bandwidth.

4.2 I/O Path in Cognitive SSD

Bandwidth Analysis: At first, we analyze and prove that the internal bandwidth of NAND flash can satisfy the demand of deep neural network running on the DLG-x accelerator. Assuming that the DLG-x and flash controller runs on the same frequency and the NPE unit of the DLG-x comprises N_{PE} PEs. The single channel bandwidth of NAND flash is BW_{flash}. Thereby, the bandwidth of M channels equals to:

$$BW_{flash}^{m} = M \times BW_{flash} \tag{1}$$

Suppose that a convolution layer convolves a $I_c \times I_h \times I_w$ input feature map (IF) with a $K_c \times K_h \times K_w$ convolution kernel to produce a $O_c \times O_h \times O_w$ output feature map (OF). The subscript c, h, and w correspond to the channel, height, and width respectively. The input/weight data uses an 8-bit fixed-point representation. It is easy to derive that the computation latency $L_{compute}$ and the data access latency L_{data} from NAND flash to produce one channel of feature map are:

$$L_{compute} = \frac{OP_{compute}}{OP_{PE}} = \frac{2 \times K_c \times K_h \times K_w \times O_h \times O_w}{2 \times N_{PE}} \tag{2}$$

$$L_{data} = \frac{S_{param}}{BW_{flash}^{m}} = \frac{K_c \times K_h \times K_w}{BW_{flash}^{m}} \tag{3}$$

Where the $OP_{compute}$ and S_{param} is the operation number and the parameters volume of a convolutional layer. OP_{PE} gauges the performance of the DLG-x measured in operations/cycle. To avoid NPE stalls,we must have $L_{compute} >= L_{data}$, and O_w is usually equal to O_h, so we have

$$O_w >= \sqrt{N_{PE}/BW_{flash}^{m}} \tag{4}$$

The above equation indicates that if only the width and height of the output feature map is larger than or equal to the right side of formula 4, which is four in our prototype with $N_{PE} = 256$ and $BW_{flash}^{m} = 16 bytes/cycle$, the NPE will not stall. For example, in the Hash-AlexNet mentioned in § 2.1, the minimum width of the output feature map in convolution layers is 7, which already satisfies in inequality 4 design. However, in the FC layers, $L_{compute}$ is smaller than L_{data}, so the data transfer time becomes the bottleneck. Thereby, the DLG-x accelerator only uses a column of PEs to deal with a FC layer because our prototype hardware design only supports eight channels, which does not meet inequality 4 with $M = 128$ and consequently causes PE underutilization. Besides, the parameter-induced flash reads will be minimized if the size of the weight buffer meets the condition: $S_{buffer} >= Max(K_c \times K_h \times K_w)$. The parameters exceeding the size of weight buffer will be repetitively fetched from the flash. To further improve the performance, we utilize ping-pong weight buffers to overlap the data loading latency with computation.

Data Layout in flash devices: Owing to the bandwidth analysis on the base of multi-channels data transmission, we propose flash-aware data layout to fully exploit flash bandwidth with the advanced NAND flash command-*read page cache*

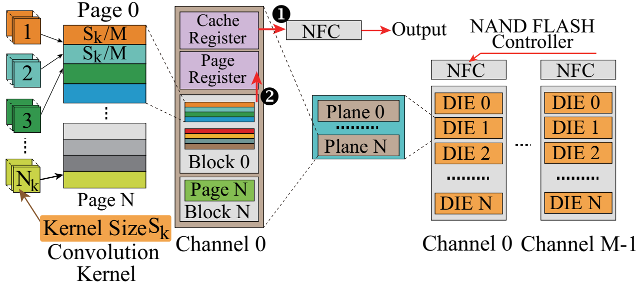

Fig. 5. The Data Layout in NAND flash.

command [11]. The read page cache sequential command provided by NAND flash manufacturer can continuously load the next page within a block into the data register (❷) while the previous page is being read to the buffer of the DLG-x or the cache region of the SSD from the cache register(❶). Thus, based on the NAND flash architecture with the provided page cache command, we choose to split the convolution kernels and store them into flash devices for parallel fetch. As shown in Fig. 5, assuming there are N_k convolution kernels with S_k kernel size, and M NAND flash channels are used by the DLG-x accelerator, each convolution kernel is divided into S_K/M sub-blocks and all such sub-blocks are interleaved to the flash channels. The convolution kernels exceeding the size of a page are placed into continuous address space in the NAND flash because the cache command reads out the next page automatically without any extra address or operation.

Data Flow: Taking the Hash-AlexNet as an example, when a request arrives at the DLG-x accelerator, the input data and the first kernel of the first convolution layer is transferred in parallel to the InOut buffer-0 and the weight buffer-0. After that, the DLG-x accelerator begins to compute the output feature map and stores them into the InOut buffer-1. When the first kernel is processed, the second kernel is being transferred from the NAND flash to weight buffer-1, then followed by the third and fourth kernel in sequence. Once the hash code is generated, it is sent to the graph search registers of NPE to locate the data structures similar to the query data if the *DLG task scheduler* decodes and dispatches a following *DLG_index* command.

4.3 Fusing Deep Learning and Graph Search

For fast and accurate database indexing, the DLG-x accelerator fuses the deep learning and graph search mechanism into unified hardware, and reuses the computation and memory resources for higher efficiency. Once the hash code of the query data has been generated, the DLG-x uses it to initially index the corresponding data graphs and searches for the closest data entries from graphs.

The graph search method originates from Navigating Spreading-out Graph [27] (NSG), which well fits the limited memory space of the Cognitive SSD for the large-scale multimedia data retrieval. The NSG algorithm includes an offline stage and an online stage. In the offline phase, the NSG method constructs a directed $K_{nbors}-NN$ graph for the storage data structures to be retrieved. In a graph, a vertex represents a data entry by keeping its ID and hash code. The unique ID represents a file and the hash code is the feature vector of this file, which could be obtained by invoking the *DLG_hashing* API in advance. The bit-width of ID (W_{id}) and hash code (W_{hash_code}) are user-configurable parameters in the API. In a graph, a vertex may be connected to many vertices, which have different distances from each other. However, only the top-K_{nbors} closest vertices of a vertex could be defined as its "neighbors", where K_{nbors} is also a reconfigurable parameter and enables users to pursue the trade-off between accuracy and retrieval speed. The DLG-x accelerator only accelerates the online retrieval stage and the database update occurs offline because the latter task is infrequent. The database update consists of hash code extraction stage and $K_{nbors}-NN$ graph construction stage, where the former is accelerated by the DLG-x accelerator and the latter is completed with the DLG library on CPUs. At offline graph construction, it takes about 10∼100 seconds to update the $K_{nbors}-NN$ graph on million-scale data on a server CPU. The hardware architecture for online graph search is presented in Fig. 4.

The graph search function of the DLG-x starts from evaluating the distance of random initial vertices in the graph and walks the whole graph from vertex to vertex in the neighborhood to find the closest results. As shown in Fig. 4, to maximize the utilization of on-chip memory, the weight buffer and InOut buffer are reused to store the neighbors of vertices and the search results of the graph search engine respectively. Since the Hamming distance (H-distance) is an integer value, the InOut buffer is divided into blocks according to the range of H-distance. For instance, the first block of the InOut buffer B_0 only stores the vertices with zero Hamming distance away from the query vertex, and the second block B_1 corresponds to the distance of one hop. The last area B_{others} stores the vertices with Hamming distance larger than the final value V_{final}, where the V_{final} is a re-definable parameter and calculated with formula 5.

$$V_{final} = \left\lfloor \frac{S_{buffer}}{D_{block} \times W_{id}} - 1 \right\rfloor \quad (5)$$

In the above equation, S_{buffer} is the on-chip buffer size of the DLG-x accelerator and D_{block} represents the number of vertex IDs that can be stored in each block. W_{id} is usually equal to 32bits. For instance, in our design, with $S_{buffer} = 256KB$ and $D_{block} = 5000$, it is easy to have $V_{final} = 12$. Note that the limited size of the region B_{others} cannot hold all the distant data vertices generated at runtime, and thus B_{others} is configured to a ring buffer to accommodate the incoming vertices cyclically.

A Vertex Detector Unit (VDU) is inserted to check whether the selected vertex has been evaluated. In VDU, the vertex will be discarded once found to have been walked before, otherwise it will be sent to the NPE unit to compute the Hamming distance from the query vertex. With the distance

provided by the NPE, the Buffer Address Generator (BAG) module allocates memory space in the InOut buffer for the vertex and then puts the vertex into the assigned areas of the InOut buffer. The unevaluated vertices will be fetched from the InOut buffer and the neighbors of these vertices are loaded from the weight buffer by the control unit. Meanwhile, the control unit will finally return the top-T closest vertices when the number of vertex in the InOut buffer reaches the threshold configured by users, where T is also configured by users via the *DLG_index* API.

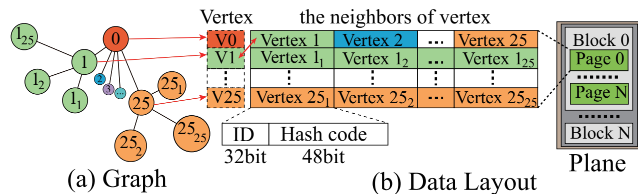

Fig. 6. The data organization on one page.

Data Layout for fast In-SSD NSG search: NAND flash read operations are performed at a page granularity (16KB), so that every time the DLG-x accesses the neighborhoods of one vertex (250bytes), it must read one whole page from flash, which perhaps causes low bandwidth utilization if locality is not well preserved. In our design that $K_{nbors} = 25$, $W_{id} = 32bits$ and $W_{hash_code} = 48bits$. Inspired by the intuition that the neighbor of a neighbor is also likely to be a neighbor of the query data in the graph, we can infer that the neighbors of the accessed vertex will be used soon due to the spatial locality. Therefore, as shown in Fig. 6, V_0 and all its neighbors $(V_1, V_2, ..., V_{25})$, are continuously aligned and stored from the beginning of a page. As a result, such a layout with redundancy is able to reduce flash access by 37x compared to a non-optimized graph layout. However, such a layout cause duplicates of vertices in storage and sacrifice additional storage space for better data access performance, which is worthwhile regarding the large capacity of SSDs.

Besides data layout transformation, the bit-width of the hash code is also worth elaborating. Due to the limited page size S_{page}, W_{hash_code} and K_{nbors} must conform to the resource constraint given by:

$$K_{nbors}^2 \times (W_{hash_code} + W_{id}) < S_{page} \quad (6)$$

Generally $S_{page} = 16KB$, and W_{id} is 32-bit wide and can represent 2^{32} files. Because the parameters W_{hash_code} and K_{nbors} directly impact the deep hashing performance by influencing the indexing accuracy and also the memory bandwidth consumption during graph search, once S_{page} is determined, W_{hash_code} and K_{nbors} must be adjusted to reach a perfect balance between accuracy and retrieval time at the offline stage. Thus, the DLG-x must support different parameter formats in order to achieve best-effort computing efficiency for databases of different volume and complexity.

Note that our graph layout and the according searching strategy are adapted to the underlying hardware for higher energy efficiency, and they will lead to a marginal amount

Table 3: The accuracy loss.

Dataset		Accuracy(%) at T samples				
		200	400	600	800	1000
CIFAR-10	Original	86.65	86.58	86.56	86.51	86.54
	Our	85.49	85.02	84.75	84.47	84.28
	Loss	1.16	1.56	1.81	2.04	2.26
ImageNet	Original	33.78	33.77	33.48	32.89	31.83
	Our	30.66	29.79	29.13	28.43	27.47
	Loss	3.12	3.98	4.35	4.45	4.36

of query accuracy losses compared to the original algorithm. Table 3 indicates the accuracy loss compared with the original lossless DLG algorithm (denoted as Original) on the CIFAR-10 [9] and ImageNet [45] datasets. The result shows that when *T=1000*, the accuracy drops by 2.26% and 4.36%, as a side-effect of the ~ 37x performance boost. Fortunately, the DLG library APIs are flexible enough to allow the developers to trade-off between accuracy and performance by manipulating the API arguments.

Data Flow: we show an example to brief the overall flow of the DLG-x based data retrieval. Firstly, when a query comes, the DLG-x fetches the input data and parameters of the deep learning model from the NAND flash into the InOut buffer and the weight buffer of the DLG-x respectively. Then, the NPE unit generates the hash code for the input data and writes it to the graph search registers of the NPE unit. After that, the DLG-x transfers the $K_{nbors} - NN$ graph from the NAND flash array to the weight buffer. At the first stage, the initial vertices are calculated and sent into the corresponding areas of the InOut buffer. At the second stage, the DLG-x control unit reads the first unevaluated vertex from the InOut buffer in ascending order of Hamming distance. Then, the graph search engine obtains the neighbors of the unevaluated vertex from the NAND flash and transfers the neighbors to NPE to generate their Hamming distances from the query vertex as well. Next, the Buffer Address Generator unit generates the write addresses for these neighbor vertices in the InOut buffers according to the calculated Hamming distance and writes these vertices to the InOut buffers. Meanwhile, the counter in the graph search engine determines whether the termination signal should be issued by monitoring the total number of vertices stored in the InOut buffer. Once the termination signal is generated, the Cognitive SSD runtime reads out the vertices from the InOut buffer and then transfers the ID-directed results stored in NAND flash to the host server via the PCIe interface.

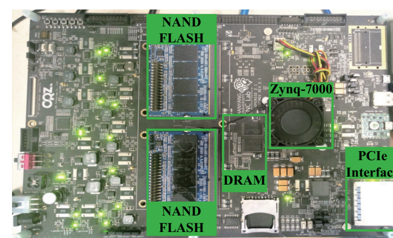

Fig. 7. Cognitive SSD prototype.

5 Evaluation

5.1 Hardware Implementation

To explore the advantages of the Cognitive SSD system, we implemented it on the Cosmos plus OpenSSD platform [7]. The Cosmos plus OpenSSD platform consists of an XC7Z045 FPGA chip, 1GB DRAM, an 8-way NAND flash interface, an Ethernet interface, and a PCIe Gen2 8-lane interface. A DLG-x accelerator is designed with DeepBurning [55] and integrated to the modified NAND flash controllers, and they are all implemented on the programmable logic of XC7Z045. The Cognitive SSD runs its firmware on a Dual 1GHz ARM Cortex-A9 core of XC7Z045. The Cognitive SSD is plugged into the host server via a PCIe link. The host server manages the high-level requests and maintains the DLG library for API calls. Fig. 7 shows the Cognitive SSD prototype constructed for this work.

5.2 Experimental Setup

We first selected the content-based image retrieval system (CBIR) based on deep hashing and graph search (DLG) algorithm as workload and evaluated the performance of DLG solution compared to other conventional solution (§5.3). we evaluated the DLG-x of the Cognitive SSD prototype in §5.4, and deployed the Cognitive SSD prototype to a single node and multi-node system, and evaluated them in §5.5, and §5.6, respectively. Except for the Cognitive SSD prototype, our experimental setup also consists of a baseline server running Ubuntu 14.04 with two Intel Xeon E5-2630 CPU@2.20GHz, 32GB DRAM memory, four 1TB PCIe SSDs and an NVIDIA GTX 1080Ti. Meanwhile, we implemented the CBIR system in C++ on the baseline server, where the deep hashing is built on top of Caffe [31]. Based on this platform, we constructed four solutions baselines: B-CPU, B-GPU, B-FPGA, and B-DLG-x. For B-CPU, the DLG algorithm runs on the CPU. For B-GPU, the deep hashing runs on the GPU and graph search runs on the CPU. For B-FPGA, we use ZC706 FPGA board [12] to replace Cognitive SSD, and the deep hashing runs on ZC706 FPGA board and graph search runs on the CPU. B-DLG-x implements the DLG algorithm on ZC706 FPGA board without any near-data processing technique compared to Cognitive SSD.

5.3 Evaluation of DLG algorithm

Experimental Setup. We used the precision at top T returned samples ($Precision@T$), measuring the proportionality of corrected retrieved data entries, to verify the performance of our deep hashing method on different models and datasets [36]. The performance is contrasted with traditional hash methods with 512-dimensional GIST feature, including Locality-Sensitive Hashing (LSH) [54] and Iterative Quantization (ITQ) [28]. The used datasets are listed in Table 4.

Evaluation. Fig. 8(a)-(d) shows the $Precision@T$ on different datasets with different deep hashing models. Due to the poor performance of LSH and ITQ [28] methods on ImageNet, we added the AlexNet-ITQ (A+ITQ) and AlexNet-CCA-ITQ (AC+ITQ) methods [58] that uses the output of the FC layer on Alexnet as the feature vector for search. Our DLG solution performs better than the other approaches on different datasets with different scales regardless of the choice of T value, especially compared to the conventional hash method. It also shows the robustness of the DLG solution when deploying on a real-world system. Meanwhile, Fig. 8(d) shows the performance of our approach is significantly improved when the code length increases to 64 bits. Thereby, the DLG-x accelerator is configured to support different hash code length to achieve the trade-off between retrieval accuracy and latency.

Table 4: Datasets used in our experiments

Dataset	Total	Train/Validate	Labels
CIFAR-10 [9]	60000	50000/10000	10
Caltech256 [29]	29780	26790/2990	256
SUN397 [57]	108754	98049/10705	397
ImageNet [45]	1331167	1281167/50000	1000

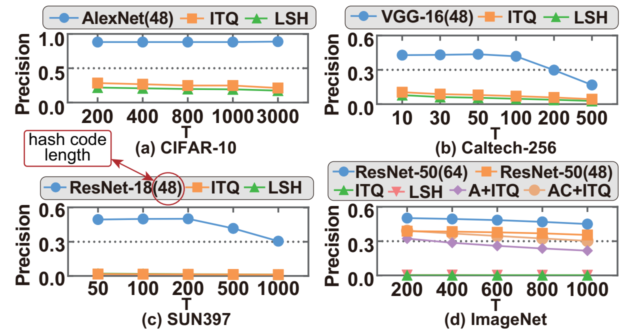

Fig. 8. Precision curves w.r.t top-T.

5.4 Evaluation of DLG-x

Experimental Setup. We implemented the deep hashing and graph search algorithm (DLG) on the DLG-x accelerator of Cognitive SSD and compared the latency and power of the DLG-x to the solutions based on CPU and GPU, where we ignore the FPGA baseline because its computational units are the same as the DLG-x. Firstly, we only compared the latency and power of the deep hashing unit on the DLG-x running various deep hashing models to CPU and GPU, where GPU only reports the total power consumed by NVIDIA GTX 1080Ti without the power of the CPU. Secondly, we only evaluated the latency of graph search function on the DLG-x with respect to different number (T) of top retrieved data entries on the CIFAR-10 and ImageNet dataset.

Performance. Firstly, Table 5 shows the latency of the DLG-x on various deep hashing schemes outperforms the solution based on CPU. While the latency of the DLG-x is higher than GPU because of the hardware resource and frequency limitation, it consumes less power compared to GPU. More importantly, the latency of the CPU and GPU on Table 5 only contains the computation delay of neural network without the delay of parameters transmission between storage and

Table 5: Deep hashing performance on different platforms.

Model	-	Latency (ms)	Power (Watt)
Hash-AlexNet	DLG-x	**38**	**9.1**
	CPU	114	186
	GPU	1.83	164
Hash-ResNet-18	DLG-x	**94**	**9.4**
	CPU	121	185
	GPU	7.13	112

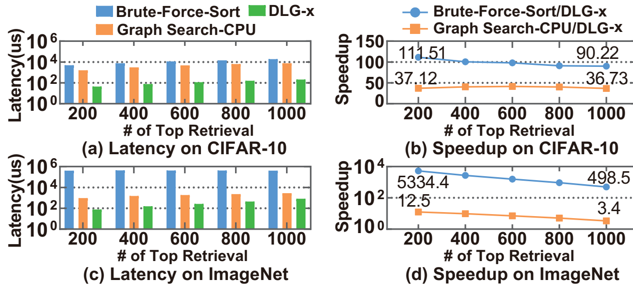

Fig. 9. Graph search performance of the DLG-x.

memory. When considering the delay of parameters transmission between storage and memory, the deep hashing occupies about 87.7% and 73.9% of the total processing time on the DLG-x accelerator and CPU baseline, on average, respectively. And the GPU only accounts for 3.5% of the total runtime on average because the high-speed data processing capability of GPU makes the data transmission becomes the bottleneck of system. Besides, the latency of deep hashing on the GPU occupies 54.17∼26.06% without considering the delay of data movement because the latency of graph search increases with the increase of T value.

Secondly, in this experiment, we utilized the Hash-AlexNet model to generate the hash code database for the construction of a $K_{nbors}-NN$ graph on the CIFAR-10 and ImageNet dataset. We compared the retrieval speed of the DLG-x accelerator with two counterparts: the brute-force search method that evaluates all the hash codes stored in the database, and the CPU executed graph search algorithm. The result is depicted in Fig. 9. For the CIFAR-10 dataset, the DLG-x accelerator is 111.51-90.22x and 37.12-36.73x faster than the brute-force method and the CPU-run graph search algorithms respectively, while for the ImageNet dataset it achieves a 5334.4-498.5x and 12.5-3.4x speed up over the latter two baselines. As introduced in § 4.3, the retrieval accuracy is only degraded by 2.26% and 4.36% when $T = 1000$ on the CIFAR-10 and ImageNet datasets, respectively.

Power Consumption. We measured and compared the power consumption of Cognitive SSD system with four baselines: B-CPU, B-GPU, B-FPGA, and B-DLG-x by using a power meter under two different situations: (1) IDLE: No retrieval requests need to respond, and (2) ACTIVE: A user continuously accesses the Cognitive SSD system. The result is illustrated in Table 6. When the Cognitive SSD+CPU system is IDLE, its power consumption is slightly higher than B-CPU and B-GPU because the Cognitive SSD prototype board IDLE

Table 6: Power consumption.

Power (Watt)	Cognitive SSD	Cognitive SSD+CPU	B-DLG-x	B-FPGA	B-CPU	B-GPU
IDLE	17	98.5	89	89	80	90
ACTIVE	20	122	185.7	195.6	186	330

Table 7: The hardware utilization of Cognitive SSD.

Module	#	LUT	FF	BRAM	DSP
Flash Controller	8	11031	7539	21	0
NVMe Interface	1	8586	11455	28	0
DLG-x Accelerator	1	67774	18144	137	197
`In Total`	1	203099	145078	354	197
Percent(%)	-	92.91	33.18	64.95	21.8

power is higher than that of the PCIe SSD and GPU. For active power, when delivering comparable data retrieval performance, the Cognitive SSD system reduces the total power consumption by up to 34.4% and 63.0% compared with B-CPU and B-GPU. Simply replacing the GPU with the FPGA board reduces power consumption by 40.7%. Furthermore, putting the DLG-x on an identical FPGA board without the NDP decrease power consumption by 43.72%, which is attributed to the efficiency of hardware specialization. Placing the DLG-x into the Cognitive SSD system further eliminates power consumption by another 19.3%, which is the benefit of near-data processing. In the case of the Cognitive SSD+CPU solution, the power of CPU is low because it is only responsible for instruction dispatch without any data transfer between storage and CPU. In other cases, the CPU is not only in charge of data transfer management but also for instruction dispatch or executing the graph search algorithm.

FPGA Resource Utilization. The placement and routing were completed with Vivado 2016.2 [8]. Table 7 shows the hardware utilization of Cognitive SSD. It only reports the resources overhead of the flash controller, NVMe controller, and the DLG-x accelerator module. The item of `In Total` counts in all FPGA resources spent by the Cognitive SSD.

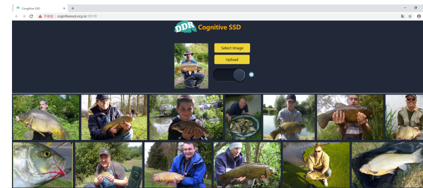

Fig. 10. A CBIR system based on Cognitive SSD.

5.5 The Single-node System Based on Cognitive SSD

Experimental Setup. We implemented the CBIR system by using the ImageNet dataset on the Cognitive SSD with a baseline server, where the baseline server is only responsible for receiving and sending retrieval requests to Cognitive SSD. The deep hashing architecture is a Hash-AlexNet network and the hash code length is 48 bits. As shown in Fig. 10, we built a web-accessible CBIR system based on web framework CROW [30] to evaluate the latency and query per second (QPS) of the system by simulating the user requests sent to

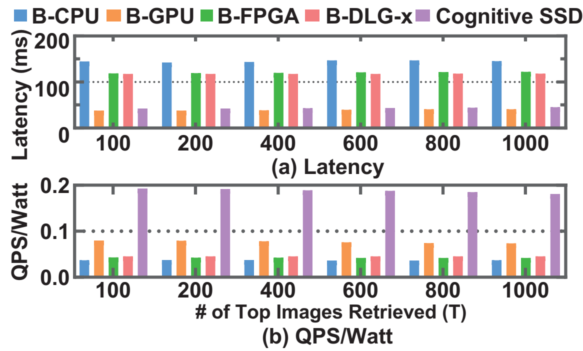

Fig. 11. System performance.

the URL address via ApacheBench (ab) [1]. The latency measurement indicates the time between issuing a request and the arrival of the result. The QPS is a scalability measuring metric characterizing the throughput of the system. The latency and QPS are affected by the software algorithm and the hardware performance of the system. Meanwhile, we utilized the metric of QPS per watt (QPS/Watt) to evaluate the energy-efficiency of the system.

Evaluation. We evaluated the performance of the Cognitive SSD system and four baselines under the assumption that data (weight/graph) cannot be accommodated in DRAM and must travel across the SSD cache, I/O interface, and DRAM before reaching a compute unit. The performance of the Cognitive SSD system and four baselines are shown in Fig. 11. With the increased number of top images retrieved, the retrieval time spent on the DLG-x accelerator will rise. It leads to increased retrieval latency and decreased QPS for the Cognitive SSD. Meanwhile, we also observe the 95% requests complete in time in experiments when write operations and garbage collection are inactive on the Cognitive SSD. Note that write operations and garbage collection are rare for the Cognitive SSD compared to read operations and usually occur offline. The workloads on the Cognitive SSD are read-only, which sustains the latency of the Cognitive SSD at a steady level with little fluctuation. Besides, in comparison to the B-CPU, the Cognitive SSD reduces latency by 69.9% on average. The performance improvement stems from the high-speed of data processing on the DLG-x accelerator compared to B-CPU. Due to the overhead of data movement caused by the bandwidth limitation of the I/O interface and onboard memory, the latency of B-FPGA and B-DLG-x is higher than B-GPU. Compared to the B-FPGA and B-DLG-x baselines, the Cognitive SSD reduces latency by 63.79% and 63.02% on average, which benefits from near-data processing. The average retrieval speed of B-GPU is 1.11x faster than Cognitive SSD because the execution of deep hashing costs more time on the resource-limited DLG-x compared to powerful GPUs. However, Cognitive SSD is more energy-efficient (QPS/Watt) than a GPU-integrated system by 2.44x, which is shown in Fig. 11(b). More importantly, the Cognitive SSD is implemented with FPGA and the operating frequency is only 100MHz. The performance will be better if the Cognitive SSD

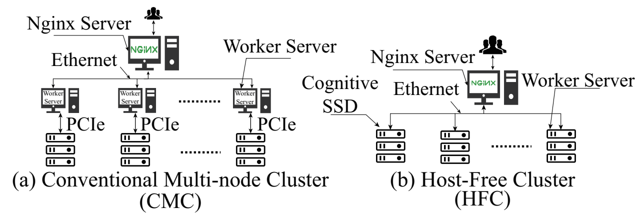

Fig. 12. The architecture of the conventional multi-node cluster(CMC)(a) and host-free cluster(HFC)(b).

is implemented with ASIC or escalated operating frequency.

5.6 The Cluster of Connected Cognitive SSDs

Experimental Setup. We evaluated the performance and the scalability of the Cognitive SSD when it scales into a multi-node cluster system. Fig. 12(a) shows the architecture of a conventional low-cost small-scale cluster system in a data warehouse. The cluster system consists of 10 worker servers and 1 Nginx [5] server. The Nginx server is responsible for load balancing. The worker nodes connect to the Nginx server by using TCP connections. In this case, we constructed four cluster system baselines by extending above four baselines: **BC-CPU**, **BC-GPU**, **BC-FPGA**, and **BC-DLG-x**. We issued requests to measure the QPS and the latency per request of the Cognitive SSD based cluster system when multiple users are accessing the web service shown in Fig. 10 concurrently via the ab tool.

Evaluation. Fig. 13(a) illustrates that when concurrent users equal to 400, all evaluated schemes rise slowly in experiments, which is limited by the thread of worker server and the node number of clusters. Meanwhile, the variation of peak QPS is due to the change of the performance bottleneck in different solutions. For example, the saturation performance of BC-GPU and CMC is constrained by the thread of the server while that of BC-CPU, BC-FPGA, and BC-DLG-x is determined by the latency of deep hashing inference and data movement. Fig. 13(b) shows that the QPS and latency per request of four baselines and CMC also change with the scale of the node cluster when the number of concurrent users reaches 400. As the number of nodes increases, the QPS gradually increases to the peak value, and the latency gradually decreases owing to improvement of service parallelism. When the nodes increase, the load-balancing mechanism of Nginx prevents a large hotspot formation in the cluster, which greatly increases the waiting time of requests.

We also measured the power consumption of the CMC system while running the CBIR service and compared it to BC-CPU, BC-GPU, BC-FPGA, and BC-DLG-x. When the cluster system is active, as shown in Fig. 14, the power consumption of a single node in the BC-CPU and BC-GPU are respectively 1.52x and 2.70x higher than a single node in the CMC. Similarly, Fig. 15 indicates the power of BC-CPU and BC-GPU is 1.45x and 2.46x than that of a CMC. Meanwhile, we also compared the QPS/Watt of CMC with other four baseline in Fig. 13(c). The energy-efficiency (QPS/Watt) of CMC

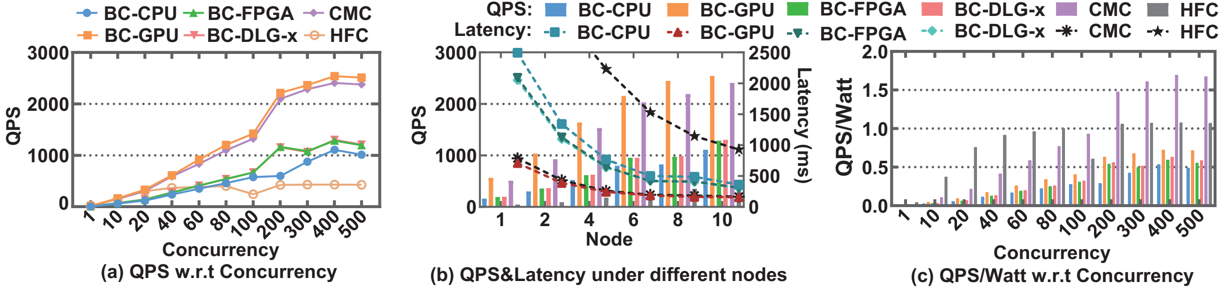

Fig. 13. Performance comparison.

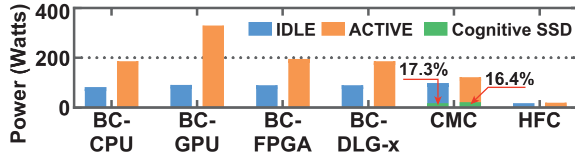

Fig. 14. Power dissipation of a single node.

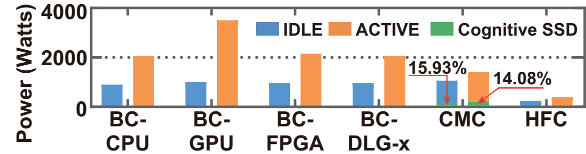

Fig. 15. Power dissipation of cluster.

is higher than the other four baselines because of short data movement path and the energy-efficient DLG-x accelerator. When the cluster system is IDLE, the power consumption is slightly higher than BC-CPU and BC-GPU because of the power consumption of the Cognitive SSD prototype is higher than the enterprise SSD.

It is noted that Fig. 15 indicates the power consumption of the Cognitive SSD only occupies about 15.93% (IDLE) and 14.08% (ACTIVE) of the entire system in the CMC architecture. The Cognitive SSD contains one Dual 1GHz ARM Cortex-A9 core, which could run embedded Linux system and has lower power consumption compared with the Intel Xeon CPU. Thereby, as shown in Fig. 12(b), to further reduce power consumption, we proposed the architecture of the host-free cluster (HFC) system, where the Cognitive SSD is directly connected to the Ngnix server via TCP connection, and the embedded Linux system runs a simple NAND flash management daemon and crow web framework.

We measured the performance of the host-free cluster system under the same experimental setup, which is illustrated in Fig. 13, Fig. 14, and Fig. 15. Fig. 14 shows that the power dissipation of a single node in the host-free cluster system is reduced by up to 89.2%, 93.9%, and 83.6% compared with that of BC-CPU, BC-GPU, and the original CMC when system is active. Considering the host server contains two Intel Xeon E5-2630 CPU that outperforms the dual Cortex-A9 in the Cognitive SSD, thereby, we measured the QPS per watt (QPS/Watt) to illustrate the energy-efficiency of the HFC system. The result (Fig. 13(c)) shows that when system concurrency is low, HFC delivers better energy-efficiency than the other four baselines and even better than the CMC architecture. The reason is that using high-performance machines to handle infrequent requests results in low energy-efficiency. Therefore, Fig. 13(c) witnesses the energy-efficiency of HFC relatively decreases with the increasing concurrency of the system. The performance growth of HFC under different node numbers also project that the level-off throughput is limited by the embedded CPU power instead of the DLG-x. In analysis, the HFC system will have much lower power consumption and higher performance if the Cortex-A9 processor is replaced by the latest Cortex-A series, e.g., a quad-core or octo-core Cortex-A75. Therefore, connecting the Cognitive SSD directly via interconnects contributes to much higher energy efficiency in Cognitive SSD system and guaranteed service throughput as well.

6 Conclusion

In this paper, we have introduced the Cognitive SSD, a near-data deep learning device that actively performs low latency, low power and high accuracy unstructured data retrieval. We have designed and implemented the Cognitive SSD with a direct flash-access deep hashing and graph search accelerator, to combat the complex software stack and inefficient memory hierarchy barriers in the conventional multimedia data retrieval systems. Our prototype demonstrates that the Cognitive SSD reduces latency by 69.9% on average compared to CPU, and more than 34.4% and 63.0% power saving against CPU and GPU respectively. Furthermore, the Cognitive SSD can scale to a multi-SSD system and significantly reduces the cost and power overhead of large-scale storage nodes in data centers. The demo of the retrieval system based on Cognitive SSD is available at [3] and part of the source code is available at [2].

SIMD-X: Programming and Processing of Graph Algorithms on GPUs

Hang Liu
University of Massachusetts Lowell

H. Howie Huang
The George Washington University

Abstract

With high computation power and memory bandwidth, graphics processing units (GPUs) lend themselves to accelerate data-intensive analytics, especially when such applications fit the single instruction multiple data (SIMD) model. However, graph algorithms such as breadth-first search and k-core, often fail to take full advantage of GPUs, due to irregularity in memory access and control flow. To address this challenge, we have developed SIMD-X, for programming and processing of single instruction multiple, complex, data on GPUs. Specifically, the new Active-Compute-Combine (ACC) model not only provides ease of programming to programmers, but more importantly creates opportunities for system-level optimizations. To this end, SIMD-X utilizes just-in-time task management which filters out inactive vertices at runtime and intelligently maps various tasks to different amount of GPU cores in pursuit of workload balancing. In addition, SIMD-X leverages push-pull based kernel fusion that, with the help of a new deadlock-free global barrier, reduces a large number of computation kernels to very few. Using SIMD-X, a user can program a graph algorithm in tens of lines of code, while achieving 3×, 6×, 24×, 3× speedup over Gunrock, Galois, CuSha, and Ligra, respectively.

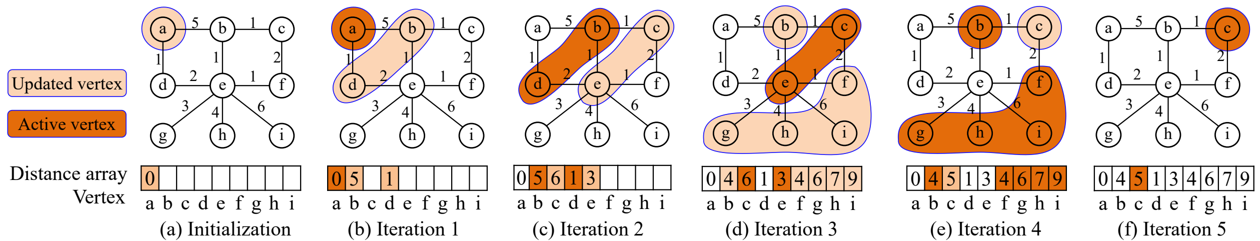
1 Introduction

The advent of big data [40, 27, 35, 36, 37, 5, 25, 26, 28, 14, 83] exacerbates the need of extracting useful knowledge within an acceptable time envelope. For performance acceleration, many applications utilize graphics processing units (GPUs) whose huge success comes from exploiting the data-level parallelism in these applications. Implicitly, the traditional single instruction multiple data (SIMD) model of GPUs assumes regular programming and processing, that is, not only the same instruction is executed but also the same amount of work is expected to perform on each piece of data. Unfortunately, neither assumption holds true for many emerging irregular applications, especially graph analytics which is the focus of this work. That is, such applications do not conform to the SIMD model, where different amount of work, or worse, completely different work, need to be performed on the data in parallel.

To enable graph computation on GPUs, this work advocates a new parallel framework, SIMD-X, for the programming and processing of *single instruction multiple, complex, data* on GPUs. At the heart of SIMD-X is the decoupling of programming and processing, that is, SIMD-X utilizes the *data-parallel* model for ease of expressing of graph applications, while enabling system-level optimizations at run time to deal with the *task-parallel* complexity on GPUs. With SIMD-X, a programmer simply needs to define what to do on which data, without worrying about the issues arisen from irregular memory access and control flow, both of which prevent GPUs from achieve massive parallelism.

SIMD-X consists of three major components: First, SIMD-X utilizes a new Active-Compute-Combine (ACC) programming model that asks a program to define three data-parallel functions: the condition for determining an *active* vertex, *computation* to be performed on an associated edge, and *combining* the updates from edge compute to vertex state. As we will show later, ACC is able to support a large variety of graph algorithms from breadth-first search, k-core, to belief propagation. While ACC adopts the Bulk Synchronous Parallel (BSP) model [49], it differs from traditional CPU-based graph abstractions such as edge- or vertex-centric models in that ACC avoids atomic operation, enables collaborative early termination (for BFS) and fine-grained task management on GPUs.

Second, SIMD-X relies on just-in-time (JIT) task management to balance parallel workloads across different GPU cores with minimal overhead. A good task list can increase not only parallelism, but also sequential memory access for the computation of next iteration, both



(a) Initialization (b) Iteration 1 (c) Iteration 2 (d) Iteration 3 (e) Iteration 4 (f) Iteration 5

Figure 1: SSSP on a graph, with nine vertices {a, b, c, d, e, f, g, h, i} and ten undirected edges (with weights). SSSP iteratively computes on the graph and generates the distance array. Particularly, heavy and light shadows represent active and most recently updated vertices, respectively.

of which are crucial for high-performance computing on GPUs. To this end, we have designed a set of new task management mechanisms, that is, online and ballot filters, each of which excels at the complementary scenarios, i.e., the former favors a small amount of tasks while the latter larger tasks. At runtime, SIMD-X judiciously selects the more suitable filter to assemble the active work list for the next iteration. Our JIT task management can largely reduce the memory consumption, thereby accommodate the graphs much larger than prior work [50, 77]. Moreover, SIMD-X delivers 16×, on average, speedup across various algorithms and graphs.

Third, SIMD-X designs a new technique of push-pull based kernel fusion which aims to further accelerate graph computing by reducing kernel invocation overhead and global memory traffic. SIMD-X addresses the deadlock issue which occurs in existing software global barrier [79] that is adopted by Gunrock [77]. Besides, instead of aggressively fusing the algorithm into one giant kernel, SIMD-X fuses the kernels around the pull and push stages within each computation to minimize both register consumption and kernel relaunching. The evaluation shows that the new fusion technique can reduce the register consumption by half and thus double the configurable thread count, leading to 42% and 25% performance improvement over non-fused and aggressive fusion, respectively.

SIMD-X is different from prior work in several aspects. First, despite an array of graph frameworks has surged, majority of them are for CPU systems while SIMD-X is for GPU accelerators that come with mounting programming challenges. In order to use GPUs efficiently, a programmer needs to possess an in-depth knowledge of GPU architecture [16, 1], e.g., Gunrock requires explicit management of GPU threads and memory [76], and B40C [50] and Enterprise [41] need thousands of lines of CUDA code for BFS specific optimizations. One of the goals of this work is to provide a simple programming model and delegate the responsibility of task management to SIMD-X. Second, current systems either ignore workload imbalance as in [33, 91], or resolve it reactively as in [76, 72], both of which result in undesired system performance. Lastly, because GPUs lack support for global synchronization, existing systems [73, 76, 41, 43, 69] either rely on the multi-kernel design or runtime tunning, both of which come with considerable overhead, especially for graph algorithms with high iteration count. SIMD-X addresses these challenges with new filters, and a deadlock-free software barrier.

2 SIMD-X Challenges and Architecture

2.1 Graph Computing on GPUs

Generally speaking, regular applications present uniform workload distribution across the data set. As a result, such applications lend themselves to the data-parallel GPU architecture. For development and evaluation, this work mainly uses NVIDIA GPUs, which have tens of streaming processors and in total thousands of Compute Unified Device Architecture (CUDA) cores [1, 56]. Typically, a *warp* of 32 threads execute the same instruction in parallel on consecutive data.

On the other hand, task management for irregular applications is challenging on GPUs. In this work, we focus on a number of graph algorithms such as breadth-first search, k-core, and belief propagation. Here we use one algorithm – Single Source Shortest Path (SSSP) – to illustrates the challenges. Simply put, a graph algorithm computes on a graph $G = (V, E, w)$, where V, E and w are the sets of vertices, edges, and edge weights. The computation updates the algorithmic metadata which are the states of vertices or edges in an iterative manner. A typical workflow of SSSP is shown in Figure 1. Initially, SSSP assigns the infinite distance to each vertex in the *distance array*, which is represented as blank in the figure. Assuming the source vertex is a, the algorithm assigns 0 as its initial distance, and now vertex a becomes active. Next, SSSP computes on this vertex, that is, calculating the updates for all the neighbors of vertex a. In this case, vertices $\{b, d\}$ have their distances updated to 5 and 1 in the distance array. At the next iteration, the vertices with newly updated distances become active and perform the same computation again. This process continues until no vertex gets updated. Different from breadth-first search, SSSP may update the distances of some vertices across multiple iterations, e.g., vertex b is updated in iteration 1 and 3.

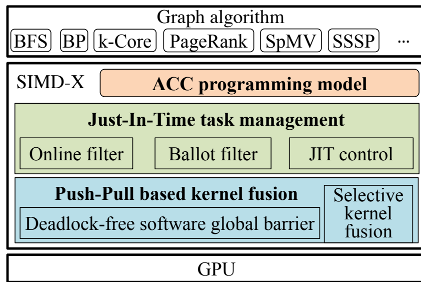


Figure 2: SIMD-X architecture

In this example, not every vertex is active at all time, and vertices with different degrees (number of edges) yield varying amounts of workloads. For instance, at iteration 3 of Figure 1(d), one thread working on vertex *c* computes two neighbors, while another thread on vertex *e* four neighbors.

2.2 Architecture

SIMD-X is motivated to achieve two goals simultaneously: providing ease of programming for a large variety of graph algorithms, whereas enabling fine-grained optimization of GPU resources at the runtime. Figure 2 presents an overview of SIMD-X architecture. To achieve the first goal, SIMD-X utilizes a simple yet powerful Active-Compute-Combine (ACC) model. This data-parallel API allows a programmer to implement graph algorithms with tens of lines of code (LOC). Prior work requires significant programming effort [50, 41, 76], or runs the risk of poor performance [33].

In SIMD-X, high-performance graph processing on GPUs is achieved through the development of two components: (1) JIT task management, which is responsible for translating data-parallel code to parallel tasks on GPUs. Essentially, SIMD-X "filters" the inactive tasks and groups similar ones to run on the underlying SIMD architecture. In particular, SIMD-X develops online and ballot filters for handling different types of tasks, and dynamically selects the better filter during the execution of the algorithm. And (2) Pull-push based kernel fusion. Graph applications are iterative in nature and thus require synchronizations. Fusing kernels across iterations would yield indispensable benefits, because kernel launching at each iteration incurs non-trivial overhead. In SIMD-X, we observe that with aggressive kernel fusion, register consumption would increase dramatically, lowering the occupancy and thus performance. To this end, SIMD-X deploys kernel fusion around pull and push stages of each graph computation, seeking a sweet spot that not only maximizes the range of each kernel fusion but also minimizes the register consumption. It is worthy noting that we also address the deadlock issue faced by software global barrier in SIMD-X.

3 ACC Programming Model

The novelty of SIMD-X lies at achieving both ease of programming and efficient workload scheduling, which is *especially hard on GPUs*. When it comes to graph computing, there are two main programming models: vertex-centric vs. edge-centric. Vertex-centric model, also referred to as "Think like a vertex" [49, 90] focuses on active vertices in a graph, whereas the latter one [61, 60] iterates on edges and simplifies programming.

3.1 Motivation

Graph programming converges to either *vertex-centric* or *edge-centric* models. In particular, the vertex-centric model contains two functions: `vertex_scatter` defines what operations should be done on this vertex, and `vertex_gather` applies the updates on the vertex. This model has been adopted by a number of existing projects, e.g., Pregel [49], GraphLab [45], PowerGraph [18], GraphChi [39], FlashGraph [90], Mosaic [47], and GridGraph [92], as well as GPU-based implementation such as CuSha [33] and Gunrock [76]. On the other hand, the edge-centric model is initially introduced by the external-memory graph engine X-stream [61] to improve IO performance. It requires a programmer to define two functions needed on each edge, `edge_scatter` and `edge_gather`. As such, this model schedules threads by the edge count. Particularly, one thread needs to send the information of the source vertex and the outbound edge to the destination vertex (`edge_scatter`), which atomically applies the new updates in `edge_gather`.

In this work, we believe the many-threaded nature of GPU architecture demands a new abstraction. We intend to exploit various thread scheduling options to better tackle workload imbalance [41, 77], while minimizing the overhead with regards to atomic operations on GPUs [46]. Table 1 summarizes the designs of recent GPU-based graph analytics systems. To avoid wasting the threads to compute on inactive vertices, *task filtering* is essential in generating a list of active vertices. Once task lists are ready, *workload imbalance* caused by skewed degree distribution in many graphs becomes the next concern. Since handling this issue in a vertex centric model involves nontrivial programming efforts [41], edge-based computing presents a desirable alternative. However, traditional edge-centric approach would result in atomic updates at the destination vertex, thus a proper schedule before applying the update is essential to *avoid atomic operation*. It is also important to note that *compressed sparse row* (CSR) is a preferable graph format which can save around 50% of the space over edge list format, as contemporary GPUs only feature tens of GB memory [1]. The proposed ACC framework is designed to address these three challenges.

Table 1: Comparison between ACC and relevant GPU-based programming models. [green] denotes desirable feature.

Abstraction	Related Work	Stages			Graph format
		Task filtering	Workload balancing	Avoid atomic operation	
ICU	CuSha [33], Lux [30]		Init/Compute (Edge)	Update	Edge list
ICRU	WS [32]		Init/Compute (Edge)	Reduce/IsUpdate	CSR
AFC	Gunrock [77]	Advance/Filter	Compute (Vertex, with atomic update)		CSR
GAS	GTS [34], GraphReduce [62]		Gather (Edge)	Apply/Scatter	Edge list
ACC	SIMD-X	Active	Compute (Edge)	Combine	CSR

3.2 ACC Model

The new ACC model contains three functions: **A**ctive, **C**ompute, and **C**ombine. ACC supports a wide range of graph algorithms and requires much fewer lines of code compared to prior work. In this following, we will discuss the three functions.

Active allows a programmer to specify the condition whether a vertex is active. Formally it can be defined:

$$\exists_v \leftarrow active(M_v, v)$$

where v is the vertex ID and M_v represents its metadata. Depending on the algorithm, the Active function may vary. Belief propagation (BP) is simple which treats all vertices as active. In comparison, SSSP, as shown in Figure 3(a), considers the vertices active when their current metadata differs from the prior iteration.

Simply put, SIMD-X distinguishes active vertices from inactive ones, and focuses on the calculation needed for each vertex. This is different from the vertex-centric model which deals with not only the active vertex but also its neighbors. Because two vertices may have different numbers of neighbors, existing systems [49, 18] likely suffer from workload imbalance. To this end, SIMD-X leverages a classification technique, similar to Enterprise [41], to group the active vertices depending on the expected workload.

Compute defines the computation that happens on each edge. In particular, it specifies the operations on the metadata of edge $(v,\ u)$ and two vertices v and u, which can be written as follows:

$$update_{v \to u} \leftarrow compute(M_v, M_{(v,u)}, M_u)$$

where the return value of $update_{v \to u}$ will be used by the Combine function. For example, SSSP can be defined as shown in Figure 3(a).

Combine merges all the updates, once the computations are completed. It can be represented:

$$update_u \leftarrow \bigoplus_{v \in Nbr[u]} update_{v \to u}$$

where $\oplus$ must be commutative and associative, e.g., sum and minimum, and is being applied to all the neighbors of vertex u. Figure 3(a) presents the Combine examples of SSSP. Particularly, BP summarizes all updates, where SSSP combines all updates from compute by selecting the minimum.

SIMD-X optimizes two types of combine operations, i.e., aggregation and voting. Particularly, aggregation cannot tolerate overwrites, that is, all updates are needed to arrive at the correct results. PageRank, SSSP and k-Core are representative examples of such operation. In contrast, voting relaxes this condition, that is, the algorithm is correct as long as one update is received because all updates are identical. For instance, BFS is valid once one parent vertex successfully visited the child vertex. Other algorithms, such as, weakly connected component and strongly connected component algorithms [67] also fall into this category.

3.3 Processing with ACC

This section uses SSSP an example to illustrate how the SIMD-X framework works. SSSP computes the shortest paths between the source vertex and the remaining vertices of the graph. Although similar to Breadth-First Search (BFS), SSSP is more challenging as only one vertex with the shortest distance should be computed at one time. To improve the parallelism, we adopt the delta-step [51] algorithm which permits us to simultaneously compute a collection of the vertices whose distances are relatively shorter. We assume positive edge weights.

As shown in line 12 - 21 of Figure 3(b), SIMD-X structures graph computation as a loop. Similar to popular GPU-based frameworks [77, 33, 32], ACC follows BSP model, that is, synchronization is required at the end of each iteration. As we will discuss in the next section, SIMD-X employ three kernels to balance the workload, Thread, Warp and CTA kernels working on small_list, med_list and large_list, respectively. During computing, the online_filter (Section 4) attempts to track the active vertices with the thread bins (i.e., small_bin, med_bin and large_bin). Note that each active vertex is stored in one of these three bins based upon its degree. After a deadlock free software global barrier (Section 5), SIMD-X checks whether an overflow happens in any of the thread bins, which leads to either a ballot filter-based active lists generation or a simple prefix-scan based concatenation of all thread bins to produce the active lists (line 17-21).

In Figure 3(b), Line 1 - 8 exemplifies the interactions between ACC and SIMD-X. Firstly, SIMD-X will schedule a warp of threads to work on the neighbors of one active vertex from med_list. Similarly, Thread and CTA will schedule a thread and CTA to work on each active vertex from small_list and large_list, respectively. During

```

```

Figure 3: (a) SSSP in ACC model and (b) ACC abstraction and task management within SIMD-X framework.

computation, each thread will conduct a local Compute and Combine at line 4. Once finished, a cross Warp Combine happens at line 5. Eventually, the first thread from the Warp applies the final updates (without atomic operation) and store this vertex (if active) into corresponding thread bins.

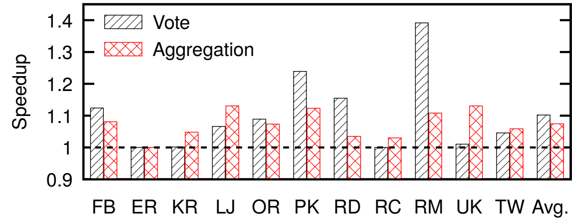

Figure 4: Speedup of our ACC model over Gunrock. Note vote and aggregation operations are materialized by BFS and SSSP algorithms, respectively, and x-axis contains the graph datasets which are defined in Table 3.

Comparison Figure 4 studies the performance impact of ACC vs. Gunrock. The new ACC model follows a computation then combine approach which pays the extra overhead (i.e., assembling all updates residing in shared memory from participating threads) in order to achieve the benefits of atomic-free updates. Gunrock, in contrast, directly applies the update to vertex status with atomic operations, thereby avoids inter-thread communication but experiences heavier overhead from atomic operation. One can see that ACC is, on average, 12% and 9% faster on vote and aggregation operations, respectively. For vote, the speedup comes from that ACC can schedule all threads to collaboratively determine early termination, which is not possible in Gunrock. Aggregation gains the performance from the elimination of atomic updates.

4 Just-In-Time Task Management

Workload balancing is essential for graph applications. The key is to ensure each GPU core, regardless of from which streaming processor, accounts for a similar amount of workload, which is often achieved with the following twin steps. Particularly, in **step I: task management**, the tasks are classified into various lists, namely small_list, med_list and large_list. In **step II: thread assignment**, various granularity of GPU threads are scheduled to work on different worklists. That is, a single thread per small task, a warp per medium task and a CTA per large task. Note, Figure 3(b) presents the pseudo code of step II and the bottom part of Figure 6 paints the corresponding workflow. We refer the readers to Enterprise [41] for more details regarding the landscape of this attempt.

Unlike prior work [41, 77, 50] which places particular efforts at step II, SIMD-X focuses on step I as we find it to be the major culprit that offsets the benefits of workload balancing. In the following, we will first analyze the drawback of existing batch filter method, then describe two new filters, and JIT selection mechanism.

Drawback of batch filter. This approach [76, 50, 11] first loads all the edges of the active vertices to construct an active edge list. Still using the example of SSSP in

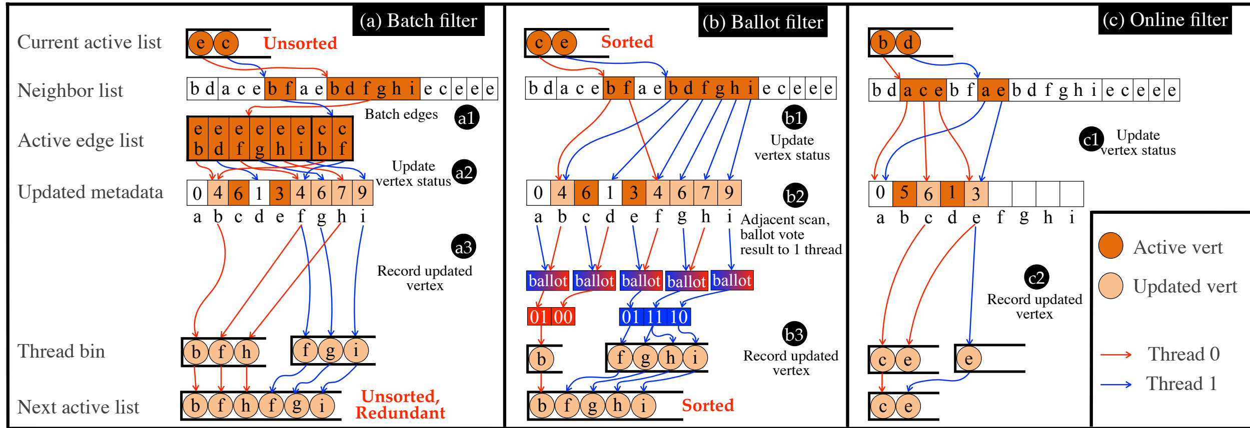

Figure 5: Three task management methods. Particularly, batch filter and ballot filter work on Figure 1(d) to produce a task list for next iteration. Online filter does that for Figure 1(c). Note, we assume the arrow flows of red and blue indicate the execution paths of red and blue threads.

Figure 1(c), this step loads neighbors of vertex {e, c} and constructs the active edge list in (a1) of Figure 5 (a). Next, batch filter checks these edges and updates vertex metadata (a2), followed by recording the updated vertices in thread bin at step (a3). Eventually, batch filter will concatenate these thread bins to arrive at a potentially *unsorted and redundant* next active list – $\{b, f, h, f, g, i\}$. Note, thread private local storage – thread bin – is used to avoid the expensive atomic operations, because multiple threads would need atomic operation to put active vertices directly into next active list.

We observe several drawbacks when using the batch filter for various graph algorithms. First, the active list can consume up to 2·|E| memory space because majority of the vertices in a graph can become active at one iteration [4, 41], which is especially true for popular social and web graphs. Considering GPU has very limited onboard memory (e.g., 16 GB), this restriction makes large-scale GPU-based graph computing intractable. Second, batch filter produces a worklist with unsorted and redundant active vertices, e.g., next active list – $\{b, f, h, f, g, i\}$ of Figure 5(a), which will lead to poor memory performance for next iteration computation.

Ballot filter is designed to overcome all these shortcomings. It first loads the neighbors of active vertices and immediately updates vertex metadata. As shown at step (b1) in Figure 5(b), the neighbors of {e, c} get updated immediately. Afterwards, thread 0 and 1 (red and blue lines) will exploit ballot scan to inspect the updated metadata and record those updated vertices in local thread bin at step (b3). The eventual step is similar to batch filter – we concatenate these two thread bins to get the next active list, whereas, with *sorted nonredundant* active vertices.

Ballot scan is the key to comprehend why we arrive at a better next active list. In steps (b2) and (b3) of Figure 5(b), threads 0 and 1 perform coalesced scan of vertex metadata, and with the CUDA *__ballot*() primitive, return a bit variable '01' to the first thread. Here 1 means active and 0 otherwise, in this case, vertex a is not active while b is. Through collaboratively working on the entire metadata array, the first thread eventually gets the bit value '0100' for the first four vertices, while the second thread '011110' for the remaining six vertices. Consequently, this approach produces a sorted active list, that is, $\{b, f, g, h, i\}$ in (b3).

We intentionally schedule thread 0 and 1 to collaboratively scan the metadata in order to achieve coalesced memory access during scan, as well as, making thread 0 and 1 account for a continuous range of vertices, that is, vertices a - d to thread 0 and e - i to thread 1. This achieves the dual benefits: coalesced scan and sorted active vertices in next active list. Last but not the least, this scheduling lends ballot filter to be many-thread safe.

We also notice an unpublished parallel efforts from Khorasani's dissertation [31] which is closely related to ballot filter. However, his design relies on atomic operation to compute the offsets of active vertices from each Warp in the next active list and subsequently assigns merely a single thread from the Warp to enqueue all these active vertices. This design implies twin disadvantages comparing to ours. First, atomic operation-based offset computation cannot yield sorted active lists. Second, single thread-based active vertices recording tends to be slower than Warp-based one which is our design.

Ballot filter is not without its own issue, especially when the amount of active vertices is low. In that case, scanning the metadata array would account for the majority of the runtime. For instance, in ER and RC graphs, 99.23% and 96.67% of the time is spent on scanning metadata in ballot filter alone solution, respectively.

Online filter is designed to accommodate the issue faced by ballot filter. In the first step, this method loads the ac-

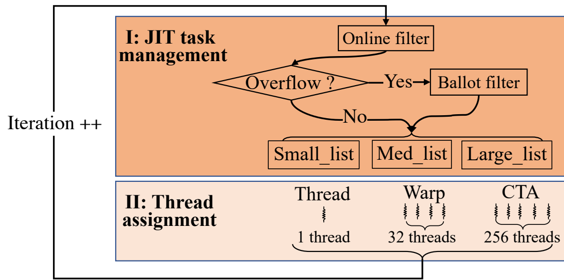

Figure 6: Workload balancing with the essential two steps: the novel JIT task management from SIMD-X and the thread assignment.

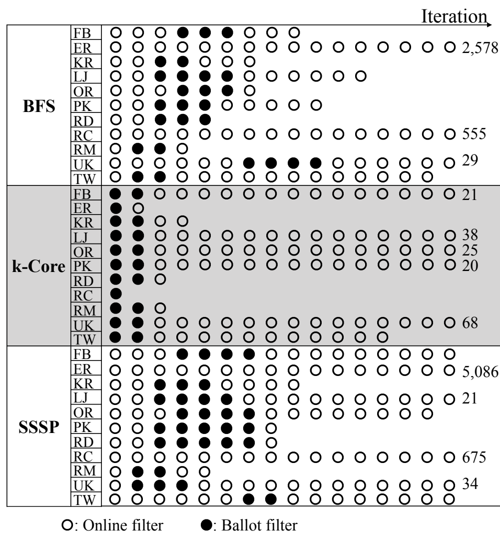

Figure 7: Ballot filter activation patterns.

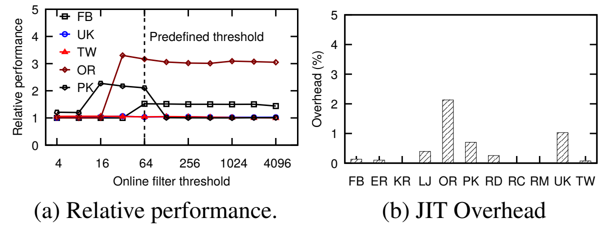
tive neighbors, updates the destination vertex, and simultaneously records the active vertices in the thread bin. In the last step, it assembles all thread bins together as the next active list. When the number of active vertices is small, this approach turns out to be extremely fast. Here we use the early stage of SSSP as an example to explain its working process. As shown in Figure 5(c), $\{b, d\}$ are active vertices, this approach loads their neighbors for computation (c1), and immediately records the destination vertices. Eventually, it generates $\{e, c\}$ as the active list for the next iteration as shown in c2. It is also important to note that for online filter, the vertices in the active list may become redundant, and out of order.

In graph computing, it is possible that one GPU thread may encounter exceeding amount of active vertices, e.g., our tests on Twitter graph shows one GPU thread can reap more than 4,096 active vertices. Clearly, one cannot afford such a large thread bin for all threads, thus online filter will inevitably suffer from an overflow problem. Fortunately, ballot filter largely avoids this issue because it first updates the metadata of active vertices b2, which, to some extent, averages out the active vertices across threads in step b3.



(a) Relative performance. (b) JIT Overhead

Figure 8: The (a) relative performance of JIT management with respective to various online filter overflow thresholds on BFS and (b) the overhead of JIT on SSSP.

Just-In-Time control adaptively exploits ballot and online filters to retain the best performance. As shown in Figure 6, SIMD-X always activates the online filter first. Once a thread bin overflows, SIMD-X will switch on ballot filter to generate the correct task list for the next iteration. It is also worthy of mentioning that after JIT task management, we assign various granularity of threads to different lists in order to balance workload.

Interestingly, we find out that various algorithms and graph datasets present different selection patterns which tie closely to the amount of workload, that is, the higher volume of workload often results in the activation of ballot filter. As shown in Figure 7, BFS and SSSP typically use the ballot filter in the middle of the computation and online filter at the beginning and end. For high-diameter graphs, BFS and SSSP avoid the use of ballot filter. For instance, ER and RC always use the online filter along 2,578, 555, 5,086 and 675 iterations. k-Core activates the ballot filter at the initial iterations, i.e., typically the first two iterations except RC which only experiences one iteration because all its vertices have < 16 neighbors. At the extreme, BP and PageRank need the ballot filter at exactly the first iteration of computation.

Overflow thresholds for online filter. Clearly, this parameter directly determines when to switch on ballot filter, thereby affects the overall performance. Figure 8(a) presents the normalized performance with respect to various thresholds. As expected, a too low or too high threshold limits the performance because in either case, SIMD-X is forced to switch to ballot filter either too early or too late, leading to performance penalty. As such, in this work we select 64 as the predefined overflow threshold for all algorithms.

Overhead of online filter. After switching to ballot filter, JIT task management also executes the online filter in case it needs to switch back. Figure 8(b) studies the overhead of this design. On average, there is 0.02% slowdown, with the maximum of 2.1% observed for the OR graph. The reason for the small overhead is because online filter only tracks upto 64 (predefined threshold) active vertices for the next iteration and this operation is not on the critical path of the execution.

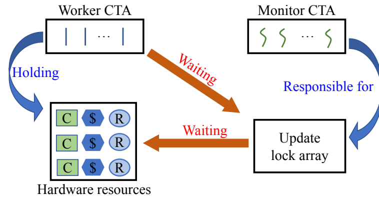


Figure 9: Deadlock in software global barrier, where ‘C’, ’$’, and ‘R’ represent core, L1 cache and register, respectively.

5 Push-Pull Based Kernel Fusion

Kernel fusion [73], a common optimization for a collection of iterative GPU applications, such as graph computing and deep learning [2, 58, 29, 10, 8], reduces expensive overhead of kernel invocation, as well as minimizes the global memory traffic as the life time of registers and shared memory is limited in each kernel. However, traditional efforts, such as Gunrock [77] and Xiao et al [79], fail to achieve cross the global barrier kernel fusion. This section starts with our observation and analysis of potential deadlock in the mainstream global barrier design [79, 82] and subsequently introduces a lightweighted deadlock free solution which enables the global thread synchronization within the fused kernel. However, aggressive kernel fusion requires a large amount of the registers and thus supports fewer parallel warps which could hurt the overall performance. To this end, we introduce a push-pull based kernel fusion to minimize the kernel invocation times and register consumption.

Software global barrier is needed to enable the balanced kernel fusion. Generally speaking, this approach uses an array – *lock* – to synchronize all GPU threads upon arrival and departure. During the processing, it assumes the thread CTA as the monitor while the remaining threads as workers. At arrival, each worker CTA updates its own *status* in *lock*. Once all worker CTAs have arrived, the monitor changes the *statuses* of all CTAs to *departure*, allowing all threads to proceed forward.

This approach, unfortunately, suffers from potential deadlock [79], as illustrated in Figure 9. Specifically, the worker thread CTAs may hold all GPU hardware resources, such as streaming processors, registers and shared memory, while waiting for the monitor to update the *lock* array. In the meantime, the monitor cannot update the *lock* array, due to lack of hardware resources (e.g., thread over subscription).

Compiler-based deadlock free barrier. SIMD-X utilizes the barrier in a way to ensure that every CTA, regardless of a work or the monitor, can obtain hardware resources when needed. This is achieved through comparing the resources needed by the kernels, against the total available resources. Based on the GPU architecture, we can obtain the total amount of registers (*#registerPerSMX*) that can be provided by each streaming processor, e.g., 65,536 registers of NVIDIA K40 GPUs and 32,768 from K20 GPUs. On the other hand, we can collect the register consumption (*#registerPerThread*) of each kernel at the compilation stage. Putting together, SIMD-X is able to calculate the appropriate thread configuration for kernels.

The number of CTA can be computed as follows:

$$\#CTA = floor(\frac{\#registersPerSMX}{\#registersPerThread \cdot \#threadsPerCTA}) \cdot \#SMX \quad (1)$$

where *#threadsPerCTA* is configured by a user, i.e., 128 by default. For example, when deploying a kernel, each thread consumes 110 registers, and on K40 that contains 15 SMXs, each of which contains 65,536 registers. If *#threadsPerCTA* is set to 128, one gets $\#CTA = ceil(\frac{65536}{110 \times 128}) \times 15 = 60$. As a result, we can configure this kernel as CTA and thread count per CTA as 60 and 128, respectively.

Notably, portable Inter-Block Barrier [69] is closely relevant to our effort. However, this method proposes extremely complicated thread block management mechanism that requires to distinguish whether one thread block will execute useful workloads or not during runtime. This requires nontrivial programmer efforts and scheduling overhead. In comparison, our method achieves this deadlock-free configuration before runtime and is completely transparent to the end users.

Push-Pull based kernel fusion. As shown in Table 2, the register consumption (using the compilation flag *-Xptxas -v*) increases from average 25 to 110, that is a 4.4× difference. Note, consuming too many registers will curb the number of active threads (according to equation 1). Unfortunately, majority of the graph algorithms are data intensive, thus prefer a higher volume of active threads because more active threads can better hide the frequent memory access stalls caused by data intensive applications. Consequently, we need a balanced fusion strategy that keeps both register consumption and kernel invocation low.

To this end, SIMD-X leverages the push-pull model used in the graph algorithms. That is, such algorithms often use push or pull based computing in several consecutive iterations. Lines 12 - 21 from Figure 3(b), for example, discuss the pull model and we can fuse these lines into a single GPU kernel. Similarly, push model can also be fused into a single kernel. Section 6 details how pull/push iterations occur in various graph algorithms.

SIMD-X adopts the pull-push model as in [66, 4, 41], by controlling where (in/out edge) Compute happens and how to Combine the results and apply (in atomic or atomic free manner). Particularly, in the push model, SIMD-X conducts Compute on the out neighbors of each active vertex, and relies on atomic operations to apply the

Table 2: Register consumption for various kernels.

Kernel	Push (no fusion)				Pull (no fusion)				Selective fusion		All fusion
	Thread	Warp	CTA	Task mgt	Thread	Warp	CTA	Task mgt	push	pull

updates to the destination vertices. In contrast, the pull model schedules Compute on the in neighbors of active vertices, and uses atomic-free strategy to Combine all updates and apply to the destination vertices. As different iterations favor one model over the other, we follow a similar rule as in Ligra [66] to alternate between the push and pull models. That is, when the workload on the push model works on more than 30% of the edges, SIMD-X will switch to pull model.

The idea of push-pull based kernel fusion is to fuse kernels around the pull and push computing. In other words, for the push-based iterations, SIMD-X fuses different compute kernels (for thread, warp, CTA), as well as task management kernel, into one push kernel. The kernel only terminates when the computation finishes or it needs to switch to pull computing according to the criterion discussed in Section 3.3. Similar optimizations are done for the pull-based iterations.

Using the new push-pull based fusion, the register consumption decreases to 48 and 55 thus increases the configurable thread count by 50%. Table 2 presents the register consumption and kernel invocation of different kernel fusion techniques. By using the push-pull based kernel fusion, the kernel relaunch is merely three while its register consumption is cut by half.

6 Graph Algorithms and Datasets

In addition to SSSP that is discussed in Section 3.3, this section further presents a variety of algorithms which are implemented on SIMD-X to examine the expressiveness of ACC programming model, and performance impacts of task management and kernel fusion techniques.

BFS [41] traverses a graph level by level. At each level, it loads all neighbors that are connected to vertices visited in the preceding level, inspects their statuses (metadata), and subsequently marks those unvisited neighbors as active for the next iteration. Notably, BFS conducts synchronizations at the end of each level, relies on vote to combine the updates. During the entire process of traversal, BFS typically experiences light workload at the beginning and end of the computation while heavy workload in the middle.

Belief propagation (BP), also known as sum-product message passing algorithm, infers the posterior probability of each event based on the likelihoods and prior probabilities of all related events. Once modeled as a graph (Bayesian network or Markov random fields), each event becomes a vertex with all incoming vertices and edges as related events and corresponding likelihoods. In BP, vertex possibility is the metadata.

***k*-Core** (KC), which is widely used in graph visualization application [42, 53], iteratively deletes the vertices whose degree is less than k until all remaining vertices in this graph possess more than k neighbors. k-Core experiences large volume of workloads at initial iterations and follows with light workloads. This work uses a default value of $k = 16$.

PageRank (PR) [57] updates the rank value of one vertex based on the contribution of all in-neighbors iteratively till all vertices have stable rank values. Because the contributions of in neighbors are summarized to the destination vertex, we start PageRank with the pull model and *agg_sum* as the merge operation. At the end of PageRank, we switch to the push model because the majority of the vertices are stable [87]. The switch is decided by a decision tree.

Graph Benchmarks. We evaluate on a wide range of graphs as shown in Table 3, which falls into four types, i.e., social networks, road maps, hyperlink web and synthetic graphs. Particularly, Facebook [17], LiveJournal [68], Orkut [68], Pokec [68], and Twitter [38] are common social networks. Europe-osm [12] and

RoadCA-net [70] are two large roadmap graphs, and UK-2002 [70] is a web graph. Furthermore, we use Graph500 generator to generate Kron24 [6], and GTgraph [19] for R-MAT and random graphs. Europe-osm and RoadCA-net are high diameter graphs, with 2570 and 555 as their diameters, respectively. LiveJournal, Pokec, Twitter and UK-2002 are medium diameter graphs, i.e., 10 - 30 as their diameters. The diameters of the remaining graphs are all smaller than 10. For graphs without edge weight, we use a random generator to generate one weight for each edge similar to Gunrock [76]. These graphs are stored in *compressed sparse row* (CSR) format.

7 Experiments

We implement SIMD-X[1] with 5,660 lines of CUDA and C++ code. All the algorithms presented in Section 6 are implemented with around 100 lines of C++ code. The source code is compiled by GCC 4.8.5 and NVIDIA nvcc 7.5 with the optimization flag as O3. In this work, we evaluate SIMD-X on a Linux workstation with two Intel Xeon E5-2683 CPUs (14 physical cores with 28 hyperthreads), and 512GB main memory. Throughout the evaluation, we use uint32 as the vertex ID and uint64 as index and evaluate our system on NVIDIA K40 GPUs unless otherwise is specified. We also test SIMD-X on earlier K20 and latest P100 GPUs. The timing is started once the graph data is loaded in GPU global memory. Each result is reported with an average of 64 runs.

7.1 Comparison with State-of-the-art

Table 4 summarizes the runtime of SIMD-X against Galois and Gunrock which are state-of-the-art CPU and GPU graph processing systems, respectively, as well as CuSha (GPU) and Ligra (CPU), two popular graph frameworks. The take aways of this table are two folds.

First, SIMD-X is both space efficient and robust. As one can see, since CuSha requires edge list as the input for computation, it cannot accommodate large graphs (e.g., FB and TW) across all algorithms. Besides, since Gunrock requires large amount of space for batch filter, it suffers out of memory (OOM) error for all larger graphs in SSSP. Even CPU systems (Galois and Ligra) enjoys affluent memory space (512 GB) from CPU, they cannot converge to a result for high diameter graphs. That is, Galois cannot converge for SSSP on ER while Ligra fails to obtain result for BFS on UK graph.

Second, SIMD-X outperforms all graph processing frameworks. In general, SIMD-X is 24×, 2.9×, 6.5× and 3.3× faster than CuSha, Gunrock, Galois and Ligra, respectively. In BFS, SIMD-X bests CuSha, Gunrock, Galois and Ligra by 9.6×, 4.8×, 2.1× and 2.4×, respectively. We also notice that SIMD-X is slower than Galois on the RD graph because workload balancing brings negligible benefits to uniform-degree graph (RD). Also, SIMD-X is slightly worse than Ligra on RM graph since this graph only has a diameter of four thus both JIT task management and kernel fusion brings trivial benefits to GPU based graph systems, as evident by much lower performance on CuSha and Gunrock.

In PageRank, SIMD-X achieves 1.2×, 2.1×, 2.3× and 4× speedups over CuSha, Gunrock, Galois and Ligra, respectively. Note, even CuSha cannot support all large graphs due to large memory space consumption, it performs roughly similar to SIMD-X with even outperforming SIMD-X on LJ and OR. This is generally because PageRank tends to be more computation intensive than other graph algorithms and needs to compute all edges, curbing the benefits of task management and kernel fusion. However, edge list format (of CuSha) doubles memory consumption, facing OOM for large graphs.

For SSSP, SIMD-X wins 21×, on average, over all four projects. We project SIMD-X to better outperform all systems than observed for BFS algorithm because SSSP experiences more iterations with larger volume of active tasks, placing more favor towards ACC model, JIT task management and push-pull based kernel fusion. However, because Gunrock fails to accommodate all large graphs, our benefits cannot surface – ending with merely 1.8× speedup. Second, CuSha spends 519,674 ms on the high diameter ER graph which is 480× slower than SIMD-X because task management is absent from CuSha. We also notice Galois performs better than SIMD-X in RD, again, due to the uniform degree distribution.

For k-Core, where $k = 32$, SIMD-X wins Ligra by 20×. Such a striking advantage comes from three parts. First, as reflected by Figure 11(b), k-Core generates extensive amount of workload variations thus benefits tremendously from JIT task management. Second, k-Core's iterative nature also enjoys the benefits from push-pull based kernel fusion, as shown in Figure 12(c). Lastly, the flexibility of ACC allows innovative k-Core algorithm designs – we will stop further subtracting the degree of destination vertex once the destination vertex's degree goes below k – this reduces tremendous unnecessary updates. Note comparisons of Belief Propagation, as well as other systems for k-Core are not included because those systems fail to support such algorithms.

7.2 Benefits of Various Techniques

This section studies the performance impacts brought by JIT task management and push-pull based kernel fusion. As we have presented in Section 4, JIT task management only works for applications that experience work-

[1] SIMD-X source `https://github.com/asherliu/simd-x`.

Table 4: Runtime (ms) of SIMD-X and Gunrock, and Galois. A K40 GPU is used to test SIMD-X and Gunrock, and a CPU with 28 threads for Galois. The **blank space** indicates the test cannot complete for the given algorithm and graph.

Alg	System	FB	ER	KR	LJ	OR	PK	RD	RC	RM	UK	TW	Avg. speedup

(a) BFS (b) k-Core (c) SSSP

Figure 11: Benefit of just-in-time task management, normalized to the performance of the ballot filter.

load variations, that is, BFS, k-Core and SSSP. On the other hand, push-pull based kernel fusion is applicable for all five algorithms

On average, JIT task management presented in Figure 11, is 16×, 26× and 4.5× faster than the ballot filter for BFS, k-Core and SSSP. As expected, online filter alone cannot work for many graphs, particularly large ones, e.g., Facebook, Twitter and UK2002 graphs in BFS and SSSP. Without considering overflow problem (ER and RC graphs), JIT task management adds a small 1-2% overhead on top of the online filter on BFS and SSSP.

On k-Core, JIT task management is, on average, 28.5× and 5% faster than ballot and online filter, respectively. We also observe that the ballot filter outperforms the online filter on ER and RC graphs by 3.4× and 1.7×, because k-Core removes a large volume of vertices which favors the former to produce a non-redundant and sorted work list.

Push-pull based kernel fusion brings, on average, 43% and 25% improvement over non-fusion and all-fusion across all algorithms and graphs. In particular, push-pull based kernel fusion tops non-fusion by 74%, 11%, 85%, 10% and 66% on BFS, BP, k-Core, PageRank and SSSP. BFS, k-Core and SSSP achieves more performance gains because they are not computation intensive and tend to run a higher number of iterations. For all fusion, our new kernel fusion is 55%, 6%, 62%, 25% and 11% faster on BFS, BP, k-Core, PageRank and SSSP. It is important to note that all fusion is not always beneficial, i.e., all fuse option of PageRank is average 13% slower than no fusion because all fusion limits the amount of configurable threads. However, for memory intensive applications, like BFS and SSSP on ER and RC, all fusion is on average 2× better.

7.3 Performance on Different GPUs

We also evaluate SIMD-X, Gunrock and CuSha on various GPU models, such as K20 and P100 GPUs. It is not surprising to see tht SIMD-X presents the biggest performance gain on the latest GPUs. In detail, SIMD-X on K40 and P100 performs 1.7× and 5.1× better than K20 GPU. In contrast, Gunrock merely gets 1.1× and 1.7× performance improvement when moving from K20 to K40 and P100, respectively. Similarly for CuSha, its performance on K40 and P100 are 1.2× and 3.5× better than K20, respectively. The root cause of this disparity is that SIMD-X's kernel fusion technique can dynamically configure its GPU kernels to the fitting thread count on the corresponding hardware so as to achieve the peak performance. For instance, the thread count increases by 1.2× and 5.1× on K40 and P100 than on K20 for BFS.

8 Related Work

Recent advance in graph computing falls in algorithm innovation [51, 87, 15], framework developments [49, 18, 45, 39, 42, 90, 92, 22, 66, 63, 61, 23, 54, 60, 74, 7, 80, 84, 65, 88, 75, 55, 89, 86, 85, 3, 78, 52, 21, 9, 81] and accel-

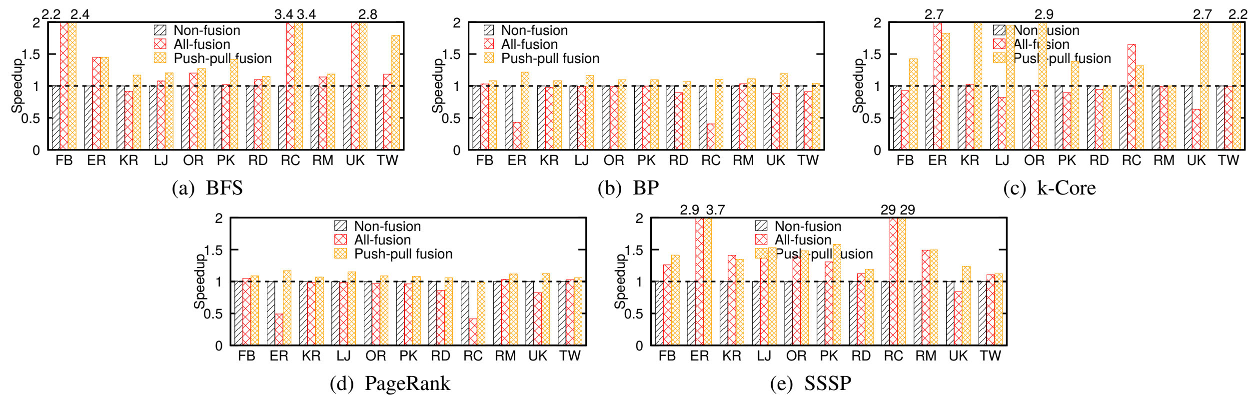

Figure 12: Benefit of push-pull based kernel fusion, normalized to the performance of no fusion.

erator optimizations [76, 41, 50, 33, 43, 59, 64, 13]. This section covers relevant work from three aspects: programming model, task management and kernel fusion.

Recently, we witness an array of graph analytical models. For instance, "think like a graph" [71] requires each vertex to obtain the view of the entire partition on one machine in order to minimize the communication cost. Furthermore, domain specific programming language systems, such as Galois [54], Green-Marl [23] and Trinity [63], allow programmers to write single-threaded source code while enjoying multi-threaded processing. In comparison, SIMD-X decouples the goal of programming simplicity and performance: with ACC, SIMD-X ultimately designs a data-parallel abstraction for deploying irregular graph applications on GPU. With JIT task management and push-pull based kernel fusion, SIMD-X is an order of magnitude faster than state-of-the-art CPU and GPU frameworks.

Task management is an important optimization for GPU-based graph computing. Besides batch filter [76, 50], there also exist other task management approaches – strided filter [41, 43] and atomic filter [46]. Particularly, strided filter resembles ballot filter but the former one experiences strided memory access when scanning the metadata thus performs up to 16× worse than ballot filter. Atomic filter relies is similar to online filter but it relies on atomic operation to put active vertices into global active list which suffers from orders of magnitude slow down than online filter. Besides ballot and online filter bests batch, stride and atomic filter, SIMD-X goes further via introducing a JIT controller to adaptively use online filter and ballot filter to further improve the performance. We also find that JIT task management can be exploited to help manage active lists for other applications such as warp segmentation [32] and CSR5 [44].

Kernel fusion affects applications far beyond graph computations. SIMD-X is closely related to global software barrier [79, 82]. However, previous work fails to identify the deadlock issue in this global software barrier problem, thus no solution towards this issue. In contrast, SIMD-X unveils, systematically analyzes, and resolves this problem. To avoid high register consumption, SIMD-X further selectively fuse kernels via exploiting the special kernel launching patterns of graph algorithms. It is also important to mention existing work [73] that only fuse kernels to barrier boundary. In comparison, SIMD-X fuses kernels across barriers. Our design can also benefit the popular Persistent Kernel [20] designs which have been found suffer from deadlock issues when the occupancy exceed an unknown bound [48, 24].

9 Conclusion

In this work, we propose SIMD-X, a parallel graph computing framework that supports programming and processing of *single instruction multiple, complex, data* on GPUs. Specifically, the Active-Compute-Combine (ACC) model provides ease of programming to programmers, while just-in-time task management and push-pull based kernel fusion leverage the opportunities for system-level optimization. Using SIMD-X, a user can program a graph algorithm in tens of lines of code, while achieving significant speedup over the state-of-the-art.

Acknowledgment

The authors would like to thank the anonymous reviewers and Shepherd Chris Rossbach for their feedback and suggestions. Hang Liu did part of this work at the George Washington University. This work was partially supported by National Science Foundation CAREER award 1350766 and grants 1618706 and 1717774 at George Washington University and CRII Award No. 1850274 at University of Massachusetts Lowell. We also would like to gracefully acknowledge the support from XSEDE supercomputers and Amazon AWS, as well as the NVIDIA Corporation for the donation of the Titan Xp and Quadro P6000 GPUs to the University of Massachusetts Lowell.

LUMOS: Dependency-Driven Disk-based Graph Processing

Abstract

Out-of-core graph processing systems are well-optimized to maintain sequential locality on disk and minimize the amount of disk I/O per iteration. Even though the sparsity in real-world graphs provides opportunities for out-of-order execution, these systems often process graphs iteration-by-iteration, hence providing Bulk Synchronous Parallel (*synchronous* for short) mode of processing which is also a preferred choice for easier programmability. Since out-of-core setting limits the view of entire graph and constrains the processing order to maintain disk locality, exploiting out-of-order execution while simultaneously providing synchronous processing guarantees is challenging. In this paper we develop a generic dependency-driven out-of-core graph processing technique, called LUMOS, that performs out-of-order execution to proactively propagate values across iterations while simultaneously providing synchronous processing guarantees. Our cross-iteration value propagation technique identifies future dependencies that can be safely satisfied, and actively computes values across those dependencies without sacrificing disk locality. This eliminates the need to load the corresponding portions of graph in future iterations, hence reducing disk I/O and accelerating the overall processing.

1 Introduction

Disk-based processing of large graphs enables processing to scale beyond the available main memory in both single machine [1, 8, 9, 13, 14, 16, 17, 24, 34, 35, 38] and cluster based [23] processing environments. With limited amount of main memory available for processing, out-of-core graph systems first divide the graph into partitions that reside on disk, and then process these partitions one-by-one by *streaming* through them, i.e., by sequentially loading them in memory and immediately processing them. As expected, such out-of-core processing is I/O intensive and systems often spend significant amount of time in loading the partitions from disk; for example, GridGraph [38], a recent state-of-art out-of-core graph processing system, spends 69-90% of time in loading edges from disk partitions.

A common concern across graph processing systems is the nature of consistency semantics they offer for programmers to correctly express their graph algorithms. Consistency semantics in the context of iterative graph processing fundamentally decide when should a vertex's value (that is computed in a given iteration) become visible to its outgoing neighbors. The most popular consistency semantics is offered by the Bulk Synchronous Parallel (BSP) [27] model (hereafter called *synchronous* processing semantics) that separates computations across iterations such that vertex values computed in a given iteration become visible to their outgoing neighbors in the next iteration, i.e., values in a given iteration are computed based on values from the previous iteration. Such clear separation between values being generated v/s values being used allows programmers to clearly reason about the important convergence and correctness properties. Hence, synchronous processing semantics often becomes a preferred choice for large-scale graph processing [18, 24, 36, 38].

While out-of-core graph processing systems that provide synchronous processing semantics have been well-optimized to maintain sequential disk locality and to minimize the amount of disk I/O per iteration, they process graphs iteration-by-iteration such that processing for a given iteration starts only after all the partitions have been processed for the corresponding previous iteration. Such synchronous processing enforces dependencies between all values across subsequent iterations. However, dependencies in graph computation are determined by the structure of the input graph, and real-world graphs are often large and sparse. This means, more often than not, two randomly chosen vertices will not be directly connected to each other, hence deeming the dependency between their values to be unnecessary in synchronous processing. This sparsity in edges provides an opportunity to perform out-of-order execution such that unrelated values across multiple iterations get simultaneously computed to amortize the disk I/O cost across multiple iterations. However, achieving such out-of-order execution in an out-of-core setting without sacrificing sequential disk locality, as well as simultaneously providing synchronous processing guarantees is challenging.

In this paper, we develop a *dependency-aware cross-iteration value propagation technique* called **LUMOS** to enable future value computations that reduce disk I/O while still guaranteeing synchronous processing semantics. We refine vertex computations into two key components: the first step performs concurrent aggregation of incoming vertex values, and the next step uses the result of concurrent aggregation to compute the final vertex value. Upon doing so, we identify that computing aggregations requires all incoming vertex values to be available which is a strong precondition that limits future computations. However, values can be safely propagated to compute *partial aggregations* that lifts off the precondition of requiring all incoming vertex values. When the partial aggregations receive all required values, they can be used to compute the final future vertex values which can be propagated further down across subsequent future iterations.

We enable such cross-iteration value propagation across partitions as partition boundaries become natural points to capture the set of value dependencies that can be safely satisfied. We further increase cross-iteration propagation via locality-aware intra-partition propagation to exploit the inherent locality in real-world graphs which has been identified in recent works [36]. While LUMOS can also correctly process asynchronous algorithms (e.g., traversal algorithms like shortest paths), we further optimize LUMOS for asynchronous algorithms by exposing relaxed processing semantics in its processing model. Finally, to achieve maximum benefits we enhance LUMOS with several key out-of-core processing strategies like selective scheduling and light-weight partitioning that have been shown to be seminal in extracting performance in out-of-core processing.

While our dependency aware cross-iteration propagation model is general enough to be incorporated in any synchronous out-of-core graph processing system, we develop LUMOS by extending GridGraph which is a state-of-art out-of-core graph processing system that guarantees synchronous processing semantics. Our evaluation shows that LUMOS is able to compute future values across 71-97% of edges which eliminates the corresponding amount of disk I/O across those iterations, and hence, LUMOS is 1.8× faster than GridGraph while it still retains the same synchronous processing semantics. To the best of our knowledge, this is the first out-of-core graph processing technique that enables future value computation across iterations, while still retaining the synchronous processing semantics throughout all the iterations, which is crucial for easy programmability.

2 Background & Motivation

We first discuss about semantics of synchronous execution, and then summarize out-of-core graph processing techniques.

2.1 Synchronous Processing Semantics

The Bulk Synchronous Parallel (BSP) model [27] is a popular processing model that provides synchronous stepwise execution semantics with separated computation and communication/synchronization phases. Under the BSP model, values in a given iteration are computed based on values from the previous iteration. We illustrate the *synchronous processing semantics* of BSP model using the PageRank algorithm as an example [1] in Algorithm 1. The algorithm computes vertex values (`newPr`) using the ones computed in previous iteration (`pr`) as shown on line 6. The flow of values across iterations is explicitly controlled via SWAP() on line 11.

Algorithm 1 Synchronous PageRank

```
1: G = (V, E)                          ▷ Input graph
2: pr = {1, 1, ..., 1}                 ▷ Floating-point array of size |V|
3: while not converged do
4:     newPr = {0, 0, ..., 0}          ▷ Floating-point array of size |V|
5:     par-for (u, v) ∈ E do
6:         ATOMICADD(&newPr[v], pr[u] / |out_neighbors(u)|)
7:     end par-for
8:     par-for v ∈ V do
9:         newPr[v] = 0.15 + 0.85 × newPr[v]
10:    end par-for
11:    SWAP(pr, newPr)
12: end while
```

Such clear separation of values being generated v/s values being used allows programmers to clearly reason about the important convergence and correctness properties. Hence, synchronous processing semantics often becomes a preferred choice for large-scale graph processing [18, 24, 36, 38].

2.2 Out-of-Core Graph Processing

Disk-based graph processing has been a challenging task due to ever growing graph sizes. The key components in efficient out-of-core graph processing systems is a disk-friendly partition-based data-structure, and an execution engine that processes the graph in a partition-by-partition fashion that maximizes sequential locality. Figure 1 shows how a given graph is represented as partitions on disk. Each partition represents incoming edges for a range of vertices (*chunk*-based partitioning [38]); partition p_0 holds incoming edges for vertices 0 and 1, p_1 holds for vertices 2 and 3, and p_3 for vertices 4 and 5. The iterative engine processes the graph by going through these partitions in a fixed order; it sequentially loads edges from partition p_0 to process them in memory, then from partition p_1, and finally from the last partition p_2. Once all the partitions are processed, the iteration ends by performing computations across vertex values, that may reside on disk or in-memory (depending on availability of memory). This entire process is repeated for multiple iterations until algorithm-specific termination condition is satisfied.

Several works aim to improve out-of-core graph processing [1, 8, 9, 13, 14, 16, 17, 24, 31, 32, 34, 35, 38] as summarized in Table 1. Depending on the processing semantics they offer, they fall in two categories:

[1] Algorithm 1 is simplified to eliminate details like selective scheduling.

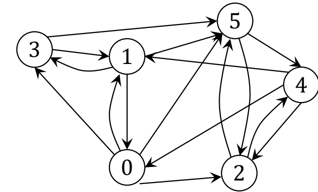
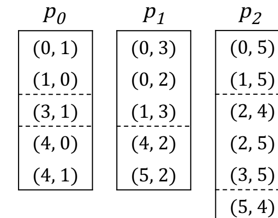
Table 1: Key characteristics of existing out-of-core graph processing systems and **LUMOS**.



(a) Example graph.



(b) Edge partitions.

Figure 1: An example graph partitioned into three partitions (p_0, p_1 and p_2) that reside on disk.

(A) Synchronous Out-of-Core Graph Processing. GraphChi [13], X-Stream [24], GridGraph [38], and others provide synchronous processing semantics. While initial systems like GraphChi [13] and X-Stream [24] proposed efficient processing models, their performance is limited due to management of edge-scale intermediate values in every iteration (edge values in GraphChi and edge updates in X-Stream).

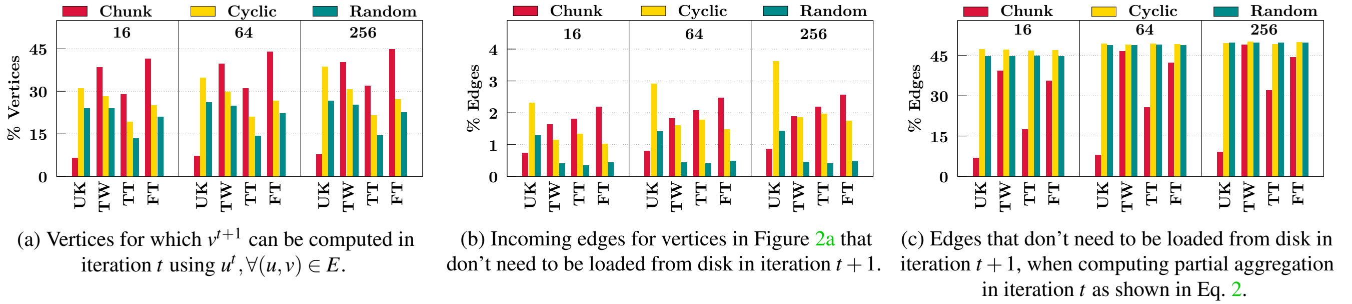
GridGraph [38] is an efficient out-of-core graph processing system that eliminates edge-scale intermediate updates. It divides vertices into subsets called *chunks* and partitions edges into 2D grid based on these chunks. In Figure 1b, the dashed-horizontal lines represent boundaries of *blocks* such that the entire representation becomes a 2D grid. The 2D grid is processed by streaming through edge-blocks. Furthermore, GridGraph enables selective scheduling which eliminates unnecessary edges to be loaded from disk by skipping partitions. Since its processing model is designed to minimize disk I/O, it is the state-of-art out-of-core graph processing system that provides synchronous processing semantics.

(B) Asynchronous Out-of-Core Graph Processing. Recent works like CLIP [1] and Wonderland [34] are customized for asynchronous algorithms like path-based algorithms (e.g., BFS and shortest paths). These frameworks leverage the algorithmic properties (e.g., monotonicity [28, 29]) to process partitions based on newly computed values, resulting in faster convergence. CLIP [1] processes partitions multiple times in memory while Wonderland [34] performs abstraction-guided processing for faster information propagation. Even though these techniques perform out-of-order computations (see Table 1), they do not provide synchronous processing semantics since they violate the processing order across computed vertex values. Hence, they cannot be used for synchronous graph algorithms.

Limitations with Out-of-Core Systems. As shown in Table 1, none of the systems perform *future value computation* (i.e., beyond a single iteration) while simultaneously providing synchronous processing semantics. In synchronous out-of-core frameworks, the processing model is tied down to strict iteration-by-iteration processing. Such tight coupling between synchronous semantics and strict processing order limits the performance of out-of-core graph processing. Particularly, the sparsity in real-world graphs often presents opportunities to proactively compute future values based on when value dependencies get resolved; realizing such processing across future iterations can be beneficial in out-of-core setting since edges corresponding to values that have already been computed for future iterations do not need to be loaded in those iterations, hence directly reducing disk I/O. However, such acceleration via future value computation is not achieved in out-of-core systems due to their strict iteration-by-iteration processing.

It is crucial to note that out-of-order execution does not necessarily result in computing across future values. Specifically, DynamicShards [31] performs out-of-order execution to dynamically capture the set of active edges to be processed in a given iteration. It achieves this by dropping inactive (or useless) edges across iterations and delaying computations that cannot be performed due to missing edges. While the delayed computations get periodically processed in shadow iterations (i.e., out-of-order execution), they do not compute across future values to leverage sparse dependencies. Asynchronous systems [1,34], on the other hand, do compute beyond a single iteration, but do not provide processing semantics.

This poses an important question: *how to process beyond a single iteration to reduce disk I/O in out-of-core processing while simultaneously guaranteeing synchronous processing semantics?*



(a) Vertices for which v^{t+1} can be computed in iteration t using $u^t, \forall(u,v) \in E$.

(b) Incoming edges for vertices in Figure 2a that don't need to be loaded from disk in iteration $t+1$.

(c) Edges that don't need to be loaded from disk in iteration $t+1$, when computing partial aggregation in iteration t as shown in Eq. 2.

Figure 2: Percentage of vertex computations and edge savings across three light-weight partitioning strategies (chunking, cyclic hashing and random partitioning) and three partition sizes (#partitions = 16, 64 and 256) on four large graphs (UK, TW, TT and FT from Table 4).

3 LUMOS: Dependency-Driven Cross-Iteration Value Propagation

Since our goal is to provide synchronous processing semantics while overlapping computations across multiple iterations, we first characterize cross-iteration dependencies to capture synchronous semantics and then develop our out-of-core value propagation strategy that guarantees those captured semantics.

3.1 Characterizing Synchronous Dependencies

Synchronous iterative graph algorithms compute vertex values in a given iteration based on values of their incoming neighbors that were computed in the previous iteration. Since computations are primarily based on graph structure, such cross iteration dependencies can be captured via the graph structure as follows:

$$\forall(u,v) \in E, \;\; u^t \mapsto v^{t+1} \tag{1}$$

where u^t and v^{t+1} represent values of vertex u in iteration t and vertex v in iteration $t+1$ respectively, and $\mapsto$ indicates that v^{t+1} is value-dependent on u^t. It is important to note that there are no dependency relationships among vertices that are not directly connected by an edge. With limited view of graph structure available at any given time in out-of-core graph processing, the cross-iteration dependencies get satisfied by processing vertices and edges in a given iteration only after processing for the previous iteration is completed.

3.2 Out-of-core Value Propagation

We ask two important questions that allow us to identify the interplay between cross-iteration value propagations to satisfy future dependencies and partition-by-partition processing orchestrated by out-of-core graph systems.

3.2.1 When to propagate?

A straightforward way to enable processing beyond a given single iteration t is to compute vertex values for the subsequent iteration $t+1$ if incoming neighbors' values corresponding to t are available at the time when those vertices are processed. With partition-by-partition out-of-core processing, we know that values for vertices belonging to a given partition p become available when p is processed; hence, we can allow outgoing neighbors to use these available values and compute for subsequent iterations if their partitions get processed after p in the same iteration. While theoretically this appears to be a promising direction, we profile the large graphs from Table 4 to measure the number of vertices for which future values can be computed (shown in Figure 2a), and the number of edges that don't need to be loaded for the corresponding vertices in future iterations (shown in Figure 2b). To eliminate the impact of partitioning, we profiled across three light-weight partitioning schemes, chunk-based partitioning (as used in [38]), cyclic partitioning (where vertex ids are hashed to partitions) and random partitioning; and, across three partition sizes corresponding to number of partitions being 16, 64 and 256. Even though Figure 2a shows up to 45% of vertices can compute values for subsequent iterations, it contributes to only 1-4% of edge savings as shown in Figure 2b. This means, future values can be computed for vertices that have low in-degree and, as expected, high in-degree vertices cannot compute future values since values for all of their incoming neighbors do not become available in time.

To achieve high amount of cross-iteration value propagation, we want to relax the precondition such that availability of *all* incoming neighbor values does not become a requirement. We achieve this by computing only the aggregated values for future iterations instead of computing final vertex values. Let $\bigoplus$ denote the aggregation operator that computes the intermediate value based on incoming neighbors and f denote the function to compute vertex's value based on aggregated intermediate value. For example, in PageRank (Algorithm 1), ATOMICADD on line 6 represents $\bigoplus$ and line 9 shows f. In a given iteration t, we aim to compute [2]:

$$v^t = f\Big(\bigoplus_{\forall e=(u,v)\in E} (u^{t-1})\Big) \quad \text{and} \quad g(v^{t+1}) = \bigoplus_{\substack{\forall e=(u,v)\in E \\ s.t.\;\; p(u)<p(v)}} (u^t) \tag{2}$$

[2] Values residing on edges (i.e., edge weights) have been left out from equations for simplicity as they do not impact cross-iteration dependencies.

where $g(v)$ represents aggregated value of v and $p(v)$ is the partition to which v belongs. It is important to note that $\bigoplus_{\forall e=(u,v)\in E}$ represents a complete aggregation while $\bigoplus_{\substack{\forall e=(u,v)\in E \\ s.t.\ p(u)<p(v)}}$ represents partial aggregation as the precondition $p(u) < p(v)$ may not be satisfied by all edges. Since $\forall u \in V, u^{t-1}$ is available in iteration t (due to barrier semantics), we can perform complete aggregation and also compute the vertex's value using f. However, since u^t becomes available as partitions get processed in the same iteration t, at a given point in time only the available u^t values can be propagated to compute the partial aggregation which satisfies the future cross-iteration dependency $u^t \mapsto v^{t+1}$. Since typically partitions get processed in numerical order, with P being total number of partitions, we know that $\forall i, j \in [0,P)$, if $i < j$, partition i gets processed before partition j. This ordering is captured in the precondition for partial aggregation $g(v^{t+1})$. Hence, in Figure 1, as p_0, p_1 and p_2 get processed in that order, v_0^t is available for $g(v_2^{t+1})$, $g(v_3^{t+1})$ and $g(v_5^{t+1})$ via $(0,2)$, $(0,3)$ and $(0,5)$ respectively, while v_3^t is not available for $g(v_1^{t+1})$ during iteration t.

As shown in Figure 2c, the percentage of values propagated (via partial aggregation) increases to 40-50%; the edges corresponding to these propagations need not be loaded in the subsequent iteration (i.e., directly reducing disk I/O), which is significantly higher compared to that in Figure 2b. We also observe that random partitioning compares well with other techniques and enables higher cross-iteration propagation; this can be reasoned with the high chances of an edge (u,v) being placed across partitions such that $p(u) < p(v)$. In Section 5.3, we will explore more light-weight partitioning strategies that will further enable cross-iteration propagation.

Note that the above value propagation requires vertex values for the current iteration to be computed as partitions get processed. We developed our processing model to simultaneously compute vertex values as corresponding partition's edges get processed (discussed further in Section 5.1).

3.2.2 How far (in iteration space) to propagate?

Cross-iteration dependencies are linear in iteration space and hence, we can potentially propagate values for future iterations beyond $t+1$. In order to guarantee synchronous processing semantics, we need to ensure that v^{t+1} gets computed in iteration t before it is further propagated to out-neighbors of v. We define a value v^x to be *computable* when all its incoming values corresponding to iteration $x-1$ have been propagated to $g(v^x)$ (i.e., a complete aggregation has occurred in $g(v^x)$). Since out-of-core processing propagates values to vertices based on its partitions, values can become computable when the corresponding vertex's partition gets processed. Computable values get computed by applying f on $g(v^x)$ to achieve v^x which can be further propagated to out-neighbors of v for $x+1$. For example in Figure 1, vertex 3 has two incoming edges $(0,3)$ and $(1,3)$, both of which contribute to $g(v_3^{t+1})$ during iteration t; hence, we can compute $v_3^{t+1} = f(g(v_3^{t+1}))$ during iteration t itself and further propagate v_3^{t+1} across the outgoing edge $(3,5)$ in the same iteration t.

$D=3$	0.38 - 0.52	0.13 - 0.25	0.11 - 0.44	0.04 - 0.26
$D=4$	< 0.01	< 0.01	< 0.01	< 0.01

Table 2: Percentage (min-max range) of edge propagations across three partitioning strategies from Figure 2.

For a given iteration t, we know that v^t becomes computable when $p(v)$ gets processed. Hence, for any arbitrary k, v^{t+k} becomes computable when $\forall(u,v) \in E, p(u) < p(v)$ and u^{t+k-1} is computable. This is because the partial aggregation $\bigoplus_{\substack{\forall e=(u,v)\in E \\ s.t.\ p(u)<p(v)}}$ becomes equivalent to complete aggregation $\bigoplus_{\forall e=(u,v)\in E}$ when $\forall(u,v) \in E, p(u) < p(v)$. These computable values that get further propagated lead to I/O reduction in the corresponding future iterations. We define distance of propagation (in iteration space) based on the difference between the current iteration number and the iteration number for which any value propagation occurs in the current iteration. Formally, the *distance of propagation D* is defined as:

$$D = \max_{\forall t} \left(\max_{\forall g(v^{t+k})} (k+1) \right)$$

In traditional out-of-core graph systems, barriers across iterations ensure that $D = 1$. Our dependency-aware cross-iteration propagation achieves $D > 1$; for example, with propagation for immediately subsequent iteration, D is 2. Table 2 summarizes the percentage of edge propagations that occur across distances 2, 3 and 4. As we can see, propagations decrease drastically at distance 3, and are close to 0% after that. Since achievable benefits are minor beyond propagation distance 2, we perform cross-iteration propagation until distance 2, i.e., for the current iteration t and the next iteration $t+1$.

3.3 Graph Layout

Since cross iteration dependencies are primarily based on the input graph structure, value propagations beyond current iteration can be statically determined based on the precondition involved in Eq. 2. In order to completely avoid reading edges whose dependencies have been satisfied, we create separate graph layouts for subsequent iterations. In this way, the execution switches between different graph layouts on disk. In theory, we can create D separate graph layouts to propagate values across D iterations; however, to simplify exposition we discuss the layout for $D = 2$ since larger propagation distances provide diminishing benefits (as discussed in Section 3.2). With $D = 2$, we have two graph layouts: the *primary* layout consisting of all edges, and the *secondary* layout containing only subset of edges. Figure 3 shows the secondary layout and its corresponding graph representation for the primary graph

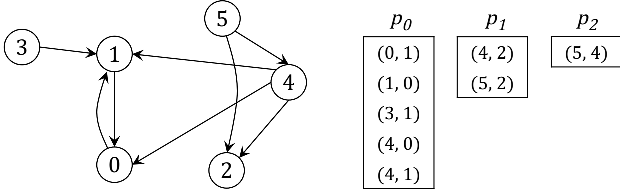

Figure 3: Secondary layout for graph from Figure 1.

Graph	Without Intra-Partition Propagation	With Intra-Partition Propagation
UK	6.84 - 49.69	49.76 - 92.47
TW	39.24 - 50.09	50.31 - 62.22
TT	17.43 - 49.74	43.32 - 61.87
FT	35.58 - 49.80	47.20 - 56.19

Table 3: Percentage (min-max range) of edge propagations with and without intra-partition propagation across three partitioning strategies from Figure 2.

layout in Figure 1. The secondary layout does not contain 8 out of 16 edges since the corresponding dependencies get satisfied while processing primary layout.

We analyze the reduction in I/O caused by our secondary graph layout. Since $|E| >> |V|$, out-of-core graph processing systems like GridGraph achieve high performance by ensuring that the edges are loaded only once in every iteration. Hence, for each iteration, their I/O amount is $|E| + k \times |V|$ where $k \geq 2$ captures batch loading of vertices for each partition. While our I/O amount for the iteration using primary layout remains the same, it reduces significantly when secondary layout is used. Let α be the ratio of edges for which values are propagated for subsequent iteration when primary layout is processed. Since those edges are not present in secondary layout, the I/O amount directly reduces by $\alpha \times |E|$. Hence, the total I/O amount is:

$$C = \begin{cases} (1-\alpha) \times |E| \; + \; k \times |V| & \ldots \text{ secondary layout} \\ |E| \; + \; k \times |V| & \ldots \text{ primary layout} \end{cases}$$

As we will see in Section 6, α is typically over 0.7 which drastically reduces the I/O amount.

3.4 Intra-Partition Propagation

So far cross-iteration propagation is performed for edges across partitions as dictated by Eq. 2. While this captures a large subset of edges that don't need to be loaded in the subsequent iteration, it has been recently shown in [36] that real-world graphs often possess natural locality such that adjacent vertices are likely to be numbered close to each other due to the traversal nature of graph collection strategies (e.g., crawling, anonymization, etc.). This means, chunk-based partitioning strategies where contiguous vertex-id ranges get assigned to partitions have several edges such that both end-points belong to the same partition.

In order to leverage this natural locality, in a given iteration t, we aim to propagate value for subsequent iteration across edge (u, v) where $p(u) = p(v)$. However, since u^t becomes available as partition $p(u)$ gets processed in the same iteration t, u^t can only be propagated after $p(u)$ has been processed. Hence, if (u, v) can be held in memory until $p(u)$ gets fully processed, we can propagate u^t to satisfy the future cross-iteration dependency $u^t \mapsto v^{t+1}$. This means, intra-partition cross-iteration propagation relaxes our precondition for partial aggregation to become:

$$g(v^{t+1}) = \bigoplus_{\substack{\forall e=(u,v)\in E \\ s.t.\ p(u) \leq p(v)}} (u^t) \tag{3}$$

Table 3 summarizes the increase in cross-iteration propagation when intra-partition propagation is enabled. As we can see, cross-iteration propagation increases to 43-92% with intra-partition propagation, which further saves disk I/O.

We enable intra-partition cross-iteration value propagation by ensuring that partition sizes remain small enough such that they can be entirely held in memory. As shown in Section 5.1, our processing model holds the partition in memory until it gets processed, and then performs cross-iteration propagation for edges whose both end-points belong in the partition.

3.5 Value Propagation v/s Partition Size

The amount of cross-iteration value propagation not only depends on the partitioning strategy, but also varies based on the size of partitions. As we can observe in Figure 2c, the same partitioning strategy with different partition sizes enables different amount of cross-partition propagation. In general, since cross-partition propagation is achieved on edges crossing partition boundaries, smaller partitions lead to higher cross-partition propagation compared to that by larger partitions. As an extreme case, each vertex residing in its own partition would result in smallest partitions, and would cause highest amount of cross-partition value propagation.

Intra-partition propagations, on the other hand, are amenable to large partitions as they enable propagations across edges within the partitions. Even though smaller partitions allow lesser intra-partition propagations compared to that allowed by larger partitions, the set of edges crossing smaller partitions is larger, hence allowing cross-partition propagations through edges that get missed by intra-partition propagations. It is interesting to note that as partitions become smaller, edges that were originally participating in intra-partition propagation get cut across partition boundaries either in forward direction (i.e., $p(u) < p(v)$ for edge (u, v)) or in backward direction. Since cross-partition value propagation occurs on forward edges only, the overall cross-iteration value propagation (combined cross-partition and intra-partition) reduces as partitions become smaller. Hence, it is preferable to have large partitions that can fit in main memory to maximize cross-iteration value propagation. In Section 5.3, we propose light-weight partitioning heuristics that increase the amount of cross-iteration value propagation, which in turn reduces the severity of partition size's impact.

3.6 LUMOS with DynamicShards

LUMOS can be combined with DynamicShards [31] to perform cross-iteration value propagation with dynamic edge selection. Specifically, primary layout partitions can be made dynamic (by dropping inactive edges) while secondary layout partitions can be left static since they are already small in size. Furthermore, shadow iterations require the missing graph edges to process delayed computations, and hence, shadow iterations must be scheduled during primary iterations in order to amortize loading costs. It is interesting to note that even though secondary layouts are kept static, computations from secondary layouts can get delayed due to transitive delays occurring from previous iterations' primary layouts.

4 LUMOS for Asynchronous Algorithms

Several graph analytics algorithms like traversal based monotonic algorithms (e.g., shortest paths, BFS, connected components, etc.) are asynchronous, i.e., they do not require synchronous processing semantics to guarantee correctness [28, 30]. Nevertheless, having synchronous semantics does not hurt the correctness guarantees for asynchronous algorithms because synchronous execution is one of the legal executions under the set of asynchronous executions. In other words, the dependencies enforced by synchronous processing semantics in Eq. 1 are only stricter (while still being legal) than that required by asynchronous semantics. Since LUMOS's out-of-order value propagation technique does not violate the dependencies defined in Eq. 1, LUMOS works correctly on asynchronous algorithms like shortest paths and connected components as well.

Furthermore, LUMOS can be optimized to efficiently process asynchronous algorithms by incorporating relaxed processing semantics in its processing model. For example, traversal based monotonic algorithms often rely on selection functions [29] like MIN() that enable vertex's value to be computed based on value coming from its single incoming edge. This means, intermediate vertex values computed based on subset of their incoming values represent a valid final value (instead of a partial aggregation) that can be instantly propagated to outgoing edges. In other words, computations in Eq. 2 do not require separation of values across iterations t and $t+1$, and $g(v^t)$ can be directly incorporated in v^t. Hence, LUMOS can enable value propagation for asynchronous algorithms by maintaining a single version of vertex values and directly propagating the updated values across edges.

Such *asynchronous value propagation* is achieved both across (inter-partition) and within (intra-partition) partitions; intra-partition propagations are achieved by recomputing over in-memory partition as described in Section 3.4. An interesting side effect of asynchronous value propagation is that secondary graph layout is no longer necessary because any value propagation across edges in the primary graph layout does not violate asynchronous semantics, and hence, entire processing can occur on the primary graph layout itself.

5 The LUMOS System

So far we discussed value propagation in a generalized out-of-core processing context without focusing on any particular system. This makes our proposed cross-iteration value propagation techniques useful for existing out-of-core processing systems. We now discuss the important design details involved in incorporating LUMOS into GridGraph. We choose GridGraph since its streaming-apply processing model is designed to minimize I/O amount, making it state-of-art synchronous out-of-core graph processing system.

5.1 Propagation based Processing Model

LUMOS's processing model is similar to out-of-core processing systems where edges are loaded from disk in batches and processed in memory. We discuss the processing model at partition level to showcase how cross-iteration propagations are performed. Algorithm 2 shows how primary and secondary partitions are processed; LUMOS offers three key programming interfaces: (a) PROCESSPRIMARY performs standard propagation and cross-iteration propagation across primary partitions; (b) PROCESSSECONDARY performs standard propagations across secondary partitions; and, (c) VERTEXMAP performs updates across vertices. PROCESSPRIMARY processes both, edges (lines 4, 6, 13) and vertices (line 9). PROCESSSECONDARY's structure is kept similar to PROCESSPRIMARY to enable easier programmability of graph algorithms. The primary partitions get processed in even iterations using PROCESSPRIMARY while the secondary partitions get processed in odd iterations using PROCESSSECONDARY. Figure 4 illustrates how partition-by-partition processing is achieved using primary and secondary layouts across two consecutive iterations. Along with the traditional cross-iteration barriers, we also have cross-partition barriers while processing primary partitions to ensure that precondition in Eq. 2 gets correctly satisfied for cross-iteration propagation; these cross-partition barriers are not required while processing secondary partitions. Algorithm 3 shows PageRank algorithm using our propagation interface. Beyond the standard edge function PROPAGATE and vertex function COMPUTE, we also use the cross-iteration edge propagation function CROSSPROPAGATE. While the shape of CROSSPROPAGATE is similar to PROPAGATE, they operate on different values for the same edge, i.e., PROPAGATE aggregates for current iteration while CROSSPROPAGATE aggregates for subsequent iteration. The aggregation for subsequent iteration is made available using ADVANCE (line 13).

5.2 Selective Scheduling

One of the strengths of 2D grid layout is that it enables selective scheduling of edge computations so that edge-blocks can be skipped to reduce unnecessary I/O [38]. LUMOS carefully incorporates selective scheduling with cross-iteration propagation to ensure that scheduling gets correctly managed for primary and secondary partitions.

Algorithm 2 Propagation Interface

```
1:  function PROCESSPRIMARY(PROPAGATE,
                        CROSSPROPAGATE, COMPUTE)
2:    for partition ∈ primaryPartitions do
3:      par-for edge ∈ partition do
4:        PROPAGATE(edge)
5:        if p(edge.source) < p(edge.target) then
6:          CROSSPROPAGATE(edge)
7:        end if
8:      end par-for
9:      VERTEXMAP(COMPUTE, vertex_chunk(partition))
10:     if Locality-Aware Intra-Partition Propagation then
          /* partition is held in memory (see Section 3.4) */
11:       par-for edge ∈ partition do
12:         if p(edge.source) = p(edge.target) then
13:           CROSSPROPAGATE(edge)
14:         end if
15:       end par-for
16:     end if
17:   end for
18: end function
19: function PROCESSSECONDARY(PROPAGATE, COMPUTE)
20:   for partition ∈ secondaryPartitions do
21:     par-for edge ∈ partition do
22:       PROPAGATE(edge)
23:     end par-for
24:     VERTEXMAP(COMPUTE, vertex_chunk(partition))
25:   end for
26: end function
27: function VERTEXMAP(VFUNC, VS = V)          ▷ V is default arg.
28:   sum = 0
29:   par-for v ∈ VS do
30:     sum += VFUNC(v)
31:   end par-for
32:   return sum
33: end function
```

Algorithm 3 PageRank Example

```
1:  function PROPAGATE(e)
2:    ATOMICADD(&sum[e.target], pagerank[e.source] / outdegree[e.source])
3:  end function
4:  function CROSSPROPAGATE(e)
5:    ATOMICADD(&secondary_sum[e.target],
                sum[e.source] / outdegree[e.source])
6:  end function
7:  function COMPUTE(v)
8:    sum[v] = 0.15 + 0.85 × sum[v]
9:  end function
10: function ADVANCE(v)
11:   diff = |pagerank[v] − sum[v]|
12:   pagerank[v] = sum[v]
13:   sum[v] = secondary_sum[v]
14:   secondary_sum[v] = 0
15:   return diff
16: end function
17: pagerank = [1, ..., 1]
18: sum = [0, ..., 0]
19: secondary_sum = [0, ..., 0]
20: iteration = 0
21: converged = false
22: while ¬converged do
23:   if iteration % 2 == 0 then
24:     PROCESSPRIMARY(PROPAGATE, CROSSPROPAGATE,
                      COMPUTE);
25:   else
26:     PROCESSSECONDARY(PROPAGATE, COMPUTE);
27:   end if
28:   d = VERTEXMAP(ADVANCE);
29:   converged = d / |V| ≤ threshold
30:   iteration = iteration + 1
31: end while
```

An *active* edge-block represents edges that will be loaded from disk; otherwise, they will be skipped. When processing primary partitions (i.e., during even iterations), depending on the state (active/inactive) of an edge-block for primary and secondary layouts at the time when it needs to be processed, there can be four cases. While three of those cases can be handled in the same way as done for primary partitions, the case when the edge-block is inactive for primary layout but is active for secondary layout need to be considered carefully. In this case, while processing secondary partitions in the subsequent iteration, the corresponding edge-block gets loaded from the primary layout instead of secondary layout to ensure that all necessary edges within the edge-block participate correctly in value propagation. LUMOS maintains this cross-iteration selective scheduling information using 2-bits per edge-block; first bit indicating whether the edge-block is active or inactive, and second bit indicating whether to load edge-block from primary layout or secondary layout.

5.3 Graph Layout & Partitioning

For a graph $G = (V, E)$, V is divided into P disjoint subsets of vertices (called *chunks*), $C = \{c_0, c_1, ..., c_{P-1}\}$ such that $\bigcup_{c \in C} c = V$ and $\forall c_i, c_j \in C, c_i \cap c_j = \varnothing$. The edges are represented as a 2D grid of $P \times P$ edge-blocks on disk. An edge (u, v) is in edge-block b_{ij} if $u \in c_i \wedge v \in c_j$. It is important to note that a column i in the 2D grid has incoming edges for vertices belonging to c_i, and similarly a row j has outgoing edges for vertices belonging to c_j. Hence, each column is a partition for LUMOS in accordance with the precondition in Eq. 2 that satisfies the dependency relation. Similarly, each row is a partition for LUMOS when values need to be propagated across incoming edges (i.e., a transposed view).

As discussed in Section 3.3, we create a primary layout and a secondary layout. This means, we create two separate 2D grids on disk, one for each layout. An important issue in creating grid layouts is partitioning V into P chunks. Out-of-core processing systems use a simplified structure-oblivious partitioning strategy based on vertex-id ranges, i.e., assuming vertices are numbered between 0 to $|V|$, chunks are formed as contiguous range of vertex numbers: vertices 0 to $k-1$ form chunk 0, vertices k to $2k-1$ form chunk 1, and so on. While such structure-oblivious partitioning enables good amount of cross-iteration propagation (shown in Section 3), we develop greedy partitioning strategies that carefully use the vertex degree information to maximize cross-iteration value propagation.

Let $\mathscr{P} = \{p(v_0), p(v_1), ..., p(v_{|V|-1})\}$ capture the partition-

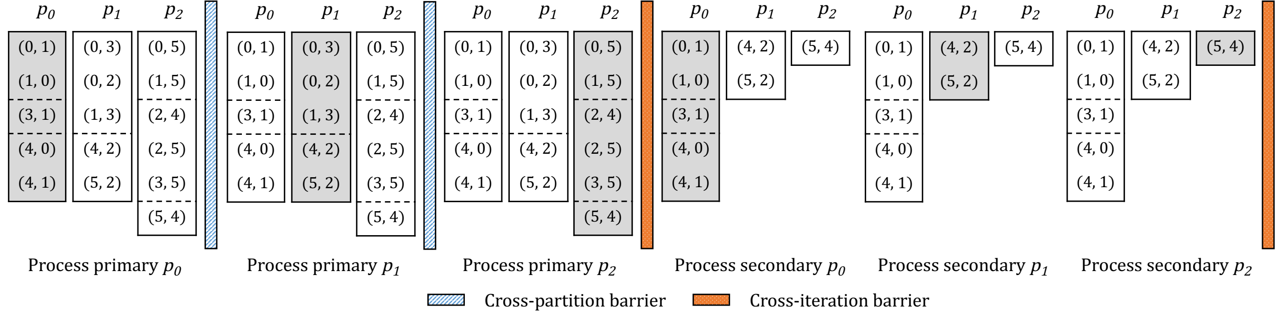

Figure 4: Execution using primary and secondary layouts across two consecutive iterations.

ing information that maps vertices in V to chunks in C. We define our partitioning objective as:

$$\underset{\mathscr{P}}{\arg\max}\ |\{(u,v) : (u,v) \in E \ \wedge\ p(u), p(v) \in \mathscr{P} \ \wedge\ p(u) < p(v)\}| \quad (4)$$

Note that with intra-partition propagation, the above condition becomes $p(u) \leq p(v)$ and there is an additional constraint to limit partition sizes:

$$\forall c_i \in C, \sum_{\substack{\forall v \in c_i \ \wedge \\ \forall (u,v) \in E}} (u,v) \ < \ T$$

where T is a threshold based on available memory.

Since the condition in Eq. 4 can be directly viewed as u's outgoing edges contributing to cross-iteration dependencies, a straightforward greedy heuristic can be to place vertices with higher out-degree in earlier partitions. However, an interesting dual to this reasoning can be that v's incoming edges contribute to cross-iteration dependencies and hence, the greedy heuristic can be to place vertices with higher in-degree in later partitions. Based on these insights, we develop three key partitioning heuristics to assign vertices in V to chunks in C:

(A) Highest Out-Degree First: $\forall u, v \in V$,
if $p(u) < p(v)$, then $out_degree(u) \geq out_degree(v)$

(B) Highest In-Degree Last: $\forall u, v \in V$,
if $p(u) < p(v)$, then $in_degree(v) \geq in_degree(u)$

(C) Highest Out-Deg. to In-Deg. Ratio First: $\forall u, v \in V$,
if $p(u) < p(v)$, then $\frac{out_degree(u)}{in_degree(u)} \geq \frac{out_degree(v)}{in_degree(v)}$

Note that the above heuristics are simpler than structure-based partitioning since computing degrees of vertices only requires a single pass over the edge list.

6 Evaluation

We evaluate LUMOS using billion-scale graphs and synchronous graph algorithms, and compare its performance with GridGraph [38] which is the state-of-art out-of-core graph processing framework that provides synchronous semantics.

Graphs	Disk Size	|E|	|V|
UKDomain (UK) [2]	6.9-20.7GB	1.0B	39.5M
Twitter (TW) [12]	11-33GB	1.5B	41.7M
TwitterMPI (TT) [3]	15-45GB	2.0B	52.6M
Friendster (FT) [5]	20-60GB	2.5B	68.3M
Yahoo (YH) [33]	50-150GB	6.6B	1.4B
RMAT29 (RM)	66-198GB	8.6B	537M

Table 4: Real world & synthetic graphs.

6.1 Experimental Setup

LUMOS's evaluation is carried out across three different AWS EC2 storage optimized instances. For performance experiments (Section 6.2), we use h1.2xlarge with 8 vCPUs, 32GB memory and 2TB HDD. Its disk sequential read bandwidth [3] is 278MB/sec whereas the memory subsystem read bandwidth is 9.6GB/sec. To study the effect of I/O scaling (Section 6.3), we use d2.4xlarge and i3.8xlarge instances. The d2.4xlarge instance is used with 16 vCPUs, 32GB memory and 1 to 4 2TB HDDs providing disk bandwidth of 195MB/sec to 768MB/sec, whereas the i3.8xlarge instance is used with 32 vCPUs, 64GB memory and 1 to 4 1.9TB SSDs providing disk bandwidth of 1.2GB/sec to 3.9GB/sec.

We use six synchronous graph algorithms. PageRank (PR) [22] is an algorithm to rank web-pages while Weighted Pagerank (WPR) is its variant where edges have weights as applied for social network analysis. Co-Training Expectation Maximization (CoEM) [21] is a semi-supervised learning algorithm for named entity recognition. Belief Propagation (BP) [10] is an inference algorithm to determine states of vertices based on sum of products. Label Propagation (LP) [37] is a learning algorithm while Dispersion (DP) [11] is a simulation based information dispersion model. We run each algorithm for 10 iterations; PR and DP operate on unweighted graphs while CoEM, LP, WPR and BP require weighted graphs. This adds 4 bytes per edge for CoEM, LP and WPR, and 16 bytes per edge for BP; hence, increasing graph sizes to 1.5× and 3× respectively.

We evaluate LUMOS using billion scale graphs from Ta-

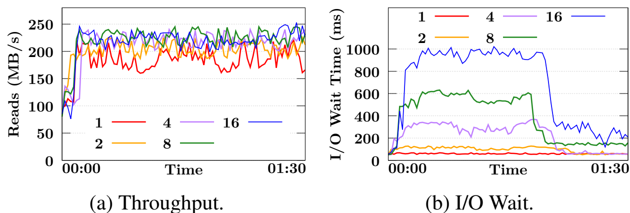
Table 5: Execution times (in seconds) for LUMOS, LUMOS-BASE and GridGraph. Bold numbers indicate speedups of LUMOS over GridGraph.



(a) Throughput. (b) I/O Wait.

Figure 5: I/O throughput and waiting times for PR on TT across 1, 2, 4, 8 and 16 threads.

ble 4. For experiments on h1.2xlarge, we use TT, FT and YH whereas RMAT29 is used for I/O scaling experiments. Since unweighted TT fits within 32 GB (on h1.2xlarge), we limit the memory of unweighted TT experiments to 16 GB.

We compare the following three versions:

1. **GridGraph (GG):** is the GridGraph system [38].
2. **LUMOS-BASE (LB):** is LUMOS based on Eq. 2. It performs cross-iteration propagation only across partitions.
3. **LUMOS (L):** is LUMOS based on Eq. 3. It also performs intra-partition cross-iteration propagation.

6.2 Performance

Table 5 shows the execution times for GridGraph, LUMOS-BASE and LUMOS on h1.2xlarge. We use Highest Out-Degree

Version	TT	FT	YH
LUMOS-BASE	75.6%	67.5%	88.3%
LUMOS	81.1%	72.6%	93.8%

Table 6: Percentage of cross-iteration propagations.

to In-Degree Ratio First strategy which enables high cross-iteration propagations as shown in Table 6 (we will evaluate different partitioning strategies in Section 6.4). As we can see, LUMOS-BASE and LUMOS accelerate GridGraph in all cases. LUMOS is 1.65-1.74× faster than GridGraph while LUMOS-BASE is 1.28-1.59× faster; this is due to the reduced amount of I/O performed which gets enabled via cross-iteration propagation. Figure 6 shows the time spent in reading partitions in each case normalized w.r.t. execution time of GridGraph. As expected in out-of-core graph processing, the execution time is dominated by disk reads; for HDD we observe that GridGraph typically spends 74-83% of the time in performing disk reads, while LUMOS spends only 27-41% of the time performing disk reads compared to GridGraph. This reduction in read times results from our cross-iteration propagation technique that eliminates repetitive I/O using secondary layouts.

To study disk utilization, we vary the number of threads and measure the disk throughput and wait latencies for LUMOS. Figure 5 shows the disk throughput and wait latencies for PR on TT across 1, 2, 4, 8 and 16 threads. As we can see, the utilization is high even when using a single thread and having more threads only helps to maintain the high utilization (230-240 MB/sec) whenever the utilization drops for single thread (red trenches in Figure 5). With more threads issuing more I/O requests and utilization remaining same, the cores essentially wait more for I/O requests to complete as threads increase for HDD (shown in Figure 5b). We also observe high wait latencies as threads increase in Figure 5b due to high number of I/O requests.

It is interesting to observe that a single thread is easily able to keep the disk busy (wait times 150-200 ms) as its measured sequential read bandwidth is 278 MB/sec. Furthermore, we observe a significant dip in waiting times between ∼60-90 seconds (shown in Figure 5b) which appear while processing secondary layout; these secondary layouts are smaller, and hence the I/O requests get served quickly.

6.3 I/O Scalability

We study the impact of scaling I/O on LUMOS by setting up a RAID-0 array of 2 to 4 HDDs on d2.4xlarge, and 2 to 4 SSDs on i3.8xlarge instance. The resulting read bandwidths are shown in Table 7.

	Single Drive	RAID-0 with k drives		
		$k = 2$	$k = 3$	$k = 4$
d2.4xlarge (HDD)	195MB/s	368MB/s	590MB/s	768MB/s
i3.8xlarge (SSD)	1.2GB/s	3.8GB/s	4.1GB/s	3.9GB/s

Table 7: Sequential read bandwidth.

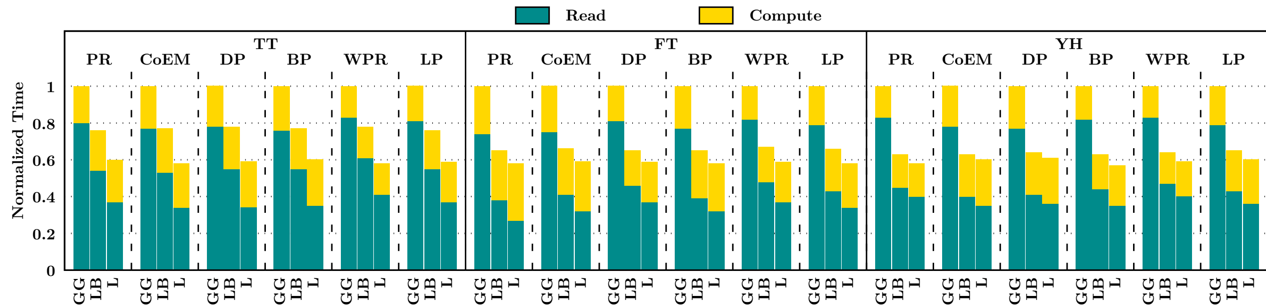


Figure 6: Read times and computation times of LUMOS and LUMOS-BASE normalized w.r.t. GridGraph's execution time.

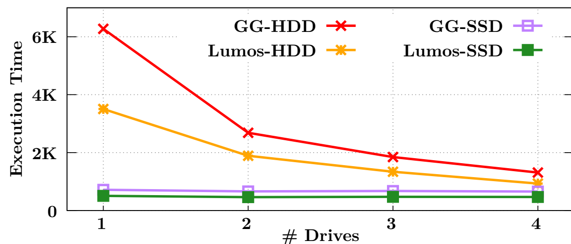

Figure 7: Execution times (in seconds) for LUMOS and GridGraph (GG) with varying number of drives. GG-HDD and LUMOS-HDD use HDDs on d2.4xlarge, while GG-SSD and LUMOS-SSD use SSDs on i3.8xlarge (see Table 7).

We ran PR on RAMT29 graph (8.6B edges) on the above setup with 64GB main memory. Figure 7 compares the execution times of LUMOS and GridGraph as number of drives increase from 1 to 4. LUMOS on d2.4xlarge scales gradually as I/O scales; it performs 1.8×, 2.6× and 3.8× faster with 2, 3 and 4 drives. It is interesting to observe that benefits of LUMOS over GridGraph diminish as number of drives increase. LUMOS performs 1.8× faster than GridGraph on a single drive and 1.3-1.4× faster on 2-4 drives. This is because GridGraph benefits from increased I/O bandwidth, which in turn leaves lesser room for effects of cross-iteration value propagation to become visible.

Contrary to HDDs, performance of LUMOS and GridGraph doesn't vary much as SSDs increase. Going from a single SSD to 2 SSDs reduces LUMOS's execution time from 505 sec to 460 sec, and the benefits of LUMOS over GridGraph also remain low with more SSDs (1.4×). This is again due to the high bandwidth provided by SSDs on i3.8xlarge (see Table 7) that alleviate I/O bottlenecks.

6.4 Partitioning Strategies

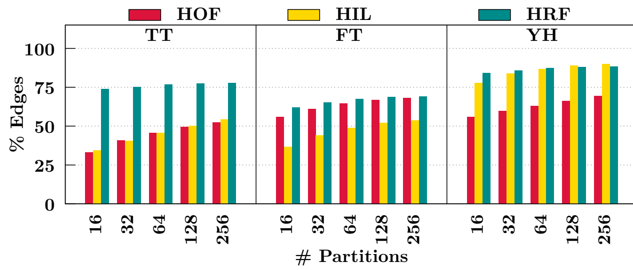
We evaluate our three light-weight partitioning strategies proposed in Section 5.3: Highest Out-Degree First (HOF), Highest In-Degree Last (HIL) and Highest Out-Degree to In-Degree Ration First (HRF). In Figure 8, we measure the amount of cross-iteration propagation for each of these strategies with and without intra-partition propagation and study sensitivity of these strategies to partition sizes.

While cross-iteration propagation depends on the structure of graph, HOF and HIL achieve 13-89% propagations across partitions whereas HRF captures the best of both and achieves significantly higher propagations (51-88%). With intra-partition propagations, all three strategies achieve significantly higher cross-iteration propagation (up to 92% for TT, 96% for FT, and 97% for YH). It is interesting to note that HOF slightly outperforms HRF and HIL for FT while HIL slightly outperforms HRF and HOF for TT; nevertheless, HRF remains useful since it achieves the middle ground between out-degree and in-degree metrics.

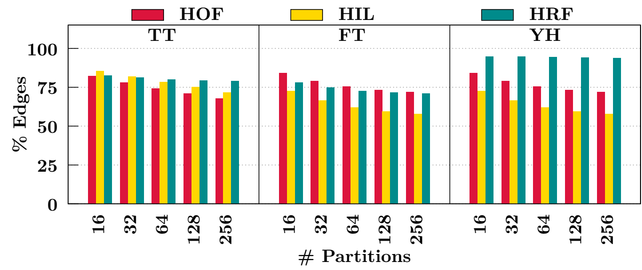
Finally, we observe that cross-iteration propagations across partitions increase as number of partitions increase and partitions become smaller; this is expected since edges within the same partition become potential candidates for propagations as they move to other partitions when partitions become smaller. Furthermore, when intra-partition propagation is enabled, there are fewer candidates within the same partition as number of partitions increase and hence, we observe a decreasing trend of cross-propagations. However, the scale of cross-iteration propagations remains high for HRF (70-97%) across different partition sizes, making it effective in all cases.

6.5 Preprocessing

Figure 9a shows the preprocessing times normalized w.r.t. GridGraph. While our light-weight partitioning strategy requires an additional pass over edges to compute vertex degrees, the pass is lightweight since it doesn't incur simultaneous writing of edges. Furthermore, edges don't need to be sorted and vertices are ordered across buckets that determine partitions. Finally, since majority of edges enable cross-iteration propagation, secondary layouts are smaller and hence, writing them out on disk is less time consuming than that for the original graph. Figure 9b shows the increase in disk space normalized w.r.t. GridGraph; as expected, the increase is only 12-33% for LUMOS-BASE because 67-88% of edges participate in cross-iteration propagation and hence, only remainder edges are present in the secondary layouts. With intra-partition propagation, the disk space requirement increases only by 7-26%.



(a) Without locality-aware intra-partition propagation.



(b) With locality-aware intra-partition propagation.

Figure 8: Cross-iteration propagation enabled by three partitioning strategies: Highest Out-Degree First (HOF), Highest In-Degree Last (HIL), and Highest Out-Degree to In-Degree Ratio First (HRF).

(b) Disk Space.

Figure 9: Preprocessing time and disk space for LUMOS and LUMOS-BASE normalized w.r.t. GridGraph whose absolute time/space numbers are: TW = 217s/11GB; TT = 248s/15GB; FT = 334s/20GB; YH = 815s/50GB.

7 Related Work

We classify out-of-core graph processing systems into two categories based on the guarantees they provide.

(A) Synchronous Out-of-Core Graph Processing.
We discussed GridGraph [38] in Section 2; here, we briefly discuss the remaining works. GraphChi [13] pioneered single machine based out-of-core graph processing by designing partitions called *shards*, and developing a parallel sliding window model to process shards such that random disk I/O gets minimized. X-Stream [24] performs edge-centric processing using scatter-gather model. To reduce random vertex accesses, X-Stream partitions vertices and accesses edge list and update list based on partitioned vertex sets. Chaos [23] scales out X-Stream on multiple machines. FlashGraph [35] is a semi-external memory graph engine that stores vertex states in memory and edge-lists on SSDs. TurboGraph [8] is an out-of-core computation engine for graph database based on sparse matrix-vector multiplication model. Mosaic [17], GraFBoost [9] and Garaph [16] perform out-of-core processing on heterogeneous architecture containing high-bandwidth NVMe SSDs, massively parallel Xeon Phi processors, FPGAs and GPUs. Graphene [15] uses an I/O request centric graph processing model to simplify IO management by translating high-level data accesses to fine-grained IO requests. DynamicShards [31] develops dynamic partitions that eliminate unnecessary edges from partitions to reduce disk I/O.

Limitation: Since all of these works focus on computations within a single iteration, none of them leverage cross-iteration value propagation as LUMOS does. Furthermore, since these systems effectively process in partition-by-partition fashion, they can be further improved using LUMOS.

(B) Asynchronous Out-of-Core Graph Processing.
CLIP [1] exploits algorithmic asynchrony by making multiple passes over the partitions in memory. Wonderland [34] extracts effective graph abstractions to capture certain graph properties, and then performs abstraction-guided processing to infer better priority processing order and faster information propagation across graph. While the abstraction-based technique is powerful, its scope of applications is limited to path-based monotonic graph algorithms beyond which its applicability remains undefined (as mentioned in [34]). AsyncStripe [4] uses asymmetric partitioning & adaptive stripe-based access strategy to process asynchronous algorithms.
Limitation: Since synchronous guarantees are not provided by these works, their applicability is limited to asynchronous path-based algorithms. LUMOS with asynchronous processing semantics (Section 4) leverages relaxed dependencies for asynchronous algorithms as well.

Beyond Out-of-Core Graph Processing.
Google's Pregel [18], PowerGraph [6], GraphX [7], GPS [25] and Gemini [36] provide a synchronous processing model in a distributed environment, while Galois [20] and Ligra [26] offer similar guarantees in a shared memory setting. GraphBolt [19] provides synchronous processing semantics while processing streaming graphs.

8 Conclusion

We developed LUMOS, a dependency-driven out-of-core graph processing technique that performs out-of-order execution to proactively propagate values across iterations while simultaneously providing synchronous processing guarantees. Our evaluation showed that LUMOS computes future values across 71-97% of edges, hence reducing disk I/O and accelerating out-of-core graph processing by up to 1.8×.

Abstract

Recent deep learning models have moved beyond low dimensional regular grids such as image, video, and speech, to high-dimensional graph-structured data, such as social networks, e-commerce user-item graphs, and knowledge graphs. This evolution has led to large graph-based neural network models that go beyond what existing deep learning frameworks or graph computing systems are designed for. We present NeuGraph, a new framework that bridges the graph and dataflow models to support efficient and scalable parallel neural network computation on graphs. NeuGraph introduces graph computation optimizations into the management of data partitioning, scheduling, and parallelism in dataflow-based deep learning frameworks. Our evaluation shows that, on small graphs that can fit in a single GPU, NeuGraph outperforms state-of-the-art implementations by a significant margin, while scaling to large real-world graphs that none of the existing frameworks can handle directly with GPUs.

1 Introduction

Graphs are natural representations of many real-world data; examples include web graphs, social networks, e-commerce user-item graphs, and knowledge graphs. With a graph representation, graph-based learning tasks, such as vertex classification and link prediction, can be optimized effectively. There has been a recent surge of interest in extending neural network models to graph data [7, 8, 13, 17–19, 23, 25, 29, 37]. These methods, known as graph neural networks (GNNs), combine standard neural networks with iterative graph propagation: the property of a vertex is computed recursively (with neural networks) from the properties of its neighbor vertices.

However, neither the existing deep learning frameworks nor the existing graph systems could support GNN algorithms sufficiently. The lack of system support has seriously limited the ability to explore the full potentials of GNNs at scale. Deep learning (DL) frameworks such as TensorFlow [4], PyTorch [2], MXNet [12], and CNTK [50] are designed to express deep neural networks (DNNs) but do not naturally express and efficiently execute graph propagation models. Deep graph library (DGL) [1] supports programming GNNs by wrapping DL systems with a graph-oriented message-passing interface. While DGL addresses the expressiveness challenge, it does not yet explore deeply the opportunities to leverage graph-aware operations for efficient executions. Furthermore, none of these frameworks, including DGL, offer the needed scalability to handle large graphs: The highly connected nature of graphs means that graph propagation could easily involve a large portion of a large graph, especially for power-law or dense graphs. Processing even a single vertex requires that deep learning frameworks load a large amount of graph-related data (e.g., structure and feature data) into limited GPU memory.

With the vertex-program abstraction and graph-specific optimizations, existing graph processing systems [10, 15, 26, 28, 47] can naturally express iterative graph algorithms like PageRank and community detection, and scale them to graphs with billions of vertices and edges. But graph systems can hardly express neural networks (NNs) and lack key capabilities required by efficient DNN executions, such as the tensor abstraction, automatic differentiation and dataflow programming model.

We therefore advocate bridging deep learning systems and graph processing systems to enable a new framework for scalable GNN training. In this paper, we explore the design of a GNN processing framework on top of dataflow-based DL systems. We argue that by introducing the graph model to dataflow and recasting graph-specific optimizations as dataflow optimizations, we can enable the DL frameworks to support efficient and scalable DNN computation on graphs. To support this argument, we developed NeuGraph, an efficient GNN processing framework built on top of an existing dataflow engine.

NeuGraph combines the dataflow abstraction with the vertex-program abstraction in a new programming model called SAGA-NN (Scatter-ApplyEdge-Gather-ApplyVertex with Neural Networks). SAGA can be considered as a variant of graph-parallel abstraction (e.g., GAS [26]). Unlike a traditional system where user-defined functions (UDFs) express vertex programs, UDFs in SAGA-NN express NN computation on tensors as vertex or edge data, e.g., vertex or edge data. With the new programming model, NeuGraph allows users to express a GNN algorithm without worrying about the underlying system implementation (e.g., GPU memory management or scheduling). The graph-aware dataflow engine in NeuGraph judiciously partitions the graph data (vertex and edge data) into *chunks* (subgraphs), constructs the dataflow that operates at the chunk granularity, and schedules parallel executions of the dataflow on GPUs.

Naively adapting optimizations developed in the context of graph processing systems can lead to inefficient dataflow executions on DL frameworks. NeuGraph achieves high efficiency by introducing a range of optimizations both in the scheduling of parallel chunk processing, as well as the execution of core graph propagation procedures (i.e., Scatter-ApplyEdge-Gather stages) over the often-sparse graph structure. With fine-grained graph partitioning, NeuGraph achieves efficient *selective scheduling* and *pipeline scheduling* on top of the dataflow, to hide data movement between GPU and host when scaling a model out of the GPU core. To continue performance scaling, NeuGraph further adopts a new topology-aware scheduling strategy to efficiently distribute GNN models over modern multi-GPU systems. Finally, NeuGraph introduces computation-related optimizations for graph propagation, which is often hard to accelerate using GPUs.

We implemented NeuGraph on top of TensorFlow. We show that NeuGraph can support a variety of GNN algorithms on large graphs with millions of vertices and hundreds of millions of edges, as well as hundreds of feature dimensions over vertices, which existing DL frameworks cannot directly handle with GPUs. Compared on large graphs that TensorFlow can handle only with CPUs, NeuGraph achieves $16 \sim 47\times$ speedups. Even on small graphs that can fit into a GPU's memory, NeuGraph can still achieve a up to $5\times$ speedup over the state-of-art implementation on TensorFlow and a up to $19\times$ speedup over DGL [1]. Moreover, NeuGraph achieves nearly linear scalability over multiple GPUs.

As one of our key contributions, NeuGraph bridges two largely parallel threads of research, graph processing systems and dataflow-based DL frameworks, in the new GNN setting. NeuGraph significantly expands the capabilities of existing DL frameworks to support GNNs in the following key dimensions: programming model, graph partition and dataflow translation, graph propagation operations, and execution scheduling. We have also demonstrated, through extensive evaluation on real graphs with typical GNNs, significant benefits in scalability and efficiency by connecting graph processing and DL frameworks.

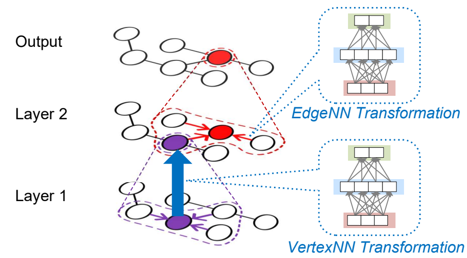

Figure 1: Feed-forward computation of a 2-layer GNN.

The rest of the paper is organized as follows. Section 2 introduces the SAGA-NN programming abstraction. Section 3 describes the optimizations in the NeuGraph system. Section 4 discusses the implementation and Section 5 presents our experimental results. We discuss related work in Section 6 and conclude in Section 7.

2 NeuGraph Programming Abstraction

In this section, we first reveal the essential structure of graph neural networks, and then propose our programming model that combines graph-parallel and dataflow abstractions.

2.1 Graph Neural Networks

Deep learning, in the form of deep neural networks, is a class of machine learning algorithms that use a cascade of multiple layers of nonlinear processing units for feature extraction and transformation. Each successive layer uses the output from the previous layer as input. Deep learning has been gaining popularity due to its success in areas such as speech, vision, and natural language processing. In these areas, the coordinates of the underlying data representation often have a regular grid structure, which is friendly to hardware accelerators (e.g., GPU) with massive SIMD-style parallelisms.

Graph neural networks are deep learning based methods that operate neural networks on graph data, and have been adopted for many applications due to convincing in terms of model accuracy. Recently, several surveys [5, 46, 52, 54] provided a thorough review of different graph neural network models as well as a systematic taxonomy of the applications. A majority of GNN models can be categorized into *graph convolutional networks* [7, 9, 13, 19, 23], *graph recursive networks* [25, 33], and *graph attention networks* [43, 51].

We discuss 3 representative categories of GNNs with 3 representative models: (1) GCN [23] is a graph convolutional network that generalizes the notion of the convolution operation, typically for image datasets, and applies it to an arbitrary graph (e.g., a knowledge graph). GCN has been widely used in real-world scenarios like recommendation [6, 49]. Initially, each vertex in the graph has a feature vector. First, each vertex collects its neighbor vertices' feature vectors along edges, and

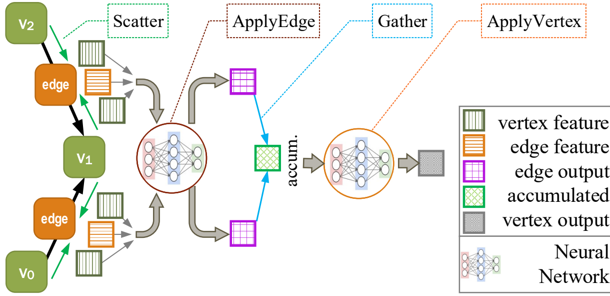

Figure 2: SAGA-NN stages for each layer of GNN.

sums the collected vectors (weighted by edge values). Then, a fully-connected NN is used to compute the vertex feature vector as the output. This is a layer of GCN. Stacking multiple GCN layers makes the vertex features representative enough for tasks. Taking the recommendation system as an example, a bipartite graph is constructed from the user-item ratings: There will be an edge with the rating as the edge value between the user vertex and the item vertex if a user rates an item. Then, the embeddings of both users and items can be learned by the GCN from the graph and the features of users and items. Finally, these embeddings are used to predict the missing user-item ratings to make a recommendation. (2) GG-NN [25] is a graph recursive network. It has an architecture similar to GCN, but uses different parameters for different edge types, as well as a Gated Recurrent Unit (GRU) in the NN to process accumulated features. (3) As a graph attention network, GAT [43] differs GCN mainly in that it computes an *attention* value for each edge during transferring vertex features.

In general, these GNN models share the same basic idea of collectively aggregating information following the graph structure. Specifically, each vertex or edge in the graph can be associated with a set of tensor data (normally a vector) as its feature or embedding. A GNN can consist of multiple layers, with an iterative propagation procedure conducted layer-by-layer over the same graph, as illustrated in Figure 1. At each layer, the vertex or edge features are transformed and propagated along edges, and then aggregated at the target vertices to produce new features for the next layer. Different from traditional graph algorithms (e.g., PageRank), the transformation on either vertices or edges can be arbitrary DNN computation. The GNN may also contain a label for each vertex, each edge, or the entire graph, for computing a loss function at the top layer. A feed-forward computation is then performed from the bottom layer to the top, with back-propagation conducted reversely.

Comparing with DNNs, the complexity due to graphs in GNNs creates a significant scalability challenge. First, real-world graphs, such as social networks or e-commerce networks, can easily have millions of nodes and edges. Second, vertices and edges in the graph are interconnected and need to be modeled as a whole neural network (i.e., a large, sparse neural network architecture defined according to a graph structure). This is particularly challenging on GPUs given the limited GPU memory capacity. Finally, unlike image, audio, or text that have clear grid structures, graph data are irregular, making it hard to conduct parallel GNN computation efficiently on GPUs.

2.2 A Running Example

We take the Gated Graph ConvNet (G-GCN) algorithm [7,29] as a concrete running example (see Example 2.1). G-GCN incorporates the gating mechanism into graph convolution. This model can be used to extract vertex features for community detection.

Example 2.1. *Let $\mathbf{h}_u^\ell$ denote the feature vector of a vertex u at layer ℓ, and W^ℓ, W_H^ℓ, and W_C^ℓ be the weight parameters to learn. G-GCN recursively defines the feature of a vertex u as follows:*

$$\mathbf{h}_u^{\ell+1} = ReLU\left(W^\ell \otimes \left(\sum_{v \to u} \eta_{vu} \odot \mathbf{h}_v^\ell\right)\right) \tag{1}$$

where $\otimes$ refers to matrix multiplication, $\odot$ refers to element-wise multiplication, and η_{vu} (for each edge $v \to u$) acts as edge gate,

$$\eta_{vu} = sigmoid\left(W_H^\ell \otimes \mathbf{h}_u^\ell + W_C^\ell \otimes \mathbf{h}_v^\ell\right) \tag{2}$$

where ReLU and sigmoid are nonlinear activation functions in neural networks.

G-GCN can be mapped to the pattern of computing a layer in Figure 1: Equation 2 represents the EdgeNN to compute the edge weight. $\sum_{v \to u} \eta_{vu} \odot \mathbf{h}_v^\ell$ in Equation 1 collects features from neighbors, and ReLU $(W^\ell \otimes \cdots)$ in Equation 1 is the VertexNN to process the accumulated features.

2.3 SAGA-NN Model

Based on the common pattern observed in GNN models, we propose SAGA-NN (Scatter-ApplyEdge-Gather-ApplyVertex with Neural Networks) as a new programming model for GNNs. It combines dataflow and vertex-program to express the recursive parallel computation at a layer of a GNN. SAGA-NN splits the feed-forward computation into four stages: *Scatter*, *ApplyEdge*, *Gather*, and *ApplyVertex*, as illustrated in Figure 2.

SAGA-NN provides two user-defined functions (UDFs) for ApplyEdge and ApplyVertex respectively, for users to declare neural network computations on edges and vertices. The **ApplyEdge** function defines the computation on each edge, which takes `edge` and `p` as input, where `edge` refers to the edge data and `p` contains the learnable parameters of the GNN model. Each `edge` is a tuple of tensors [`src`, `dest`, `data`] representing the associated data of the source and destination vertices connected by the edge, as well as the edge associated data (e.g., edge weight). This function can be used to apply a

```
G-GCN(vertex^ℓ):  // computing vertex^{ℓ+1}
  params p = [W_H^ℓ W_C^ℓ W^ℓ]
  // Passing data over edges
  edge^ℓ=Scatter(vertex^ℓ)
  // edge-parallel computation
  acc = ApplyEdge(edge^ℓ, p):
    η = sigmoid(p.W_H^ℓ ⊗ edge^ℓ.dest + p.W_C^ℓ ⊗ edge^ℓ.src)
    return η ⊙ edge^ℓ.src
  set Gather.accumulator = sum
  accum = Gather(acc)
  // compute new vertex data
  vertex^{ℓ+1} = ApplyVertex(vertex^ℓ, accum, p):
    return ReLU(p.W^ℓ ⊗ accum)
  return vertex^{ℓ+1}
```

Figure 3: Gated Graph ConvNet at layer ℓ in *SAGA-NN* model.

neural network model on edge and p, and outputs an intermediate tensor data associated with the edge. The **ApplyVertex** function defines the computation on a vertex, which takes as input a vertex tensor data vertex, the vertex aggregation accum, and learnable parameters p, and returns the new vertex data after applying a neural network model. The SAGA-NN abstraction builds on a dataflow framework, so users can symbolically define the dataflow graphs in UDFs by connecting mathematical operations (e.g., *add*, *tanh*, *sigmoid*, *matmul*) provided by the underlying framework.

The other two stages, **Scatter** and **Gather**, perform data propagation and prepare data collections to be fed to ApplyEdge and ApplyVertex as input. They are triggered and conducted by the system implicitly. We chose not to expose UDFs for Scatter and Gather, because these functions, if provided, are highly coupled with the propagation procedure, whose computations flow through the irregular graph structure and are difficult to express as dataflow that NeuGraph optimizes—users would have to implement the corresponding derivative functions of the UDFs, a serious burden. Following the same principle, NeuGraph also avoids exposing user-defined aggregation methods. It provides a set of default ones instead, including *sum*, *max* (e.g., *max-pooling* operator [18]), and concatenation, which can be chosen by setting **Gather**.accumulator.

NeuGraph models a GNN as a sequence of SAGA stages. The *Scatter* passes the vertex data vertex onto its adjacent edges to construct edge data edge, including both the source and destination vertex data. The subsequent *ApplyEdge* then invokes a parallel computation defined by the UDF on the edge data to produce an intermediate tensor value for each edge as its outputs. The *Gather* then propagates those outputs along the edges and aggregates them at the destination vertices through commutative and associative accumulate operations. Finally, the *ApplyVertex* executes the computation defined in UDF on all vertices to produce updated vertex data for the next layer. The procedure in Figure 1 fits in the SAGA-NN model: The *ApplyEdge* and *ApplyVertex* represent the EdgeNN and VertexNN, respectively; the *Scatter* and *Gather* perform the propagation along edges. This mapping indicates that the GNNs following the procedure in Figure 1 could be implemented with SAGA-NN model, hence presents the generality of SAGA-NN.

Figure 3 illustrates the description of G-GCN (at layer l) in the SAGA-NN model. Scatter gives each edge $v \to u$ with vertices data $[\mathbf{h}_v^\ell, \mathbf{h}_u^\ell]$, and ApplyEdge computes per-edge update $\mathtt{acc}_{vu} = \eta_{vu} \odot \mathbf{h}_v^\ell = \mathtt{sigmoid}\left(W_H^\ell \otimes \mathbf{h}_u^\ell + W_C^\ell \otimes \mathbf{h}_v^\ell\right) \odot \mathbf{h}_v^\ell$. Next, Gather performs $\mathtt{accum}_u = \sum_{v:v\to u} \mathtt{acc}_{vu}$, and ApplyVertex computes $\mathbf{h}_u^{\ell+1} = \mathtt{ReLU}\left(W^\ell \otimes \mathtt{accum}\right)$.

The dataflow abstraction makes it easy to express neural network architectures and leverage auto-differentiation. With the dataflow abstraction in SAGA-NN, NeuGraph enjoys the flexibility of executing operations on vertices or edges in batch for increasing efficiency. The vertex-program in SAGA-NN allows users to express computations naturally by thinking like a vertex, and models common patterns in GNNs as well-defined stages, thereby enabling optimizing in both graph computation and dataflow scheduling.

3 NeuGraph System

NeuGraph provides a combination of the dataflow and vertex-program abstractions as the user interface. Under this abstraction, NeuGraph proposes graph-aware optimizations for GNN processing to achieve efficiency and scalability.

At a high level, NeuGraph consists of: 1) a translation engine that translates GNN expressed by the SAGA-NN model into a dataflow graph at chunk-granularity to enable GNN computation over large graphs in GPUs; 2) a streaming scheduler that minimizes data movement across the host and GPU memory and maximizes its overlap with computation. The scheduler also needs to be topology-aware for use of multiple GPUs; 3) a graph propagation engine for deep learning that employs a set of fast propagation kernels and fuses operations to remove redundant memory copies; 4) a dataflow execution runtime. NeuGraph requires no modifications to existing dataflow-based DL frameworks, offering a general method to combine graph and NN computation within existing DL frameworks. In this section, we focus on the first three design points as they are main contributions of NeuGraph.

3.1 Graph-Aware Dataflow Translation

Just as with DNNs, efficient use of GPUs is critical to the performance of GNNs, especially for large graphs. However, existing DL frameworks cannot handle large graphs directly on a GPU because graph data cannot fit into GPU memory.

To achieve scalability beyond the physical limitation of GPU memory, NeuGraph introduces graph-specific partitioning on top of the dataflow abstraction. Note that both vertex feature data and graph structure data can be large. NeuGraph thus applies a 2D graph partitioning: As illustrated in Figure 4, it slices vertex data into P equally-sized disjoint vertex chunks, and tiles the adjacency matrix (representing edges)

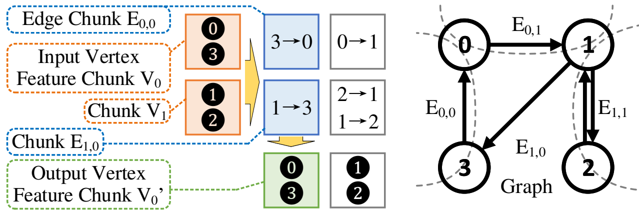

Figure 4: 2D Partitioning of a graph, here $P = 2$.

into $P \times P$ edge chunks. Edges in an edge chunk E_{ij} connect vertices in two vertex chunks V_i and V_j , respectively. By splitting graph data into chunks, NeuGraph can process edge chunks one by one, with only the source and destination vertex chunks needed for the edge chunk being processed. To achieve this, NeuGraph generates a dataflow graph with operators on data chunks, each of which fits in GPU memory, as illustrated in Figure 5.

For the forward computation at a layer, NeuGraph translates a dataflow subgraph for each destination vertex interval (e.g., a column in Figure 4): The Scatter operator inputs a specific edge chunk, i.e., the edge chunk in the i-th row and j-th column, and the associated i-th and j-th vertex chunks, and outputs an edge data chunk containing tuples in the form of [`src`, `dest`, `data`]. Each edge data chunk can be processed by operators specified in the ApplyEdge UDF to produce another edge data chunk with the result data `acc` (as in Figure 3). The operators at the Gather stage accumulate each edge's data based on its destination vertex to generate the corresponding vertex accumulation data chunk. After the processing of all the edge chunks for a destination vertex interval is done, the operators specified in the ApplyVertex UDF process the vertex accumulation chunks and output new vertex data chunks for the next layer.

For back-propagation, as the UDFs for ApplyEdge and ApplyVertex are expressed as dataflow computations over regular tensors, NeuGraph can leverage auto-differentiation provided by the DL frameworks. Additionally, NeuGraph further provides the *backward*-Gather operator to distribute the accumulation gradient returned by the *backward*-ApplyVertex stage across edges, and the *backward*-Scatter operator to accumulate all the partial gradients returned by the *backward*-ApplyEdge stage for a vertex in the previous layer.

Note that it is not necessary to enforce strict global barriers between stages in the SAGA-NN model. NeuGraph can flexibly schedule the chunk-based operators simply based on the data dependencies described in the dataflow graph. The system maintains the working set of operators within GPU memory by employing explicit device-to-host (D2H) and host-to-device (H2D) operators to conduct data swapping between the host and GPU memory. Also, during a training process, some intermediate feature data (e.g., the result of matrix multiplication in the ApplyEdge stage as in Figure 5) relevant to vertex chunks or edge chunks will be used in back-

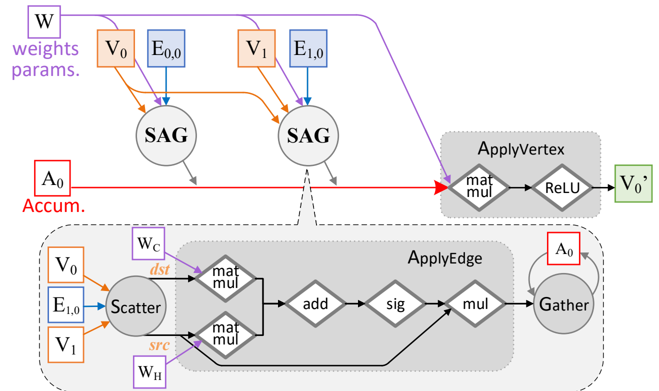

Figure 5: Chunk-based dataflow graph for a destination interval V_0 at a G-GCN layer. The backward dataflow graph and the swapping of intermediate results to host memory for backward are omitted for a clear visualization.

propagation. To save GPU memory, they are swapped out to host memory during the feed-forward computation and swapped back in during the back-propagation.

Discussion. The source vertex determines the row of the edge chunk and the destination vertex determines the column of the edge chunk. For every GNN layer, edge processing can be done in either a row-oriented or a column-oriented manner, based on the update pattern. For the forward computation, data flows from the source vertex to the destination vertex. With this pattern, row-oriented processing loses the opportunity of reusing the accumulated vertex data chunks, whose total size can be larger than the size of GPU memory. NeuGraph therefore adopts a column-oriented approach as illustrated in Figure 5, where it continuously executes operators in the Scatter-ApplyEdge-Gather (SAG) stages for V_0 and V_1 to produce A_0, which is subsequentially consumed by operators in the ApplyVertex stage. The destination vertex chunk and the corresponding accumulated vertex data chunk (e.g., A_0 in the figure) can be reused in GPU memory when NeuGraph processes edge chunks in the same column, so that data movement can be minimized.

By contrast, for the backward computation, a vertex gradient is propagated from the destination vertex to the source vertex. In this case, row-oriented processing is preferred. The vertex gradient data chunk can be reused from GPU memory when NeuGraph processes edge chunks in the same row. In the rest of this section, we focus on the discussion of the forward-pass execution of chunk-based dataflow, the backward-pass execution is done in a similar manner.

Besides the chunk processing order, determining the number of vertex chunks P is also important. Assuming edge chunks are accessed in the column-oriented manner in the forward pass, each edge chunk is accessed once, and each source vertex chunk is loaded P times. Thus, a smaller P is preferred to reduce I/O. NeuGraph selects P as the minimum integer to fit each chunk in GPU memory. Given a chunk-size choice

and the scheduling plan of the dataflow graph, NeuGraph computes the GPU memory requirement of the execution. If this requirement is beyond GPU's capacity, NeuGraph shrinks the chunk size by increasing P.

3.2 Streaming Processing out of GPU Core

For each layer, NeuGraph can scale GNN computation beyond the GPU core by processing the dataflow subgraph for a column of edge chunks (illustrated in Figure 5) in a column-by-column way. As we show later in the experiments (Table 2), the CPU-GPU data transfer has a significant impact on the overall performance, especially for sparse graphs. NeuGraph introduces a streaming scheduler with two innovations: selective scheduling that reduces data transfer on unnecessary vertices, and pipeline scheduling that maximizes the overlap between computation and data transfer.

Selective Scheduling. Unlike traditional graph algorithms (e.g., PageRank), the vertex data in GNNs can be much larger due to their high-dimensional feature vectors. To reduce the transfer cost of vertex chunks, NeuGraph exploits sparsity inherent in real-world graphs: To compute a specific edge chunk, not all vertices in the corresponding vertex chunks will be used due to the sparse graph structure (e.g., some vertices have no edges in this chunk). So, when processing an edge chunk E, NeuGraph applies a filter in CPU to select the useful vertices from E's source vertex chunk, and only transfers the selected vertex data into GPU.

We notice that a random graph partition (e.g., a permutation of the vertices) makes selective scheduling inefficient. Therefore, NeuGraph adopts a locality-aware graph partitioning algorithm (e.g., Kernighan-Lin algorithm) to condense as many edges that are connected to the same vertex as possible into one chunk (e.g., a diagonal one in the matrix of edge chunks). In this way, better access locality can be achieved for vertex data and hence more potential in selective scheduling.

Interestingly, when the majority of the vertices are useful (e.g., in a dense subgraph), directly transferring the full vertex chunk can be faster as it does not require additional memory copies for filtering. So for an edge chunk, we dynamically determine whether to apply the filtering in CPU based on the fraction θ of useful vertices. Given the host memory copy throughput T_{copy} on the CPU side, the filtering cost is $\frac{\theta}{T_{copy}}$. Let T_{trans} be the bulk transfer throughput from CPU to GPU. For a vertex chunk, if $\theta < \frac{T_{copy}}{T_{copy}+T_{trans}}$, NeuGraph chooses to apply filtering as it benefits the overall data transfer efficiency. Otherwise, NeuGraph skips the filtering and directly loads the entire vertex chunk into GPU.

Pipeline Scheduling. Besides the filtering optimization, NeuGraph further overlaps data transfer and computation through a pipeline scheduling to hide the transfer latency. Instead of streaming one edge chunk each time into GPU, NeuGraph can stream multiple chunks into the GPU device memory.

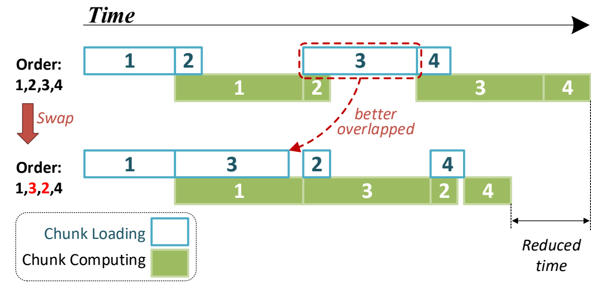

Figure 6: The swapping heuristic for a case of streaming two edge sub-chunks ($k = 2$).

In this case, a smaller chunk size can increase overlapping potential, which seems opposite to the requirement of a large chunk size to reduce vertex access I/O.

To deal with this dilemma, we apply the second-level partitioning over the edge grid to improve streaming efficiency without increasing the total I/O amount. Specifically, we horizontally partition an edge chunk and its associated source vertex chunk into k ($k \geq 2$) fine-grained sub-chunks, which enables parallel streaming processing of k sub-chunks. While performing computation on an edge sub-chunk, NeuGraph can simultaneously stream in other edge sub-chunks and their associated source vertex sub-chunks.

Recall that different edge sub-chunks could have distinct data transfer and computation cost due to different sparsity levels. NeuGraph carefully makes a scheduling plan for streaming heterogeneous sub-chunks. Given a column of edge sub-chunks, the system first generates the initial schedule plan by assigning a random order for processing. Next, it repeatedly swaps the order of a pair sub-chunks such that a better schedule plan with less time can be obtained. This process stops when it converges or reaches maximum iterations.

Then, NeuGraph exploits the cyclic pattern inherent in GNNs: Both the computation time and data transfer time of each sub-chunk can be profiled in the first several iterations and used in refining the scheduling plan for processing in the following iterations. Specifically, the system simulates the execution of the current schedule order based on the profiled execution information of individual sub-chunks. As illustrated in Figure 6, by examining the overlapping result in this simulation, the system finds a sub-chunk whose data transfer time is much shorter than the computation time, and within the same chunk, another sub-chunk is an opposite case. By swapping the order of these two heterogeneous edge sub-chunks, the system enables a better balance between the computation and data transfer.

3.3 Parallel Multi-GPU Processing

To improve scalability further, we can parallelize the training by partitioning the chunk-based dataflow (model parallelism) over multi-GPUs. Our dataflow graph is easy to parallelize due to its parallel nature, where GPUs can be assigned

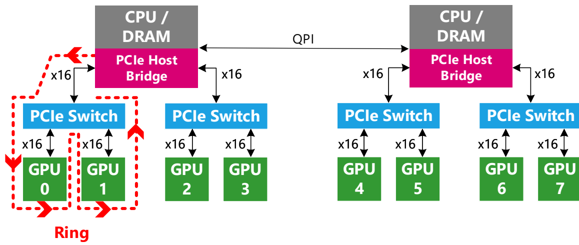

Figure 7: Multi-GPU architecture

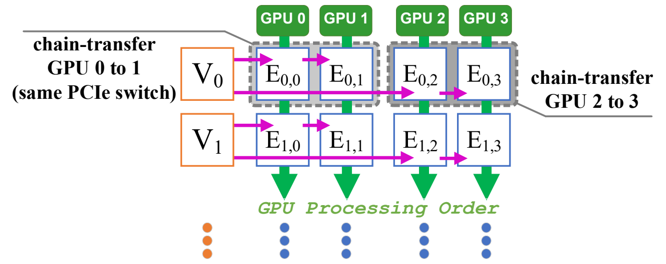

Figure 8: NeuGraph transfers vertex chunks along the chain.

dataflow subgraphs for different columns for cooperative processing.

However, with recent advances in hardware, modern multi-GPU systems introduce complex inter-connections among GPUs and across GPUs and CPUs, which presents new challenges to parallelize a dataflow graph. To illustrate this issue, Figure 7 shows the topology of a typical 8-GPU server, where GPUs are connected to CPU/DRAM (host memory) via a multi-level PCIe interface hierarchy. The upper level links that are shared by multiple communication paths can easily become a bottleneck. For example, GPUs 0 and 1 can only reach half of their peak bandwidth when reading edge/vertex data from host memory simultaneously, as limited by the link from the left-most PCIe switch to DRAM. Connecting the host to an accelerator like GPU via PCIe is the most common channel at present. We start from a common case, which may apply to other architectures.

To maximize the parallelism degree on multiple GPUs and prevent shared inter-connection links from becoming a bottleneck, NeuGraph employs a chain-based streaming scheduling scheme. Note that a vertex chunk is required by all the GPUs processing different columns of edge chunks. So, our idea is to let a GPU forward the vertex chunk (once loaded to its memory) to its neighbor GPU under the same PCIe switch, which can eliminate the bandwidth contention on the upper-level shared inter-connection link. NeuGraph therefore *logically* considers the GPUs under the same PCIe switch as a large *virtual GPU* and enables them to share data in a chain order as illustrated by the red dotted line in Figure 7.

In chain-based scheduling, each GPU streams one column of edge chunks and all vertex chunks to compute a destination vertex chunk. Note that the vertex data chunk for the destination interval can be initially loaded and cached in GPU memory. For simplicity, we assume that only the source vertex data is required for the computation. In particular, a GPU needs to take the following two operations: 1) loading an edge chunk from the host memory, and a data chunk from the host memory or from the device memory of its previous GPU in the chain, and 2) performing local computations. NeuGraph employs a coordinated scheduling to better overlap the two operations. As illustrated in Figure 8, we group GPUs into multiple virtual GPUs according to the inter-connection topology; e.g., GPUs 0 and 1 constitute one virtual GPU; GPUs 2 and 3 constitute another. Initially, GPUs 0 and 2 load vertex data chunk V_0 from the host memory. After loading, GPUs 0 and 2 start computing over chunk V_0, and also begin loading chunk V_1 from the host memory. Meanwhile, GPUs 1 and 3 start fetching chunk V_0 from GPUs 0 and 2, respectively. Next, GPUs 1 and 3 drop the data chunk V_0 after processing it locally as the chunk has already been consumed by all virtual GPUs. The whole process continues in such a pipelining fashion until all vertex data chunks have been loaded and processed.

In Section 3.2, we introduce the selective scheduling that can help reduce data movement between the host and GPU device memory. However, to apply selective scheduling in chain-based streaming, we need to select the useful vertex data required by the corresponding edge chunks in a virtual GPU; e.g., $E_{0,0}$ and $E_{0,1}$ in Figure 8. In a multi-GPU execution, we use the threshold $\theta = \frac{T_{copy}}{T_{copy}+T_{trans}}$ to determine whether or not to apply selective scheduling, where T_{copy} and T_{trans} are aggregative memory-copy and aggregative data-transfer throughput on both the CPU and GPU sides, respectively. Thus, given limited CPU resources shared by a large number of GPUs, NeuGraph applies selective scheduling on more sparse chunks with a larger θ.

3.4 Graph Propagation Engine

Besides ensuring high streaming efficiency, NeuGraph also introduces several important optimizations to reduce computation time in the execution of the Scatter-ApplyEdge-Gather (SAG) stages, which are not easily amenable to efficient GPU acceleration due to the often sparse edge structure of a graph.

First, NeuGraph incorporates a *dataflow graph optimization* to remove redundant computations in the SAG stage by considering the semantics of the SAGA-NN model. Consider the matrix multiplication operations in the ApplyEdge stage in Figure 5. These operations are conducted on vertex data that are scattered to a subset of edges and the learnable parameters W_C or W_H that are shared by all edges. Because a vertex may have multiple edges to which that the vertex data can be scattered, such a multiplication for a vertex can be conducted multiple times, leading to redundancies. NeuGraph therefore moves the computations that are related only to the source or destination vertices from the ApplyEdge stage of the current layer to the ApplyVertex stage of the previous layer.

Second, to support the Scatter and Gather stages efficient-

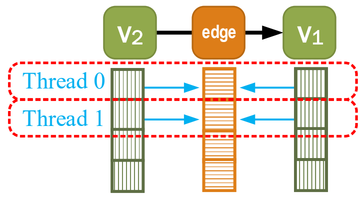

Figure 9: Parallelism along the dimension of feature vector.

ly on GPUs, NeuGraph provides *scatter/gather operation kernels* optimized for GPU executions. The design carefully considers the data structure layout to allow the kernel to better leverage the massive parallelism provided by GPU. In most GNNs, the data of each vertex is a dense vector rather than a scalar. We therefore exploit parallelism in per-vertex data access that fits better to GPU with SIMD architectures. Figure 9 illustrates the scatter kernel passing the vertex data, from both the source and the destination, onto an edge to form the edge data. We assign a thread block to process incoming edges with the same destination vertex. For vertices with a large in-degree, we divide the incoming edges into consecutive subgroups to be processed by multiple thread blocks. In a thread block, threads copy the source/destination vertex data into the edge data in parallel along the dimension of the vertex feature vector, ensuring good coalesced memory access. The gather kernel reduces the partial accumulation vectors `acc` from a set of edges that end at the same destination vertex `accum` into an accumulated vector. We employ a similar principle of exploiting parallelism for the scatter operator. A block of threads first cooperatively enumerate an edge group, accumulate the features of every edge into a temporary vector in GPU register, and finally write the result back to the corresponding destination vertex.

Finally, NeuGraph supports *Scatter-ApplyEdge-Gather (SAG) stage fusion* as another kernel optimization on execution of the propagation procedures. We find that, on most GNN applications, especially after the dataflow graph optimization, the ApplyEdge function only performs element-wise operations, such as +, -, ×, ÷, *tanh*, *sigmoid*, *ReLU*. In this case, we can optimize SAG stages by allowing the vertex/edge data to be directly updated with element-wise operations in GPU registers and then written back to their destination vertices in a single pass, without any extra cost of creating intermediate edge data in the GPU global memory. To achieve that, NeuGraph automatically detects such a case and replaces the whole SAG stages using a specially customized operation called *Fused-Gather*. This operation processes each edge chunk as follows: It first loads the inputs of Scatter; i.e., source vertices and edge data, into GPU registers, and then uses GPU threads to perform in-place updates directly on elements in registers based on user-defined element-wise operations in ApplyEdge. It finally produces the vector `acc`, which is summed onto the corresponding vertex accumulation vector `accum` with the user-defined Gather.accumulator.

4 Implementation

We implemented NeuGraph on top of TensorFlow (v1.7) with about 5,000 lines of C++ code and 3,000 lines of Python code. NeuGraph uses TensorFlow as the dataflow execution runtime, and additionally provides three specialized modules for GNN applications: (1) an engine translating a vertex-centric symbolic program into dataflow; (2) a streaming scheduler implementing the core scheduling logic; (3) a graph propagation engine with optimized kernels for the proposed Gather/Scatter operators. We discuss several important aspects of our implementation next.

Dataflow Translation. NeuGraph provides a base class `GNNlayer` in addition to the conventional operators; users can easily define each layer of a GNN algorithm by providing a symbolic vertex-program. Then NeuGraph divides vertices and edges into chunks, and generates a chunk-based dataflow graph by appropriately connecting GNN-layers with Gather and Scatter according to the user program. NeuGraph preprocesses the graph using the min-cut partition of METIS [21], and organizes each edge chunk in the compressed sparse column (CSC) format for the feed-forward computation, while using the compressed sparse row (CSR) format for back-propagation computation.

Streaming Scheduler. To improve performance, the streaming scheduler first analyzes the received dataflow graph and incorporates the optimizations described in Section 3.2. NeuGraph implements a filtering operator running on the CPU side, and determines whether to apply it before the H2D operator of each vertex chunk based on the percentage of relevant vertices (i.e., selectivity). Also, NeuGraph profiles the transfer/computation information of edge chunks and revises the dataflow graph based on the refined scheduling plan discussed in Section 3.2.

Multi-GPU Execution. Different devices in NeuGraph need to communicate with one another for coordination. In existing DL frameworks, an operator is usually dispatched to a specific device, with its input and output tensors on the same device. The multi-GPU communication in NeuGraph is executed by a series of concurrent operators from different devices. In each operator, after memory is allocated on a device for communication, it will exchange addresses with other devices for upcoming device-to-device data transfer. Parameters in different GPUs also need synchronization in each iteration. This is implemented by all-reduce.

Graph Propagation Engine. The graph engine contains graph-specific operator kernels. NeuGraph has optimized implementations for the proposed operators (*gather*, *scatter*, *fused-gather*). Specifically, *scatter* is a map operator that turns vertex data into edge data, and *gather* is a reduce operator that accumulates edge data for each vertex. Also, NeuGraph implements *fused-gather* operator described in Section 3.4 to enable one-pass edge computation when the edge computa-

tion is element-wise.

5 Evaluation

In this section, we demonstrate the efficiency and scalability of NeuGraph by evaluating it on multiple GNNs and datasets.

GNN Models. NeuGraph can support many different types of graph-based neural networks [7, 8, 13, 18, 19, 23, 25, 29, 41]. We use the following three representative GNN models.

Communication neural network (*CommNet*) [41] is a model with which cooperating agents learn to communicate among themselves before taking actions. This network can be used to solve multiple learning communication tasks like traffic control. In CommNet, there is no computation on the edge, so the ApplyEdge stage is simply a passthrough (see Figure 10).

Graph convolutional network (*GCN*) [19, 23] applies convolutional operations to an arbitrary graph, and has been used in many semi-supervised or unsupervised graph clustering problems, such as entity classification in a knowledge graph. GCN (see Figure 11) has a computation (without neural networks) on the edge for weighted neighbor activation.

Gated graph sequence neural network (*GG-NN*) [25] applies recurrent neural networks (RNNs) to graph data and is used for NLP tasks. GG-NN performs NN-based edge computation (see Figure 12), with different parameters for different edge types. It also performs a heavy Gated Recurrent Unit (GRU) computation on vertices.

We chose these GNNs as the benchmark algorithms in the evaluation not only because of their different computation patterns, but also for the purpose of comparing with TensorFlow: the propagation stage in these cases can be treated as a sparse matrix multiplication and therefore expressible in TensorFlow. Certain algorithms such as G-GCN in our running example cannot be directly supported using the TensorFlow multiplication operators.

Datasets. Table 1 lists the real-world datasets used for evaluation, including the PubMed citation network (pubmed) [38], the BlogCatalog social network (blog) [42], the Reddit online discussion forum (reddit-small, reddit-full) [18], the Wikipedia data dump (enwiki) [3], and the Amazon data dump

Dataset	vertex#	edge#	feature	label	avg. degree

enwiki	3.6M	276.1M	300	12	77
amazon	8.6M	231.6M	96	22	27

Table 1: Datasets (K: thousand, M: million).

(amazon) [30]. The column *feature* in Table 1 reports the sizes of the vertex feature vectors, and the *label* column contains the numbers of label classes. As different GNN tasks share the same GNN architecture and differ only on the output layer, we tested the performance of our system on the task of vertex classification (e.g., classifying academic papers into different subjects in the PubMed citation dataset, which contains sparse bag-of-words feature vectors for each document and a list of citation links between documents) and set the number of layers $\ell = 2$ in experiments.

Environment and Baselines. We evaluated NeuGraph on a multi-GPU server, which is equipped with dual 2.6 GHz Intel Xeon E5-2690v4 processors (28 cores in total), 512 GB memory, and 8 NVIDIA Tesla P100 GPUs. The installed operating system is Ubuntu 16.04, using the libraries CUDA 9.0 and cuDNN 7.0.

We compared NeuGraph (NG) with TensorFlow v1.7 (TF) [4], GraphSAGE [18] (TensorFlow backend) and DGL v0.1.3 (PyTorch v1.0 [2] backend) [1]. GraphSAGE is a modeling framework for inductive representation learning on graphs and is widely used to generate low-dimensional vector representations for vertices. DGL is a Python package that serves as an interface between any existing tensor libraries and data expressed as graphs, thereby making it easy to implement GNNs.

We took the existing open-source implementations [1, 18, 23] [i]. We also implemented a basic extension, integrating TensorFlow with the chunk-based dataflow translation (TF-SAGA). The TF-SAGA can support larger GNN models, but

[i] For fair comparison, we took minor optimizations (e.g., replacing inefficient *feed_dict* with preloaded data tensors in memory to avoid redundant memory copies from python runtime to TensorFlow runtime).

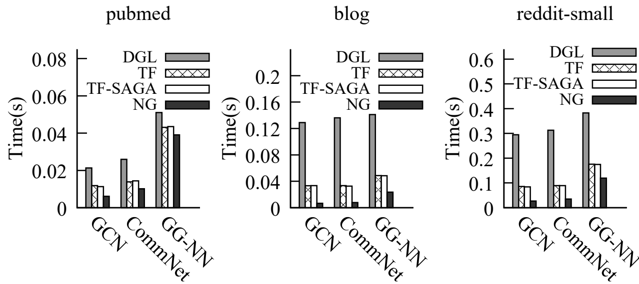

Figure 13: End-to-end performance comparison among DGL, TensorFlow (TF), TF-SAGA and NeuGraph (NG) on small datasets. GraphSAGE runs OOM.

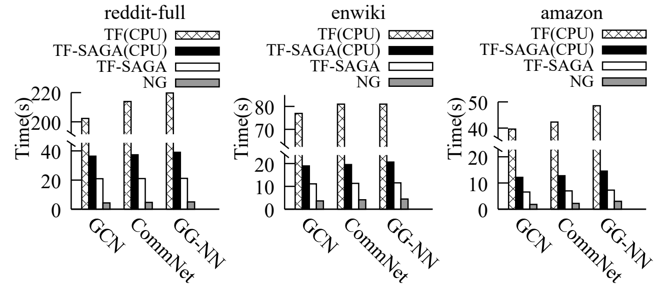

Figure 14: NeuGraph end-to-end performance comparisons on different large datasets. TensorFlow uses CPU-only mode as OOM occurs on GPU. TF-SAGA (CPU) is configured to run on CPU only, whereas TF-SAGA is GPU-enabled.

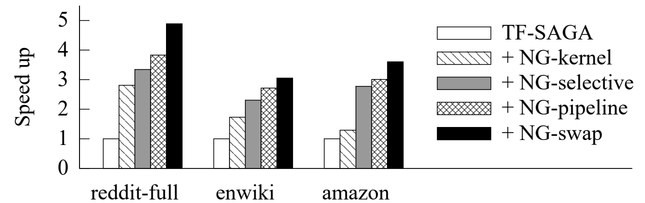

Figure 15: NeuGraph performance improvement breakdown of end-to-end on GCN model over different large datasets. The speedup is measured over the TF-SAGA (speedup = 1).

with all other optimizations described in Section 3 disabled. The comparison with TF-SAGA can reveal how much each optimization contributes to the overall performance.

We focused on metrics for system performance; e.g., time to scan one epoch of data. NeuGraph produces the same numerical results as TensorFlow and DGL, and hence has the same per-epoch convergence. All performance numbers in our experiments are calculated by computing the averages over 10 epochs.

5.1 Performance on a Single GPU

First, we evaluated NeuGraph by comparing it with the state-of-the-art frameworks TensorFlow, DGL, and GraphSAGE. As TensorFlow and DGL can only process graphs that fit in the device memory of a single GPU, we conducted these experiments on the first three small graphs in Table 1.

Figure 13 shows the end-to-end comparison results among different models and datasets. Overall, NeuGraph achieves on average a 2.5× speedup (up to 5.0×) compared with TensorFlow, and on average an 8.1× speedup (up to 19.2×) compared with DGL. We found that the properties of both graphs and models impact performance. NeuGraph achieves the largest speedup with GCN on the blog dataset. This is mainly because the high average vertex degree of the blog graph leads to greater graph propagation (i.e., SAG stages) costs, which NeuGraph can optimize more effectively.

Due to lack of graph support on TensorFlow, GraphSAGE implements GNNs through sampling neighbors and padding to convert irregular graphs to regular tensors. It leads to out of memory even on small graphs using the same evaluation setup (i.e., processing the whole graph with the sampler disabled). Moreover, it still runs about 5× slower than NeuGraph for GCN on pubmed even if the sampler is set to sample exactly one neighbor per vertex.

5.2 Scaling-up on a Single GPU

Since TensorFlow failed to process large graphs on GPU due to the out of memory (OOM) exceptions, we ran TensorFlow only on CPU. Accordingly, besides running TF-SAGA on GPU, we also ran it on CPU. DGL also experienced OOM exceptions when directly processing large graphs on GPU, therefore requiring additional graph sampling to alleviate memory pressure at the expense of model capacity and convergence guarantee. By contrast, NeuGraph can scale GNNs beyond GPU memory without loss on the model scale. Note that NeuGraph can also support the same graph sampling approaches as DGL. In this case, the results in Section 5.1 have already demonstrated that NeuGraph significantly outperforms DGL for small model scales on a single GPU. Hence, we do not compare them again here but focus instead on model scales that cannot fit in GPU memory.

End-to-end Comparison. Figure 14 shows the end-to-end comparison results among different models and datasets. Under the same CPU-only mode, TF-SAGA can achieve on average a 4.3× speedup over TensorFlow. That is because TF-SAGA on CPU contains finer grained chunk-level operators, which can be processed concurrently on the CPUs and make better use of the CPU resources. Moreover, NeuGraph achieves 16 $\sim$ 47× speedups compared to TensorFlow-CPU, which is the current solution for large graphs.

Compared with TF-SAGA on GPU, NeuGraph could provide even better performance with its additional optimizations. Figure 14 shows that NeuGraph achieves 2.4 $\sim$ 4.9× speedups over the GPU-enabled TF-SAGA on different models and datasets. Similar to those on small graphs, the speedups on large graphs depend on the graph structure. The average speedup across all models on the reddit-full graph with the highest vertex degree is 4.6× over the GPU-enabled

Time (s)	TF-SAGA			NeuGraph		
Dataset	IO	Comp.	Runtime	IO	Comp.	Runtime
reddit-full	7.67	13.27	20.94	3.84	2.46	4.28
enwiki	5.93	5.13	11.07	3.24	1.77	3.63
amazon	5.11	1.44	6.55	1.56	1.18	1.82

Table 2: GCN on large graphs: TF-SAGA vs. NeuGraph. NeuGraph overlaps I/O and computation time.

TF-SAGA, as opposed to 2.8× on the enwiki graph with moderate vertex degree and 3.1× for the amazon graph with the lowest vertex degree.

Breakdown Comparison. Both streaming and kernel optimizations can play important roles in achieving good overall performance after scaling GNN out of GPU core. To understand how much each optimization contributes to the overall performance, we disabled the graph propagation kernel optimization (NG-kernel) described in Section 3.4, as well as selective scheduling (NG-selective) and pipeline scheduling (NG-pipeline and NG-swap) described in Section 3.2. It effectively turns NeuGraph into the TF-SAGA. We then turned on these optimizations one by one and measured the resulting speedups they brought. To better understand the improvement, we also profiled the GCN execution on both TF-SAGA and NeuGraph with nvprof [32].

Figure 15 shows the improvement of each optimization over TF-SAGA for GCN. The results under other models are similar. We found that the graph kernel optimization works better on dense graphs (like reddit-full), whereas selective scheduling is more effective on sparse graphs (like amazon). For example, the graph kernel optimization can achieve a 2.8× speedup on the reddit-full graph, but only a 1.2× speedup on the amazon graph. However, selective scheduling can still bring an additional 2.6× speedup on the amazon graph. That is because a high-density graph leads to a higher computation cost on SAG stage, which is the target of the graph kernel optimization, whereas a low-density graph with selective scheduling can filter more unnecessary vertices. The figure also shows that our swap-based pipeline scheduling can bring significant improvement by effectively overlapping data transfer and computation, especially on the reddit-full graph where data chunks highly heterogeneous.

Table 2 shows the time of the host-device data transfer (I/O) and computation (Comp.) for TF-SAGA and NeuGraph. Compared to TF-SAGA, the optimizations in NeuGraph reduce both I/O and computation significantly and achieve good overlapping with pipeline scheduling.

As described in Section 3.1, the processing order of chunks may also impact performance. To examine the exact effect of processing order, we ran NeuGraph with the streaming processing optimizations described in Section 3.2 disabled. Figure 16 shows that, for the forward-backward pass, the column-row-oriented strategy is 1.4 ∼ 1.7× faster than the row-column-oriented one.

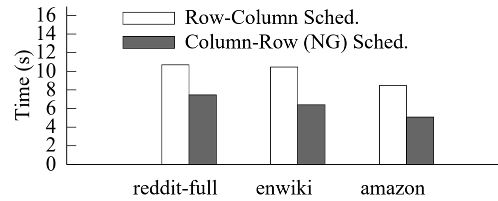

Figure 16: NeuGraph with row/column-oriented chunk scheduling: GCN on large graphs.

5.3 Scaling-out on Multiple GPUs

As described in Section 3.3, we can easily extend TF-SAGA from one GPU to multiple GPUs by allowing each GPU to process a dataflow subgraph, without considering the bandwidth contention. We compared it to NeuGraph with the chain-based scheduling disabled or enabled, in order to understand the performance of our topology-aware scheduling.

Figure 17 shows the results of the GCN model on three large graphs; the results of other GNN models are similar. NeuGraph significantly outperforms the multi-GPU TF-SAGA with the chain-based scheduling enabled or disabled. The average speedup of NeuGraph is 3.6×/2.7× over multi-GPU TF-SAGA with varying numbers of GPUs.

The benefit of the chain-based scheduling is highlighted in the comparison between enabling and disabling this topology-aware scheduling. For example, when scaling from 1 GPU to 2 GPUs, the average speedup of the disabled case even decreases, whereas the enabled one can improve from 3.8× to 5.5× over the single GPU TF-SAGA. This is mainly because, without the chain-based scheduling, two GPUs within the same PCIe switch need to load input edge/vertex data through a shared link concurrently, which can easily become the bottleneck. By contrast, the chain-based mechanism allows the second GPU to load vertex data directly from the first one, reducing the pressure on the shared PCIe link.

We observed that the chain-based scheduling achieves nearly linear speedup on the reddit-full and enwiki graphs, but exhibits less optimal results on the relatively sparse amazon graph. The reason is that NeuGraph tends to apply selective scheduling on relatively sparse graphs. However, given the limited CPU resources shared by an increasing number of GPUs, NeuGraph has to decrease usage of the CPU for per-GPU filtering. Also, the current TensorFlow implementation cannot support NUMA-aware tensor allocation well, which imposes a performance impact on the CPU filtering, especially on sparse graphs like the amazon where the filtering is often used.

6 Related Work

The growing scale and importance of graph data has driven the development of numerous specialized graph processing systems, including Pregel [28], GraphLab [26], Power-

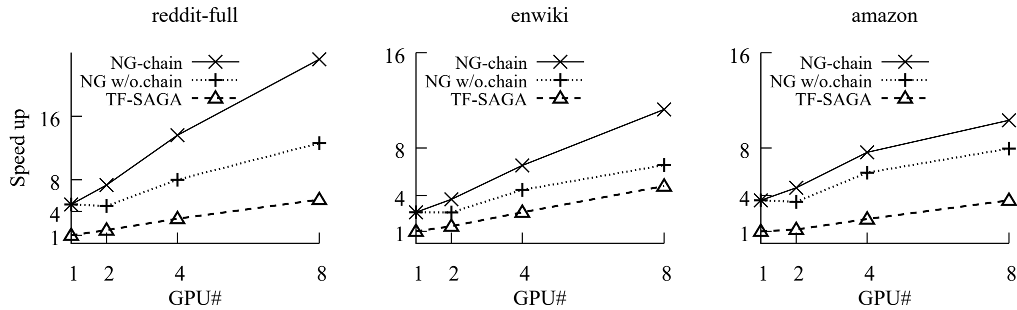

Figure 17: Scaling out GCN with NeuGraph on large graphs (w/o refers to without). The speedup is measured over the single GPU TF-SAGA (speedup = 1). Chain-base scheduling works on multi-GPU, resulting in the same 1 GPU point with it enabled/disabled.

Graph [15] and GraphX [16]. There are many other following works with optimizations on different aspects including graph layout, sequential data access, and secondary storage (e.g., GraphChi [24], Grace [34], FlashGraph [53], XStream [36] and Chaos [35]), distributed shared memory and RDMA (e.g., Grappa [31] and GraM [45]), NUMA-awareness, scheduling, and graph partitioning (e.g., PowerLyra [10] and Bi-Graph [11]). All these works focus on CPU based computation.

There is another series of system works that focus on exploiting GPU for large graph processing. GraphReduce [39] can process out-of-memory graphs on a single GPU and optimize memory coalescing by using two different formats. GTS [22] can also process out-of-memory graphs on multiple GPUs by fully exploiting the asynchronous GPU streams. Garaph [27] exploits edge-centric parallelism and dynamic scheduling to achieve the best performance on the CPU/GPU hybrid platform. Lux [20] investigates the placement of graph data over the CPU memory hierarchy on multiple nodes. All these graph processing systems are driven by basic graph benchmarks such as PageRank and shortest path, but lack the support for neural network computation, such as the tensor abstraction and auto-differentiation. To be compatible with existing DL libraries, NeuGraph chooses to recast the graph-specific optimizations as dataflow optimizations on top of DL frameworks (e.g., TensorFlow). This does not limit the capability of expressing a general DL computation, and allows users to benefit from both graph and DL optimizations.

TuX^2 [47] aims to bridge the gap between graph and traditional machine learning computation, while NeuGraph targets neural network computation on graphs, which connects graph processing and deep learning supported by the dataflow frameworks like TensorFlow [4], PyTorch [2], MXNet [12], and CNTK [50], etc. Most recently, Cavs [48] introduces the vertex-centric programming model into dynamic neural networks to address the problems that each sample has a unique dataflow graph and the training is iterative on batches of samples. NeuGraph addresses different problems and challenges regarding scalability and performance in supporting GNN models on large real-world graphs. DGL [1] wraps DL systems with a message-passing programming interface for GNNs, while NeuGraph addresses the system challenges (e.g., scalability and efficiency) by translating graph-aware computation on dataflow and recasting graph optimizations.

From the modeling perspective, there are several modeling works (e.g., GraphSAGE [18], MPNN [14], and GN-Block [5]) that attempt to unify existing GNNs into a single modeling framework. These generalized modeling frameworks can be implemented easily and executed efficiently at scale by NeuGraph. Recently developed graph sampling approaches (e.g., DGL [1], GraphSAGE [18], PinSAGE [49], and FastGCN [9]) alleviate scalability challenges of GNNs at the expense of model capacity and convergence guarantee. These approaches are orthogonal to and compatible with our work. NeuGraph frees users from choosing appropriate sample sizes and worrying about GPU memory limitations.

7 Conclusion and Future Work

GNN is an emerging computation model that arises naturally from the need to apply neural network models on graphs. Supporting efficient and scalable parallel computation for GNN training is demanding due to its inherent complexity. Given this new requirement, we advocate unifying graph computation and deep learning systems for GNNs. NeuGraph represents a critical step in this direction by showing not only the feasibility, but also the potential of such unification. We accomplish this by defining a new, flexible SAGA-NN model to express GNN algorithms by fusing graph-related optimizations into the management of data partitioning, scheduling and parallelism in deep learning frameworks.

One potential future direction is to scale GNN further to multiple servers, by leveraging the work in distributed graph systems [40, 44, 45].

Abstract

Many important graph algorithms are based on the breadth first search (BFS) approach, which builds itself on recursive vertex traversal. We classify algorithms that share this characteristic into what we call a BFS-like algorithm. In this work, we first analyze and study the I/O request patterns of BFS-like algorithms executed on disk-based graph engines. Our analysis exposes two shortcomings in executing BFS-like algorithms. First, we find that the use of the cache is ineffective. To make use of the cache more effectively, we propose an in-memory static cache, which we call BFS-Aware Static Cache or Basc, for short. Basc is static as its contents, which are edge lists of vertices that are pre-selected before algorithm execution, do not change throughout the execution of the algorithm. Second, we find that the state-of-the-art ordering method for graphs on disks is ineffective with BFS-like algorithms. Thus, based on an I/O cost model that estimates the performance based on the ordering of graphs, we develop an efficient graph ordering called *Neighborhood Ordering* or *Norder*. We provide extensive evaluations of Basc and Norder on two well-known graph engines using five real-world graphs including Twitter that has 1.9 billion edges. Our experimental results show that Basc and Norder, collectively have substantial performance impact.

1 Introduction

Algorithms such as breadth first search (BFS) [26], shortest paths (SP) [15], all pairs shortest path (APSP) [35], diameter computation (DIAM) [1], finding weakly connected components (WCC) [15], and betweenness centrality (BC) [4] are popular graph algorithms widely used in many domains including bioinformatics, social science, and economics. These algorithms share a commonality that they start from a given set of vertices and then recursively traverse their neighboring vertices. Together, we call algorithms with these characteristics BFS-like algorithms.

In BFS-like algorithms, only a subset of vertices are active at any given time. Furthermore, which of the vertices are to be activated among all the vertices is difficult to predict. Due to this reason, the locality of memory access in BFS-like algorithms is generally worse than that of other graph algorithms such as PageRank, where all vertices are active and regularly accessed [27].

Due to their poor locality of memory access, it is difficult to optimize the performance of BFS-like algorithms, particularly on disk-based graph engines that store the input graph on external storage such as SSDs. Although several optimization techniques have been suggested for disk-based graph systems, their impact on BFS-like algorithms is limited. Existing optimizations such as overlapping I/O and CPU operations [12,19] or merging small I/O requests into a single larger request [40] do not consider the characteristics of BFS-like algorithms hence, have substantial room for improvement [2,27].

The focus of this paper is on BFS-like algorithms, and our contribution can be summarized as follows. First, we present a thorough analysis of BFS-like algorithms running on disk-based graph engines. We observe and report characteristics not previously revealed such as the fact that the number of I/O requests for each vertex is similar among the vertices, regardless of their degrees or relative positions in graphs.

Second, based on our observations, we propose a new form of a cache, which we call Basc (an acronym for BFS-Aware Static Cache). Basc has three distinct characteristics as a cache: 1) it is separate space set aside from the typical page cache[1], 2) it holds edge lists of

[*]Participated in this research as graduate students at UNIST
[†]Corresponding author and principal investigator

[1]Without loss of generality, we will use the term ‘page cache’ to refer to typical caches that are deployed to improve I/O performance in graph engines or within operating systems.

certain pre-selected vertices, and 3) it is static, that is, the contents of the cache do not change throughout the execution of the algorithm. We show that by judiciously making use of Basc, performance of BFS-like algorithms can be substantially improved.

Finally, our observation shows that the performance of BFS-like algorithms is highly sensitive to the layout of the graphs. Based on this observation, we devise a simple model that estimates the I/O costs of BFS-like algorithms based on the layout of the graph on disk. We experimentally validate that the model is fairly accurate in estimating performance. Moreover, guided by the cost model, we develop a simple, yet efficient graph ordering scheme that we call *Neighborhood Ordering* or *Norder* for short, which substantially improves the performance of BFS-like algorithms, even while the time to compute the ordering takes substantially less than existing ordering schemes.

The methodologies that we propose are for disk-based graph systems adopting the vertex-centric computation model. As this model is widely adopted in large-scale graph analytics, our work is applicable to many existing graph processing systems [12, 21, 28, 34, 40]. For fair comparison with previous schemes we implement our methods in FlashGraph and Graphene, two recent graph engines [21, 40]. Note that all discussions hereafter are done in the context of disk-based graph systems.

The rest of the paper is organized as follows. Section 2 describes our analysis of BFS-like algorithms running on disk-based graph systems. Section 3 introduces Basc, our BFS-aware static cache, as well as the vertex selection algorithm that we propose. In Section 4, we develop our I/O cost model based on graph orderings, then propose an optimized graph ordering that we call Neighborhood Ordering. We evaluate our proposed techniques in Section 5 and discuss related work in Section 6. Finally, we end with conclusions in Section 7.

2 Characteristics of BFS-like Algorithms

In this section, we first discuss the basic workings of disk-based graph engines and BFS-like algorithms. We focus on semi-external graph engines that store vertex attributes in memory, as main memory of commodity computers today is typically large enough to hold vertex attributes in their entirety. Then, through Sections 2.2∼2.4, we discuss the characteristics of BFS-like algorithms that we observe in our analysis.

2.1 Basics of Disk-based Graph Engines

In vertex-centric computations, the entire set or a subset of vertices are activated as they receive messages in each iteration. Then the edge lists of the activated vertices are accessed when necessary to send messages to the neighboring vertices [25]. As they are accessed, these edge lists are retrieved from disk to memory in page granularity, whose size typically ranges from 1KB to a few MBs [7, 12, 34, 40]. These pages are then stored in the page cache, which is either controlled by the graph engine or the file system [7, 12, 19, 40].

The edge lists are generally sorted and indexed by the owner vertex ID and stored sequentially on disk. Some graph engines apply optimized partitioning schemes such as hybrid-cut partitioning, instead of the more general vertex-cut or edge-cut partitioning, to reduce I/O [6, 39, 43]. Also, when I/O requests are issued to retrieve the pages, requests for adjacent pages may be merged for higher throughput [21, 40].

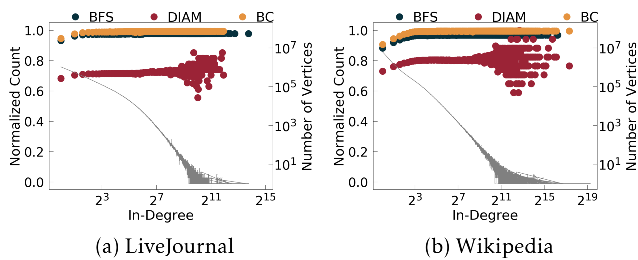
Performance of graph algorithms on disk-based graph engines depends largely on the efficiency of accessing the input graph [7, 19]. In disk-based engines, both the vertex attributes and input graphs are stored on disk that are randomly accessed by the graph algorithms. However, the overhead of accessing the input graph is generally higher than that of accessing vertex attributes as a large portion of vertex attributes are typically cached in memory. In particular, as mentioned previously, semi-external graph engines store all the vertex attributes in main memory.

Graph algorithms written in the vertex-centric model run iteratively, with a varying subset of vertices activated per iteration depending on the algorithm type. In BFS and BFS-like algorithms, only the "frontier" vertices are activated in each iteration. Thus, only the edge lists of these vertices are accessed in a random manner.

As the edge lists of activated vertices are accessed, pages containing these edges are loaded into the page cache. As page units are large, edges of unactivated vertices may also be in the retrieved page and hence, needlessly loaded to memory. To achieve high cache utilization, and consequently, high performance, we want the page cache to contain edges of as many activated vertices as possible. This requires the vertices in the input graph to be ordered such that the edges of activated vertices in the same iteration are stored in proximity.

2.2 Uniform Edge List Reference

Retrieving edge lists on disk has a significant effect on performance [19, 43]. To alleviate this burden, it would be desirable to cache the frequently requested edge lists of the vertices. To this end, we observe the edge list request pattern in representative BFS-like algorithms. Common logic tells us that for a vertex with a large edge list, that is, a large number of neighbor vertices, more requests will be targeted to that vertex and its edge list. However, interestingly and contrary to this



(a) LiveJournal (b) Wikipedia

Figure 1: Distribution of edge list reference counts: reference counts for vertices of the same in-degree are averaged and plotted relative to the vertex with the largest reference count for each algorithm. The gray line shows the number of vertices corresponding to each in-degree.

logic, we find that there are no substantial differences in the number of edge list accesses among the vertices, even for vertices that have widely varying degrees.

Figure 1, which are representative results, shows the distributions of the number of edge list requests for the BFS, DIAM, and BC algorithms with the LiveJournal and Wikipedia dataset [2]. The graphs show the average number of requests for the vertices with the same in-degrees, that is, having the same number of in-bound edges, normalized to the maximum average request count.

Initially, our conjecture was that the number of requests for a vertex (and thus, to its edge list) would be roughly proportional to its in-degree because messages (hence requests) are sent over edges in a vertex-centric model. However, Figure 1 shows that there is only a small difference in the number of edge requests between high and low in-degree vertices. The average counts are nearly constant and the variance (not shown) are low.

The reason for such uniform reference count is that in the vertex computation model, the edge list of a vertex is accessed only once per iteration as multiple requests to a vertex are merged into a single request if they are issued in the same iteration. Thus, for a high in-degree vertex whose neighbor vertices are densely connected to each other in real-world graphs [10, 20], the majority of requests to the vertex are sent as a single request. Moreover, in some BFS-like algorithms such as BFS, each vertex is processed only once in the entire running of the algorithm, with the exception of unreachable vertices. So the edge lists are also requested only once for each vertex. Thus, the number of edge list references is independent of the in-degrees and close to a constant.

The observation that there is no substantial difference in the number of references to the edge list tells us that strategies such as simply storing frequently accessed edge lists in memory is not an effective approach for improving performance. We take this observation to

[2]The full dataset descriptions are provided in Table 1.

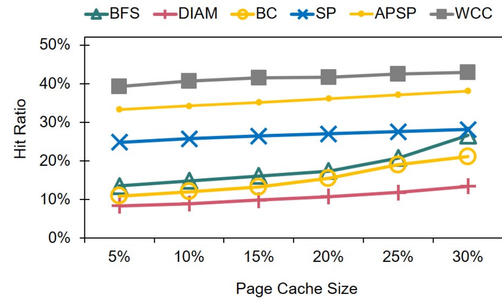


Figure 2: Page cache hit ratios for BFS-like algorithms. The page cache size is varied from 5% to 30% of the input graph size.

propose a different method for caching the edge lists of vertices, which we discuss in Section 3.

2.3 Ineffectiveness of the Page Cache

Locality per I/O access is known to be poor for BFS-like algorithms running on disk-based systems. This is because pages are brought into the page cache by active vertices and these active vertices are determined in a rather random manner at each iteration [23, 27]. To quantify this, we run experiments using the BFS-like algorithms provided in FlashGraph and observe the hit ratio of the page cache. Figure 2 depicts the results for page cache sizes ranging from 5% to 30% of the input graph run on the Twitter dataset. We see that all algorithms show low hit ratios. WCC, which shows the highest hit ratio, operates differently as the algorithm starts out with all the vertices, and as the component ID of each vertex converges, the number of active vertices decreases[3]. However, a small number of vertices linger around in later iterations, and those vertices fit in the page cache resulting in the higher hit ratio. More importantly, though, we find that for all algorithms, increasing the page cache has little impact on the hit ratio, improving only by 5 to 10% even with a six factor increase in page cache size.

Our conclusion here is that the page cache in disk-based graph engines does not play a major role in regards to performance for BFS-like algorithms. Simply increasing the page cache cannot be a solution, and there needs to be a different approach to resolve this ineffectiveness, for which Basc in Section 3 is proposed.

2.4 Impact of Graph Layout on Disk

Both SSDs and HDDs show faster performance with sequential reads than random reads [31]. Thus, how a graph is stored and accessed by the running algorithm has substantial impact on performance. In this section,

[3]Section 5 describes in detail how the algorithms are implemented.

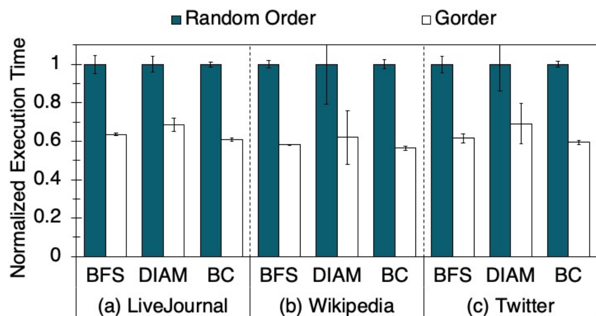

Figure 3: Performance of BFS, DIAM, and BC for Gorder normalized to random ordering for three datasets.

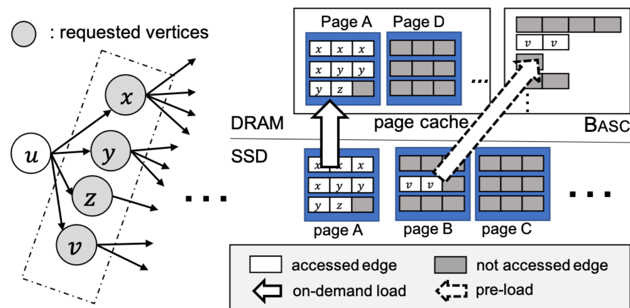

Figure 4: BASC and page cache interaction.

we perform experiments to help us understand the performance impact of graph layouts.

For the experiments, we restructure a graph in two different orderings and measure the performance of the graph algorithms. In the first, we randomly assign the vertex IDs, and in the second, we use Gorder [38], which was proposed to improve the locality of access to vertices and their edge lists for main memory graph systems. In particular, Gorder computes the ordering of vertices and their edge lists by optimizing its locality score, which is defined based on whether densely connected vertices are ordered closely within a given distance. Then, the graph is stored in CSR (Compressed Sparse Row) format, where the edge lists of vertices are ordered by their vertex IDs and stored sequentially.

Figure 3 compares the performance of three BFS-like algorithms with Gorder and random ordering on three datasets. We can see that the algorithms perform consistently better with Gorder than with random ordering. Clearly, ordering strongly affects the performance of BFS-like algorithms. In Section 4, we propose a novel ordering scheme that benefits BFS-like algorithms.

3 BFS-Aware Static Cache

In Section 2.3, we discussed how the page cache is ineffective and that simply growing its size does not help BFS-like algorithms. In this section, we propose a different caching scheme to help improve the performance of BFS-like algorithms.

Aside from the typical cache that a graph engine or the system software manages, we propose to have a separate static cache, which we call the BFS-Aware Static Cache or BASC. BASC is loaded with the edge lists of some pre-selected vertices before the algorithm starts. Hence, there is overhead involved with the initial selection process, which we describe later in this section. Also, unlike a typical page cache that dynamically stores and replaces edge lists as they are accessed, BASC is static, that is, the cache contents do not change throughout its execution and no replacement is involved.

As the edge list of only some selected vertices are statically stored in BASC, it is important to identify the vertices that are likely to improve performance so that they can be stored in BASC. Note that naively storing the edge lists of frequently accessed vertices does not suffice. This is because, as was discussed in Section 2.2 and shown with Figure 1, the number of accesses to the edge lists of each vertex is similar for all vertices. Thus, our approach is to consider the interaction between BASC and the page cache, which we elaborate below.

The key optimization point with BASC is memory utilization. While BASC is separate cache space, we do not make use of extra space, but rather take space from the page cache, that is, reduce the page cache size, and use this space for BASC. Thus, when selecting the vertices for BASC, our goal is to utilize the space for BASC much more efficiently than when used as a page cache. For example, consider a case in Figure 4, where u's neighbor vertices (i.e., their edge lists) are about to be retrieved. (Note that in real graphs, an edge list can be composed of in-bound and/or out-bound edges. Here, we show an illustration using out-bound edges.) Notice that while the edge lists of u's neighbor vertices x, y, and z are stored in page A, the edge list of vertex v is stored in page B. Thus, while a cached page A would be well used, page B, on the other, would be retrieved only to access the edge list of v with the rest of the page being brought in for naught. In such a case, v would be pre-selected and it's edge list stored in BASC, so that the entire page containing the data (page B, in this case) need not be retrieved to the page cache during execution. Selecting vertices for BASC in this manner to improve overall memory utilization is formally discussed in the next section.

3.1 The Vertex Pre-Selection Problem

We formulate the problem of pre-selecting vertices for BASC as a problem of minimizing the overall weighted I/O requests for accessing edge lists. To define the problem, we first make the following assumptions:

Assumption 1 The neighbor vertices of each vertex are accessed simultaneously. Thus, their edge lists are retrieved at the same time.

Assumption 2 The number of edge list requests for each vertex is equivalent among all the vertices.

Assumption 3 Each edge (u,v) probabilistically issues a request to access the edge list of target vertex v. Due to Assumption 2, the probability of issuing the request is inversely proportional to v's in-degree.

We now define the problem of selecting vertices for BASC as a problem of minimizing the overall weighted requests:

$$\underset{C}{\text{minimize}}\ F(C)=\sum_{v\in V}\sum_{\substack{(v,u_1)\in E\\u_1\notin C}}\left(\frac{1}{r(u_1)d_i(u_1)}\frac{1}{\sum_{\substack{(v,u_2)\in E\\u_2\in P(u_1)\\u_2\notin C}} d_o(u_2)}\right)$$

$$\text{subject to } \sum_{v\in C} deg(v)\le M,\ \sum_{v\in C} deg(v)\ge M-\epsilon, \text{ where}$$

- ϵ is a small positive number
- C represents the set of cached vertices
- E is the set of all edges in the given graph
- $P(u)$ is the set of vertices whose edge lists are stored in the same page as vertex u
- $r(u)$ is the expected number of requests to the page where u is stored, which we assume to be proportional to the number of vertices whose edge lists are stored in the page
- $d_i(u)$, $d_o(u)$ are the in- and out-degree of vertex u, respectively
- M represents the size of available memory for BASC.

Function F represents the penalty accrued by misuse of pages in the cache. If the cache is fully utilized, there is no penalty. F increases as the cache is more and more underutilized. Hence, our goal is to minimized F.

More concretely, F iterates over all the edges in a graph; for each vertex, we take every edge $((v,u_1)\in E)$ that is not in the cache $(u_1\notin C)$ and adds up the penalty, which is represented by the terms in parenthesis. Within the left term in the parenthesis, $1/d_i(u_1)$ represents the probability of issuing the request for a given edge. If the page is already in the page cache, we do not need to issue the request (realized by $u_1\notin C$). To consider only those pages not in the cache, we include the other term $1/r(u_1)$, as we assume that the probability of the page holding u_1 to be in the cache is proportional to the number of expected requests to the page. Thus, the left term in the parenthesis represents the probability of issuing a request over the edge (v,u_1) for u_1 not in the cache. The right term in the parenthesis represents the actual penalty incurred, which is inversely proportional to the utilization of the page. Page utilization is computed as the summation of $d_o(u_2)$ because under Assumption 1, the neighbor vertices of each vertex are accessed simultaneously. The right term, $(1/\sum d_o(u_2))$, is minimized for (v,u_1) if all the other neighbor vertices (u_2) of v is stored in the same page as u_1 and they tightly fit in a single page.

Our intent here is to minimize the overall *weighted*, that is, penalized, requests. If we were to simply minimize the number of requests, we just need to cache the vertices in descending order of their degrees. In the evaluation, we demonstrate that our approach results in better performance than simply caching the vertices in degree order.

The above optimization problem is an integer programming problem. As the objective function $F(C)$ is nonlinear and non-convex, the problem is NP-hard [13]. Thus, a fast algorithm that provides an optimal solution does not exist. We propose a heuristic algorithm to solve this problem in the next section.

Algorithm 1: Greedy Vertex Selection (GVS) for BASC

```
   Input: G = (V,E), M: BASC size, K: iteration number
   Output: A set of selected vertices C
1  Function SelectVertices (G=(V,E), K, M )
2      C = ∅,   m = 0
3      for k := 1 to K do
4          for v ∈ V do
5              T[v] = 0
6          for v ∈ V do
7              for u1 ∈ neighbor(v) \ C do
8                  t = 0
9                  for u2 ∈ neighbor(v) ∩ P(u1) \C do
10                     t ← t + deg_o(u2)
11                 T[u1] ← T[u1] + 1/r(u1) · 1/t · 1/deg_i(u1)
12         while T ≠ ∅ do
13             u ← n ∈ T with minimum T[n]/deg_o(n)
14             if m + deg_o(u) ≥ (k/K)M then
15                 break;
16             C ← C ∪ {u},   m ← m + deg_o(u)
17     return C
```

3.2 Vertex Selection for BASC

We now present a heuristic algorithm for selecting vertices for BASC. Our algorithm, called Greedy Vertex Selection (GVS), takes a greedy approach based on the profits per cost for the vertex. In particular, a vertex is selected to be cached if the overhead, that is, the penalty, of the request for a vertex is high, where the penalty calculations are based on $F(C)$ described in Section 3.1.

Algorithm 1 shows the overall procedure of GVS. It takes as input G, the input graph, M, the memory size available for BASC, and K, the number of iterations, and

at each iteration selects vertices for M/K amount of memory. The outer-most Σ in $F(C)$ is covered by lines 6–11 and the next Σ by the `for` loop in line 7. The `for` loop in line 9 represents the Σ in the denominator of the second term within the parenthesis. Finally, line 11 represents the calculations for the two terms in the parenthesis for $F(C)$. Instead of summing up the penalties, GVS attributes the computed penalty to target vertices of individual edges – $T[u_1]$ in line 11. After each iteration, the penalty of each vertex is normalized by its degree (line 13). GVS selects the vertices with the highest normalized penalty whose degrees amount to $1/K$ of Basc and puts them in Basc. This is repeated for K iterations to completely fill Basc.

As K becomes larger, we select smaller number of vertices at each iteration and more frequently compute the changes in I/O penalty as the result of the selection. Thus, larger K gives more fine-grained and accurate vertex selection, but incurs more computational overhead.

The time complexity of GVS is $O(K(|E|+|V|))$ as the computation of the page utilizations in lines 10–11 can be calculated once and re-used per each vertex v, and the loop in lines 12–16 can be implemented using selection algorithms for finding the k'th smallest number.

We can further optimize the algorithm by computing the page utilization only for those vertices that are affected by the selection in the previous iteration. The vertices that require re-computation are those that are stored in the same pages as the selected vertices and are in neighbor relations. Let us now consider the complexity of GVS with this optimization. The number of selected vertices in an iteration is $O(M/K)$, if the selected ones have the same degree. The number of vertices for re-computation is proportional to the number of disk pages that the selected vertices are stored in. In one extreme, all the selected vertices may be in a same disk page, while in the other extreme, all may be in separate pages. If the layout of the graph is carefully ordered to improve locality, the selected vertices in an iteration will tend to be grouped and stored in a small number of pages. Thus, we derive the complexity assuming that the number of pages is bounded by the square root of the selected vertices, which is in between the two extremes. Then, the cost for the re-computation in lines 6 through 11 is $O(\sqrt{M/K})$. Furthermore, the sorting and selection of the M/K vertices in lines 12 through 16 can be done incrementally using a heap data structure, thus its complexity is $O(M/K \cdot log(|V|))$. Thus, the complexity of GVS is $O(|E|+|V|+\sqrt{K \cdot M}+M \cdot log(|V|))$, where the first two terms are for the first iteration and the rest are for the remaining $K-1$ iterations. In Section 5, we experimentally show that our complexity analysis for GVS is reasonable and that GVS time is roughly proportional to $\sqrt{K}$ and M.

4 Bringing New Order

In Section 2.4, we showed how ordering affected the performance of BFS-like algorithms and presented the need for effective graph layouts. In this section, we present an ordering scheme that we call Neighborhood Ordering (Norder, for short) that is tailored to BFS-like algorithms. Before so doing, we first present the I/O cost model that forms the basis for the development of Norder.

4.1 Modeling I/O Cost

In all BFS-like algorithms, the vertices that are activated in a particular iteration are the neighbor vertices of the frontiers of the previous iteration. How these activated vertices are ordered on disk substantially affects I/O performance. If these vertices could be stored together, the number of I/O requests could be reduced, leading to improved performance.

From this intuition, we empirically derive the following cost model for BFS-like algorithms, where cost is the edge list access cost, which we want to minimize:

$$Cost = \sum_{v \in V} deg(v) \cdot \sigma^2(nbr(v)) \qquad (1)$$

where $deg(v)$ is the in-degree of vertex v and $\sigma^2(nbr(v))$ is the variance of v's neighbor vertex IDs, assuming CSR format. The first term, $deg(v)$, which implies that cost increases with higher in-degree, that is, with more neighbors, comes from empirical and algorithmic analysis. Consider a vertex with high in-degree. Such a vertex is likely to be accessed in an early iteration of BFS traversal. Thus, it is also likely that the majority of its neighbor vertices have not yet been traversed, which, in turn, incurs access to new edge lists, and thus, increases I/O cost. In contrast, a vertex with low in-degree is likely to be traversed in a later iteration. At this point of traversal, it is also likely that the majority of its neighbors would have already been traversed and thus, not incur any more I/O cost. Thus, we conclude that I/O cost is proportional to the degree of the vertex. The second term, $\sigma^2(nbr(v))$ is the overhead of I/O based on the neighbors' vertex ID variance. That is, neighbors whose vertex IDs show large variance are likely to be scattered across the disk, in contrast to those whose IDs are close together. Neighbors widely scattered along the disk will naturally incur more I/Os to have them retrieved.

To assess the model's accuracy, we compare the costs estimated by the model and the actual execution times for three BFS-like algorithms with the datasets YT, FL, and LJ (which we describe in detail in Section 5). For each algorithm and dataset, we generate 20 graph orderings that yield different I/O costs. This is done by, first, applying three orderings – PageRank-sorted, Gorder, and the original ordering, and then, incrementally and partially shuffling the vertex IDs of each ordering.

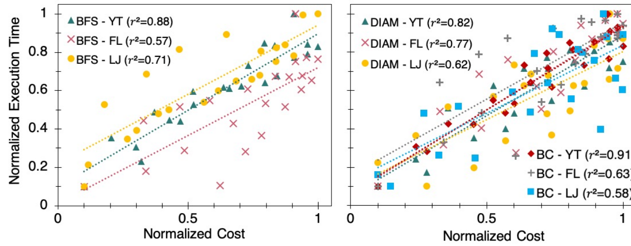

Figure 5: Regression of I/O cost model for three BFS-like algorithms with three datasets YT, FL, and LJ.

Figure 5 shows the results, where each data point represents one of the 20 graph orderings with its position determined by the cost of the model (x-axis) and the execution time (y-axis), both normalized to the maximum value on each axis. The lines are the results of applying linear regression on the data points, with the r^2 values of each dataset shown in parentheses. We see that our cost model results in reasonably high r^2 values, meaning that the estimation is quite accurate.

4.2 Neighborhood Ordering

Based on the cost model in the previous section, we propose a simple, yet effective graph ordering that we call *Neighborhood Ordering* or Norder. The key component of Norder is to simply assign consecutive IDs to the neighbors of all vertices, in particular, to the neighbors of high in-degree vertices. This simple strategy has the effect of decreasing the variance of the neighbor vertex IDs of high in-degree vertices resulting in increased locality, thus minimizing the overall cost of Equation 1.

To reorder a graph with Norder, we first arrange the vertices in descending order of their in-degrees. Then, starting from the vertex with the highest in-degree going downward, we perform a bounded breadth first search and assign a vertex ID in the traversed order. The depth bound for the traversal is set to two as we empirically found it to be effective for overall performance. Depth beyond two showed minimal performance gains, but incurred high overhead for ordering.

This simple ordering scheme is inexpensive to compute compared to other schemes such as Gorder, yet effective for disk-based graph engines. For example, it takes less than five minutes to compute Norder for the Twitter graph with 1.9 billion edges, while Gorder takes more than three hours. We quantify this and other performance issues in the next section.

5 Evaluation

We evaluate the effect of Basc and Norder with six BFS-like algorithms – breadth first search (BFS), measuring diameter of graph (DIAM), betweenness centrality (BC), shortest paths (SP), all-pair shortest paths (APSP), and weakly connected components (WCC). These algorithms represent, to the best of our knowledge, all the BFS-like algorithms in the field, except for Influence Maximization (IM). IM, however, is simply a repetitive execution of BFS, hence omitted from our evaluation [16].

BFS and SP are written as described in Pregel [25]. DIAM runs BFS multiple times, first from a random vertex and then from the vertices with the maximum distances in previous runs. For APSP, we sample 128 source vertices and compute the distances from those sources using a modified SP that computes the distances from a group of source vertices, the same as it is written in Graphene [21]. BC implements the algorithm proposed by Brandes [4]. It runs SP from each source vertex and counts the number of paths passed for each vertex. This is repeated for all the source vertices. As computation is intense, an approximate approach is taken by computing the centrality scores with 128 randomly sampled source vertices [5]. WCC is implemented in the typical manner of propagating component IDs for each vertex and then computing the minimum IDs.

Table 1: Datasets used in evaluation.

Graph	V	E	Graph	V	E
Youtube (YT)	3.2M	9.4M	LiveJournal (LJ)	4.8M	68M
Flickr (FL)	2.3M	33M	Twitter (TW)	53M	1.9B
Wikipedia (WK)	18M	172M			

The experiments are conducted with five real-world networks that are publicly available from KONECT [36] and are shown in Table 1. The datasets include one large network, Twitter (TW) and two relatively small graphs, Youtube (YT) and Flickr (FL), that are used to understand the scalability of our techniques.

We implement and evaluate our optimizations mainly on FlashGraph, a semi-external graph engine optimized for SSDs. We choose FlashGraph because 1) it is a representative semi-external graph engine, 2) it is recently developed thus, most known I/O optimizations are provided, and 3) it is actively maintained and core graph algorithms are already implemented in the system. Of the six algorithms, SP and APSP are our own implementations that we added, while the other four are those provided by FlashGraph. Additionally, we test our optimizations on Graphene [21], an SSD-based graph engine optimized with fine-grained I/O management. Details of these experiments are discussed in Section 5.4.

For all experiments, we run the algorithms with eight computation threads and a separate single I/O thread. We run the experiments ten times and report the average execution times as well as the standard deviation. All the experiments are performed on a machine with Intel Xeon E5-2683 v4 having 128GB physical memory running Ubuntu 16.04. Of the 128GB memory the system is configured to use only a portion of the memory (maximum 10GB) for caching. The actual cache size

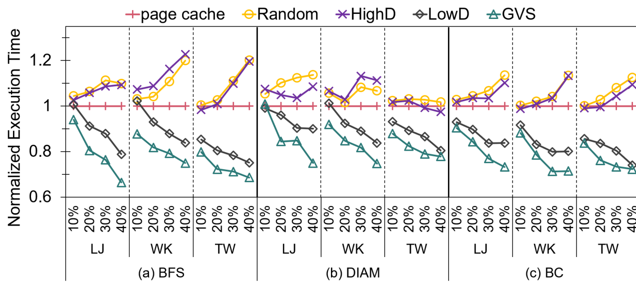

Figure 6: Execution times of graph algorithms on SSD with Basc using different vertex selection schemes normalized to the page cache only case. We vary the cache size to be 10% to 40% of the input graph size.

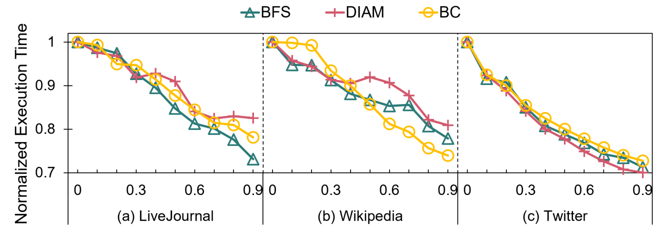

Figure 7: Execution times with varying Basc and page cache size ratios normalized to the page cache only case. The x-axis represents the Basc usage portion.

used varies for the algorithm and dataset, hence, for each experiment, we specify the cache size relative to the input graph size. Note that our goal is to show the effectiveness of our techniques on disk-based graph engines. Hence, we intentionally control memory to exercise the disks. The memory used is controlled by fixing the memory size that each part of the graph system uses and monitoring the total amount of memory used.

An Intel 400GB SSD connected via the SATA 6.0Gb/s interface is used as external storage as this is a common setting. We also run the same experiments on a typical HDD setting, but do not present the results in the interest of space and as the results do not deviate much from the results for the SSD. For each experiment, only a single disk is used. Unless otherwise stated, we set the page size to be 8KB, which is the typical access unit for NAND flash-based SSDs [8]. We use the page cache implemented in the graph system and hence, no OS kernel modification is involved. We completely clear the page cache for each experiment, and the OS page cache is turned off by setting the *O_DIRECT* flag for I/O operations so as to remove the system effect.

Note that, unless otherwise mentioned, we present results only for three datasets, LJ, WK, and TW for the BFS, DIAM, and BC algorithms only. This is done in the interest of space and as the results for the other datasets and algorithms show similar trend. However, we present statistical numbers for all algorithms and datasets and, where there are unique points of interest, we explicitly elaborate on those points separately.

5.1 Evaluation of Basc

In this section, we evaluate Basc and the Greedy Vertex Selection (GVS) algorithm in various settings. In evaluating Basc, we compare the 'page cache plus Basc' setting with the 'page cache only' setting, where both settings use the same amount of memory. To compare with GVS, we test three other selection schemes for Basc: selecting vertices with high degrees (HighD), selecting vertices with low degrees (LowD), and selecting vertices randomly (Rand), of which the last is used as the baseline. For GVS, we set the total number of iterations (K in Algorithm 1) to be 1,000 for YT, FL, LJ, WK, and 200 for TW. (Even though we do not show results for YT and FL, the settings for all experiments are presented for reproducibility.) As was previously discussed, with large K values, a smaller number of vertices are selected per iteration. This results in more frequent computation of I/O penalty changes, thus increased computation overhead. Hence, for feasibility reasons we choose a smaller K value for the large input graph TW. For the experiments in this section we do not apply any reordering algorithm and use the input graphs as they are given in KONECT [36]. We evaluate the combined effect of ordering and Basc separately in Section 5.3.

Evaluation Result. Figure 6 shows the results for experiments where the page cache size is set to 5% of the graph size and an additional 10% to 40% of the graph size is provided for Basc. As mentioned earlier, for the 'page cache only' setting (denoted 'page cache'), the page cache size is equally set, that is, 15% to 45% of the graph size is used. All results are shown normalized to that of 'page cache only'. The results presented here exclude the time to load Basc, which must be done before the algorithms are executed. We discuss this and other forms of overhead in the last part of this section.

Overall, Basc with GVS shows substantially better performance than the other schemes. We see that low-degree selection generally is a sound choice performing, in most cases, better than page cache, though, we do observe cases where it does worse. Overall, for all algorithms and datasets (including those not shown here), Basc with GVS is the clear winner, being 28.87% faster on harmonic average than page cache for all the cases.

To compare the efficiency of 'page cache' and Basc with GVS, we vary the ratio of the page cache and Basc sizes and measure their performance. Figure 7 shows the results as the total size of the two caches is set to 20% of the graph size and as the size of Basc varies from 0% to 90% of the total cache size. We see that the performance consistently improves as Basc size is increased. This is because BFS-like algorithms show

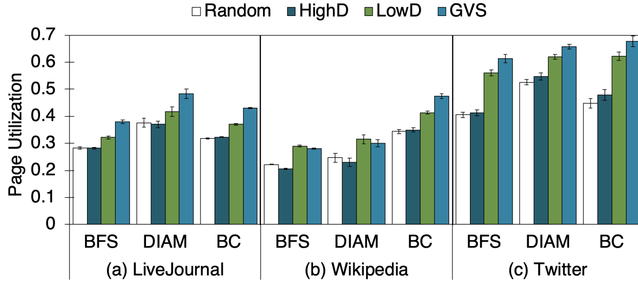

Figure 8: Mean and standard deviation of page cache utilization when executed with BASC with Random, HighD, LowD, and GVS algorithms.

poor temporal locality and using the space as BASC is more effective than using the space as a page cache.

Effect on page cache utilization. To verify that BASC with GVS improves page cache utilization, we evaluate BFS-like algorithms with BASC and measure the page cache utilizations for the different vertex selection algorithms (GVS, HighD, LowD, and Rand).

Page cache utilization is measured as follows. For the entire execution of the algorithms, for each page retrieved to the page cache, individual 64 byte granularity units of the page are monitored throughout while the page resides in the page cache. Utilization of the page, calculated when the page is evicted, is the fraction of the total accessed units within the page size. Page cache utilization that is reported is the average of all the pages evicted as well as those still residing in the page cache at the end of the algorithm execution. Note that the contents in BASC are not considered in these calculations. Essentially, this value tells us how efficiently contents brought in to the page cache are being used.

Figure 8 compares the page cache utilizations for different vertex selection algorithms when the page cache and BASC size is 5% and 20%, respectively, of the input graph size. For all the graphs across the three algorithms, GVS shows highest page cache utilization for most cases. For all algorithms and datasets experimented with (for the same page cache and BASC sizes as above), GVS shows 33.8% higher utilization than random selection in harmonic mean, and in the best case, is almost twice that of random selection (FL with BFS, not shown), with the worst case, being equivalent (YT with DIAM, also not shown). Compared to LowD, GVS shows up to 22.5% higher utilization (FL with APSP). However, there are also occasions where low-degree selection shows slightly higher utilization (WK with BFS and DIAM).

Vertex Selection and Loading Overhead. There are two sources of overhead in deploying BASC. One is the cost for running GVS to select the vertices to load and the other is the overhead to actually load the selected vertices into BASC. Both must be executed before the algorithm is executed. We quantify these overheads by measuring the running time of Algorithm 1 separately with varying K from 1 to 1000, as well as the time to load to BASC. Table 2 shows the results when BASC size is 20% of the dataset. We observe that vertex loading overhead is generally lower compared to the vertex selection overhead. For vertex selection, as we increase the value of K, the execution time increases sublinearly. The results also show that the selection time increases proportionally to the graph size, or more accurately, BASC size. (Refer to Table 1 for the characteristics of the dataset and note that we are setting BASC size (M) to be 20% of input graph size, which is proportional to the number of edges.)

Table 2: Execution times of running GVS and loading the selected vertices to BASC (unit: seconds).

	K	YT	FL	LJ	WK	TW
GVS	1	4.6	4.9	7.8	19.8	132
	10	5.9	7.6	11.3	29.2	321
	100	16.7	24.7	26.3	76.4	1581
	1000	94.8	103	146	449	5612
Loading		2.5	3.2	4.3	6.2	44.8

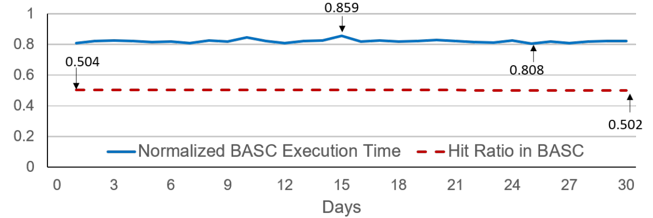

Figure 9: Efficiency of BASC over a graph (LJ) that changes 0.2% each day. Execution time of BFS with BASC is normalized to that of page cache only each day.

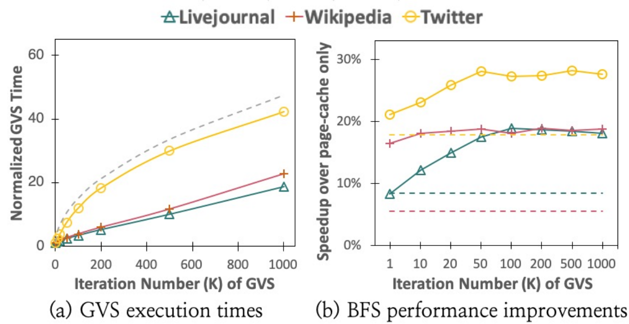
Although the selection and loading times are not negligible, once loaded, the algorithm of choice is executed 100s, if not 1000s or even more times [11,42], more than compensating for the overhead for selection and loading. For example, running of DIAM a hundred times on LJ or BC just ten times on TW with BASC improves the overall running time even with the selection and loading overhead. Furthermore, this selection process can be run in the background independent of and without influencing the execution of the graph algorithms.

More importantly, these actions need to run only sparingly. Reports have shown that the social graph in Facebook changes by 0.2% a day [9], which means that in a one month period the graph would only differ by 6%. To quantify how much effect small changes in the input graph have on BASC, we conduct a series of experiments where we change the graph (LJ) by 0.2% over 30 times to simulate changes in a one month period [9].



(a) GVS execution times (b) BFS performance improvements

Figure 10: The sensitivity of GVS on iteration number K. (a) Execution time normalized by that with $K = 1$, where the dotted gray line represents $1.5 \times \sqrt{K}$. (b) Speedup over page cache only where the solid lines are for GVS and the dotted lines are for LowD.

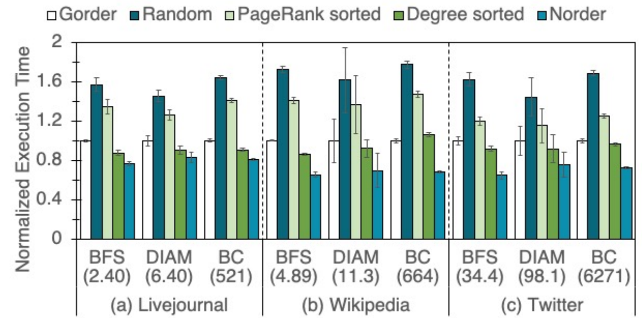


Figure 11: Mean and standard deviation of execution times of five graph orderings normalized to that of Gorder. The numbers in parenthesis below each algorithm are the absolute execution time, in seconds, of the reference, in this case, Gorder. (Note that we use similar presentation format in subsequent figures.)

We randomly add or remove edges with preferential attachment [3] where the ratio to add and remove is 8 to 2. Then, we run BFS with Basc, set to 20% of the data size, for which the selection and loading is done for the initial graph. Figure 9 shows the results of the experiments where the execution times with Basc is normalized to those of page cache only for each day. We observe that the relative performance of Basc over page cache only is nearly constant with only a 5% difference – maximum 19.2% and minimum 14.1%. In addition, the hit ratio of Basc, which is measured as the number of edge list access in Basc over the total number of edge list requests, declines slowly each day from 50.4% to 50.2%. This tells us that selection and loading can be performed over long periods, for example, once every month incurring only minimal overhead.

Sensitivity of GVS on iteration number K. As GVS execution time and its selection outcome rely on the iteration number K, we evaluate their sensitivity on K. We run GVS with varying values of K, starting from 1 up to 1000, and measure the GVS execution time. The size of Basc is set to be 20% of the input graph size. Figure 10(a) plots the results normalized to the execution times with $K = 1$. We observe that execution time increases by less than 45×, even for $K = 1000$, and that the plots for the three input graphs are all below the $1.5 \times \sqrt{K}$ line represented by the gray dotted line.

We also measure the performance of Basc with GVS as K is varied. Figure 10(b) shows the performance improvements over the page cache only settings. The solid lines are for Basc with GVS and the dotted lines are for Basc with LowD (low-degree vertex selection). We observe that Basc with GVS performs consistently better than LowD even when $K = 1$. Moreover, as K increases, the performance improvement by GVS quickly saturates, that is, the performance improvement with $K = 50$ is almost the same as that with $K = 1000$. Hence, for extremely large graphs whose GVS overhead can be potentially quite high, we can reduce the value of K to trade off the performance improvements of running the graph algorithms and GVS running time.

5.2 Evaluation of Neighborhood Ordering

We now consider the performance impact of Norder. For comparison, we use Gorder, the state-of-the-art graph ordering scheme for in-memory graph analysis. Also, we evaluate three other ordering schemes: PageRank sorted ordering, degree sorted ordering, and random ordering. For Gorder we set its parameter w (window size) to be the average number of edge lists in a single page for all the algorithms. Note that only the page cache is used and Basc is not deployed in these experiments. The size of the page cache is set to 25% of the input graph size.

Figure 11 shows the performance of the algorithms on an SSD normalized to Gorder, with the absolute execution times (in seconds) of Gorder also presented in the parentheses below each algorithm name for reference. We use this format of presentation for subsequent results as well. For all three algorithms, graph ordering has strong influence, with Norder performing the best. For all algorithms and datasets, Norder is 31.3% and 68.5% faster in harmonic mean than Gorder and PageRank sorted ordering, respectively. For all algorithms and datasets Norder showed fastest performance except for WCC with TW and FL, for which Degree sorted order was fastest. This is due to the characteristics of WCC. In the later iterations of the algorithm, a small number of vertices linger on; these vertices typically have small in-degrees, hence storing them closely on disk improves the performance of the page cache for WCC.

Cost of ordering: The cost of applying Norder is much lower than that of Gorder. Table 3 compares the computation times of the two ordering schemes. As Gorder stores the input graph in main memory to compute the ordering, all data is loaded to the 128GB memory in our

Table 3: Computation times (unit: seconds)

	YT	FL	LJ	WK	TW
Gorder	12.5	39.6	45.6	169.3	11687.1
Norder	2.0	2.7	7.2	16.9	243.5

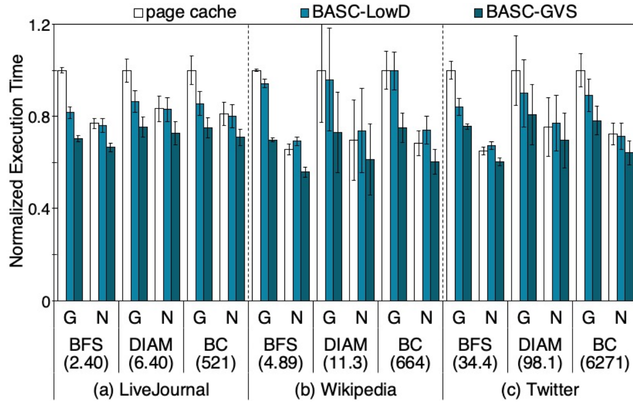

Figure 12: Mean and standard deviation of execution times of three caching schemes with Gorder and Norder normalized to that of page cache with Gorder.

system for these measurements. All orderings are computed using a single thread as this is how it is provided with the open-sourced Gorder. We observe that Norder is 6 to 14 times faster than Gorder for small graphs, while for the large graph TW, it is close to fifty times faster. If we consider the ordering time with the execution time of the algorithms, we can see that BFS-like algorithms benefit even more with Norder.

5.3 Combining Basc and Norder

Now we evaluate the overall performance gain by applying the two optimizations together. For comparison we also perform experiments with Gorder and two caching schemes, page cache and Basc with LowD. For caching, the default setting of 5% of the input graph size is used for the page cache and an additional 20% is added on as Basc or the page cache.

Figure 12 shows the performance results for all combinations of ordering and caching. The two optimizations together noticeably improve the performance of all the algorithms. Overall, for all algorithms and datasets (including those not shown here) Basc with Norder is 1.54 times faster than page cache with Gorder in harmonic mean. In the best case, Basc with Norder is 2.56 times faster for APSP with YT and in the worst case, it is 1.37 times faster for DIAM with LJ.

More importantly, however, the results demonstrate that the two optimizations can be synergistic. For example, low-degree vertex selection sometimes brings about performance degradation compared to page cache (WK with BFS and DIAM), implying that the two optimizations (LowD and Norder) do not interact well. However, GVS consistently and substantially improves performance in all cases with the two orderings, especially with Norder.

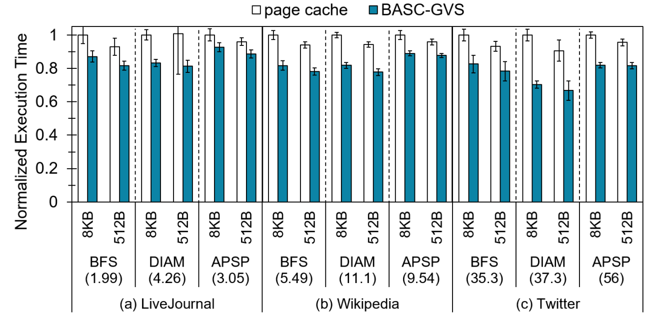

Figure 13: Mean and standard deviation of execution times of BFS-like algorithms in Graphene, with and without Basc, normalized to that of page cache only case with 8KB page size.

5.4 BASC with Graphene

The problem of low page cache utilization for disk-based graph systems was studied by Liu and Huang [21]. In their proposed graph system, Graphene, they address this problem by supporting finer-grained I/O. Specifically, Graphene stores input graphs in 512-byte pages instead of 8KB and applies bitmap-based request management to reorder and merge I/Os.

In this section, we incorporate Basc on Graphene and observe its effect. To do so, we simply modify the page cache mechanism within Graphene to accommodate Basc. Here we evaluate the effect of Basc with three algorithms – BFS, APSP, and DIAM. The first two are provided in Graphene and we implement DIAM for our experiments. We were unable to implement BC due to the complexity of Graphene's interface. Note that in Graphene, APSP is implemented to run BFS from 32 random sources and stores the result in a 4-byte attribute, of which each bit indicates if the traversal from the corresponding source vertex is reached. We compare performance with and without Basc in Graphene with the typical 8KB and the 512-byte page sizes. The page cache is set to 30% of the input graph without Basc and with Basc, the page cache is set to 10%, plus 20% space set for Basc, along with the default thread setting. Norder is not considered in these experiments as this is an optimization independent of Graphene.

Figure 13 shows the evaluation results. The results are normalized to the 8KB 'page cache only' results for every algorithm for each dataset. For most of the results the average performance of fine-grained management is better than the coarse-grained 8K page size, though for some, the variance for fine-grained management is larger. We observe that overall, Basc provides similar

improvements with Graphene showing that BASC is orthogonal to Graphene's fine-grained I/O optimizations.

6 Related Work

Disk-Based Graph Engines. GraphChi is the first disk-based graph engine [19]. Its *Parallel Sliding Windows* helps it run efficiently on HDDs. TurboGraph is a disk-based graph engine for SSDs [12]. Its *pin-and-slide* technique overlaps random I/O with CPU computation. TurboGraph and other graph systems such as GTS and GraphZ [17, 41] that use the page cache for random I/O can take advantage of BASC or Norder.

While the vertex-centric computation model is widely used, an alternative *edge-centric* computation model was recently proposed for disk-based graph systems; this model sequentially streams edges into memory to eliminate random disk access [24, 32, 43]. While the edge-centric model shows good performance for algorithms accessing the entire graph repeatedly, its performance for BFS-like algorithms is not as efficient.

In semi-external graph engines, vertex attributes are stored in main memory for fast updates [18, 30, 34, 40]. Pearce et al. proposed asynchronous optimization techniques for graph traversal algorithms for semi-external graph processing [30]. FlashGraph implements several I/O optimizations for SSDs and SSD arrays such as merging I/O requests and overlapping I/O and computation [40]. Building on top of these optimizations, our methods improve BFS-like algorithms having poor I/O locality even with those previous optimizations.

Several other I/O optimizations have recently been proposed. Vora et al. employs a dynamic partitioning scheme that prevents loading unnecessary edges [37]. GridGraph supports 2D edge partitioning [43]. In Graphene, a bitmap based I/O optimization is applied to merge small I/O requests [21]. Our proposed optimization techniques are applicable on top of these I/O optimizations as we have shown with Graphene.

Main Memory Graph Processing. For large-scale graph processing, the vertex-centric computation model was first proposed in Pregel [25], a distributed in-memory graph system. GraphLab and its successor PowerGraph is a distributed machine learning and graph analysis system with the vertex-centric model [11, 22]. SociaLite is a Datalog-based query language for distributed graph analysis [33]. Green-Marl is a domain-specific language for writing parallel graph algorithms for shared-memory [14]. Galois supports an implicitly parallel vertex iterator for graph processing [29].

Wei et al. studied graph ordering for main memory graph processing [38]. They proposed Gorder that optimizes the locality of accessing vertex attributes. While Gorder is designed for main memory systems, Norder is for disk-based graph engines. Norder is based on an I/O cost model and its optimization that we derive for BFS-like algorithms on disk-based graph engines.

7 Conclusion

In this paper, we conducted an analysis of BFS-like algorithms running on disk-based graph systems. We showed that BFS-like algorithms have poor I/O performance and the page cache in existing systems is not effective. To supplement the page cache, we proposed a BFS-Aware Static Cache or BASC that stores edge lists of a select set of vertices in memory aside from the page cache. We formulate the problem of selecting the optimal set of such vertices as a problem of maximizing overall I/O efficiency of BFS-like algorithms. As this problem is NP-hard, an approximate algorithm, called Greedy Vertex Selection (GVS), is developed. Also, based on our analysis of BFS-like algorithms, we proposed an I/O cost model upon which we develop an efficient graph ordering scheme called *Neighborhood Ordering* (abbreviated Norder) that stores neighboring vertices closely on disk.

We implemented our methodologies in two well-known graph engines and evaluated them using five real-world graphs for six BFS-like algorithms. Through a vast set of experiments, we show that the execution of BFS-like algorithms can be improved with BASC and GVS compared to simply using the page cache. We also show that Norder is less costly to compute than Gorder, yet achieves considerable performance improvements over Gorder. Our experimental results show that the two optimizations collectively and synergistically provide substantial performance gains for BFS-like algorithms.

From Laptop to Lambda: Outsourcing Everyday Jobs to Thousands of Transient Functional Containers

Stanford University, [+]Unaffiliated

Abstract

We present gg, a framework and a set of command-line tools that helps people execute everyday applications—e.g., software compilation, unit tests, video encoding, or object recognition—using thousands of parallel threads on a cloud-functions service to achieve near-interactive completion times. In the future, instead of running these tasks on a laptop, or keeping a warm cluster running in the cloud, users might push a button that spawns 10,000 parallel cloud functions to execute a large job in a few seconds from start. gg is designed to make this practical and easy.

With gg, applications express a job as a composition of lightweight OS containers that are individually transient (lifetimes of 1–60 seconds) and functional (each container is hermetically sealed and deterministic). gg takes care of instantiating these containers on cloud functions, loading dependencies, minimizing data movement, moving data between containers, and dealing with failure and stragglers.

We ported several latency-sensitive applications to run on gg and evaluated its performance. In the best case, a distributed compiler built on gg outperformed a conventional tool (`icecc`) by 2–5×, without requiring a warm cluster running continuously. In the worst case, gg was within 20% of the hand-tuned performance of an existing tool for video encoding (ExCamera).

1 Introduction

Public cloud-computing services have steadily rented out their resources at finer and finer granularity. Sun's Grid utility (2005), Amazon's EC2 (2006), and Microsoft's Azure virtual machines (2012) began by renting virtual CPUs for a minimum interval of one hour, with boot-up times measured in minutes. Today, the major services will rent a virtual machine for a minimum of one minute and can typically provision and boot it within 45 seconds of a request.

Meanwhile, a new category of cloud-computing resources offers even finer granularity and lower latency: cloud functions, also called serverless computing. Amazon's Lambda service will rent a Linux container to run arbitrary x86-64 executables for a minimum of 100 milliseconds, with a startup time of less than a second and no charge when it is idle. Google, Microsoft, Alibaba, and IBM have similar offerings.

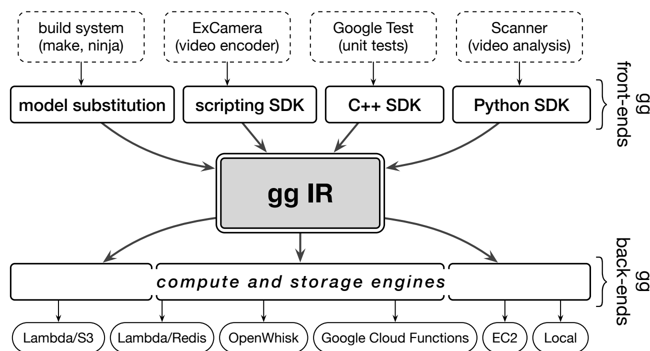

Figure 1: gg helps applications express their jobs as a composition of interdependent Linux containers, and provides back-end engines to execute the job on different cloud-computing platforms.

Cloud functions were intended for asynchronously invoked microservices, but their granularity and scale has allowed researchers to explore a different use: as a burstable supercomputer-on-demand. These new systems launch a *burst-parallel* swarm of thousands of cloud functions, all working on the same job. The goal is to provide results to an interactive user—much faster than can be accomplished on the user's own computer or by booting a cold cluster, and cheaper than maintaining a warm cluster for occasional tasks.

Recent work has validated this vision. ExCamera [15] and Sprocket [3] launch thousands of cloud functions, with inter-thread communication over TCP, to encode, search, and transform video files quickly. PyWren [23] exposes a Python API and uses AWS Lambda functions for linear algebra and machine learning. Serverless MapReduce [35] and Spark-on-Lambda [36] demonstrate a similar approach.

Unfortunately, building applications on swarms of cloud functions is difficult. Each application must overcome a number of challenges endemic to this environment: (1) workers are stateless and may need to download large amounts of code and data on startup, (2) workers have limited runtime before they are killed, (3) on-worker storage is limited, but much faster than off-worker storage, (4) the number of available cloud workers depends on the provider's overall load and can't be known precisely upfront, (5) worker failures occur

when running at large scale, (6) libraries and dependencies differ in a cloud function compared with a local machine, and (7) latency to the cloud makes roundtrips costly. Past applications have addressed only subsets of these challenges, in application-specific ways.

In this paper, we present gg, a general framework for building burst-parallel cloud-functions applications, by building them on an abstraction of transient, functional containers, or *thunks*. gg helps applications express their jobs in terms of interrelated thunks (hermetically sealed, short-lived containers that may reference the output of other thunks or produce other thunks as output), then schedules, instantiates, and executes those thunks on a cloud-functions service.

gg can containerize and execute existing programs, e.g., software compilation, unit tests, video encoding, or searching a movie with an object-recognition kernel. gg does this with thousands-way parallelism on short-lived cloud functions. In some cases, this yields considerable benefits in terms of performance. Depending on the frequency of the task (e.g., for compilation or unit tests every few minutes), cloud functions are also much less expensive than keeping a comparable cluster running continuously.

gg and other parallel execution systems. In its goals and approach, gg is kin with container-orchestration systems such as Kubernetes [5] and Docker Swarm [10], outsourcing tools like the Utility Coprocessor [12] and `icecc` [20], and cluster-computation tools such as Hadoop [38], Dryad [22], Spark [40], and CIEL [27].

But gg also differs from these systems in its focus on a new computing substrate (cloud functions), mode of execution (burst-parallel, latency-sensitive programs starting from zero), and target application domain (everyday "local" programs, e.g. software compilation, that depend on an environment captured from the user's own laptop).

For example, the "stateless" nature of cloud functions (they boot up with no dependable transient state) makes gg place a large focus on efficient containerization and dependency management: loading the minimal set of the right files into each container at boot-up. Cluster-computation systems like Dryad, Spark, and CIEL do not do this—although they can interface with existing code and systems (e.g., a video encoder or a database server), these components must be loaded in advance by the user on a long-lived compute node. Container systems like Kubernetes do this, but they are not aimed at efficient execution of a transient interactive task—gg is more than 45× faster than Google Kubernetes Engine at startup, and 13× faster than Spark-on-Lambda (Figure 7). We discuss related work more completely in Section 2.

1.1 Summary of Results

We ported four applications to express their jobs in gg's format: a description of each container, and how it depends on other containers, that we call the *intermediate representation*, or IR (§3). One of them does it automatically, by inferring the IR from an existing software build system (e.g., `make` or `ninja`). The rest write out the description explicitly: a unit-testing framework (Google Test [17]), parallel video encoding with inter-thread communication (ExCamera [15]), and object recognition using Scanner [30] and TensorFlow [1].

Compiling Inkscape

Tool	Time	Cost
single-core `make`	32m 34s	—
`icecc` to a warm 48-core EC2 machine	6m 51s	$2.30/hr
`icecc` to a warm 384-core EC2 cluster	6m 57s	$18.40/hr
gg to AWS Lambda	1m 27s	50¢/run

Figure 2: Compiling Inkscape using gg on AWS Lambda is almost 5× faster than outsourcing the job to a warm 384-core cluster, without the costs of maintaining a warm cluster for an occasional task.

We then implemented gg back-ends, which interpret the IR and execute the job, for five compute engines (a local machine, a cluster of warm VMs, AWS Lambda, IBM Cloud Functions, and Google Cloud Functions) and three storage engines (S3, Google Cloud Storage, and Redis) (Figure 1).

For compiling large programs from a cold start, gg's functional approach and fine-grained dependency management yield significant performance benefits. Figure 2 shows a summary of the results for compiling an open-source software, Inkscape [21]. Running "cold" on AWS Lambda (with no pre-provisioned compute resources), gg was almost 5× faster than an existing system (`icecc`), running on a 48-core or 384-core cluster of warm VMs (i.e., not including time to provision and boot the VMs[1]).

In summary, gg is a practical tool that addresses the principal challenges faced by burst-parallel cloud-functions applications. It helps developers and users build applications that burst from zero to thousands of parallel threads to achieve low latency for everyday tasks. gg is open-source software and the source code is available at https://snr.stanford.edu/gg.

2 Related Work

gg has many antecedents—cluster-computation systems such as Hadoop [38], Spark [40], Dryad [22], and CIEL [27]; container orchestrators like Docker Swarm and Kubernetes; outsourcing tools like `distcc` [8], `icecc` [20], and UCop [12]; rule-based workflow systems like `make` [13], CMake [7], and Bazel [4]; and cloud-functions tools like ExCamera/mu [15], PyWren [23], and Spark-on-Lambda [36].

Compared with these, gg differs principally in its focus on targeting a new computing substrate (thousands of cloud functions, working to accelerate a latency-sensitive local-

[1] Current cloud-computing services typically take an additional 0.5–2 minutes to provision and boot such a cluster.

application task). We discuss how gg fits with the prior literature in several categories:

Process migration and outsourcing. The idea of accelerating a local application's interactive operations by using the resources of the cloud has a long pedigree; earlier work such as the Utility Coprocessor (UCop) also sought to "improve performance from the coffee-break timescale of minutes to the 15–20 second timescale of interactive performance" by outsourcing to a cloud VM [12]. gg shares the same goal.

gg's architectural differences from this work come from its different needs: instead of outsourcing applications transparently to a *single* warm cloud VM, gg orchestrates *thousands* of unreliable and stateless cloud functions from a cold start. Unlike UCop, gg is not transparent to the application—we require applications to be ported to express jobs in gg's format. In return, gg provides optimized orchestration of swarms of cloud functions and fault tolerance (failed functions are rerun with the same inputs). Unlike UCop's distributed caching filesystem, gg's IR, which is based on content-addressed immutable data, allows cloud workers to be provisioned with all necessary dependencies in a single roundtrip and to communicate intermediate values directly between each other.

Container orchestration. gg's IR resembles container and environment-description languages, including Docker [10] and Vagrant [34], and container-orchestration systems such as Docker Swarm and Kubernetes. In contrast to these systems, gg's thunks are designed to be efficiently instantiated within a cloud function, expressible in terms of other thunks to form a computation graph, and deterministic and defined by their code and data, allowing gg to provide fault tolerance and memoization. These systems were not designed for transient computations, and gg has much quicker startup. For example, starting 1,000 empty containers with gg takes about 4 seconds on a VM cluster or on AWS Lambda. Google Kubernetes Engine, given a warm cluster, takes more than 3 minutes (§5.1). Recent academic work has shown how to lower this overhead to provide faster cloud-functions services [28].

Workflow systems. Workflow systems like Dryad [22], Spark [40], and CIEL [27] let users execute a (possibly dynamic) DAG of tasks on a cluster. However, gg differs from these systems in some significant ways:

- gg is aimed at a different kind of application. For example, while Spark is often used for data analytics tasks, it is not commonly used for accelerating the sorts of "everyday" local applications that gg is designed for. No prior work has successfully accelerated something like "compiling Chromium" using Spark, and the challenges in accomplishing this (capturing the user's local environment and the information flow of the task, exporting the job and its dependencies efficiently to the cloud, running thousands of copies of the C++ compiler in a fault-tolerant way) are simply not what Spark does.
- gg uses OS abstractions: it encapsulates arbitrary code and dependency files in lightweight containers, somewhat similar to a tool like Docker. gg focuses on efficiently loading code and its minimal necessary dependencies on cloud functions that boot up with no dependable state. By contrast, systems like Dryad and Spark principally use language-level mechanisms. While their jobs can interface with existing software (e.g., the Dryad paper [22] describes how a node can talk to a local SQL Server process, and Spark jobs routinely invoke system binaries such as `ffmpeg`), these systems do not take care of deploying the existing code, worrying about how to move the container in a way that minimizes bytes moved across the network, etc. The user is responsible for loading the necessary code and dependencies beforehand on a pool of long-lived machines.
- gg is considerably lighter weight. In practice, attempts to port workflow systems to support execution on cloud functions (scaling from zero) have not performed well, partly because of these systems' overheads. Because of its focus on transient execution, gg carries an order-of-magnitude less overhead. For example, gg is 13× faster at invoking 1,000 "sleep 2" tasks than Spark-on-Lambda (Figure 7).
- gg supports dynamic data access (a function can produce another function that accesses arbitrary data) and non-DAG dataflows (e.g., loops and recursion). It does this while remaining agnostic to the application's programming language. For example, gg has no language-level API binding to launch a new subtask. (CIEL also allows subtasks to spawn new subtasks, but requires use of its Skywriting programming language to do this.)

Burst-parallel cloud functions. Researchers and practitioners have taken advantage of cloud-functions platforms to implement low-latency, massively parallel applications. ExCamera [15] uses AWS Lambda to scale out video encoding and processing tasks over thousands of function invocations, and PyWren [23] exposes a MapReduce-like Python API that executes on AWS Lambda. Spark-on-Lambda [40] is a port of Spark that uses AWS Lambda cloud functions. In contrast, gg helps applications use cloud-functions platforms for a broader set of workloads, including irregular execution graphs and ones that change as execution evolves. gg's main contribution is specifying an IR that permits a diverse class of applications (written in any programming language) to be abstracted from the compute and storage platform, and to leverage common services for dependency management, straggler mitigation, and scheduling.

Build tools. Several build systems (e.g., `make` [13], Bazel [4], Nix [11], and Vesta [19]) and outsourcing tools (such as `distcc` [8], `icecc` [20], and `mrcc` [26]) seek to incrementalize, parallelize, or distribute compilation to more-powerful

remote machines. Building on such systems, gg automatically transforms existing build processes into their own IR. The goal is to compile programs quickly—irrespective of the software's own build system—by making use of cloud-functions platforms that can burst from complete dormancy to thousands-way parallelism and back.

Existing remote compilation systems, including `distcc` and `icecc`, send data between a master node and the workers frequently during the build. These systems perform best on a local network, and add substantial latency when building on more remote servers in the cloud. In contrast, gg uploads all the build input once and executes and exchanges data purely within the cloud, reducing the effects of network latency.

3 Design and Implementation

gg is designed as a general system to help application developers manage the challenges of creating burst-parallel cloud-functions applications. The expectation is that users will take computations that might normally run locally or on small clusters for a long time (e.g., test suites, machine learning, data exploration and analysis, software compilation, video encoding and processing), and outsource them to thousands of short-lived parallel threads in the cloud, in order to achieve near-interactive completion time.

In this section, we describe the design of gg's intermediate representation (§3.1), front-end code generators (§3.2), and back-end execution engines (§3.3).

3.1 gg's Intermediate Representation

The format that gg uses—a set of documents describing a container and its dependency on other containers—is intended to elicit enough information from applications about their jobs (fine-grained dependencies and dataflow) to be able to efficiently execute a job on constrained and stateless cloud functions. It includes:

1. A primitive of a content-addressed cloud *thunk*: a codelet or executable applied to named input data.
2. An intermediate representation (IR) that expresses jobs as a lazily evaluated lambda expression of interdependent thunks.
3. A strategy for representing dynamic computation graphs and data-access patterns in a language-agnostic and memoizable way, using tail recursion.

We discuss each of these elements.

3.1.1 Thunk: A Lightweight Container

In the functional-programming literature, a thunk is a parameterless closure (a function) that captures a snapshot of its arguments and environment for later evaluation. The process of evaluating the thunk—applying the function to its arguments and saving the result—is called *forcing* it [2].

For gg, our goal is to simplify the creation of new applications by allowing them to target the IR, which lets them leverage the common services provided by the back-end engines. Accordingly, the representation of a thunk follows from several design goals. It should be: (1) simple enough to be portable to different compute and storage platforms, (2) general enough to express a variety of plausible applications, (3) agnostic to the programming language used to implement the function, (4) efficient enough to capture fine-grained dependencies that can be materialized on stateless and space-limited cloud functions, and (5) able to be memoized to prevent redundant work.

To satisfy these requirements, gg represents a thunk with a description of a container that identifies, in content-addressed manner, an x86-64 Linux executable and all of its input data objects. The container is hermetically sealed: it is not allowed to use the network or access unlisted objects or files. The thunk also describes the arguments and environment for the executable, and a list of tagged output files that it will generate—the results of forcing the thunk. The thunk is represented as a Protobuf [31] structure (Figure 3 shows three thunks for three different stages of a build process). This container-description format is simple to implement and reason about, and is well-matched to the statelessness and unreliability of cloud functions.

In the content-addressing scheme, the name of an object has four components: (1) whether the object is a primitive value (hash starting with `V`) or represents the result of forcing some other thunk (hash starting with `T`), (2) a SHA-256 hash, (3) the length in bytes, and (4) an optional tag that names an object or a thunk's output.

Forcing a thunk means instantiating the described container and running the code. To do this, the executor must fetch the code and data values. Because these are content-addressed, this can be from any mechanism capable of producing a blob that has the correct name—durable or ephemeral storage (e.g., S3, Redis, or Bigtable), a network transfer from another node, or by finding the object already available in RAM from a previous execution. The executor then runs the executable with the provided arguments and environment—for debugging or security purposes, preferably in a mode that prevents the executable from accessing the network or any data not listed as a dependency. The executor collects the output blobs, calculates their hashes, and records that the outputs can be substituted in place of any reference to the just-forced thunk.

3.1.2 gg IR: A Lazily Evaluated Lambda Expression

The structure of interdependent thunks is what defines the gg IR. We use a one-way IR, a document format that applications write to express their jobs, as opposed to a two-way API (e.g., a function call to spawn a new task and observe its result)

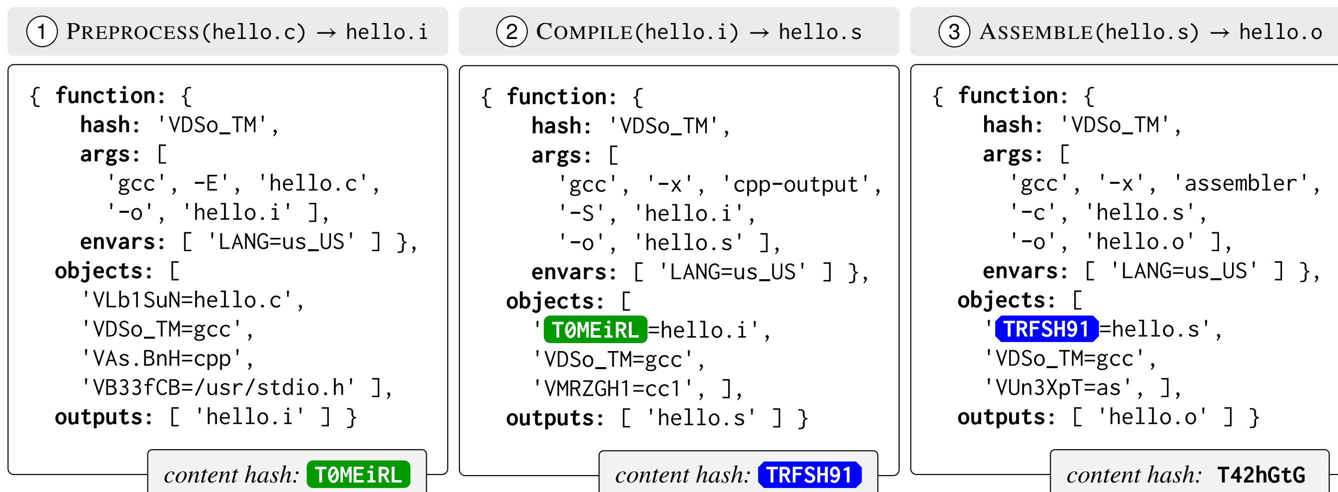

Figure 3: An example of gg IR consisting of three thunks for building a "Hello, World!" program that represents the expression ASSEMBLE(COMPILE(PREPROCESS(hello.c))) → hello.o. To produce the final output hello.o, thunks must be forced in order from left to right. Other thunks, such as the link operation, can reference the last thunk's output using its hash, T42hGtG. Hashes have been shortened for display, and dependencies between thunks are shown in color.

because we expect the application will be running on the user's own computer, at some remote cloud-functions engine: the intention is to avoid roundtrips over a long-latency path by keeping the application out of the loop. We also envision that it will be possible to better schedule and optimize a job, and easier to maintain different interoperable back-ends, if the application is out of the loop before execution begins.[2] This representation exposes the computation graph to the back-end, along with the identities and sizes of objects that need to be communicated between thunks. Based on this information, the back-end can schedule the forcing of thunks, place thunks with similar data-dependencies or an output-input relationship on the same physical infrastructure, and manage the storage or transfer of intermediate results, without roundtrips back to the user's own computer.

The IR allows gg to schedule jobs efficiently, mitigate the effect of stragglers by invoking multiple concurrent thunks on the critical path, recover from failures by forcing a thunk a second time, and memoize thunks. This is achieved in an application-agnostic, language-agnostic manner.

The application generally starts by forcing a single thunk that represents the ultimate outcome of the interactive operation. This thunk typically depends on other thunks that need to be forced first, etc., leading the back-end to lazily force thunks recursively until obtaining the final result. Figure 3 shows an example IR for computing the expression ASSEMBLE(COMPILE(PREPROCESS(hello.c))).

3.1.3 Tail Recursion: Supporting Dynamic Execution

The above design is sufficient to describe a directed acyclic graph (DAG) of deterministic tasks executing in the cloud. However, many jobs do not have a data-access pattern that is completely known upfront. For example, in compiling software, it is unknown *a priori* which header files and libraries will need to be read by a given stage. Other applications use loops, recursion, and other non-DAG dataflows.

An application may also have an unpredictable degree of parallelism. For example, an application might detect objects in a large image, and then on each subregion where an object is detected (which may be zero regions, or might be 10,000 regions), the application searches for a target object. Here, the computation graph is not known in advance.

Systems like PyWren [23] and CIEL's Skywriting language [27] handle this case by giving tasks access to an API call to invoke a new task. For gg, we aimed to preserve the memoizability and language-independence of the IR, which is challenging if tasks can invoke tasks on their own and if gg must expose a language binding. Instead, gg handles this situation through language-independent tail recursion: a thunk can write another thunk as its output.

3.2 Front-ends

We developed four front-ends that emit gg IR: a C++ SDK, a Python SDK, a group of command-line tools, and a series

[2] Systems like the LLVM compiler suite [25] (which allows front-end language compilers to benefit from a library of back-end optimization passes and assemblers, interfacing through an IR) and Halide [33] (which separates an image-processing algorithm from its schedule and execution strategy) have demonstrated the benefits of a rigid representational abstraction in other settings. gg's use of an IR is not exactly the same as these, but it has a similar value in abstracting front-ends (applications and the tools that help them express their jobs) from back-end execution engines in a way that allows efficient and portable execution.

of *model substitution* primitives that can infer gg IR from a software build system.

The C++ and Python SDKs are straightforward. Each exposes a thunk abstraction and allows the developer to describe a parallel application in terms of codelets. These codelets are applied to blobs of named data, which may be read-only memory regions or files in the filesystem.

The model-substitution primitives extract a gg IR description of an existing build system, without actually compiling the software. Instead, we run the build system with a modified PATH so that each stage is replaced with a stub: a *model* program that understands the behavior of the underlying stage well enough so that when the model is invoked in place of the real stage, it can write out a thunk that captures the arguments and data that will be needed in the future, so that forcing the thunk will produce the exact output that would have been produced during actual execution. We used this technique to infer gg IR from the existing build systems for several large open-source applications (§4.1).

3.3 Back-ends

gg IR express the application against an abstract machine that requires two components: an *execution engine* for forcing the individual thunks, and a content-addressed *storage engine* for storing the named blobs referenced or produced by the thunks. The *coordinator* program brings these two components together.

Storage engine. A storage engine provides a simple interface to a content-address storage, consisted of GET and PUT functions to retrieve and store objects. We implemented several content-addressed storage engines, backed by S3, Redis, and Google Cloud Storage. We also have a preliminary implementation (not evaluated here) that allows cloud functions to communicate directly among one another, avoiding the latency and throughput limitations of using a reliable blob storage (e.g., S3) to exchange small objects.

Execution engine. In conjunction with a storage engine, each execution engine implements a simple abstraction: a function that receives a thunk as the input and returns the hashes of its output objects (which can be either values or thunks). The engine can execute the thunk *anywhere*, as long as it returns correct output hashes that are retrievable from the storage engine. We implemented back-end execution engines for several environments: a local multicore machine, a cluster of remote VMs, AWS Lambda, Google Cloud Functions, and IBM Cloud Functions (OpenWhisk).

The coordinator. The main entry-point for executing a thunk is the *coordinator* program. The inputs to this program are the target thunk, a list of available execution engines and the storage engine. This program implements services offered by gg, such as job scheduling, memoization, failure recovery and straggler mitigation.

Upon start, this program materializes the target thunk's dependency graph, which includes all the other thunks needed to get the output. Then, the thunks that are ready to execute are passed to execution engines, based on their available capacity. When the execution of a thunk is done, the program updates the graph by replacing the references to the just-forced thunk and adds a cache entry associating the output hash to the input hash. The thunks that become ready to execute are placed on a queue and passed to the execution engines when their capacity permits. The unified interface allows the user to mix-and-match different execution engines, as long as they share the same storage engine.

The details of invocation, execution and placement are left to the execution engines. For example, the default engine for AWS Lambda/S3 invokes a new Lambda for each thunk. The Lambda downloads all the dependencies from S3 and sets up the environment, executes the thunk, uploads the outputs back to S3 and shuts down. For applications with large input/output objects, the roundtrips to S3 could affect the performance. As an optimization for such cases, the user can decide to run the execution engine in the "long-lived" mode, where each Lambda worker stays up until the job finishes and seeks out new thunks to execute. The execution engine keeps an index of all the objects that are already present on each worker's local storage. When placing thunks on workers, it selects the worker with the most data available, in order to minimize the need to fetch dependencies from the storage back-end.

The coordinator can also apply optimizations to the dependency graph. For example, multiple thunks can be bundled as one and sent to the execution engine. This is useful when the output of one thunk will be consumed by the next thunk, creating a linear pipeline of work. By scheduling all of those thunks on one worker, the system reduces the number of roundtrips.

Failure recovery and straggler mitigation. In case of coordinator failure, the job can be picked up where it was left off, as the coordinator program uses on-disk cache entries to avoid redoing the work that has already been done. In case of a recoverable error in executing a thunk, the execution engine notifies the coordinator with the failure reason, where it can decide to retry the job or pass it to another available execution engine for execution.

Straggler mitigation is another service managed by the coordinator program which duplicates pending executions in the same or a different execution engine. The program keeps track of the execution time for each thunk, and if the execution time exceeds a timeout (set by either the user or the application developer) the job will be duplicated. Since the functions don't have any side-effects, the coordinator simply picks the output that becomes ready first.

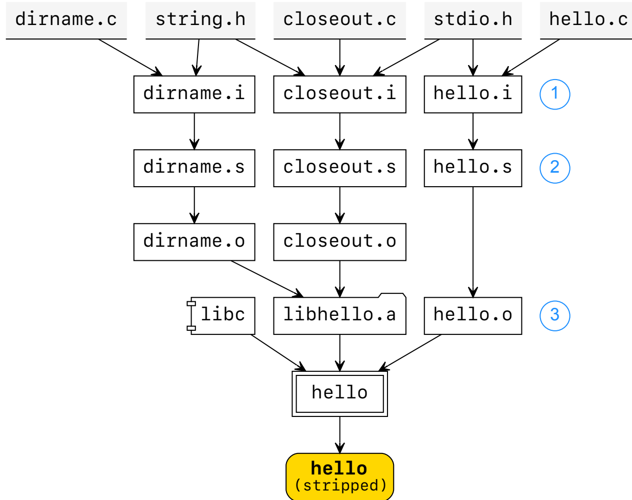

Figure 4: Part of the IR of interdependent thunks inferred with model substitution from the GNU `hello` build system. Each box represents a thunk and is labeled with the name of its output. The contents of the numbered thunks are depicted in Figure 3 (Many header files and other dependencies omitted for simplicity).

3.4 Implementation Notes

We implemented gg in about 14,000 lines of C++. The implementation consists of five compute engines (a local machine, a cluster of warm VMs, AWS Lambda, Google Cloud Functions, and IBM Cloud Functions), three storage engines (S3, Google Cloud Storage, and Redis), a series of command line tools to aid generation, execution and inspection of gg IR, a C++ and Python SDK, and several model programs for different stages of build process.

4 Applications

We used gg to implement several applications, each emitting jobs in the gg IR. We describe these in turn.

4.1 Software Compilation

The time required to compile software is an evergreen frustration for software developers; a popular cartoon even spoofs the duration of this job [39]. Today's open-source applications have grown larger and larger. For example, the Chromium Web browser takes more than four *hours* to compile on a four-core laptop computer from a cold start. Many solutions have been developed to leverage warm machines in a local cluster or cloud datacenter (e.g., `distcc` or `icecc`). We developed such an application on top of gg.

Using model substitution, we implemented models for seven popular stages of a C or C++ software build pipeline: the preprocessor, compiler, assembler, linker, archiver, indexer, and `strip`. These allow us to automatically transform some software build processes (e.g., a `Makefile` or `build.ninja` file) into an expression in gg IR, which can then be executed with thousands-way parallelism on cloud-functions platforms to obtain the same results as if the build system had been executed locally. Figure 4 illustrates the resulting IR from an example invocation (the enumerated thunks are detailed in Figure 3). These models are sufficient to capture the build process of some major open-source applications, including OpenSSH [29], Python interpreter [32], the Protobuf library [31], the FFmpeg video system [14], the GIMP image editor [16], the Inkscape vector graphics editor [21], and the Chromium browser [6].[3]

Build systems often include scripts that run in addition to these standard tools, such as a tool to generate configuration header files, but typically such scripts run upstream of the preprocessor, compiler, etc. Therefore, gg captures these script outputs by a model as dependencies.

Capturing dependencies of the preprocessor. Preprocessing is the most challenging stage to model. It requires not only capturing the source file as dependencies, but also all the header files that are both directly and indirectly included by that source file. Capturing *all* header files in a container is not feasible, because cloud functions are constrained in storage. For example, AWS Lambda has a 500 MB storage limit.

The precise header files required to preprocess a file can be discovered at fine grain, but only by invoking the preprocessor (i.e., `gcc -M`) which is an expensive operation at large scale. Finding the dependencies for each source file in Chromium takes nearly half an hour on a 4-core computer.

To solve this problem, the application uses gg's capabilities for dynamic dataflow at runtime. gg's preprocessor model generates thunks that do dependency inference in parallel on cloud functions. These thunks have access only to a stripped-down version of the user's include directories, preserving only lines with C preprocessor directives (such as `#include` and `#define`). These thunks then produce further thunks that preprocess a given source-code file by listing only the necessary header files.

4.2 Unit Testing

Software test suites are another application that can benefit from massive parallelism. Using gg's C++ SDK, we implemented a tool that can generate gg IR for unit tests written with Google Test [17], a popular C++ test framework used by projects like LLVM, OpenCV, Chromium, Protocol Buffers, and the VPX video codec library.

[3] We have to emphasize that no changes were made to the underlying build system of these programs. The main challenge here is to build correct and complete models for programs used in the build pipeline, such as `gcc` and `ld`, which is a one-time effort. However, an arbitrary build system may require other programs to be modeled, or execute these programs in an aberrant way that is outside of the scope of model substitution.

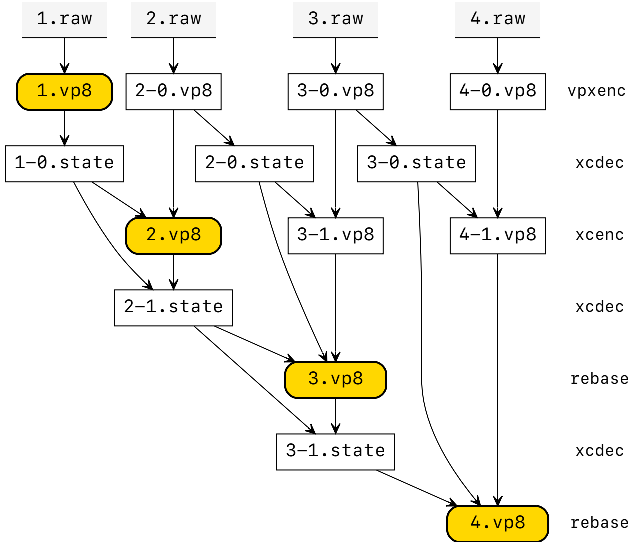

Figure 5: Visual representation of the gg IR for a video-processing workflow [15].

Typically, each test is a standalone program that can be run in parallel with other tests, with no dependency requirements between them. No changes to the code are necessary, with one exception: if a test case needs to access files on the file system, then the programmer has to annotate the test case with the list of files that it wants to access. This process can be automated by running the tests locally and then tracing the open system calls invoked by each test case. The tool uses these annotations, either handcrafted or automatically generated, to capture each test's dependencies. A separate thunk is created for each test case, allowing the execution engine to exploit the available parallelism.

4.3 Video Encoding

The ExCamera system [15] uses cloud-functions infrastructure to run interdependent video-processing tasks with 4,000-way parallelism [15]. Cloud workers exchange data through TCP connections, brokered by a tightly coupled back-end that was bound to AWS Lambda. To demonstrate gg's expressive power and performance, we ported ExCamera into a "front-end-only" version that targets gg IR.

In ExCamera, the functions necessary for parallel video encoding are ENCODE, DECODE, ENCODE-GIVEN-STATE, and REBASE. The algorithm first encodes each chunk in parallel using ENCODE and then, in a serial process, REBASEs each output on top of the state left by the previous chunk. Video-codec states must be communicated between workers in order to stitch together the overall video. Figure 5 shows the dependency graph for encoding a batch of four chunks.

The original ExCamera keeps Lambda workers warm by keeping the raw video in RAM and communicating video-codec states over TCP between workers. gg's back-end for AWS Lambda also keeps workers warm and keeps the raw video in their local filesystem. gg routes thunks to workers that already have the necessary data, but brokers inter-worker communication through S3. Finally, gg provides fault tolerance, which ExCamera's own back-end lacks.

4.4 Object Recognition

The increase in visual computing applications has motivated the design of frameworks such as Scanner [30], which is a system for productive and efficient video analysis at scale. To use Scanner, the user feeds in a compressed video and designates an operation to be applied on each decoded frame. To compare Scanner's execution engine with gg, we used the gg C++ SDK to implement a two-step analysis pipeline. In the first stage, the frames of a video V are decoded in batches of m frames, using DECODE(V,m) function. Subsequently, an object-recognition kernel, OBJECT-REC, is applied to the decoded frames and returns the top five recognized objects for each frame.

We implemented the DECODE function using FFmpeg [14] and implemented OBJECT-REC in TensorFlow's C++ API [1] using a pre-trained Inception-v3 model [37]. gg's thunks were able to bundle these pre-existing applications. We implemented the same pipeline in Scanner for comparison. To do so, we leverage Scanner's internal video decoder and the same TensorFlow kernel and pre-trained Inception-v3 model.

4.5 Recursive Fibonacci

To demonstrate the way that gg handles dynamic dataflows, we used the C++ SDK to implement a classic recursive Fibonacci program in the gg IR. The application is expressed using two functions: ADD(a,b), which returns the sum of its two input values and FIB(n) which recursively computes the n-th Fibonacci number as ADD(FIB($n-1$), FIB($n-2$)) or the base case when $n \leq 1$.

Figure 6 shows the execution steps. In the beginning, there is only one thunk, FIB(4). After execution, instead of returning a value, it returns three thunks, replacing the target with the sum of two preceding Fibonacci numbers. The IR expands (for the recursive case) and contracts (for the base case), until resolving to the final value.

In a naïve recursive implementation of the Fibonacci series, each Fibonacci value is evaluated many times. However, in gg, the functions are memoized and lazily-executed, resulting in each Fibonacci value computed only once.

5 Evaluation

We evaluated gg's performance by executing each application in gg, compared with comparable tailor-made or native applications. Although we implemented back-end engines for

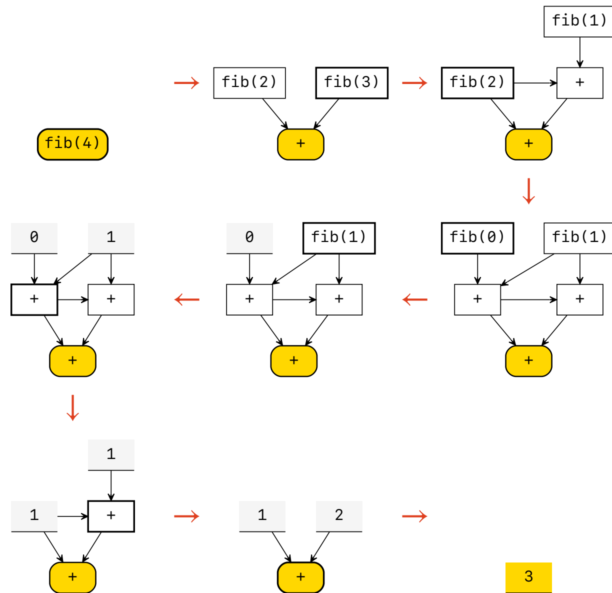

Figure 6: Evolution of the IR for a recursive Fibonacci application. Execution begins with a single thunk. As each thunk is forced, returning a new thunk or the base case, the IR expands and contracts. The engine lazily forces thunks until it can return the overall value.

1K trivial containers running "sleep 2"		
AWS Lambda	gg-λ	06s ± 01s
	PyWren	46s ± 08s
	Spark-on-Lambda	54s ± 21s
Google Kubernetes Engine	Kubernetes	03m 08s ± 03s

Figure 7: Comparison of completion time for running 1,000 `sleep(2)` tasks using four different systems. gg's lightweight design and implementation has less overhead than other systems.

Compiling Inkscape on AWS Lambda (total of 3602 thunks)	
Initial graph construction	56 ms
Mean time to read a thunk	188 µs ± 367 µs
Mean time to recompute the IR per thunk	336 µs ± 560 µs
Invocation (thunk completion to invocation of all dependent thunks)	142 ms ± 135 ms

Figure 8: gg's overheads allow for relatively fine-grained tasks.

several cloud-functions platforms (including Google Cloud Functions and IBM Cloud Functions), we found that AWS Lambda had the best performance and available parallelism. As a result, we focus on evaluation results from gg's AWS Lambda back-end.

5.1 Startup Overhead

To motivate the importance of gg's lightweight abstractions, we implemented a trivial job, 1,000 parallel tasks each executing `sleep(2)`, using four frameworks: gg, PyWren, Spark-on-Lambda, and Kubernetes. The first three frameworks were executed on AWS Lambda, and the last on Google Kubernetes Engine (GKE), which was given a warm cluster of eleven 96-core VMs (1,056 cores in total) on which to allocate containers. Figure 7 shows the results.

gg is able to quickly scale to 1,000 concurrent containers and finish the job 7.5–9× faster when compared with other two frameworks running on Lambda. After subtracting off the 2-second sleep time, this translates to 11–13× less overhead. For PyWren, on average, each worker spends 70% of its time on setting up the Python runtime (downloading and extracting a tarball). A large portion of this runtime consists of packages that are not used by our `sleep(2)` program (cf. gg fine-grained dependency tracking). Google Kubernetes Engine was not designed for transient computations and was not optimized for this use case; it is much slower to start 1,000 Docker containers.

Additionally, we measured the overheads associated with loading thunks and recomputing the IR after a thunk is done in Figure 8. These overheads, especially the invocation overhead, support an intuition about the appropriate granularity of thunks: gg works well when thunks last about 1–20 seconds each.

5.2 Software Compilation

To evaluate gg's application for software compilation, we measured the start-to-finish build times under multiple scenarios on a set of unmodified large open-source packages. We compared these times with existing tools under the same scenarios. For distributed builds outsourced from a 4-core EC2 VM, we found that gg is able to achieve significantly shorter build times than existing approaches.

5.2.1 Evaluation Set

To benchmark gg's performance, we picked four open-source programs written in C or C++: FFmpeg, GIMP, Inkscape, and Chromium. No changes were made to the code or the underlying build system of these packages. We compiled all packages with GCC 7.2.

All the 4-core machines used in the experiments are EC2 `m5.xlarge`, and all the 48-core machines are EC2 `m5.12xlarge` instances. To realistically simulate users sending applications to nearby datacenters, client machines reside in the US West (N. California) region, and outsource their jobs to machines in the US West (Oregon) region.

	Estimated SLoC	Local (make) 1 core	Local (make) 48 cores	Distributed (icecc) 48 cores	Distributed (icecc) 384 cores	**Distributed (gg)** 384 cores	**Distributed (gg)** AWS Lambda
FFmpeg	1,200,000	06m 19s	20s	01m 03s	39s	40s	44s ± 04s
GIMP	800,000	06m 48s	49s	02m 35s	02m 38s	01m 26s	01m 38s ± 03s
Inkscape	600,000	32m 34s	01m 40s	06m 51s	06m 57s	01m 20s	01m 27s ± 07s
Chromium	24,000,000	15h 58m 20s	38m 11s	46m 01s	42m 18s	40m 57s	18m 55s ± 10s

Figure 9: Comparison of cold-cache build times in different scenarios described in §5.2. gg on AWS Lambda is competitive with or faster than using conventional outsourcing (icecc), and in the case of the largest programs, 2–5× faster. This includes both the time required to generate gg IR from a given repository and then to execute the IR.

5.2.2 Baselines

For each package, we measured the start to finish build time in four different scenarios as the baseline for local and distributed builds:

make, make (48): The package's own build system was executed on a single core (make), and with up to 48-way parallelism (make -j48). The make and make (48) tests were done on 4-core and 48-core EC2 VMs, respectively. No remote machines were involved in these tests.

icecc (48), icecc (384): The package was built using the icecc distributed compiler on a 4-core client that outsources the job to a 48-core VM, or to eight 48-core VMs, for a total of 384 cores.

5.2.3 gg's Benchmarks

We conducted the following experiments for each package to evaluate gg:

1. **gg (384)**: The package was built with the same configuration as the icecc (384) experiment: a 4-core client farming out to eight 48-core machines, using gg's backend for a cluster of VMs.
2. **gg-λ**: The package was built on a 4-core client outsourcing to AWS Lambda, using as many concurrent Lambdas as possible (up to 8,000 in the case of Chromium).

   For Chromium experiments, an additional standby EC2 VM acted as the *overflow* worker for thunks whose total data size exceeded Lambda's storage limit of 500 MB. Throughout building Chromium, there were only 2 thunks (out of ~90,000 thunks) that did not fit on a Lambda and had to be forced on this overflow node.

5.2.4 Discussion of Evaluation Results

Figure 9 shows the median times for the package builds. gg is about 2–5× faster than a conventional tool (icecc) in building medium- and large-sized software packages. For example, gg compiles Inkscape in 87 seconds on AWS Lambda, compared with 7 minutes when outsourced with icecc to a warm 384-core cluster. This is a 4.8× speedup. Chromium, one of the largest open-source projects available, compiles in under 20 minutes using gg on AWS Lambda, which is 2.2× faster than icecc (384).

We do not think gg's performance improvements on AWS Lambda can be explained simply by the availability of more cores than our 384-core cluster; icecc improved only modestly between the 48-core and 384-core case and doesn't appear to effectively use higher degrees of parallelism. This is largely because icecc, in order to simplify dependency tracking, runs the preprocessor locally, which becomes a major bottleneck. gg's fine-grained dependency tracking allows the system to efficiently outsource this step to the cloud and minimize the work done on the local machine.

Figure 10 shows an execution breakdown for compiling Inkscape. We observe two important characteristics. First, the large spikes correspond to Lambdas that have failed or taken longer than usual to complete. gg's straggler mitigation detects and relaunches these jobs to prevent an increase in end-to-end latency. Second, the last few jobs are primarily serial (archiving and linking), and consume almost a quarter of the total job-completion time. These characteristics were also observed in the other build jobs.

5.3 Unit Tests

To benchmark gg's performance in running unit tests created with the Google Test framework, we chose the VPX video codec library [9], which contains ~7,000 unit tests. We annotated each test with the list of required data files.

The Google Test library that is shipped with LibVPX is only capable of running the tests serially. To establish a better baseline, we used gtest-parallel, a program that executes Google Test binaries in parallel on the local machine. We ran the tests with 4- and 48-way parallelism and compared the results with gg on AWS Lambda, with 8,000-way parallelism. Figure 11 shows the summary of these results.

Using the massive parallelism available, gg was able to execute all of the test cases in parallel, and 99% of the test

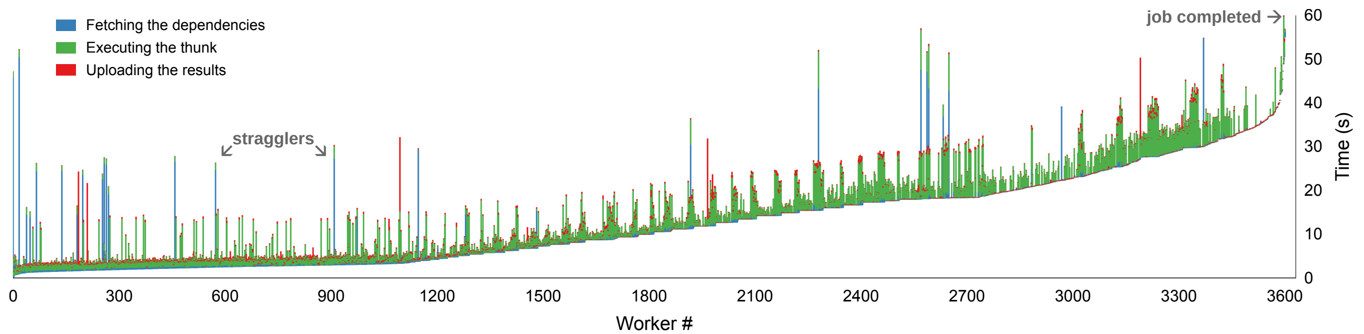

Figure 10: Breakdown of workers' execution time when building Inkscape using gg on AWS Lambda. Serial stages (archiving and linking) consume almost a quarter of the total job-completion time. Spikes indicate stragglers, which are mitigated by gg using standard techniques. In this experiment, stragglers mostly consist of Lambdas that have trouble communicating with the storage back-end (S3).

	gg-λ	gtest (4)	gtest (48)
LibVPX Test Suite	03m 25s	51m 45s	04m 40s

Figure 11: Running the LibVPX test suite using gg on AWS Lambda outperforms running the tests with 4-way and 48-way parallelism on a local machine. 99% of the test cases complete within 30 seconds.

	gg-λ	original
ExCamera	01m 30s	01m 16s

Figure 12: The gg version of ExCamera is 18% slower than the hand-optimized original ExCamera, which was written to pipeline I/O and computation within a Lambda worker.

cases finished within the first 30 seconds. From a developer's point of view, this improves turnaround time and translates into faster discovery of bugs and regressions.

5.4 Video Encoding

We evaluated the gg implementation of ExCamera on AWS Lambda, with the original implementation as the baseline. The selected configuration was the same as ExCamera's original paper (6 frames per chunk, 16 chunks per batch). The input video consisted of 888 chunks, and all chunks had been uploaded to S3 in raw format prior to execution. For the original ExCamera implementation, a 64-core VM (`m4.16xlarge`) was used as the rendezvous server to broker TCP streams between Lambda workers.

Figure 12 shows the results. The original ExCamera was hand-coded to pipeline I/O and computation to reduce end-to-end latency. By contrast, gg's abstract interface must force and load all data-dependencies before running user code, and cannot perform this optimization. ExCamera-on-gg is 18% slower than the original, but adds memoization and fault-tolerance, unlike the original ExCamera.

Object Recognition	
gg local (64 cores)	04m 30s
gg on AWS Lambda	37s
Scanner local (64 cores)	05m 39s
Scanner on cluster (140 cores)	03m 14s

Figure 13: Scanner-on-gg outperforms the original Scanner on the same hardware, and performs even faster on AWS Lambda.

5.5 Object Recognition

We compared the original Scanner [30] with the gg implementation using a 4K video with more than 6,000 frames. For the baseline, we chose the most favorable execution parameters through an exhaustive search. The optimal number of pipeline instances and frame batches were 14 and 75, respectively. Within each pipeline, each video chunk is first decoded into raw images before being passed to the TensorFlow kernel execution thread. Each execution thread only needs to load the model once per stream of frames. Scanner local was run on a 64-core machine (`m4.16xlarge`). Scanner on cluster was run with a 4-core master (`m4.xlarge`) and four 36-core workers (`c4.8xlarge`), of which Scanner uses 35 and leaves one for scheduling. For the gg implementation, the video was broken up into five-second chunks and uploaded to the cloud prior to execution. Each chunk was decoded in batches of 25 frames. For the object recognition task, the IR was configured to the optimal number of frame batches per task.

Figure 13 presents the summary of the results. While Scanner on cluster is 39% faster than gg local, it is 5.2× slower than gg on AWS Lambda. Scanner local is over 9× slower than gg on AWS Lambda. gg's lightweight scheduling and execution engine removes several layers of abstraction present in Scanner's design.

6 Limitations and Discussion

gg has a number of important limitations and opportunities for future work.

Direct communication between workers. Although commentators have noted that "*two Lambda functions can only communicate through an autoscaling intermediary service... like S3*" [18], our experience differs: we have found that on AWS Lambda, two Lambda functions can communicate directly using off-the-shelf NAT-traversal techniques, at speeds up to 600 Mbps (although the performance is variable and requires an appropriate protocol and failure-recovery strategy). We thus believe that the performance of systems such as ExCamera, PyWren, and gg is likely to improve in the future as practitioners develop better mechanisms for harnessing this computing substrate, including direct communication.

In follow-on work, we are developing a 3D ray-tracing engine on gg, that will quickly render complex scenes across thousands of nodes, where the scene geometry and textures consume far more space than any individual node's memory. To achieve sufficient performance, this will require low-latency and high-speed communication between workers, motivating the use of direct network connectivity, instead of an intermediate storage system such as S3 or Pocket [24].

Limited to CPU programs. gg specifies the format of the code as an x86-64 Linux ELF executable. The IR has no mechanism to signal a need for GPUs or other accelerators, and efficiently scheduling such resources poses nontrivial challenges, because loading and unloading configuration state from a GPU is a more expensive operation than memory-mapping a file. We plan to investigate the appropriate mechanisms for a gg back-end to schedule thunks onto GPUs.

A gg DSL to program for the IR. Currently, we have implemented a C++ and Python SDK for users to express applications that target the gg IR. However, this requires the user to explicitly provide an x86-64 executable and all of its dependencies prior to thunk generation. We envision a language in which users can write high-level code in Python or C++, using primitives such as a parallel map, fold, and other operations, which will be compiled into the gg IR.

Why cloud functions? Transient, burst-parallel execution on services like AWS Lambda produces a different cost structure from a warm cluster. It takes about the same amount of time for gg to compile Inkscape on AWS Lambda as on a 384-core cluster of warm EC2 VMs (Figure 9). The job costs about 50 cents *per run* on Lambda, compared with $18.40 *per hour* to keep a 384-core cluster running (Figure 2). Whether it is financially beneficial for the gg user to run such jobs on long-running VMs or on cloud functions depends on how often the user has a job to run. From an economic perspective, the provider is compensating the infrequent user for their elasticity; e.g., for having structured their workload to vacate compute resources when no task is active, and to tolerate variations in the exact number of nodes available for a job and the timing of when they are allocated.

In the future, we expect the performance characteristics of VMs and Lambda-like services to move closer together. There is no intrinsic reason for it to take more than 30 seconds to provision and boot an infrastructure-as-a-service VM in the public cloud. Linux itself can boot in less than a second, and KVM and VMware can provision a VM in less than 3 seconds. We understand the remaining time is largely "management plane" overhead. If this can be reduced, then cloud functions may hold no compelling advantage over virtual machines for executing burst-parallel applications—but tools like gg that aid efficient execution on remote compute infrastructure (whether VM or cloud function) may remain valuable.

7 Conclusion

In this paper, we described gg, a framework that helps developers build and execute burst-parallel applications. gg presents a portable abstraction: an intermediate representation (IR) that captures the future execution of a job as a composition of lightweight Linux containers. This lets gg support new and existing applications in various languages that are abstracted from the compute and storage platform and from runtime features that address underlying challenges: dependency management, straggler mitigation, placement, and memoization.

As a computing substrate, we suspect cloud functions are in a similar position to Graphics Processing Units in the 2000s. At the time, GPUs were designed solely for 3D graphics, but the community gradually recognized that they had become programmable enough to execute some parallel algorithms unrelated to graphics. Over time, this "general-purpose GPU" (GPGPU) movement created systems-support technologies and became a major use of GPUs, especially for physical simulations and deep neural networks.

Cloud functions may tell a similar story. Although intended for asynchronous microservices, we believe that with sufficient effort by this community the same infrastructure is capable of broad and exciting new applications. Just as GPGPU computing did a decade ago, nontraditional "serverless" computing may have far-reaching effects.

Acknowledgments

Abstract

As network, I/O, accelerator, and NVM devices capable of a million operations per second make their way into data centers, the software stack managing such devices has been shifting from implementations within the operating system kernel to more specialized kernel-bypass approaches. While the in-kernel approach guarantees safety and provides resource multiplexing, it imposes too much overhead on microsecond-scale tasks. Kernel-bypass approaches improve throughput substantially but sacrifice safety and complicate resource management: if applications are mutually distrusting, then either each application must have exclusive access to its own device or else the device itself must implement resource management.

This paper shows how to attain both safety and performance via intra-process isolation for data plane libraries. We propose *protected libraries* as a new OS abstraction which provides separate user-level protection domains for different services (e.g., network and in-memory database), with performance approaching that of unprotected kernel bypass. We also show how this new feature can be utilized to enable sharing of data plane libraries across distrusting applications. Our proposed solution uses Intel's memory protection keys (PKU) in a safe way to change the permissions associated with subsets of a single address space. In addition, it uses hardware watchpoints to delay asynchronous event delivery and to guarantee independent failure of applications sharing a protected library.

We show that our approach can efficiently protect high-throughput in-memory databases and user-space network stacks. Our implementation allows up to 2.3 million library entrances per second per core, outperforming both kernel-level protection and two alternative implementations that use system calls and Intel's VMFUNC switching of user-level address spaces, respectively.

1 Introduction

A principal task of an operating system (OS) is to multiplex hardware resources, making them accessible to multiple user-level applications, and to arbitrate use of those resources to satisfy system-wide performance and fairness goals. User/kernel isolation enables the OS to enforce its resource management decisions in the face of untrusted and potentially malicious applications. In recent years, however, developers have begun to move I/O management into user space for the sake of higher performance, specialization, and rapid development. This strategy is often referred to as *kernel-bypass* I/O. DPDK [21] and mTCP [24] move packet processing and transport layer processing into user space; SPDK [22] does the same for direct access to fast storage devices like Optane SSDs [19]. Accelerators like Google's TPU [25] and Nvidia's GPUs [34] also rely on kernel-bypass software stacks for low-latency hardware access and rapid evolution of drivers.

The trend toward kernel bypass has enabled significant improvements in device throughput and latency [4, 39, 40]. These gains, however, have typically come at the cost of granting an application exclusive access to a device, trusting other users of the device, or relying on the existence of a hardware-level arbitrator that virtualizes or partitions the device (e.g., SR-IOV [23]). Unfortunately, device-level resource isolation is not always available and typically lacks the flexibility to implement OS-level resource management policies.

The anticipated widespread availability of byte-addressable non-volatile memory (NVM) DIMMs [45] brings similar challenges. If NVM is mapped into a process's address space so that it can be accessed directly with application load/store instructions, a memory safety error within the process could corrupt data structures on the NVM [37]. Relying on OS kernel mechanisms e.g., a file system interface, to protect access to NVM would throw away the performance potential of direct loads and stores to persistent memory.

One can, of course, implement protection domains within an address space using a trusted compiler with static [17] or dynamic [52] checking. The static approach requires a type-safe language and is thus incompatible with many existing applications. The dynamic approach incurs overhead that is significant even in the simplest cases (e.g., when checking pointers against a single boundary address), and rises steeply for more complex address space layouts [44].

What we desire is a mechanism that allows services traditionally implemented in the kernel to be encapsulated as *protected libraries* in user space. Such a mechanism should be compatible with existing applications (i.e., via re-linking), provide fast transitions into and out of protected library routines, impose little or no cost on ordinary code, accommodate multiple protected code and data segments in a single application, and support independent failure to allow a protected library to be shared across distrusting applications. Toward that end, this paper proposes *Hodor*, a mechanism for low-overhead intra-process isolation. Hodor leverages the existence of user libraries to define protection domains for services previously offered by the kernel (e.g., file systems, network stack, device drivers, etc.). Relying on library boundaries, Hodor offers practical intra-process isolation without requiring any significant effort on the part of the application programmer. It allows multiple mutually distrusting libraries to be loaded into the same address space, providing each library (and the main application) with a different "view" of code and data, and protecting each from failures in the others. (When a failure occurs, library calls in non-erroneous protection domains are permitted to complete before the process terminates.) Hodor employs the standard function call/return interface but interposes a *trampoline* on each call to change the view of the address space to that of the library being entered.

Hodor can be used to provide instances of a protected library in multiple applications with access to shared resources. Instances of a network library, for example, might provide fast, user-level access to a NIC while enforcing rate-limiting policies that require coordination among otherwise uncoordinated and mutually distrusting applications.

We propose a concrete implementation of Hodor for recent Intel processors that is based on Intel's memory protection keys, called *Protection Keys for Userspace (PKU)* [20]. We introduce a novel method that uses hardware watchpoints (i.e., debug registers [20]) to efficiently monitor program execution and ensure the safety of our approach without relying on a trusted compiler, changes to application source code, or expensive dynamic binary translation.

We also describe two alternative implementations of Hodor's isolation: 1) using a system call to switch between page tables, and 2) using Intel's Extended Page Table (EPT) switching with VM function (VMFUNC) instructions [20]. We compare our PKU-based protection with each of the alternative solutions and demonstrate that the PKU approach offers better performance. While none of the implementations is fast enough to be used for fine-grained intra-process isolation (e.g., for shadow stacks [7] or code-pointer integrity [50]), our results show that both PKU- and VMFUNC-based approaches are able to support on the order of two million calls per second per core into a protected library.

In summary, our contributions are as follows:

- We introduce Hodor, a mechanism that provides a new OS abstraction to isolate fast data-plane libraries from both the calling application and each other.
- We propose a concrete implementation of Hodor for current Intel processors based on PKU. We present a novel method that combines binary inspection and hardware watchpoints to prevent bypassing of the PKU-based protection and safely isolate libraries linked in arbitrary x86 applications.
- We quantify the performance benefits of Hodor on real-world applications with respect to both unprotected kernel bypass and isolation based on kernel-mediated page table switching and EPT switching via VMFUNC.
- We present two proof-of-concept examples of protected libraries that share state between library instances in separate applications (with independent failure modes), and discuss challenges that must be addressed in such designs.

The following section describes in more detail the problem addressed by protected libraries, including the threats against which we protect, the assumptions we make about library code, the capabilities we provide to libraries, and the system components (signal interface, threading libraries, operating system kernel) that must be modified to ensure isolation. Sec. 3 then describes our candidate implementations. We evaluate the performance of these implementations in Sec. 4 using microbenchmarks, the Silo in-memory database [48], the DPDK data-plane library package [21], and the Redis [42] NoSQL server. Sec. 5 discusses related work. Sec. 6 summarizes our conclusions.

2 Protected Libraries

Hodor's *protected library* mechanism partitions an application into multiple domains of executable code. Each domain is granted access to some parts of the address space and denied access to other parts. Each domain has private stacks and possibly a private heap, but also shares access to some pages, allowing efficient communication with other domains. Domain transitions follow standard calling conventions, mediated by *trampoline* routines that switch to the appropriate address space view, switch stacks, set up arguments to maintain calling conventions, and possibly scrub any remaining registers to avoid information leaks. Trampolines also switch back to the caller's domain when a library call returns.

2.1 Threat Model

With Hodor, an untrusted application uses protected libraries to access protected resources. A resource might comprise ordinary memory, non-volatile memory, or a memory-mapped device. By default, an application shares its entire memory space with each protected library, but the library shares only the *trampoline* code needed for cross-domain calls. In addition, an application can optionally be modified to share only buffers with the library.

Figure 1 shows an example with user-space network and storage libraries. The storage library has default access to the

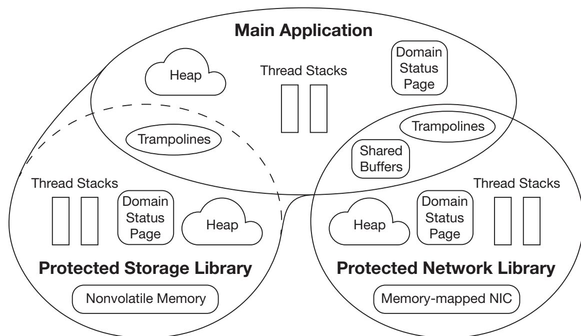

Figure 1: Protected Library Architecture. The example application has, by default, shared its entire memory space with the storage library. It has opted to share only certain buffers with the network library.

application; the network library has been given access only to shared buffers. We assume that applications may be multi-threaded and that library entry points may accept pointers to callback functions. Consequently, protected libraries must be multi-thread safe and re-entrant. When a protected library opts to share state with instances in other applications (e.g., to track resource usage and enforce fairness), the library is responsible for synchronization. We accommodate independent failures by arranging to complete the execution of any library call whose process incurs a fault in a different domain (more on this in Sec. 2.5).

As replacements for traditional kernel services, protected libraries are assumed to be written with care. Among other things, they should employ caution when dealing with potentially unsafe arguments (e.g., using methods like copy-in/copy-out) just as kernel code would. They should also ensure that transitions into other domains (e.g., invocation of a callback or a third-party library function) happen in a safe context. It would be incorrect, for example, to acquire a lock and then call an outside function, since it might terminate before returning back to the library. In our implementation, protected libraries are statically linked with all their dependencies to ensure that transitions into and out of the library conform to its API. This does not prevent use of shared libraries by the rest of the application. A more flexible implementation could dynamically link a separate instance of shared libraries in each protection domain that requires them.

A protected library is trusted to enforce security and management policies for its protected resources but is otherwise untrusted. The hardware and the operating system are part of the Trusted Computing Base (TCB), and are assumed to be correctly implemented. The application and other untrusted libraries are outside the TCB: they are not trusted to read or write protected library memory.

In this work, we are primarily interested in preserving the integrity and confidentiality of protected memory and devices from direct memory reads and writes. While side-channel attacks, and in particular those targeting transient execution [8, 27, 30], are out-of-scope, we explain the ramifications of our implementations on related transient execution attacks.

We assume that an attacker controls the application and untrusted libraries and can add arbitrary native code to the application and to untrusted libraries. We assume that the attacker cannot gain direct access to the data within a protected library's memory via the library's own API. We must consider the possibility, however, that the attacker may attempt to:

- Gain access to protected memory by changing virtual-to-physical mappings using system calls like `mmap`.
- Modify, from a compromised thread, local variables or return addresses in the stack of a thread that is running in the library.
- Subvert the loading mechanism so that a different library has access to protected memory.
- Install malicious signal handlers and then arrange for a signal to be delivered while the library is running.

We consider these issues in turn in the following subsections.

2.2 Virtual Address Space Integrity

In a standard Linux system, a process can change the page permissions of its own memory with the `mprotect` system call, and change the mappings between virtual and physical addresses with the `mmap` system call. For any given protected library *L*, we must prevent address space changes, when requested by code outside of *L*, from making *L*'s code or data accessible to the application or to another library.

This is the easiest vulnerability to address. We assume that the static and dynamic loaders are part of the trusted computing base. When asked to load a protected library, they inform the operating system of the virtual addresses used by the protected library's code and data. On any subsequent call to `mprotect`, `mmap`, etc., the kernel identifies the context in which the syscall was made (i.e., the value of `pkru` register for the PKU-based implementation and the instruction pointer for page-table switching implementations) and grants requests to change the mappings or permissions of protected library space only when made in an appropriate context.

2.3 Local Variables and Protected Stack

Within its protected memory, in addition to code, global variables, and heap, each protected library also maintains per-thread private stacks on which to store return addresses and local variables. When an application creates a new thread, we must create a new stack for each of the domains in the application. We embed this logic within the threading library (e.g., `pthreads`) so that application developers do not need to explicitly modify any application code.

When an application calls a function within a protected library, trampoline code accessible to the application must arrange for the target function to execute in the library's protection domain, where it can access its protected code and data. In particular, the trampoline must switch the stack pointer to the local stack of the calling thread. Sec. 3 describes the design of our trampolines for each intra-process isolation mech-

anism in more detail. If a protected library invokes a callback function within the application, it will also use trampoline code to switch back to the application's domain and stack.

Switching stacks can be challenging when the source or target distrusts the other. Previous work addressed this issue either by going through a trusted domain like the kernel [31] or by not supporting mutually distrusting domains [50]. While we could employ a trusted *trampoline domain*, such an implementation would double the overhead of transitions by changing the view first to the trampoline domain and then to the target domain. We address this challenge by first saving the state of the source domain (`rsp`, `fs`, etc.) in a *domain status page* accessible only in the source domain, then switching the address space view to the target domain, and finally restoring the state of the target domain from a domain status page accessible only to the target.

Like stacks, domain status pages are per-thread entities. Unfortunately, in the absence of trust, we need to access domain status pages without relying on registers such as `fs` (used for thread local storage). We can address this issue by arranging for the kernel to support a fast (vDSO-style) `gettid` call to acquire the current thread ID. The kernel maintains a list (readable, but not writable in user space) of currently running thread IDs for all CPU cores. The fast `gettid` performs a vDSO `getcpu` lookup and uses the result to find the thread ID. This enables trampoline code to access thread-local storage without relying on `fs` or performing a system call.

2.4 Program Loading

Hodor employs a trusted loader, running as root (to allow it to open I/O device files) to start up any application that uses one or more protected libraries. The trusted loader first maps all protected libraries into the virtual address space using the `mmap` system call. It then calls an initialization function within each protected library. In this function, a library can open and map the device files it needs so that it has direct read/write access to a device's memory-mapped I/O registers or to a region of persistent or shared memory. The initialization function also allocates the first stack, initializes the heap, and calls constructor functions (e.g., for C++ global variables) for the protected library.

Once all protected libraries are initialized, the trusted loader uses a system call to inform the kernel of the location of each protected library. This allows the kernel to enforce restrictions on system calls that configure the virtual address space (as per Sec. 2.2). The trusted loader then loads the application code and all other pre-loaded dynamic libraries. If inspection is required (as in the PKU-based version of Hodor that we introduce in Sec. 3.3), the loader performs it now; the kernel arranges for similar inspection on any additional libraries that are loaded on demand and on any other pages for which execute permission is enabled during execution. Finally, the trusted loader drops root privileges using the `setresuid` system call, runs the constructor functions of the application, and transfers control to the application's `main` routine.

2.5 Asynchronous Events and Termination

To support unmodified applications, Hodor must address asynchronous event delivery via signals—in particular, the possibility that the kernel might invoke a signal handler in a thread that was executing trampoline or protected library code. Such a handler might then gain access to protected library state.

In a similar vein, termination of a process while a thread is executing protected library code could leave data structures (possibly shared with library instances in other applications) in an inconsistent state or cause deadlock (by failing to release a lock). To preclude protection violations in signal handlers and to accommodate independent failures of processes whose libraries share state, we modify the kernel so that it never delivers a signal or terminates the process while threads are still running protected library or trampoline code. Instead, it places a *hardware watchpoint* (using registers `DR0`–`DR3` on an Intel machine) in the "boundary trampoline" used to exit protected libraries (line 37 of Listing 1), and delays signal delivery or termination until the watchpoint has been triggered.

As noted in Sec. 2.1, we assume that protected libraries are written with care. In particular, we assume that their operations take modest, bounded time. If a protected library does not return in a timely fashion after we install the hardware watchpoint on the trampoline (detected by expiration of a timer initiated when we arm the watchpoint), we assume that the library is defective and terminate the application (having given any other, non-defective libraries time to finish execution). We perform a similar summary cleanup if a fatal error (e.g., a `SIGSEGV`) is caused *by* library code.

Our design does not permit signal handlers to be registered for execution by a protected domain. None of the privileged library use cases we evaluated need signal handling. If they did, the kernel's signal handler API could, in principle, be extended to allow a protected library to request that a handler should execute in the library's domain. Since the kernel knows the locations of all protected library code segments in memory (see Sec. 2.4), it could confirm whether a registration request was made from trusted library code and allow or deny the request accordingly.

3 Fast Memory Isolation

This section presents three implementations of memory isolation for Hodor. The most straightforward implementation, described in Sec. 3.1, relies on separate page tables for each domain, and uses system calls to change the page table root pointer. Hodor-VMFUNC, described in Sec. 3.2, also uses per-domain page tables, and switches between them using Intel's VM Function (VMFUNC) mechanism. Both the syscall-based system and Hodor-VMFUNC rely on context identifier tags (Intel's PCID and EP4TA, respectively) to avoid flushing the translation lookaside buffer (TLB) when changing domains.

Hodor-PKU, our preferred solution (described in Sec. 3.3), uses memory protection keys to provide different access rights in the same page table. Since the access rights for each domain can be modified by user code, we need to prevent an application from bypassing our PKU-based isolation mechanism. We present a novel method in Sec. 3.3.1 that combines binary inspection and the use of hardware monitors for efficient run-time monitoring to ensure the safety of Hodor-PKU.

In an attempt to capture intuition, we speak of the domains of an application as having different "views" of a single address space. That is, conceptually, the application has a single set of virtual-to-physical mappings within which we adjust permissions on individual pages. In actuality, Hodor-VMFUNC and the syscall-based system use separate page table root pointers for separate views.

3.1 Page Table Switching via Syscalls

A straightforward way to implement protected libraries is to employ a separate page table for each domain and to use a system call to change page tables. Executable pages appear only in the tables of their corresponding domains. Protected pages rely on protection bits in the page tables of each domain to prevent undesired accesses. Unprotected application pages and trampoline pages appear in all page tables. A new system call serves to change the page table root pointer (register `CR3` on Intel machines), if and only if the requesting syscall instruction lies in the appropriate (previously registered) trampoline.

Assuming kernel page table isolation (KPTI) [13], every system call changes `CR3` on entry to the kernel. Our new syscall simply arranges (after appropriate checks) to restore the target domain's root pointer, rather than that of the calling domain, when returning to user space. This limits the overhead to only slightly more than that of a no-op system call. There may also be a rise in TLB pressure for certain applications, given that some pages will appear in the TLB more than once, with separate context tags. On hardware that has such tags, however, there is no need to flush the TLB as part of a domain switch. As a separate issue, syscalls like `munmap`, together with the TLB shootdown mechanism, are modified to remove a mapping under all applicable context tags.

In this approach, each domain of an application has a separate page table root pointer. Fortunately, the content of the tables is largely overlapping (generic heap, vDSO, kernel translations, etc.). We use a separate top-level page for each table, but many of the lower-level pages are physically shared. This approach simplifies entry manipulation and minimizes memory footprint.

3.2 Hodor-VMFUNC

Beginning with its Nehalem generation of processors, Intel has provided *extended page tables (EPT)* for virtualized environments. The traditional page table of a guest OS translates from "guest virtual" to "guest physical" addresses; the extended (second-level) page table translates from guest physical to (host) physical addresses. In the subsequent Haswell generation, Intel introduced a VM Function (VMFUNC) mechanism for fast invocation of hypervisor functions in a paravirtualized guest. This mechanism allows a guest to pre-register a set of second-level page tables and provides a (non-privileged) instruction to switch amongst them. Several systems (e.g., SeCage [32] and MemSentry [28]) have used VMFUNC to isolate a sensitive region within an application, but, they require source-code analysis and non-trivial modifications to existing applications.

Hodor-VMFUNC isolates a memory region by setting up a degenerate traditional page table that implements the identity function (with all types of access allowed) and employing a separate extended page table—analogous to the ordinary page tables of the syscall-based system—for each protection domain. An application can then switch among views with no kernel involvement. Compared to the approach of Sec. 3.1, which uses trusted kernel code to check that a domain switch is permissible, a new challenge in this approach is that we must fold the permission check into the VMFUNC instruction itself. We do so by placing the trampolines of a given library in their own page(s) and making those the only pages that are executable in the domains of both the main application and the library. A VMFUNC instruction that attempts to switch to the library's domain but lies anywhere other than an appropriate trampoline page will find the next instruction non-executable, resulting in a fault.

While the serialization overhead of an address-space-changing instruction appears inevitable (absent major architectural changes e.g., CODOMs [51] and CHERI [55], which themselves impose new overheads), using VMFUNC avoids the need for a system call when switching domains. As Sec. 4 shows, this cuts the cost of a switch by more than 50%.

Listing 1 (including the parts to the left of the vertical lines) shows the trampoline code for Hodor-VMFUNC. Line 2 saves the stack pointer of the source domain to the source domain's status page. As Sec. 2 describes, this step allows the trampoline to restore the stack when returning from the protected library; it also supports callback functions (argument copying and register scrubbing code is omitted for brevity). Line 7 sets `eax` to zero, indicating that an extended page table switch is desired. Line 8 sets `ecx` to the index (in a pre-approved table) of the domain to which to switch; line 9 effects the switch itself. Line 14 loads the stack pointer of the target domain from the target domain's status page into `rsp`; this is possible since `VMFUNC` has just enabled access to the private data of the target domain. At this point, the trampoline transfers control to a function in the target domain. Once the function returns, the trampoline saves the stack pointer of the target domain in its status page (line 19); it then resets the extended page table to the source domain (lines 25–27). Finally, it loads the source domain stack pointer from the source's status page into `rsp` (line 32) and resumes execution (line 37).

Listing 1: Hodor Trampoline: VMFUNC (left), PKU (right).

```

37 ret
```

As a starting code base, our Hodor-VMFUNC implementation uses the Dune system of Belay et al. [3], with the application running in ring 3 of VMX non-root (VM guest) mode. Running in virtualized (VMX) mode, with 2-level address translation, imposes additional overheads that are, in principle, unneeded. Most system calls, which must be handled by the operating system, incur the cost of a VM exit that is significantly more expensive than a (nonvirtualized) syscall. (That said, system calls are uncommon except during initialization in applications that use kernel-bypass data-plane libraries.) TLB refill costs increase as well, due to 2-level translation.

Ideally, we should like a hardware mechanism that allows a non-privileged instruction to switch among pre-approved page table root pointers without the need for virtualization. In the meantime, optimizations are available to mitigate the cost. First, we use huge pages to reduce the first-level (identity-function) page tables from four levels to two, eliminating half the extra cost of a VMX TLB fill. Second, it should be possible (not yet implemented) to mix virtualized and non-virtualized threads within a single application. Threads running in VMX mode will experience faster protected library calls but slower system calls; those running natively will have to use syscall-based page-table switching for library calls, but will not see additional overhead for system calls.

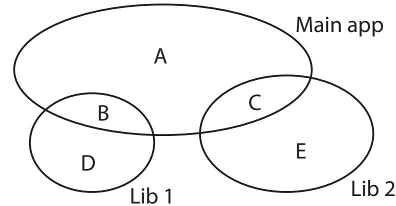

Figure 2: Address space regions in Hodor-PKU.

3.3 Hodor-PKU

In its Skylake generation of processors, Intel introduced a mechanism it calls *memory protection keys for userspace* (PKU). (Similar mechanisms have appeared in previous architectures from several other vendors.) While PKU is intended mainly as a memory safety enhancement (e.g., as a means of reducing vulnerability to stray-pointer bugs), we have realized that it can, with care, be used for protected libraries as well.

PKU [20] employs previously unused bits in each page table entry to assign a four-bit protection key to every page, allowing that page to be associated with one of 16 potential sets of access restrictions. A new 32-bit `pkru` register, writable in user space, then specifies which rights (read and/or write) should be restricted for each of the 16 key values. On every user-mode data access, the processor checks access rights in the TLB or page table as usual, then drops any rights that are found to be restricted for the PTE's key value. Since protection keys have no impact on instruction fetches (executability) and make no changes to page tables or TLB entries, the `WRPKRU` instruction, which changes the `pkru` register, does not have to serialize the pipeline, and can execute very quickly.

Hodor-PKU is based on protection keys. If we think of a protection domain as comprising a subset of the application's address space and we plot those subsets as a Venn diagram, we can assign a protection key to each separate region of the diagram and associate with each domain a `pkru` value that disables access rights for regions outside its subset of the address space. In Figure 2, the main application would disable access to regions D, and E; library 1 would disable access to regions A, C, and E; library 2 would disable access to regions A, B, and D.

Listing 1 (including the parts to the right of the vertical lines) shows the trampoline code for Hodor-PKU. Lines 6 and 7 set `ecx` and `edx` to zero; this is a required precondition of the `WRPKRU` instruction. Line 8 initializes `eax` with the appropriate set of restrictions for the domain to which the trampoline is transitioning; line 9 sets the `pkru` register to the content of `eax`. The latter change simultaneously disables the view of the source domain and enables the view of the target domain. The subsequent comparison (line 28) verifies that the expected permissions have been set, thereby avoiding an attack in which a domain puts overly generous permissions

into eax and then jumps on top of the WRPKRU instruction. Once the target function has returned and we have saved the stack pointer of the target domain (line 19), the trampoline resets the pkru register to the restrictions of the source domain (lines 24–27), and returns as in Hodor-VMFUNC.

3.3.1 Safety of Hodor-PKU

Since the processor allows user-mode code to execute the WRPKRU instruction, we must prevent a malicious application from using the instruction to attain access to a protected library's memory. One could think of employing static binary rewriting [50] to replace implicit occurrences of WRPKRU with equivalent alternatives. Unfortunately, such rewriting (including definitive determination of instruction alignment) is undecidable in the general case [41, 54], and seems inapplicable to any program that mixes read-only data into the text segment. *Dynamic* binary rewriting [6, 33] might be a viable alternative, but would likely incur prohibitive overhead (up to 2.5× for Intel Pin and 5× for DynamoRIO [33]). To address the problem, Hodor-PKU uses a trusted loader to identify all text-segment occurrences of the WRPKRU opcode outside of trampolines, and uses *hardware watchpoints* (debug registers [20]) to vet their execution at run time.

Binary Inspection The WRPKRU instruction can occur explicitly (intended by the programmer) or implicitly (unintended occurrence), as a sequence of bytes within an instruction or across the boundary between instructions. Implicit instances pose a significant threat: an adversary that seeks to bypass Hodor-PKU may attempt to corrupt control data and jump to a point in the program that happens to encode the WRPKRU instruction. By setting the contents of ecx, edx, and eax appropriately before subverting execution, the attacker could set the pkru register to any desired value, rendering the isolation useless. To address this issue, the trusted loader scans the application code and makes a list of any untrusted instances, explicit or implicit. It passes this list to the kernel, which in turn places the addresses of the potentially problematic opcodes in the debug registers. A hardware watchpoint will be triggered when any of these instructions is about to be executed, allowing the kernel to vet the instruction and let the execution proceed only if deemed safe.

Our current implementation inspects program text whenever a library is loaded and whenever execute permission for a page is enabled during execution. Once a page is marked as executable, Hodor-PKU prevents further write accesses to the page. Hodor-PKU could easily be extended to support JIT compilation by marking the faulting pages as writable but not executable, allowing JIT code to be emitted. On future attempts to execute the added code, a page fault would occur, and Hodor-PKU would reinspect the page and continue as in the current implementation.

Runtime Vetting Since the debug registers are limited in number (four—DR0 through DR3—on Intel processors [20]), we can rely on hardware to vet only a handful of WRPKRU instances at a time on each thread. Hodor therefore uses hardware watchpoints as an *LRU cache* for all the required watchpoints. Specifically, Hodor initially marks all executable pages containing WRPKRU instances as non-executable. Upon first execution, resulting in a page fault, Hodor reclaims a sufficient number of hardware watchpoints, marks the pages they formerly watched as non-executable, and uses the debug registers for the new page. If all WRPKRU instances in the page are monitored by a hardware watchpoint, Hodor marks the page as executable. In the extremely rare case of more WRPKRU instructions in a single page than the number of debug registers, we resort to single-step execution [20] for that page. We use per-thread page tables (only the root page must be unique for each thread; most lower-level pages can be shared between threads) so that the set of hardware watchpoints can be different in different threads. When watchpoints have been inserted at all appropriate locations, we rewire the page tables leading to the page containing the watchpoint for the current thread and mark it as executable.

Protection Overhead Under normal circumstances, no implicit WRPKRU will be executed. Moreover, the processor triggers a watchpoint only when a debug register points to the first byte of the executed instruction [20], so spurious traps will never occur when correctly aligned execution runs past an implicit instance.

Experiments confirm that there is no measurable overhead for this approach as long as the number of "hot" watchpoints in each thread is smaller than the number of hardware watchpoints. To assess how often this might occur, we inspected all packages in the Fedora 29 distribution for occurrences of WRPKRU. Across 58,273 rpm packages, containing about 108K executable binaries, we found only 111 binaries with a single instance of WRPKRU, 8 with two, 2 with three, none with four, and only 2 (less than 0.02%) with five or more. Most of the occurrences were implicit—typically caused by an instruction with a byte pattern ending in 0f followed by add %ebp,%edi, which has a byte pattern of 01 ef. These occurrences could easily be eliminated by modifying the compiler to insert a nop before the culprit add instructions. While such a change would not guarantee that implicit instances never occur (due to inline assembly and code generated at run time), it would almost certainly eliminate any practical performance impact.

4 Evaluation

We have evaluated Hodor using microbenchmarks and three real-world applications in which we isolated a high-throughput data-plane library or in-memory database from the rest of the application. We also constructed two proof-of-concept demonstrations of safe memory sharing among instances of a protected library in otherwise distrusting applications. We ran the microbenchmarks and in-memory database experiments on a Dell PowerEdge R640 server with two Intel Xeon Silver 4114 (Skylake) 2.20 GHz CPUs with 10 cores each and

16 GB of main memory. We ran the network experiments on Dell PowerEdge R640 servers equipped with two Intel Xeon E5-2630 v3 (Haswell) 2.40 GHz CPUs with 8 cores each and 64 GB of main memory. These machines were connected back-to-back through dual-port Mellanox ConnectX3-Pro 40 Gbps Host Channel Adapters (HCAs) to isolate their connection. All servers ran Fedora Linux 4.15 with our modifications (except for baseline experiments, which used an unmodified kernel). All machines had hyper-threading and Turbo Boost enabled.

We emulated the overhead of PKU on Haswell machines in a manner similar to previous work [28, 50]. We verified the overhead of the emulation by comparing it with the PKU transition cost on the Skylake machine.

Graphs in this section are labeled as follows:

- `unprotected`: baseline system without Hodor—kernel bypass with no intra-process isolation.
- `ptsw`: isolation via syscall-initiated page table switching, as described in Sec. 3.1.
- `ptsw-pti`: same as `ptsw`, except with kernel page-table isolation enabled.
- `vmfunc`: Hodor-VMFUNC, as described in Sec. 3.2.
- `pku`: Hodor-PKU, as described in Sec. 3.3.

Unless otherwise noted (shown in legends with `-pti`), experiments were conducted with kernel page-table isolation [13] disabled. We ran all experiments 10 times and report the arithmetic mean. We indicate 95% confidence intervals in all cases, but these are often so narrow as to be illegible in the bar graphs. The source code for Hodor is available at `http://github.com/hedayati/hodor`.

4.1 Microbenchmarks

We used microbenchmarks to measure the overhead of relevant instructions and basic operations as well as the latency of different implementations of Hodor on the Skylake machine, which supports PKU. We also implemented a no-op system call and a no-op VM call and measure their latencies. We used `rdtscp` with proper serialization [38] to measure the overhead of 1 million executions (again, computing the arithmetic mean across 10 runs).

Table 1 shows the calculated overhead of a single instance of each operation. The latency of writing to the `CR3` register impacts the syscall-based version of Hodor; the latency of `VMFUNC` and `WRPKRU` impacts Hodor-VMFUNC and Hodor-PKU, respectively. The cost of entering and leaving the kernel also impacts the syscall-based version; this cost itself depends on whether KPTI [13] is enabled. System calls with virtualization, as used in Hodor-VMFUNC, would experience the overhead of VM calls.

For reference—and to put the overheads in perspective with respect to approaches like light-weight contexts (lwC) [31] which use processes to isolate domains—we also measured the cost of a context switch caused by a semaphore and of a user-space context switch using POSIX `getcontext` and `setcontext`.

Table 1: Latency of Basic Operations

Instruction or Operation	Cycles*
write to `CR3` with `CR3_NOFLUSH`	186 ± 9
`vmfunc`	109 ± 1
`wrpkru`	26 ± 2
no-op system call w/ KPTI	433 ± 12
no-op system call w/o KPTI	96 ± 2
no-op VM call	1694 ± 131
user-space context switch	748 ± 8
process context switch using semaphore	4426 ± 41

* ± half the width of the 95% confidence interval

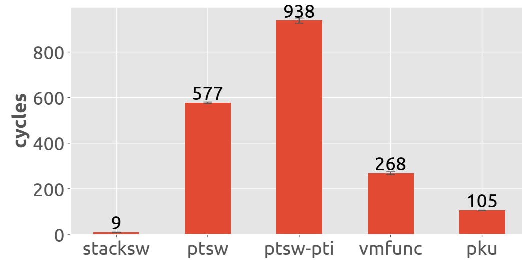

Figure 3: Transition Microbenchmarks.

Figure 3 compares the transition time from one domain to another and back again using different isolation implementations. Additionally, we measured the cost of switching stacks without providing isolation as it contributes a small amount to all implementations of Hodor. To do this, we removed the code in Listing 1 that changes domain and calls the protected library function. Figure 3 denotes the average stack switch time as `stacksw`. We also measured the cost of page table switching with kernel page-table isolation enabled; Figure 3 denotes this as `ptsw-pti`. KPTI has no impact on Hodor-VMFUNC and Hodor-PKU.

Among the implementations of isolation, Hodor-PKU has the lowest transition cost, followed by Hodor-VMFUNC. This matches the results in Table 1: changing the `pkru` register costs much less than using `vmfunc`. System calls dominate the cost of the implementations based on `ptsw`. Relative to `ptsw`, kernel page table isolation in `ptsw-pti` incurs a penalty of 62%. Stack switching itself has an almost negligible impact. As noted in Sec. 3.3, there is no measurable overhead to using debug registers to vet instances of `WRPKRU`, so long as there are no more than four watchpoints in each thread.

4.2 Silo

Silo [48] is a scalable in-memory database. It uses optimistic concurrency control and periodically-updated epochs to provide the same guarantees as a serializable database without the scalability bottlenecks. It is implemented as a library linked to the benchmark. Each benchmark thread issues transactions (of YCSB [10] or TPC-C [47]) in a loop. We configured the main Silo library as a separate domain whose pages are protected from the benchmark driver. Even in the context of a single

application, Hodor ensures that the database can be accessed only by library code—never, for example, as the result of a memory access bug in the main application. This protection may be helpful even in the course of a single execution. If the database were kept in nonvolatile memory and retained across program runs, it might be considered essential. The benchmark calls (trampolines of) library routines to perform one domain transition per transaction. All data and metadata reside in memory, and the workload is CPU intensive.

Figure 4 (i) shows the overhead of isolation for the YCSB [10] and TPC-C [47] workloads on the Skylake machine. Both use the synchronous database API in Silo, precluding batching and necessitating a very high switching rate. Both workloads were run with 20 threads.

YCSB [10] is a key-value benchmark with tiny transactions. We first filled the database with 1 million records and then ran a workload with an 80/20 read/write mix. The unmodified Silo reaches 2.27 million transactions per second on each core. Hodor incurs 44%, 54%, 27%, and 9.85% overhead in the PT-Switch, PT-Switch with KPTI, VMFUNC, and PKU implementations, respectively.

TPC-C [47] is a relational database benchmark with significantly larger transactions [10]. As a result, the maximum number of transactions per second is reduced to around 600,000 per core on unmodified Silo. With a lower rate of library transitions, the overhead of Hodor drops to 3%, 4.66%, 13.6%, and 1.5% for the PT-Switch, PT-Switch with KPTI, VMFUNC, and PKU implementations, respectively. While Hodor-VMFUNC incurs the largest overhead in this experiment, we discovered that 12% of that overhead is due to running inside a VM—apparently due to frequent use of the `nanosleep` system call in the benchmark's epoch-based garbage collector.

While we have not attempted to modify applications to remove system calls (or to replace them with equivalent functionalities that don't cause VM exits), we believe that such a change would be straightforward in this case.

4.3 DPDK TestPMD

Intel's Data Plane Development Kit (DPDK) [21] is a set of data-plane libraries that implement kernel bypass, polling drivers, and a fast packet processing framework. Packet processing applications can link against one or more of the DPDK libraries and use them to access network devices directly. We evaluate Hodor with a packet-forwarding application, `testpmd`, distributed for performance testing as a part of DPDK. Running on the Haswell machines with dual-port Mellanox ConnectX-3 HCAs, this benchmark receives raw packets from one port of the HCA and forwards them directly to another port without accessing packet contents. We connected two hosts back-to-back for endless forwarding of packets in an isolated network. We used Hodor to separate the packet-forwarding logic from the DPDK library.

Figure 4 (ii) shows the effect of Hodor on `testpmd` throughput with different thread counts and batching degrees (packets per library call / domain transition). We report throughput in packets forwarded per second as measured by `testpmd`. As a worst-case scenario for Hodor overhead, we configured the benchmark to use only a single thread and to forward packets one-by-one without batching. (Such a configuration would not be common in practice.) The unmodified DPDK in this configuration can forward more than 720,000 packets per second, and the overhead of Hodor is less than 25% with VMFUNC and 7% with PKU. As we increase the batch size (Fig. 4 (ii-a) vs. (ii-b)), the number of processed packets per transition increases and the overhead of switching becomes a smaller part of overall run time. As we provide more threads and therefore more CPUs ((b) vs. (c)), the performances of all approaches improve but the gaps decrease since the abundance of CPU resources makes the network line rate the new throughput limiter.

4.4 Redis on DPDK

Redis [42] is a NoSQL store that serves read requests from an in-memory data structure. Redis can also store data on persistent secondary storage using snapshots; we disabled this functionality in our experiments to avoid the overhead of system calls. The Redis server uses TCP to receive requests from clients. In our set-up, we use a user-space network stack called F-Stack [46] on top of the DPDK packet processing framework and driver to provide connections to Redis clients. We use Hodor to isolate the network and packet processing stack from the Redis data store logic—i.e., both F-Stack and DPDK run within the same protection domain. We run YCSB [10] on a remote client to benchmark the server configuration. Both the YCSB client and the Redis server are running on the Haswell machines, connected back-to-back via Mellanox ConnectX-3 HCAs.

The server here is the bottleneck: Redis is single-threaded; it runs a loop that waits for request arrival using an `epoll`-like call to F-Stack, receives and processes the requests, and then sends results back with F-Stack's equivalent of the `send` system call. As a result, there are at least two domain transitions per transaction.

To measure the impact of Hodor, we first loaded the Redis server with 1 million records each of length 1200 bytes. We then ran a YCSB workload [10] with a 95%/5% read-/write mix and measured how many transactions per second the Redis server supported. Figure 4 (iii) shows the results as measured and reported by the YCSB client. The unmodified server can support 220,000 transactions per second. The PT-Switch, PT-Switch with KPTI, VMFUNC, and PKU implementations of Hodor reduce the throughput of Redis by 12%, 35%, 5%, and 2.78%, respectively.

4.5 Discussion

The preceding subsections reveal significant performance differences among the three implementations of Hodor: syscall-based page table switching, Hodor-VMFUNC, and Hodor-

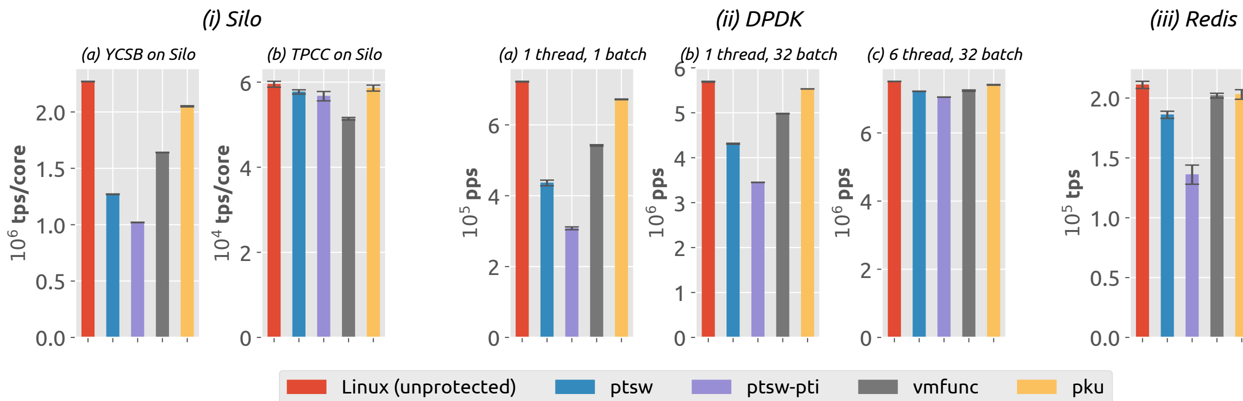

Figure 4: Hodor Overhead: (i) Silo Benchmarks, (ii) DPDK Raw Packet Forwarding Benchmarks, and (iii) Redis Benchmark.

PKU. These differences must be considered together with the issues of generality and confidentiality when applying Hodor in a particular environment.

The overhead of Hodor-PKU is very low, even at millions of domain switches per second (Fig. 4 (i-a)). With a lower number of transitions per second (Figs. 4 (i-b), 4 (iii)), possibly effected via batching or multiple worker threads (Fig. 4 (ii-b)–(ii-c)), the advantage of PKU over VMFUNC diminishes substantially. In any case, both Hodor-VMFUNC and Hodor-PKU remain considerably faster than syscall-based page table switching in most cases (Figs. 4 (ii-a)–(ii-b), 4 (iii)).

One limitation of Hodor-PKU is that current Intel hardware supports only 16 distinct memory keys. The need for a separate key for each of the regions of the "protection domain Venn diagram" (e.g., Fig. 2) thus limits us to no more than 7 mutually distrusting protected libraries in any given application—fewer if they wish to make direct calls to one another. Hodor-VMFUNC has no similar limitations on generality. There are 512 distinct function codes on current Intel machines, and a VM that uses some of these for its own purposes is still compatible with Hodor-VMFUNC. As discussed in Sec. 3.2, VMFUNC is only available in a virtualized mode. Hodor-VMFUNC, like MemSentry [28], uses Dune [3] to run applications inside a virtual machine. This restriction imposes a significant cost on system calls in the application, which now incur the latency of a VM exit; we see the impact of this latency in Figure 4 (i-b). While we don't expect frequent system calls in a data-plane library, an alternative design [32, 35] avoids VM exits on system calls by running the kernel, in addition to user programs, inside the virtual machine. Such a design has a system-wide impact on performance, since the entire software stack is virtualized, not just the intended application. Ideally, we should like to see support on future hardware for a VMFUNC-like mechanism that allows a non-privileged instruction to switch among pre-approved page table root pointers without the need for virtualization.

Absent direct access, a malicious program may attempt to steal information from protected libraries through a side channel. While such attacks are out of scope, we note that Hodor-PKU is inherently vulnerable to Meltdown-PK [8], an attack that defeats the purpose of PKU itself: the protection key bits are part of the TLB access permissions, which the processor may check late in the pipeline [8, 26]. While all Skylake processors are susceptible to this attack, the vulnerability has been fixed in more recent microarchitectures [18].

4.6 Cross-Application Sharing

Because they are protected from their calling applications, protected libraries in Hodor can, at least in principle, safely share state among library instances in separate applications. As proof-of-concept demonstrations, we have used Hodor to implement sharing in Silo and resource management in DPDK. The implementations highlight general issues that must be considered by the library designer.

Sharing in Silo: We wrote a library that uses Silo [48] internally to implement a TPCC [47]-like database. Our library provides two different views of the same database: one that can do `NewOrder`, `Payment`, and `OrderStatus` transactions, and another that can do `Delivery` and `StockLevel` transactions. Both interfaces use the same set of tables, which Silo maintains in physically shared pages. Silo guarantees consistency of the database and serializability of the transactions, while Hodor guarantees that the only way for an application to modify the database is to use the provided interface. When sharing the database between two separate applications, our library can control which interface is available to each application. More significantly, by preventing access of any kind when running outside the library, Hodor can ensure that stray memory references in a buggy application (e.g., due to out-of-bound array indexing or uninitialized pointer dereference) never compromise database invariants.

Resource management in shared DPDK: The DPDK Environment Abstraction Layer (EAL) [21] has recently added multi-process support so that mutually trusting processes can share DPDK huge-pages, memory buffers, and queues. A group of DPDK processes can then work together in a simple

transparent manner to perform packet processing or similar tasks. Using Hodor, we extended this mechanism to allow *distrusting* processes to share a single NIC. We wrote a simple library that exports several DPDK APIs (`rte_eth_rx_burst`, `rte_eth_tx_burst`, etc.). Internally, it uses shared memory to record the rate at which each application sends packets, to implement proportional share. We link this library, via Hodor, into two distrusting applications. The protected library in each application then measures its own traffic, updates shared statistics (under control of appropriate synchronization), and periodically adjusts the rate that will be allowed in the next time period.

While we were able to port the two libraries to use Hodor for sharing in just a few hundred lines of code, the experience highlighted several issues that need to be considered when tying together library instances in separate applications. As a rule of thumb, developers should think of protected libraries as extensions to the operating system. Safety-critical arguments passed by applications should be copied into library space before applying sanity checks (to avoid modification by other application threads). Libraries should also treat shared regions as potential attack vectors and should employ conventional defenses (e.g. retpolines to mitigate Spectre-type attacks [8] when relevant). Significantly, Hodor does not prevent a buggy application from invoking library routines in the "wrong" sequence, or with the "wrong" arguments. It does, however, prevent an application from undermining any invariant that is carefully maintained by those routines. It is the responsibility of the protected library to provide appropriate synchronization, scalability, and fault tolerance. The latter may be simplified by using nonblocking data structures, or by depending on Hodor to execute through to the end of library routines in the event of process failure.

5 Related Work

Hodor connects to three areas of related work: fast I/O systems that move device and resource management into user space, methods to isolate software components sharing the same virtual address space, and systems that impose security policies on operating system kernels and hypervisors.

5.1 Fast I/O Systems

Existing kernel-bypass systems do not protect libraries from untrusted applications. Arrakis [39] uses a library OS without isolation in the same address space as the application and relies on device-level SR-IOV [23] support. Device-level resource isolation policies are often rigid—e.g., limited to simple partitioning. Hodor protected libraries enable more powerful protection policies like proportional bandwidth sharing and even safe, concurrent accesses to the same data. IX [4] and ZygOS [40], both of which build on Dune [3], use virtualization to run their kernel-bypass stack in ring 0 of VMX non-root mode. While this design already isolates networking logic from the applications, it is limited to only a single trusted domain and does not support multiple distrusting data-plane libraries within the same application, as Hodor does.

Kernel-based high-throughput software stacks like MegaPipe [14] and StackMap [57] depend on aggressive batching to limit the frequency and cost of protection domain switching. Aggressive I/O batching, however, requires asynchronous programming models that are generally hard to employ and not always supported by library APIs. In Sec. 4, for example, we were unable to batch over the Silo database API [48] or F-Stack's send calls [46].

5.2 Intra-Process Isolation

There has been much previous work on intra-process isolation. The method with least overhead is to write code in a type-safe language. Work in single address space operating systems such as Singularity [17] and Verve [56] shows that application and kernel code can execute safely within the same virtual address space. The disadvantage of such systems is their incompatibility with much existing code. Hodor, in contrast, supports existing fast I/O applications.

For type-unsafe languages, approaches such as SFI [52] and XFI [49] employ either source- or binary-level instrumentation to guarantee that code cannot read or write outside of designated sections of the virtual address space. Load and store instrumentation either checks that the accessed address is within bounds or transforms out-of-bounds pointers to in-bounds pointers. SFI [52] incurs an average overhead of 17.6% for read-write protection and 4.3% overhead when only instrumenting writes. Hodor works without sophisticated binary rewriting techniques and incurs less overhead than SFI by leveraging newer hardware support.

Hardware mechanisms can isolate code running within the same virtual address space. CODOMs [51] and CHERI [55] augment instructions with capabilities. Segmentation also provides intra-process isolation [43] by requiring code to possess a *descriptor* to address a particular section of memory. By restricting which descriptors are accessible to various code components, the OS kernel can isolate untrusted components. Segmentation is supported in 32-bit but not 64-bit x86 systems [20]. ARM memory domains [2] are similar to Intel PKU [20] but available only on 32-bit processors, and memory domain permissions can be modified only in supervisor mode. Our work focuses on hardware support available in 64-bit x86 systems.

ERIM [50], developed concurrently to our work, uses protection keys like Hodor to provide an isolated domain within a single virtual address space. We believe ERIM's use of static binary rewriting to eliminate occurrences of `WRPKRU` in the application binary is insufficient to guarantee the safety of protected domains: static binary rewriting is undecidable for arbitrary x86 code [41, 54]. *Dynamic* binary rewriting (not considered in ERIM) would incur prohibitive costs, negating the performance gain of PKU.

Several OS abstractions are similar to our work. Wedge [5]

provides privilege separation and isolation among its sthreads. Each sthread is a lightweight process that inherits only a subset of the memory mappings and file descriptors of its parent, as specified in a security policy. Shreds [9] use ARM memory domains [2] to divide execution within a user-space thread. Each shred is a thread fragment with a private memory pool in which to store secret data and sensitive code. Light-weight contexts (lwCs) [31] isolate units within an address space. Each lwC has its own virtual memory mappings, file descriptors, access rights and execution state. Secure Memory Views (SMV) [15] use per-thread page tables to enforce isolation while allowing sharing between threads. SMV does not support multiple domains within a thread. Each of these systems requires a system call to change domains, while Hodor does not. Hodor can also be linked to unmodified applications.

MemSentry [28] is a memory isolation framework that provides compiler support for multiple hardware features, including EPT-switching VMFUNC and PKU, to create a safe region within a process. It analyzes and instruments applications with code which, like Hodor's trampolines, enables and disables access to the protected domain using the desired isolation mechanism. SeCage [32] uses static and dynamic compiler analysis to decompose a monolithic program into different domains and uses EPT-switching VMFUNC to prevent memory disclosure attacks even when running on a compromised OS. Unlike SeCage and MemSentry, Hodor relies on existing explicit library boundaries, alleviating the need for compiler analysis to extract components. SeCage places the entire OS and its applications in a virtual machine, while Hodor-VMFUNC and MemSentry leverage Dune's [3] process-level virtualization to expose the VMFUNC EPT-switching mechanism to individual applications. Executing the intended application in non-root mode affects the performance of that application only. SeCage [32] compensates for the system-wide performance impact of the virtualization layer with its additional protections against a malicious OS.

SkyBridge [35] uses VMFUNC to improve the latency of IPCs in a micro-kernel setting. Unlike Hodor, SkyBridge does not enforce a single way to cross protection boundaries (Hodor ensures that *only* trampolines are mapped in both source and target EPTs), which introduces the possibility for malicious VMFUNCs. To address this, SkyBridge uses static binary rewriting (inspired by ERIM [50]), which as discussed earlier, is undecidable for an arbitrary x86 binary [41, 54]. Finally, EPTI [16] uses VMFUNC to provide isolation between kernel and user-space page tables to mitigate Meltdown [8].

VMFUNC has been used for communication between components isolated at coarse granularity. High-throughput network function virtualization has used VMFUNC and EPT-switching to provide efficient communication between VMs hosting different network functions [36]. CrossOver [29] proposes a cross-world interaction mechanism that provides communication between VMs as well as different address spaces and privilege levels in or between VMs. It uses EPT-switching VMFUNCs to approximate the cost of cross-world interaction and suggests architectural changes to VMFUNC to allow such calls. While CrossOver can theoretically be used for intra-process isolation, the paper focuses on providing cross-world calls as a generic communication mechanism.

5.3 OS and Hypervisor Security

Hodor builds on previous work on security enforcement in OS kernels and hypervisors. The design of the Hodor-PKU trampoline is inspired by the Nested Kernel [12] trampoline code. Both Hodor-PKU and Nested Kernel must check that the inputs to domain switching instructions are correct because neither system enforces control flow integrity [1]. Finally, Hodor's restrictions on `mmap` to enforce code segment integrity are similar to protections in Secure Virtual Architecture [11], HyperSafe [53], and Nested Kernel [12].

6 Conclusions

We have introduced Hodor, an in-process isolation system for protection and sharing of fast data-plane libraries. Our proposed solution uses Intel's memory protection keys (PKU) to isolate components within a single address space. We also presented two alternative implementations based on separate user-level address spaces—one uses system calls for page-table switching, the other Intel's VMFUNC switching of extended page tables. Additionally, Hodor uses asynchronous event delivery and a novel application of hardware watchpoints to ensure that when multiple processes share a protected library, failure in one will not affect the others.

Our evaluation with microbenchmarks, Silo, DPDK, and Redis confirm that Hodor can provide full isolation of protected libraries while approaching unprotected kernel bypass performance. Hodor-PKU, in particular, provides 90–98% of kernel-bypass throughput in all of our experiments.

Hodor could benefit from a VMFUNC-like instruction that switches among pre-approved page table root pointers without requiring virtualization. We encourage hardware designers to consider such an extension. We would also welcome a variant of PKU with a larger number of keys and with coverage of execute rights. In future work, we hope to evaluate the cost of a Hodor implementation based on software fault isolation [52] and to explore hardware-supported implementations for additional processor architectures (e.g., ARM and Power).

Abstract

System-level Dynamic Binary Translation (DBT) provides the capability to boot an Operating System (OS) and execute programs compiled for an Instruction Set Architecture (ISA) different to that of the host machine. Due to their performance-critical nature, system-level DBT frameworks are typically hand-coded and heavily optimized, both for their guest and host architectures. While this results in good performance of the DBT system, engineering costs for supporting a new, or extending an existing architecture are high. In this paper we develop a novel, retargetable DBT hypervisor, which includes guest specific modules generated from high-level guest machine specifications. Our system simplifies retargeting of the DBT, but it also delivers performance levels in excess of existing manually created DBT solutions. We achieve this by combining offline and online optimizations, and exploiting the freedom of a Just-in-time (JIT) compiler operating in a bare-metal environment provided by a Virtual Machine (VM) hypervisor. We evaluate our DBT using both targeted micro-benchmarks as well as standard application benchmarks, and we demonstrate its ability to outperform the de-facto standard QEMU DBT system. Our system delivers an average speedup of 2.21× over QEMU across SPEC CPU2006 integer benchmarks running in a full-system Linux OS environment, compiled for the 64-bit ARMv8-A ISA and hosted on an x86-64 platform. For floating-point applications the speedup is even higher, reaching 6.49× on average. We demonstrate that our system-level DBT system significantly reduces the effort required to support a new ISA, while delivering outstanding performance.

1 Introduction

System-level DBT is a widely used technology that comes in many disguises: it powers the Android Open Source Project (AOSP) Emulator for mobile app development, provides backwards compatibility for games consoles [52], implements sandbox environments for hostile program analysis [41] and enables low-power processor implementations for popular ISAs [17]. All these applications require a complete and faithful, yet efficient implementation of a guest architecture, including privileged instructions and implementation-defined behaviors, architectural registers, virtual memory, memory-mapped I/O, and accurate exception and interrupt semantics.

The broad range of applications has driven an equally broad range of system-level DBT implementations, ranging from manually retargetable open-source solutions such as QEMU [4] to highly specialized and hardware supported approaches designed for specific platforms, e.g. Transmeta Crusoe [17]. As a de-facto industry standard QEMU supports all major platforms and ISAs, however, retargeting of QEMU to a new guest architecture requires deep knowledge of its integrated Tiny Code Generator (TCG) as it involves manual implementation of guest instruction behaviors. Consequently, retargeting is time-consuming and error-prone: e.g. the official QEMU commit logs contain more than 90 entries to bugfixes related to its ARM model alone.

In this paper we present **Captive**, our novel system-level DBT hypervisor, where users are relieved of low-level implementation effort for retargeting. Instead users provide high-level architecture specifications similar to those provided by processor vendors in their ISA manuals. In an offline stage architecture specifications are processed, before an architecture-specific module for the online run-time is generated. Captive applies aggressive optimizations: it combines the offline optimizations of the architecture model with online optimizations performed within the generated JIT compiler, thus reducing the compilation overheads while providing high code quality. Furthermore, Captive operates in a virtual bare-metal environment provided by a VM hypervisor, which enables us to fully exploit the underlying host architecture, especially its system related and privileged features not accessible to other DBT systems operating as user processes.

The envisaged use of Captive is to provide software developers with early access to new platforms, possibly hosted in a cloud environment. To facilitate this goal, ease of retargetability is as important as delivering performance levels sufficient

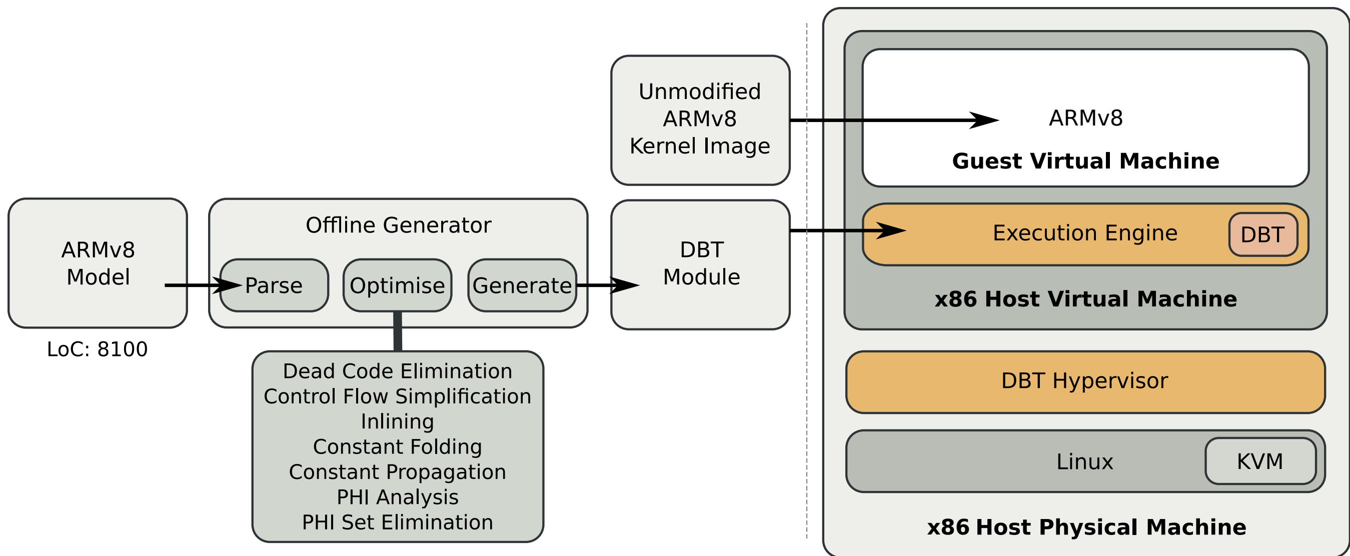

Figure 1: High-level overview of Captive.

to drive substantial workloads, i.e. software development tool chains and user applications. Whilst we currently focus on a single-core implementation, the key ideas can be translated to multi-core architectures.

We evaluate the implementation of Captive using a 64-bit ARMv8-A guest model and an x86-64 host. From a description comprising just 8100 lines of code[1] we generate a DBT hypervisor outperforming QEMU by a factor of 2.21× for SPEC CPU2006 integer applications, and up to 6.49× for floating-point workloads. This means Captive is capable of hosting a full and unmodified ARM Linux OS environment while delivering around 40% of the performance of a physical system comprising a 2.0GHz server-type Cortex-A57 processor.

1.1 Overview and Motivating Example

Figure 1 shows a high-level overview of Captive: an ARMv8-A[2] architecture description is processed by an offline tool to produce a platform-specific DBT module. Already at this stage optimizations are applied, which aid later JIT code generation. The software stack on the x86-64 host machine comprises a Kernel Virtual Machine (KVM)-based DBT hypervisor, operating on top of the host's Linux OS. This provides a *virtual* bare-metal x86-64 Host Virtual Machine (HVM) in which Captive together with the previously generated DBT module and a minimal execution engine reside to provide the Guest Virtual Machine (GVM), which can boot and run an unmodified ARMv8-A Linux kernel image. Since the JIT compiler in our system-level DBT system operates in a bare-metal HVM it has full access to the virtual host's resources and can generate code to exploit these resources.

For example, consider Figure 2. A conventional system-level DBT system hosted on an x86-64 architecture, e.g. QEMU, operates entirely as a user process in protection ring 3 on top of a host OS operating in ring 0. This means that any code generated by QEMU's JIT compiler, either guest user or system code, also operates in the host's ring 3, which restricts access to system features such as page tables. Such a system operating exclusively in ring 3 needs to provide software abstractions and protection mechanisms for guest operations, which modify guest system state. In contrast, Captive operates in VMX root mode, and provides a bare-metal HVM with rings 0-3. Our execution engine and DBT operate in the virtual machine's ring 0, and track the guest system's mode. This enables us to generate code operating in ring 0, for guest system code, and ring 3, for guest user code. This means we can use the HVM's hardware protection features to efficiently implement memory protection or allow the hypervisor to modify the HVM's page tables in order to directly map the GVM's virtual address space onto host physical memory.

Porting to a different host architecture can be accomplished by utilising similar features offered by that architecture, e.g. Arm offers virtualization extensions that are fully supported by KVM, and privilege levels `PL0` and `PL1`, which are similar to x86's ring 3 and ring 0, respectively. These similarities also enable our accelerated virtual memory system to work across platforms.

1.2 Contributions

Captive shares many concepts with existing DBT systems, but it goes beyond and introduces unique new features. We

provide a feature comparison in Table 1, and present further information on related work in Section 4. Among the contributions of this paper are:

1. We develop a generic system-level DBT framework, where the effort to support new guest platforms is reduced by using **high-level architecture descriptions**.

2. We use split compilation in a DBT, combining **offline and online optimization** to reduce pressure on the performance critical JIT compiler while maintaining code quality.

3. We pioneer a DBT approach where the integrated JIT compiler is part of a **DBT hypervisor** and can generate code that takes full advantage of this execution context.

Captive has been released as an open-source project, to enable community-driven development and independent performance evaluation.[3]

2 Retargetable DBT Hypervisor

2.1 Overview

In this section, we describe the key concepts of Captive, which comprises two main components, (1) an **offline** generation component, and (2) an **online** runtime component.

The offline phase involves describing the target machine architecture, and is discussed in Section 2.2. In this phase, modules for inclusion in the runtime component are generated. Complex architectural behaviour (such as the operation of the

Memory Management Unit (MMU)) are described in regular source-code files, and compiled together with the generated source-code. The online runtime component is discussed in Section 2.3, and comprises a further two sub-components, (1) a **user-mode application** that activates and configures a KVM Virtual Machine, and (2) a **unikernel** that runs inside the KVM VM, and implements guest instruction translation and general guest machine execution.

The DBT system itself runs inside a VM with no standard OS support. Normally, a virtual machine provides a bare-metal environment in which an OS is loaded, and then user applications are executed. We instead skip the OS entirely, and implement our DBT on the virtual bare-metal hardware. Whilst this adds complexity to the implementation of the DBT, it also allows the DBT to directly use host architectural features, without having to negotiate with an OS. This is in contrast to the majority of other system-level DBTs, which typically run as user-mode applications in an OS. The trade-off here is that Captive relies on KVM, reducing host operating system portability.

2.2 Offline Stage

2.2.1 Architecture Description

The guest machine architecture is described using a high-level Architecture Description Language (ADL) that defines instruction syntax (i.e. how to decode instructions) and instruction semantics (i.e. how to execute instructions). The ADL is also used to describe architectural features, such as the register file size and layout, word sizes, endianness, etc.

The ADL is based on a modified version of ArchC [1], and our offline generator tool processes the description into an intermediate form, performs some optimization and analysis, before finally producing modules for the DBT as output.

Instruction semantics (the functional behavior of guest machine instructions) are described in a high-level C-like language. This Domain Specific Language (DSL) allows the behavior of instructions to be specified easily and naturally, by, e.g. translating the pseudo-code found in architecture manuals into corresponding C-like code.

```
1 execute(add) {
2   uint64 rn = read_register_bank(BANK0, inst.a);
3   uint64 rm = read_register_bank(BANK0, inst.b);
4   uint64 rd = rn + rm;
5   write_register_bank(BANK0, inst.a, rd);
6 }
```

Figure 3: High-level C-like representation of instruction behavior

Figure 3 provides an example description of an `add` instruction that loads the value from two guest registers (lines 3 and 4), adds them together (line 5), then stores the result to another guest register (line 6). This example shows how a typical instruction might look, and how its behavior can be naturally expressed. Of course, this is a simple example: most 'real-world' instruction descriptions contain branching paths to select specific instruction variants (e.g., flag-setting or not), more complex calculations, and floating point and vector operations, all of which can be handled by the ADL.

2.2.2 Intermediate SSA Form

During the offline phase, instruction behavior descriptions are translated into a domain-specific Static Single Assignment (SSA) form, and aggressively optimized. The optimization passes used have been selected based on common idioms in instruction descriptions. For example, very few loop-based optimizations are performed, since most individual instructions do not contain loops. Optimizing the model at the offline stage makes any simplifications utilized by the designer in the description less of a performance factor in the resulting code.

The domain-specific SSA contains operations for reading architectural registers, performing standard arithmetic operations on values of integral, floating-point and vector types, memory and peripheral device access and communication, and a variety of built-in functions for common architectural behaviors (such as flag calculations and floating point NaN/Infinity comparisons).

Additionally, meta-information about the SSA is held, indicating whether each operation is *fixed* or *dynamic*. Fixed operations are evaluated at instruction translation time, whereas dynamic operations must be executed at instruction run-time. For example, the calculation of a constant value, or control flow based on instruction fields is *fixed*, but computations which depend on register or memory values are *dynamic* [46]. Fixed operations can produce dynamic values, but dynamic operations must be executed as part of instruction emulation.

Figure 4 shows the direct translation of the instruction behavior (from Figure 3) into corresponding SSA form. A

```
action void add (Instruction sym_1_3_parameter_inst) [
  uint64 sym_14_0_rd
  uint64 sym_5_0_rn
  uint64 sym_9_0_rm
] {
  block b_0 {
    s_b_0_0 = struct sym_1_3_parameter_inst a;
    s_b_0_1 = bankregread 7 s_b_0_0;
    s_b_0_2: write sym_5_0_rn s_b_0_1;
    s_b_0_3 = struct sym_1_3_parameter_inst b;
    s_b_0_4 = bankregread 7 s_b_0_3;
    s_b_0_5: write sym_9_0_rm s_b_0_4;
    s_b_0_6 = read sym_5_0_rn;
    s_b_0_7 = read sym_9_0_rm;
    s_b_0_8 = binary + s_b_0_6 s_b_0_7;
    s_b_0_9: write sym_14_0_rd s_b_0_8;
    s_b_0_10 = struct sym_1_3_parameter_inst a;
    s_b_0_11 = read sym_14_0_rd;
    s_b_0_12: bankregwrite 0 s_b_0_10 s_b_0_11;
    s_b_0_13: return;
  }
}
```

Figure 4: Unoptimized domain-specific SSA form of the `add` instruction from Figure 3.

```
action void add (Instruction sym_1_3_parameter_inst) [] {
  block b_0 {
    s_b_0_0 = struct sym_1_3_parameter_inst a;
    s_b_0_1 = bankregread 7 s_b_0_0;
    s_b_0_2 = struct sym_1_3_parameter_inst b;
    s_b_0_3 = bankregread 7 s_b_0_2;
    s_b_0_4 = binary + s_b_0_1 s_b_0_3;
    s_b_0_5 = struct sym_1_3_parameter_inst a;
    s_b_0_6: bankregwrite 0 s_b_0_5 s_b_0_4;
    s_b_0_7: return;
  }
}
```

Figure 5: Equivalent optimized domain-specific SSA form of the `add` instruction from Figure 3.

series of optimizations (given in Table 2) are then applied to this SSA, until a fixed-point is reached. Figure 5 shows the optimized form of the SSA.

The offline optimizations allow the user to be expressive and verbose in their implementation of the model, whilst retaining a concise final representation of the user's intent. For example, dead code elimination is necessary in the case where helper functions have been inlined, and subsequently subjected to constant propagation/folding, which eliminates a particular control-flow path through the function.

2.2.3 Generator Function

The domain-specific SSA itself is not used at runtime, but instead is used in the final offline stage to build simulator-specific generator functions. These functions are either compiled in, or dynamically loaded, by the DBT, and are invoked at JIT compilation time. The generator functions call into the DBT backend, which produces host machine code. When an instruction is to be translated by the DBT, the corresponding generator function is invoked.

Figure 6 shows the corresponding generator function, produced from the optimized SSA form in Figure 5. The generator function is clearly machine generated, but *host* compiler optimizations (in the offline stage) will take care of any inefficiencies in the output source-code. Additionally (and not shown for brevity) the offline stage generates source-code comments, to assist in debugging.

2.3 Online Stage

The online stage of Captive involves the actual creation and running of the guest virtual machine. This takes the form of a KVM-based DBT hypervisor, which instantiates an empty *host virtual machine*, which then loads the *execution engine* (a small, specialized unikernel) that implements the DBT. The KVM-based portion of the hypervisor also includes software emulations of guest architectural devices (such as the interrupt controller, UARTs, etc). The DBT comprises four main phases, as shown in Figure 7: **Instruction Decoding**, **Translation**, **Register Allocation**, and finally **Instruction Encoding**.

2.3.1 Instruction Decoding

The first phase in our execution pipeline is the instruction decoder, which will decode one *guest* basic block's worth of instructions at a time. The decoder routines are automatically generated from the architecture description during the offline stage, utilizing techniques such as Krishna and Austin [27], Theiling [43].

2.3.2 Translation

During the translation phase, a generator function (that was created in the offline stage) is invoked for each decoded instruction. The generator function calls into an *invocation Directed Acyclic Graph (DAG) builder*, which builds a DAG representing the data-flow and control-flow of the instruction under translation. Operations (represented by nodes in the DAG) that have side effects result in the collapse of the DAG at that point, and the emission of low-level Intermediate Representation (IR) instructions representing the collapsed nodes.

A node with side effects is one through which control-flow cannot proceed without the state of the guest being mutated in some way. For example, a `STORE` node is considered to have side-effects, as the guest machine register file has been changed.

During emission, the tree rooted at that node is traversed, emitting IR for the operations required to produce the input values for that node. This feed-forward technique removes the need to build an entire tree then traverse it later. Collapsing nodes immediately to IR improves the performance of the DBT, as instructions are generated as soon as possible.

```
bool generator::translate_add(const test_decode_test_F1& insn, dbt_emitter& emitter) {
  basic_block *__exit_block = emitter.create_block();
  goto fixed_block_b_0;
fixed_block_b_0:  {
    auto s_b_0_1 = emitter.load_register(emitter.const_u32((uint32_t)(256 + (16 * insn.a))), dbt_types::u64);
    auto s_b_0_3 = emitter.load_register(emitter.const_u32((uint32_t)(256 + (16 * insn.b))), dbt_types::u64);
    auto s_b_0_4 = emitter.add(s_b_0_1, s_b_0_3);
    emitter.store_register(emitter.const_u32((uint32_t)(0 + (8 * insn.a))), s_b_0_4);
    goto fixed_done;
  }
fixed_done:
  emitter.jump(__exit_block);
  emitter.set_current_block(__exit_block);
  if (!insn.end_of_block) emitter.inc_pc(emitter.const_u8(4));
  return true;
}
```

Figure 6: Generator function produced from ADL code shown in Figure 3

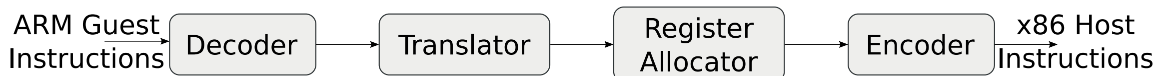

Figure 7: Online flow including decoder, translator, register allocation and instruction encoder.

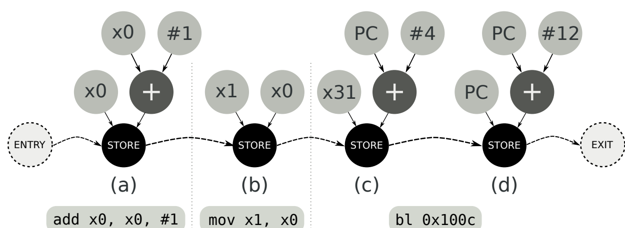

Figure 8: Example ARM assembly, and the corresponding (uncollapsed) DAG built during translation. Nodes (a), (b), (c), and (d) have side effects, causing the emission of low-level IR based on the tree rooted at that node.

```
mov (%rbp), %VREG0  ; Load guest reg. into temporary
add $1, %VREG0      ; Add one.
mov %VREG0, (%rbp)  ; Store temporary to guest reg.
mov (%rbp), %VREG1  ; Load guest reg. into temporary
mov %VREG1, 8(%rbp) ; Store temporary to guest reg.
lea 4(%r15), %VREG2 ; Load PC+4 into temporary
mov %VREG2, 0xf8(%rbp) ; Store into guest reg.
add $12, %r15       ; Increment PC by 12
```

Figure 9: As each node with side-effects is inserted into the DAG, low-level IR is emitted that implements that node. This IR represents host instructions, but with virtual registers instead of physical registers.

This strategy enables high-level operations to take place on transparent values, and implements a weak form of tree pattern matching on demand. When a node is collapsed, specializations can be made depending on how the tree is formed at the node. For example, the STORE node ((d) in Figure 8) that updates the PC by incrementing its value, can be emitted as a single x86 instruction. Instruction selection also takes place at this level, where the generator can utilize host instructions, such as fused-multiply-add when available.

In the case of an x86 host machine, the low-level IR is effectively x86 machine instructions, but with virtual register operands in place of physical registers, as shown in Figure 9. For other host machines, the IR is similar.

2.3.3 Register Allocation

After the low-level IR has been produced by the translation phase, the register allocator makes a forward pass over these instructions to discover live ranges, and then a backward pass to split live ranges into live intervals. During live-range splitting, host machine registers are allocated to virtual registers, and conflicts are resolved. Whilst not producing an optimal solution, the register allocator is fast. The allocator also marks dead instructions, so that at encoding time those instructions are ignored. Our register allocation algorithm is similar to the *simplified graph-coloring* scheme from Cai et al. [9], but with additional dead code elimination.

2.3.4 Instruction Encoding

After register allocation is complete, the low-level intermediate form of instructions can be directly lowered into machine code. The list of instructions is traversed for a final time, and the machine code is generated directly from the instruction's meta-data, into a code buffer. Any instructions that were classified as dead during register allocation are skipped.

Once machine code emission is completed, a final pass is made to apply patches to relative jump instructions, as this value is only known once each instruction has been emitted, and therefore sized.

```
1 fmov d0, #1.5    ; Store constant 1.5 in d0
2 fmul d0, d1, d2  ; Multiply d1 with d2, and store in d0
```

2.4 Exploiting Host Architectural Features

System-level DBT naturally involves emulating a range of guest architectural components, most notably the MMU. Traditionally, this emulation is performed in software, where each memory access must perform an *address translation* that takes a *virtual* address, and translates it via the guest page tables to a corresponding *guest physical address*. In QEMU, a cache is used to accelerate this translation, but in Captive we utilize the host MMU directly by mapping guest page table entries to equivalent host page table entries. This reduces the overhead of memory access instructions significantly, as we do not need to perform cache look-ups, and can work with the guest virtual address directly. Larger guest page sizes are supported by the host MMU directly, as multiple host pages can represent a single larger guest page. In the case of smaller guest pages, we must emulate memory accesses carefully to ensure permissions within a page are not violated. In general, we support an $n : m$ mapping between guest and host page sizes, where n, m are powers of 2.

This technique is not possible with a DBT that runs in user-mode, as the OS retains control of the host MMU page tables (although attempts have been made to emulate this by using the `mmap` system call [51]). However, with Captive, we are operating in a bare-metal environment (see Figure 1), and are able to configure the host architecture in any way we want. By tracking the protection ring of the guest machine, and executing the translated guest code in the corresponding host protection ring, we can take advantage of the host system's memory protection mechanism, for efficient implementation of guest memory protection.

We also take advantage of the x86 software interrupt mechanism (invoked using the `int` instruction), the x86 port-based I/O instructions (`in` and `out`), and the x86 fast system call instructions (`syscall` and `sysret`). These features are used to accelerate implementations of instructions that require additional non-trivial behaviors, e.g. accessing co-processors, manipulation of page tables, flushing Translation Lookaside Buffers (TLBs), and other operations specific to system-level DBT.

2.5 Floating Point/SIMD Support

In order to reduce JIT complexity, QEMU uses a software floating-point implementation, where helper methods are used to implement floating-point operations. This results in the emission of a function call as part of the instruction execution, adding significant overhead to the emulation of these instructions.

```
1  movabs  $0x3ff8000000000000, %rbp ; Store const FP value
2  mov     %rbp, 0x8c0(%r14)         ; of 1.5 in guest
3  movq    $0, 0x8c8(%r14)           ; register file.
4  lea     0x8d0(%r14), %rbp
5  mov     %rbp, %rdi
6  mov     $0x3bd, %esi
7  xor     %edx, %edx
8  callq   0x55d337b70220       ; call gvec_dup8 helper
9  lea     0x2b68(%r14), %rbp   ; Prepare arguments for
10 mov     0x9c0(%r14), %rbx    ; invocation of FP
11 mov     0xac0(%r14), %r12    ; multiply helper
12 mov     %rbx, %rdi           ; function.
13 mov     %r12, %rsi
14 mov     %rbp, %rdx
15 callq   0x55d337bd0050       ; Invoke helper
16 mov     %rax, 0x8c0(%r14)    ; Store result in
17 movq    $0, 0x8c8(%r14)      ; guest register file.
```

Figure 11: QEMU output assembly for the instruction sequence in Figure 10.

```
1 movabs $0x3ff8000000000000,%rax ; Store const FP value
2 mov    %rax,0x100(%rbp)         ; of 1.5 in guest
3 movq   $0x0,0x108(%rbp)         ; register file.
4 add    $0x4,%r15            ; Increment PC
5 movq   0x110(%rbp),%xmm0    ; Load FP multiply operand
6 mulsd  0x120(%rbp),%xmm0    ; Perform multiplication
7 movq   %xmm0,0x100(%rbp)    ; Store result
8 movq   $0x0,0x108(%rbp)
9 add    $0x4,%r15            ; Increment PC
```

Figure 12: Captive output assembly for the instruction sequence in Figure 10.

Figure 10 gives an example of two ARM floating-point instructions, which are translated by QEMU to the x86 code in Figure 11, and by Captive to the code in Figure 12. Whilst QEMU implements the `fmov` directly (lines 1—3), in much the same way as Captive, QEMU issues a function call for the floating-point multiplication (`fmul`). In contrast, Captive emits a host floating-point multiplication instruction, which operates directly on the guest register file.

Not all floating-point operations are trivial, however. Notably, there are significant differences with the way floating-point flags, NaNs, rounding modes, and infinities are handled by the underlying architecture, and in some cases this incompatibility between floating-point implementations needs to be accounted for. In these cases, Captive emits fix-up code that will ensure the guest machine state is bit-accurate with how the guest machine would normally operate. Captive only supports situations where the host machine is at least as precise as the guest. This is the most common scenario for our use cases, but in the event of a precision mismatch, we can either (a) use the x86 80-bit FPU (to access additional precision), or (b) utilise a software floating-point library.

Like QEMU, Captive emits Single Instruction Multiple Data (SIMD) instructions when translating a guest vector instruction, however QEMU's support is restricted to integer and bit-wise vector operations whereas Captive more aggressively utilizes host SIMD support.

2.6 Translated Code Management

Captive employs a code cache, similar to QEMU, which maintains the translated code sequences. The key difference is that we index our translations by *guest physical* address, while QEMU indexes by *guest virtual* address. The consequence of this is that our translations are retained and re-used for longer, whereas QEMU must invalidate all translations when the guest page tables are changed. In contrast, we only invalidate translations when self-modifying code is detected. We utilize our ability to write-protect virtual pages to efficiently detect when a guest memory write may modify translated code, and hence invalidate translations only when necessary. A further benefit is that translated code is re-used across different virtual mappings to the same physical address, e.g. when using shared libraries.

2.7 Virtual Memory Management

To accelerate virtual memory accesses in the guest, we dedicate the lower half of the host VMs virtual address space for the guest machine, and utilise the upper half for use by Captive. The lower half of the address space is mapped by taking corresponding guest page table entries, and turning them into equivalent host page table entries.

To make a memory access, the guest virtual address is masked, to keep it within the lower range, and if the address actually came from a higher address, the host page tables are switched to map the lower addresses to guest upper addresses. The memory access is then performed using the masked address directly, thus benefitting from host MMU acceleration.

3 Evaluation

Performance comparisons in the DBT space are difficult: most of the existing systems are not publicly available, and insufficient information is provided to reconstruct these systems from scratch. Furthermore, results published in the literature often make use of different guest/host architecture pairs and differ in supported features, which prohibit meaningful relative performance comparisons.[4] For this reason we evaluate Captive against the widely used QEMU DBT as a baseline, supported by targeted micro-benchmarks and comparisons to physical platforms.

3.1 Experimental Set-up

While we support a number of guest architectures, we choose to evaluate Captive using an ARMv8-A guest and an x86-64 host.[5] We conducted the following experiments on the host machine described in Table 3, and performed our comparison to native architectures on a Raspberry PI 3B, and an AMD Opteron A1100 (Table 4). We utilized both the integer and C++ floating-point benchmarks from SPEC CPU2006. Our comparisons to QEMU were made with version 2.12.1.

System	HP z440

Table 4: Native Arm Host Systems

3.2 Application Benchmarks

We have evaluated the performance of Captive and QEMU using the standard SPEC2006 benchmark suite with the *Reference* data set. As can be seen in Figure 13, we obtain significant speedups in most *Integer* benchmarks, with a geometric mean speedup of 2.2×. The two benchmarks where we experience a slow-down are `456.hmmer` and `462.libquantum`, which can be attributed to suboptimal register allocation in hot code. Figure 14 shows the speed up of Captive over QEMU on the *C++ Floating Point* portion of the benchmark suite.[6] Here we obtain a geometric mean speedup of 6.49×. This large speedup can mainly be attributed to QEMU's use of a software floating point implementation, while we use the host FPU and vector units directly.

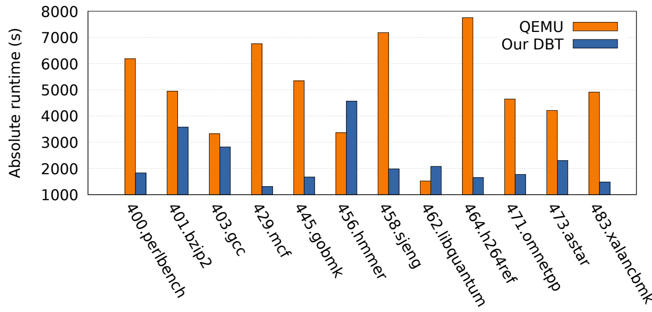
3.3 Additional Guest Architectures

We also have descriptions in our ADL for other guest architectures, detailed in Table 5. However, with the exception of ARMv7-A, these implementations currently lack full-system support. For the ARMv7-A case, we have observed similar average speed-ups of 2.5×, and up to 6× across the SPEC CPU2006 benchmark suite using Captive.

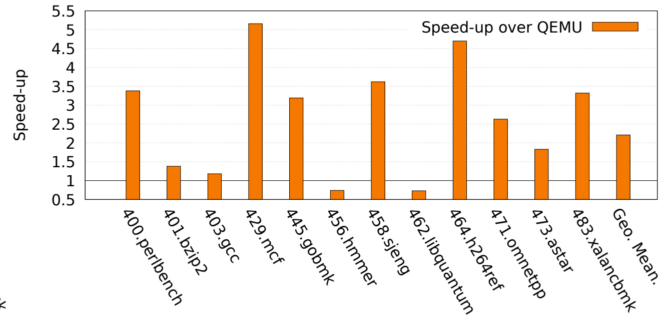
[4] For example, Harmonia [31] achieves a similar speedup of 2.2 over QEMU, but this is for user-level DBT of a 32-bit guest on a 64-bit host system whereas we achieve a speedup of 2.2 over QEMU for the harder problem of system-level DBT of a 64-bit guest onto a 64-bit host system.

[5] Additional RISC-V and x86 models will be released together with Captive.

[6] Missing Fortran benchmarks are due to the benchmarks not working both natively, and in QEMU.



(a) Absolute runtime in seconds (lower is better)



(b) Speed-up of Captive over QEMU (higher is better)

Figure 13: Application Performance: SPEC CPU2006 Integer benchmark results for Captive vs QEMU.

Architecture	Challenges	Solution
ARMv8-A	64-bit guest on 64-bit host emulation	Additional techniques for MMU emulation
ARMv7-A	If-then-else blocks, possibly spanning page boundaries	Complex control-flow handling in the JIT
x86-64	Complex instruction encoding, requiring stateful decoder.	Use of an external decoder library [23]
RISC-V	No significiant challenges	None required
TI TMS320C6x DSP	VLIW instructions, nested branch delay slots	Extensions to decoder generator, control-flow recovery
Arm Mali-G71 GPU	Complex instruction bundle headers	External "pre"-decoder for bundle headers.

Table 5: Architectures currently supported by Captive, and the architecture-specific challenges that required special attention for implementation.

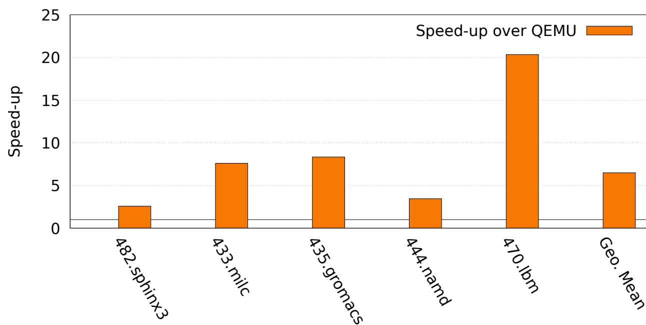


Figure 14: Speed-up of Captive over QEMU on the *Floating Point* portion of the SPEC2006 benchmark suite (higher is better)

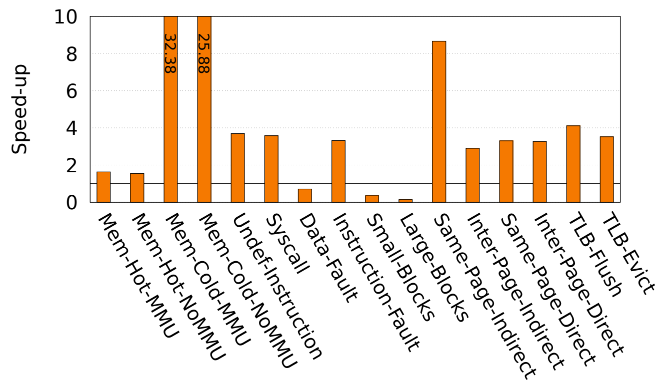

Figure 15: Speed-up of Captive over QEMU on the SimBench micro-benchmark suite

3.4 JIT Compilation Performance

Captive is on average 2.6× slower at translating guest basic blocks than QEMU. This is due in part to the more aggressive online optimizations we perform, but additionally QEMU's DBT has had years of hand-tuning, and benefits from a monolithic implementation.

However, the previous results clearly indicate that our compilation latency does not affect the runtime of the benchmarks. In fact, the extra effort we put into compilation ensures that our code quality surpasses that of QEMU's, as will be demonstrated in Section 3.6. Figure 15 shows that indeed, when using the SimBench micro-benchmark suite [47], the *Large-Blocks* and *Small-Blocks* benchmark indicate that our code generation speed is 65% and 85% slower, respectively. These benchmarks are described in Section 3.5.

Figure 16 provides a further breakdown of the time spent for JIT compilation: instruction translation (including invocation DAG generation and instruction selection) takes up more than 50% of the total JIT compilation time, followed by register allocation (including liveness analysis and dead code elimination), then host instruction encoding. Guest instruction decoding takes up 2.75% of the compilation pipeline.

We have also collected aggregate translation size statistics for `429.mcf`. We found that Captive generates larger code than QEMU, with Captive generating 67.53 bytes of host code per guest instruction, compared to QEMU's 40.26 bytes. This is due the use of vector operations in the benchmarks: while QEMU frequently emits (relatively small) function calls for

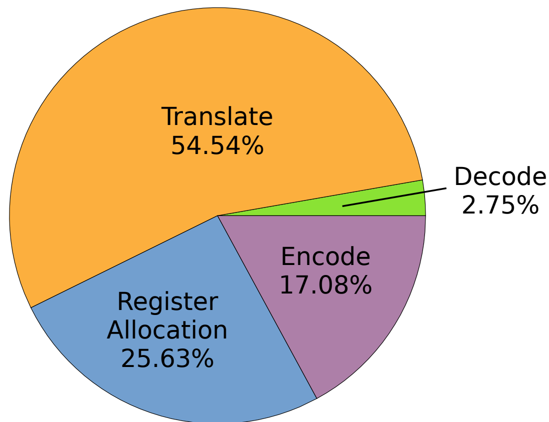

Figure 16: % time spent in each compilation phase: *Decode*, *Translate*, *Register Allocation* and *Encode*.

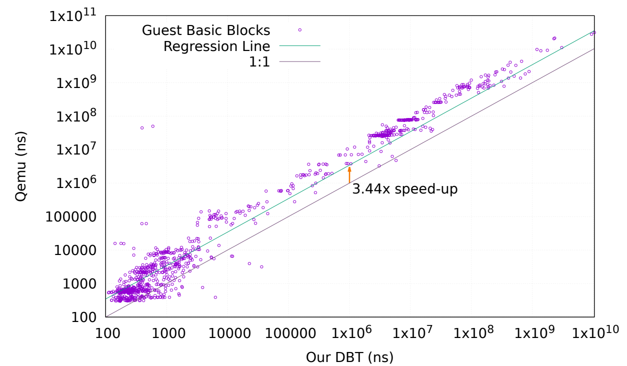

Figure 17: Measuring code quality: accumulated execution times of guest basic blocks from `429.mcf`. Blocks compiled by Captive execute, on average, 3.44× faster than their QEMU counterparts.

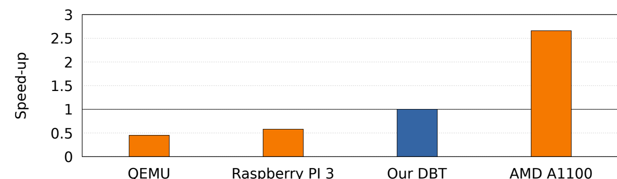

Figure 18: Comparison of Captive against native execution on two physical ARMv8-A platforms: Raspberry Pi 3 Model B & AMD Opteron A1170.

these operations, Captive emits vector operations directly. In particular, vector load and store operations require that vectors are packed and unpacked element by element, each of which can require 2–3 instructions.

3.5 Targeted Micro-Benchmarks

As well as using the SPEC benchmark suite, we have also evaluated the performance of both Captive and QEMU using SimBench[47]. This is a targeted suite of micro-benchmarks designed to analyze the performance of full system emulation platforms in a number of categories, such as the performance of the memory emulation system, control flow handling, and translation speed (in the case of DBT-based systems).

Figure 15 shows the results of running SimBench on Captive and QEMU, in terms of speedup over QEMU. Captive outperforms QEMU in most categories, except for code generation (Large-Blocks and Small-Blocks) and Data Fault handling. Captive's use of the host memory management systems results in large speedups on the memory benchmarks.

3.6 Code Quality

We assess code quality by measuring the individual basic block execution time for each block executed as part of a benchmark. For example, consider the scatter plot in Figure 17, where we show the measured aggregated block execution times across the `429.mcf` benchmark for Captive and QEMU. In order to limit the influence of infrastructure components of both platforms we have disabled block chaining for both platforms. Block execution times have been measured in the same way for both systems using the host's `rdtscp` instruction, inserted around generated native code regions representing a guest block.

A regression line and 1:1 line are also plotted in the log-log scale plot. Most points are above the 1:1 line, indicating that the vast majority of blocks are executed more quickly on Captive than on QEMU. In fact, we observe a code quality related speedup of 3.44 for this benchmark, represented by the positive shift of the regression line along the y-axis.

Further investigation reveals that Captive emits and executes, on average, 10 host instructions per guest instruction in addition to any block prologue and epilogue.

3.6.1 Impact of offline optimizations

Our offline generation system has four levels of optimization (`O1`–`O4`), although in practice we only use the maximum optimization level. These optimizations directly affect the amount of source code generated in the offline phase, where lower levels (e.g. `O1`) emit longer code sequences in the generator functions. This translates to more operations to perform at JIT compilation time, and therefore (a) larger JIT compilation latency, and (b) poorer code quality.

At the `O1` optimization level, only function inlining is performed, and results in the ARMv8A model comprising 271,299 lines of generated code. At `O4` (where a series of aggressive domain specific optimizations are performed), there is a reduction of 56%, to 120,162 lines of generated code.

3.6.2 Hardware Floating-point Emulation

In contrast to QEMU, Captive utilises a hardware emulated floating-point approach, where guest floating-point instructions are directly mapped to corresponding host floating-point instructions, if appropriate. Any fix-ups required to maintain bit-accuracy are performed inline, rather than calling out to helper functions. This increases the complexity of host portability, but significantly improves performance.

To determine the effect of this, we utilised a microbenchmark that exercised a small subset of (common) floating-point operations, and observed a speed-up of 2.17× of Captive (with hardware floating-point emulation) over QEMU (with software floating-point emulation). We then replaced our DBT's floating-point implementation with a software-based one (taken directly from the QEMU source-code), and observed a speed-up of 1.68×. This translates to a speed-up of 1.3× within Captive itself.

3.7 Comparison to Native Execution

We also compare the performance of Captive against two ARMv8-A hardware platforms: a Raspberry Pi 3 Model B and an AMD Opteron A1170 based server (see Table 4). The results of this comparison can be seen in Figure 18 and enable us to compare absolute performance levels in relation to physical platforms: across the entire SPEC CPU2006 suite Captive is about twice as fast as a 1.2GHz Cortex-A53 core of a Raspberry Pi 3, and achieves about 40% of the performance of a 2.0GHz Cortex-A57 core of the A1170. While outperformed by server processors it indicates that Captive can deliver performance sufficient for complex applications.

Finally, we compare the performance of Captive against native execution of the benchmarks compiled for and directly executed on the x86-64 host. Across all benchmarks we observe a speedup of 7.24 of native execution over system-level DBT, i.e. the overhead is still substantial, but Captive has significantly narrowed the performance gap between native execution, and system-level DBT.

4 Related Work

Due to their versatility DBT systems have found extensive interest in the academic community, especially since the mid-90s. In Table 6 we compare features and highlight specific contributions of many relevant DBT systems and techniques presented in the academic literature. The vast majority of existing DBT systems only provide support for user-level applications, but there also exist a number of system-level DBT approaches to which we compare Captive. In addition, numerous individual compilation techniques have been developed specifically for binary translators. Those relevant to our work on Captive are summarized in Table 7.

Captive is inspired by existing system-level DBT systems and we have adopted proven features while developing novel. Like Shade [13], Embra [53], and QEMU [4] Captive is interpreter-less and uses a basic block compiler with block chaining and trace caching. Our binary translator, however, is not hand-coded, but generated from a machine description. This allows for ease-of-retargeting comparable to Pydgin [29], but at substantially higher performance levels. Unlike Walkabout [12], Yirr-Ma [44], or ISAMAP [38], which similarly rely on machine descriptions, Captive employs split compilation and applies several optimizations offline, i.e. at module generation time, rather than relying on expensive runtime optimizations only. Instead of software emulation of floating-point (FP) arithmetic like QEMU or unsafe FP implementation like HQEMU [21], our FP implementation is bit-accurate, but still leverages the host system's FP capabilities wherever possible. Similar to IA-32 EL [28, 54] Captive translates guest SIMD instructions to host SIMD instructions wherever possible, but this mapping is generalized for any guest/host architecture pair. Like QuickTransit [26] or HyperMAMBO [15] Captive operates as a hypervisor, but provides a full-system environment rather than hosting only a single application. Captive shares this property with MagiXen [10], but provides full support for 64-bit guests on a 64-bit host rather than only 32-bit guests on a 64-bit host (which avoids address space mapping challenges introduced by same word-size system-level DBT).

5 Summary & Conclusion

In this paper we developed a novel system-level DBT hypervisor, which can be retargeted to new guest systems using a high-level ADL. We combine offline and online optimizations as well as a JIT compiler operating in a virtual bare-metal environment with full access to the virtual host processor to deliver performance exceeding that of conventional, manually optimized DBT systems operating as normal user processes. We demonstrate this using an ARMv8-A guest running a full unmodified ARM Linux environment on an x86-64 host, where Captive outperforms the popular QEMU DBT across SPEC CPU2006 application benchmarks while on average reaching 2× the performance of a 1.2GHz entry-level Cortex-A53 or 40% of a 2.0GHz server-type Cortex-A57.

5.1 Future Work

Our future work will consider support for multi- and many-core architectures, heterogeneous platforms, and support for various ISA extensions, e.g. for virtualization or secure enclaves, inside the virtualized guest system. We also plan to investigate possibilities for synthesizing guest and host architecture descriptions in the spirit of Buchwald et al. [8], or using existing formal specifications. We are also investigating a tiered compilation approach, to aggressively optimize hot code, and adding support for host retargeting, by using the same ADL as for our guest architectures.

MTS: Bringing Multi-Tenancy to Virtual Networking

Kashyap Thimmaraju[1] Saad Hermak[1] Gábor Rétvári[2] Stefan Schmid[3]
[1] *Technische Universität Berlin* [2] *BME HSNLab* [3] *Faculty of Computer Science, University of Vienna*

Abstract

Multi-tenant cloud computing provides great benefits in terms of resource sharing, elastic pricing, and scalability, however, it also changes the security landscape and introduces the need for strong isolation between the tenants, *also inside the network*. This paper is motivated by the observation that while multi-tenancy is widely used in cloud computing, the virtual switch designs currently used for network virtualization lack sufficient support for tenant isolation. Hence, we present, implement, and evaluate a virtual switch architecture, *MTS*, which brings secure design best-practice to the context of multi-tenant virtual networking: compartmentalization of virtual switches, least-privilege execution, complete mediation of all network communication, and reducing the trusted computing base shared between tenants. We build *MTS* from commodity components, providing an incrementally deployable and inexpensive upgrade path to cloud operators. Our extensive experiments, extending to both micro-benchmarks and cloud applications, show that, depending on the way it is deployed, *MTS* may produce 1.5-2x the throughput compared to state-of-the-art, with similar or better latency and modest resource overhead (1 extra CPU). *MTS* is available as open source software.

1 Introduction

Security landscape of cloud virtual networking. Datacenters have become a critical infrastructure of our digital society, and with the fast growth of data centric applications and AI/ML workloads, dependability requirements on cloud computing will further increase [13]. At the heart of an efficiently operating datacenter lies the idea of resource sharing and *multi-tenancy*: independent instances (e.g., applications or tenants) can utilize a given infrastructure concurrently, including the compute, storage, networking, and management resources deployed at the data center, in a physically integrated but logically *isolated* manner [38, 23].

At the level of the data center communication network, isolation is provided by the network virtualization architecture. Key to network virtualization is the *virtual switch (vswitch)*, a network component located in the Host virtualization layer of the (edge) servers that connects tenants' compute and storage resources (e.g., Virtual Machines (VMs), storage volumes, etc.), provisioned at the server, to the rest of the data center and the public Internet [38, 33, 54].

Multi-tenancy is typically provided in this design by (i) deploying the vswitches with the server's Host operating system/hypervisor (e.g, Open vSwitch aka OvS [56]); (ii) using *flow-table-level isolation*: the vswitch's flow tables are divided into per-tenant logical datapaths that are populated with sufficient flow table entries to link tenants' data-center-bound resources into a common interconnected workspace [38, 33, 54]; and (iii) overlay networks using a tunneling protocol, e.g., VXLAN [73], to connect tenants' resources into a single workspace. Alternatives to this Host-based vswitch model [56], e.g., NIC-based vswitch solutions [35, 27] and FPGA-based designs [22], share the main trait that the logical datapaths have a common networking substrate (vswitch).

Despite the wide-scale deployment [16, 22, 35], the level of (logical and performance) isolation provided by vswitches is not yet well-understood. For example, Thimmaraju et al. [69] uncovered a serious isolation problem with a popular virtual switch (OvS). An adversary could not only break out of the VM and attack all applications on the Host, but could also manifest as a worm, and compromise an entire datacenter in a few minutes. Csikor et al. [15] identified a severe performance isolation vulnerability, also in OvS, which results in a low-resource cross-tenant denial-of-service attack. Such attacks may exacerbate concerns surrounding the security and adoption of public clouds (that is already a major worry across cloud users [62]).

Indeed, a closer look at the cloud virtual networking best-practice, whereby *per-tenant logical datapaths are deployed on a single Host-based vswitch using flow-table-level isolation* [38, 33, 54], reveals that the current state-of-the-art violates basically all relevant secure system design princi-

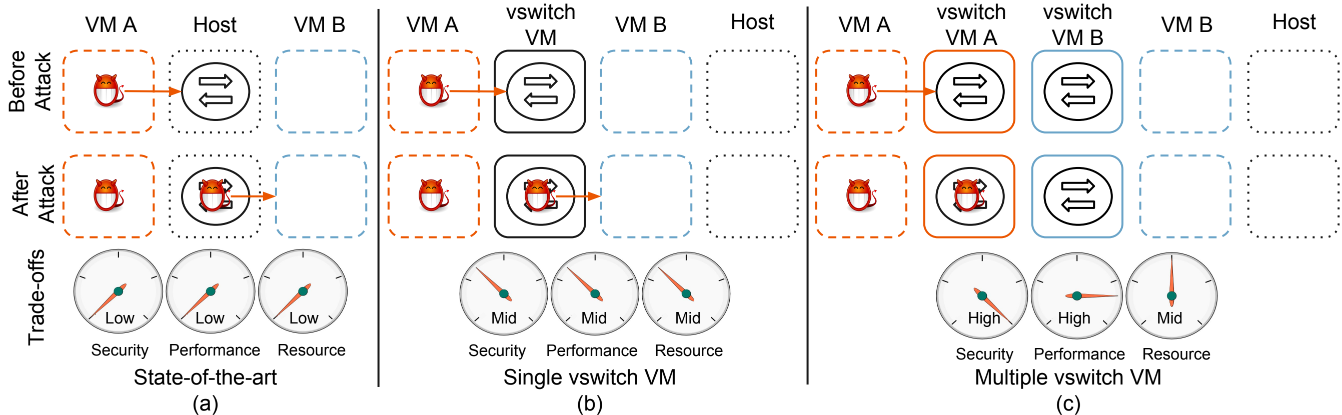

Figure 1: A high-level view of the tradeoffs between security, performance and resources for the state-of-the-art and *MTS*

ples [61, 9]. First, the principle of *least privilege* would require that any system component should be given only the minimum set of privileges necessary to complete its task, yet we see that vswitch code typically executes *on the Host* with administrator, or what is worse, with full kernel privilege [72, 28], even though this would not be absolutely necessary (see Sec. 3). Second, untrusted user code directly interacts with the vswitch and hence with the Host OS, e.g., it may send arbitrary packets from VMs, query statistics, or even install flow table entries through side channels [15], which violates the secure design principle of *complete mediation*. But most importantly, the shared vswitch design goes directly against the principle of the *least common mechanism*, which would minimize the amount of resources common to more than one tenant.

Secure vswitch design. The main motivation for our work is the observation that *current virtual switch architectures are not well-suited for multi-tenancy*. This observation leads us to revisit the fundamental design of secure vswitches. Hence, in this paper, we present, implement, and evaluate a multi-tenant (virtual) switch architecture, *MTS*, which extends the benefits of multi-tenancy to the vswitch in a secure manner, without imposing prohibitive resource requirements or jeopardizing performance.

Fig. 1 illustrates the key idea underlying the *MTS* design, by showing the security-performance-resource trade-offs for different architectures. The current vswitch architecture is shown in Fig. 1(a), whereby per-tenant logical datapaths share a common (physical or software) switch component deployed at the Host hypervisor layer (in the rest of this paper, we shall sometimes refer to this design point as the "Baseline"). As we argued above, this design is fundamentally insecure [69, 15] as it violates basic secure design principles, like least privilege, complete mediation, or the least common mechanism. In *MTS*, we address the least privilege principle by the *compartmentalization* of the vswitches (Fig. 1(b)): by moving the vswitches into a dedicated vswitch VM, we can prevent an attacker from compromising the Host via the vswitch [34]. Then, we establish a secure communication channel between the tenant VMs and the vswitch VM via a trusted hardware technique, Single Root Input/Output Virtualization, or SR-IOV, a common feature implemented in most modern NICs and motherboards [4, 35]. Thus, all tenant-to-tenant and tenant-Host networking is *completely mediated* via the SR-IOV NIC. Adopting Google's *extra security layer* design principle [1] which requires that between any untrusted and trusted component, there have to be at least two distinct security boundaries [7, 23], we introduce a second level of isolation by moving the vswitch, deployed into the vswitch VM, to the user space. Hence, at least two independent security mechanisms need to fail (user-kernel separation and VM-isolation) for the untrusted tenant code to gain access to the Host.

Interestingly, we are able to show the resultant secure vswitch design, which we call the *single vswitch VM* design, does not come at the cost of performance; just the contrary, our evaluations show that we can considerably improve throughput and latency, for a relatively small price in resources. Finally, we introduce a "hardened" *MTS* design that we call the *multiple vswitch VMs* design (Fig. 1(c)), whereby, in line with the principle of the least common mechanism, we further separate the vswitch by creating multiple separate vswitch VMs, one for each tenant (or based on security zones/classes). This way, we can maintain full network isolation for multiple tenants.

Contributions. Our main contributions in this paper are:

- We *identify requirements and design principles* that can prevent the virtual switch from being a liability to virtualization in the cloud, and we carefully apply these principles to revisit multi-tenancy in virtual networking.

- We *present* MTS*, a secure vswitch design* whereby the vswitch is moved into a separate VM that prevents malicious tenants from compromising the Host via the virtual switch, and we also show a "hardened" *MTS* design that also prevents compromising *other* tenants' virtual

networks through the vswitch. All our designs are incrementally deployable, providing an inexpensive deployment experience for cloud operators.

- We *report on extensive experiments* with our *MTS* prototype and we find a noteworthy improvement (1.5-2x) in throughput compared to the Baseline, with similar or better latency for an extra CPU. We build our prototype from off-the-shelf commodity components and existing software; *MTS* and the data from this paper are available at:

  `https://www.github.com/securedataplane`

Organization. We dive deeper into designing a secure vswitch in Section 2. In Section 3 we elaborate on *MTS* and report on two evaluations in Sections 4 and 5. We enter a discussion of *MTS* in Section 6, review related work in Section 7 and finally draw conclusions in Section 8.

2 Securing Virtual Switches

As demonstrated in previous work [15, 69], the current state-of-the-art in virtual switch design can be exploited to not only break network isolation, but also to break out of a virtual machine. This motivates us to identify requirements and design principles that make virtual switches a dependable component of the data center [68].

2.1 State-of-the-Art

Virtual networks in cloud systems using virtual switches typically follow a *monolithic* architecture, where a single controller programs a *single vswitch* running in the Host OS with per-tenant logical datapaths in the vswitch. Isolation between tenants is at the level of flow-tables [38, 33, 54]: the controller populates the flow tables in each per-tenant logical datapath with sufficient flow rules to connect the tenant's Host-based VMs to the rest of the data center and the public Internet. Those sets of flow rules are complex: with a small error in one rule potentially having security consequences, e.g., making intra-tenant traffic visible to other tenants.

As shown in Table 1, nearly all vswitches are *monolithic* in nature. A single vswitch is installed with flow rules for all the tenants hosted on the respective server. This increases the trusted computing base (TCB) of the single vswitch, as it is responsible for Layer 2-7 of the virtual networking stack. Next, nearly 80% of the surveyed vswitches are co-located with the Host virtualization layer. This increases the TCB of the server since a vswitch is a complex piece of software, consisting of tens of thousands of lines of code. The complexity of network virtualization is further increased by the fact that packet processing for roughly 70% of the virtual switches is spread across user space and the kernel (see last two columns in Table 1). These concerns are partially

addressed by the current industry trend towards offloading vswitches to *smart NICs* [35, 52, 27, 42]. Indeed consolidating the vswitch into the NIC can improve the security as it reduces the TCB of the Host. These burgeoning architectures, however, share the main trait that the per-tenant logical datapaths are monolithic, often with full privilege and direct access to the Host OS, which when compromised can break network isolation and be used as a stepping-stone to the Host.

2.2 Threat Model

We assume the attacker's goal is to either escape network virtualization by compromising the virtual switch, or to tamper with other tenant's network traffic by controlling the virtual switch [69]. Hence, she can affordably rent a VM in an Infrastructure-as-a-Service (IaaS) cloud, or has somehow managed to compromise a VM, e.g., by exploiting a webserver vulnerability [14]. From the VM she can send arbitrary packets, make arbitrary computations, and store arbitrary data. However, she does not have direct control to configure the Host OS and hardware: all configuration access happens through a dedicated cloud management system.

The defender is a public cloud provider who wants to prevent the attacker from compromising virtual network isolation; in particular, *the cloud provider wants to maintain tenant-isolation even when the vswitch is compromised*. We assume that the cloud provider already supports SR-IOV at NICs [4, 35, 22] and the underlying virtualization and net-

work infrastructure is trusted, including the hypervisor layer, NICs, firmware, drivers, core switches, and so on.

2.3 Design Principles and Security Levels

Our *MTS* design is based on the application of the secure system design principles, established by Saltzer et al. [61] (see also Bishop [9] and Colp et al. [12]), to the problem space of virtual switches.

Least privilege vswitch. The vswitch should have the minimal privileges sufficient to complete its task, which is to process packets to and from the tenant VMs. Doing so limits the damage that can result from a system compromise or misconfiguration. Current best-practice is, however, to run the vswitch co-located with the Host OS and with elevated privileges; prior work has shown the types and severity of attacks that can happen when this principle fails [69]. A well-known means to the principle of least privilege is *compartmentalization*: execute the vswitch in an isolated environment with limited privileges and minimal access to the rest of the system. In the next section, we will show how *MTS* implements compartmentalization by committing the vswitches into one or more dedicated vswitch VMs.

Complete mediation of tenant-to-tenant and tenant-to-host networking. This principle requires that the network communication between the untrusted tenants and the trusted Host is completely mediated by a trusted intermediary to prevent undesired communication. This principle, when systematically applied, may go a long way towards reducing the vswitch attack surface. By *channeling all network communication* between untrusted and trusted components *via a trusted intermediary* (a so called reference monitor), the communication can be validated, monitored and logged based on security policies. In the next section, we show how complete mediation is realized in *MTS* using a secure SR-IOV channel between the tenant VMs, vswitches and Host.

Extra security boundary between the tenant and the host. This security principle, widely deployed at Google [1], requires that between any untrusted and trusted component there has to be at least two distinct security boundaries, so at least two independent security mechanisms need to fail for the untrusted component to gain access to the sensitive component [7]. We establish this extra layer of security in *MTS* by *moving the vswitch to user space*. This also contributes to implementing the "least privilege" principle: the user-space vswitch can drop administrator privileges after initialization.

Least common mechanisms. This principle addresses the amount of infrastructure shared between tenants; applied to the context of vswitches this principle requires that the network resources (code paths, configuration, caches) common to more than one tenant should be minimized. Indeed, every shared resource may become a covert channel [9]. Correspondingly, *decomposing the vswitches themselves into multiple compartments* could lead to hardened vswitch designs.

Security levels. From these principles, we can obtain different levels of security:

- **Baseline:** The per-tenant logical datapaths are consolidated into a single physical or software vswitch that is co-located with the Host OS.
- **Level-1:** Placing the vswitch in a dedicated compartment provides a first level of security by protecting from malicious tenants to compromise the Host OS via the vswitch ("single vswitch VM" in Fig. 1b).
- **Level-2:** Splitting the vswitches into multiple compartments (based on security zones or on a per-tenant basis) adds another level of security, by isolating tenants' vswitches from each other ("multiple vswitch VMs" in Fig. 1c).
- **Level-3:** Moving the vswitches into user space, combined with Baseline or Level-1 or -2, reduces the impact of a compromise and further reduces the attack surface.

3 The *MTS* Architecture

We designed *MTS* with secure design principles from Section 2.3. We first provide an overview and then present our architecture in detail.

3.1 Overview

Compartmentalization. There are many ways in which isolated vswitch compartments can be implemented: full-blown VMs, OS-level sandboxes (jails, zones, containers, plain-old user-space processes [23], and exotic combinations of these [36, 26]), hardware-supported enclaves (Intel's SGX) [50, 3], or even safe programming language compilers (Rust), runtimes (eBPF), and instruction sets (Intel MPX). For flexibility, simplicity, and ease of deployment, *MTS relies on conventional VMs as the main unit of compartmentalization*.

VMs provide a rather strong level of isolation and are widely supported in hardware, software, and management systems. This in no way means that VM-based vswitches are mandatory for *MTS*, just that this approach offers the highest flexibility for prototyping. For simplicity, Fig. 2 depicts two vswitch compartments (Red and Blue solid boxes) running independent vswitches in their isolated VMs. The multiple compartments further reduce the common mechanisms between the vswitch and the connected tenants, achieving security Level-2. Security Level-1, although not depicted, would involve only a single vswitch VM.

Complete mediation. To mediate all interactions between untrusted tenant code and the Host OS through the vswitch, we need a secure and high-performance communication medium between the corresponding compartments/VMs. In

MTS we use Single Root IO Virtualization (SR-IOV) to interconnect the vswitch compartments (see Figure 2).

SR-IOV is a PCI-SIG standard to make a single PCIe device, e.g., a NIC, appear as multiple PCIe devices that can then be attached to multiple VMs. An SR-IOV device has one or more physical functions (PFs) and one or more virtual functions (VFs), where the PFs are typically attached to the Host and the VFs to the VMs. Only the Host OS driver has privileges to configure the PFs and VFs. The NIC driver in the VMs in turn have restricted access to VF configuration. Only via the Host, VFs and PFs can be configured with unique MAC addresses and Vlan tags. Network communication between the PFs and VFs occurs via an L2 switch implemented in the NIC based on the IEEE Virtual Ethernet Bridging standard [37]. This enables Ethernet communication not only from and to the respective VMs (vswitch and tenants) based on the destination VF's MAC address but also to the external networks.

Sharing the NIC SR-IOV VF driver and the Layer 2 network virtualization mechanism implemented by the SR-IOV NIC is considerably simpler than including the NIC driver and the entire network virtualization stack (Layer 2-7) in the TCB. Tenants already share SR-IOV NIC drivers in public clouds [4, 35, 5]. Virtual networks can be built as we will see next, as per-tenant user-space applications implementing Layer 3-7 of the virtual networking stack.

Thanks to the use of SR-IOV in *MTS*, packets to and from tenant VMs completely bypass the Host OS; instead, all potentially malicious traffic is channeled through the trusted hardware medium (SR-IOV NIC) to the vswitch VM(s). Furthermore, using SR-IOV reduces CPU overhead and improves performance (see Section 4). Finally, SR-IOV provides an attractive upgrade path towards fully offloaded, smart-NIC based virtual networking: chip [39] and OS vendors [74, 66] have been supporting SR-IOV for many years now at a reasonable price, major cloud providers already have SR-IOV NICs deployed in their data centers [4, 35, 5], and, perhaps most importantly, this design choice liberates us from having to re-implement low-level and complex network components [34]: we can simply use any desired vswitch, deploy it into a vswitch VM, configure and attach VFs to route tenants' traffic through the vswitch, and start processing packets right away.

User-space packet processing. As discussed previously, we may choose to deploy the vswitches into the vswitch VM user-space to establish an extra security boundary between the tenant and the Host OS (Level-3 design). Thanks to the advances in kernel bypass techniques, several high-performance and feature-rich user-space packet processing frameworks are available today, such as Netmap [58], FD.IO [67], or Intel's DPDK [30]. Our current design of *MTS leverages OvS with the DPDK datapath for implementing the vswitches* [60]. DPDK is widely supported, it has already been integrated with popular virtual switch products,

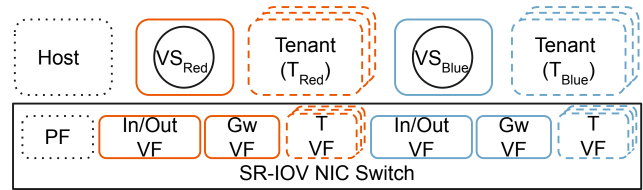

Figure 2: High-level overview of *MTS* in security Level-2. The Red and Blue vswitch compartments (VMs) are allocated dedicated virtual functions (VFs) to communicate with external networks using the *In/Out VF*, their respective tenants using the *Gw VF* and *T VF*. Communication between the vswitches, tenants and the Host physical function (PF) are mediated via the SR-IOV NIC switch.

and extensive operational experience is available regarding the expected performance and resource footprint [40]. Note, however, that using DPDK and OvS is not mandatory in *MTS*; in fact, thanks to the flexibility provided by our VM-compartments and SR-IOV, we can deploy essentially any user-space vswitch to support *MTS*.

3.2 Detailed Architecture

For the below discussion, we consider the operation of *MTS* for one vswitch compartment and its corresponding tenant VMs from the Level-2 design shown in Fig. 2. The case when only a single compartment (Level-1) is used is similar in vein: the flow table entries installed into the vswitch and the VFs attached to the vswitch compartment need to be modified somewhat; for lack of space we do not detail the Level-1 design any further.

Connectivity. Each vswitch VM is allocated at least one VF (In/Out VF) for external (inter-server) connectivity and another as a gateway (Gw VF) for vswitch-VM-to-tenant-VM connectivity as shown in Fig. 2. Isolation between the external and the tenant network (tenant VF shown as T VF in the Figure) is enforced at the NIC-level by configuring the Gw VF and the tenant VFs with a Vlan tag specific to the tenant. Different Vlan tags are used to further isolate the multiple vswitch compartments and their resp. tenants on that server.

The packets between VFs/PFs in the NIC are forwarded based on the destination MAC address and securely isolated using Vlan tags (the same security model as provided by enterprise Ethernet switches). For all packets to and from the tenant VMs to pass through the vswitch-VM, the destination MAC address of each packet entering and leaving the NIC needs to be accurately set, otherwise packets will not reach the correct destination. This can be addressed by introducing minor configuration changes to the normal operation of the tenant and the vswitches, detailed below.

Ingress chain. Fig. 3ⓐ illustrates the process by which packets from an external network reach the tenant VMs. In step ① a packet enters the server through the NIC fabric

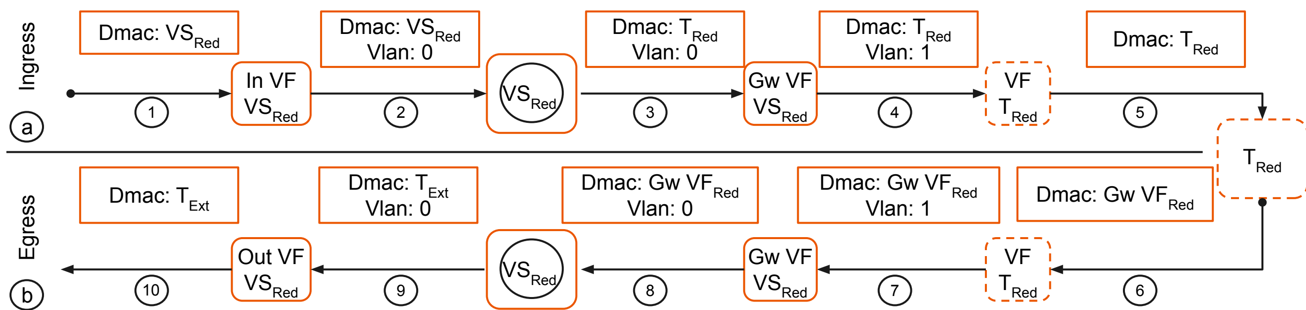

Figure 3: A step-by-step illustration of how packets enter and leave the Red tenant from Figure 2 in *MTS*. ⓐ shows how ingress packets reach Tenant$_{Red}$. ⓑ shows how Tenant$_{Red}$ packets reach an external system Tenant$_{Ext}$.

port having the Red vswitch's In/Out VF MAC address as the destination MAC address (Dmac). The NIC switch will deliver the packet to the vswitch VM untagged (Vlan 0) in ②. The Red vswitch then uses the destination IP address in the packet to identify the correct tenant VM to send the packet to, changes the destination MAC address to that of the Red tenant's VF (VF T_{Red}), and emits the packet to the Gw VF in the NIC in ③. This ensures accurate packet delivery to and from tenant VMs and the complete isolation of the tenant-vswitch traffic from other traffic instances. In ④ and ⑤, the NIC tags the packet with the Red tenant's specific Vlan tag (Vlan 1 in the figure), uses the built-in switch functionality to make a lookup in the MAC learning table for the Vlan, pops the Vlan tag and finally forwards the packet to the Red tenant's VM. The NIC forwarding process is completely transparent to the vswitch and tenant VMs, the only downside is the extra round-trip to the NIC. Later we show that this round-trip introduces negligible latency overhead.

Egress chain. The reverse direction shown in Fig. 3ⓑ, sending a packet from the tenant VM through the vswitch to the external network goes in similar vein. In ⑥ the Red tenant VM T_{Red} sends a packet through its VF (T_{Red}) with the destination MAC address set to the MAC address of the Red tenant's Gw VF; in the next subsection we describe two ways to achieve this. In ⑦ the NIC switch tags the packet (Vlan 1), looks-up the destination MAC address which results in sending the packet to the Gw VF. At the gateway VF ⑧, the NIC switch pops the Vlan tag and delivers the packet to the Red vswitch VM. The vswitch receives the packet, looks up the destination IP address, rewrites the MAC address to the actual (external) gateway's MAC address, and then sends the packet out to the In/Out VF in ⑨. Finally in ⑩, the NIC will in turn send the packet out the physical fabric port.

Communication between the two VMs of a single tenant inside the server goes similarly, with the additional complexity that packets now take *two* extra round-trips to the NIC: once on the way from the sender VM to vswitch, and once on the way from the vswitch to the destination VM. Again, our evaluations in the next sections will show that the induced latency overhead for such a traffic scenario is low.

System support. Next, we detail the modifications the cloud operator needs to apply to the conventional vswitch setup to support *MTS*. The primary requirement is to modify the centralized controllers to appropriately configure tenant specific VFs with Vlan tags and MAC addresses, and insert correct flow rules to ensure the vswitch-tenant connectivity. Second, advanced multi-tenant cloud systems rely on tunneling protocols to support L2 virtual networks. This is also supported by *MTS*, by modifying the flow tables to pop/insert the appropriate headers whenever packets need to be decapsulated/encapsulated. Note that after decapsulation the tunnel id can be used in conjunction with the destination IP address to identify the appropriate tenant VM. Third, the ARP entry for the default gateway must be appropriately set in each tenant VM so that packets from the tenant VM go to the vswitch VM. To this end, the tenant VMs can be configured with a static ARP entry pointing to the appropriate Gw VF, or using the centralized controller and vswitch as a proxy-ARP/ARP-responder [47]. Finally, to prevent malicious tenants from launching an attack on the system, the cloud operator needs to deploy security filters in the NIC. In particular, source MAC address spoofing prevention must be enabled on all tenant VMs' VFs. Furthermore, flow-based wildcard filters can also be applied in the NIC for additional security, e.g., to drop packets not destined to the vswitch compartment, to prevent the Host from receiving packets from the tenant VMs, etc. Our *MTS* implementation, described in Section 4, takes care of removing the manual management burden in applying the above steps.

Resource allocation. Additional levels of security usually come with increased resource requirement, needed to run the security/isolation infrastructure. Below, we describe two resource sharing strategies and how the VFs are allocated to the vswitch compartments. However, due to the sheer quantity and diversity in cloud setups, we restrict the discussion to plain compute and memory resources and the number of SR-IOV VFs for the different *MTS* security levels.

We consider two modes for compute and memory resources. A *shared* mode where tenants' vswitches share a single physical CPU core, while in the *isolated* mode each tenant's vswitch is pinned to a different core. However, we

assume that each vswitch compartment gets an equal share of main memory (ram) and this is inexpensive compared to physical CPU cores. Dedicating compute and memory resources for vswitching is not uncommon among cloud operators [22, 16]. Note that the *shared* and *isolated* resource allocations are merely two ends of the resource allocation spectrum, different sets of vswitch VMs could be allocated resources differently, e.g., based on application or customer requirements. In the next section we will see that the resource requirement for multiple vswitch VM compartments, i.e., Level-2 alone, is not resource prohibitive in the *shared* mode, however, Level-2 and Level-3 can be.

Regarding the number of SR-IOV VFs needed, the current standard allows each SR-IOV device to have up to 64 VFs per PF. For Level-1, the total number of VFs is given by the sum of i) the number of VFs allocated for external connectivity (In/Out VF); ii) the total number of tenant-specific gateway VFs; and iii) tenant-specific VM VFs hosted on the server. In a basic Level-1 setup hosting 1 tenant, with 1 In/Out VF and 1 gateway VF and 1 VF for the tenant VM, the total VFs is 3. Similarly for 4 tenants, the total VFs is 9. For Level-2, the total number of VFs is given by the sum of i) the tenant-specific VFs allocated for external connectivity; ii) the tenant-specific gateway VFs; and iii) tenant-specific VM VFs hosted on the server. For a basic Level-2 setup hosting 2 tenants, with 1 In/Out VF, 1 gateway VF per tenant vswitch and 1 VF for each tenant VM, the total VFs is 6. Similarly for 4 tenants, the total VFs is 12.

4 Evaluating Tradeoffs

We designed a set of experiments to empirically evaluate the security-performance-resource tradeoff of *MTS*. To this end, we measure *MTS*'s performance for different security levels under different resource allocation strategies, in canonical cloud traffic scenarios [19]. The focus is on throughput and latency performance metrics, and physical cores and memory for resources. In particular, the experiments serve to verify our expectation that our design does not introduce a considerable overhead in performance. However, we do expect the amount of resources consumed to increase; our aim is to quantify this increase in different realistic setups.

Prototype framework. We took a programmatic approach to our design and evaluation, hence, we developed a set of primitives that can be composed to configure *MTS* to conduct all the experiments described in this paper. Hence, as a first step we do not consider complex cloud management systems (CMS) such as OpenStack; this way we can conduct self-contained experiments without the possible interference cause by a CMS. Our framework is written in Python and currently supports OvS and ovs-DPDK as the base virtual switch, Mellanox NIC, and the `libvirt` virtualization framework. Our framework and data are available on-line at the following URL: `https://www.github.com/securedataplane`

Methodology. We chose a set of standard cloud traffic scenarios (see Fig. 4) and a fixed number of tenants (4). For each of those scenarios, we allocated the necessary resources (Sec. 3) and then configured the vswitch either in its default configuration (Baseline) or one of the three security levels (Sec. 2.3). The system was then connected in a measurement setup to measure the one-way forwarding performance. Important details on the topology, resources, security levels and the hardware and software used are described next.

Traffic scenarios. The three scenarios evaluated are shown in Fig. 4. *Physical-to-physical (p2p):* Packets are forwarded by the vswitch from the ingress physical port to the egress. This is meant to shed light on basic vswitch forwarding performance. *Physical-to-virtual (p2v):* Packets are forwarded by the vswitch from one physical port to a tenant VM, and then back from the tenant VM to the other physical port. Compared to the p2p, this will show the overhead to forward to and from the tenant VM. *Virtual-to-virtual (v2v):* Similar to the p2v, however, when the packets return from the tenant to the vswitch, the vswitch sends the packet to another tenant which then sends it back to the vswitch and then out the egress port. This scenario emulates service chains in network function virtualization. Since the path length increases from p2p to p2v to v2v, we expect the latency to increase and the throughput to decrease when going from p2p to p2v to v2v.

Resources. We allocated compute resources in the following two ways. *Shared:* All vswitch compartments share 1 physical CPU core and their associated cache levels. *Isolated:* Each vswitch compartment is allocated 1 physical CPU core and their associated cache levels. In case of the Baseline, we allocated cores proportional to the number of vswitch compartments, e.g., 2 cores to compare with 2 vswitch VMs. For main memory, each VM (vswitch and tenant) was allocated 4 GB of which 1 GB is reserved as one 1GB Huge page. Similarly, for the Baseline, a proportional amount of Huge pages was allocated. When using *MTS*, each vswitch VM was allocated 2 In/Out VFs (1 per physical port), and 2 appropriately Vlan tagged Gw VFs per tenant (1 per physical port). When DPDK was used in Level-3: one physical core needs to allocated for each ovs-DPDK compartment (including the Baseline), hence, only the isolated mode was used; all In/Out, gateway and tenant ports connected to OvS were assigned DPDK ports (in the case of the Baseline, the tenant port type was the dpdkvhostuser-client [18]). All the tenant VMs got two physical cores and two VFs, 1 per port (these are VMs the tenant would use to run her application) so that the forwarding app ($l2fwd$) could run without being a bottleneck.

Security levels and tenants. For each resource allocation mode, we configured our setup either in Baseline or one of the three *MTS* security levels (Section 2.3). In the Baseline and Level-1, there were 4 tenant VMs connected to the

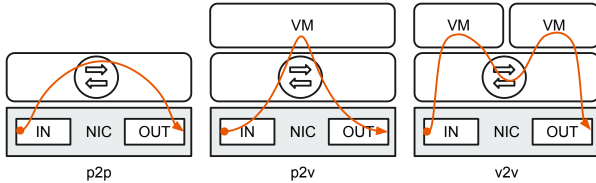

Figure 4: Traffic scenarios evaluated.

vswitch. For Level-2, we configured 2 vswitch VMs and each vswitch had 2 tenant VMs, and then we configured 4 vswitch VMs where each vswitch VM had 1 tenant VM. We repeated Level-3 with Baseline, Level-1 and the two Level-2 configurations.

Setup. To accurately measure the one-way forwarding performance (throughput and latency), we used two servers connected to each other via 10G short range optical links. The device under test (DUT) server was an Intel(R) Xeon(R) CPU E5-2683 v4 @ 2.10GHz with 64 GB of RAM with the IOMMU enabled but hyper-threading and energy efficiency disabled, and a 2x10G Mellanox ConnectX4-LN NIC with adaptive interrupt moderation and irq balancing disabled. The other server was the packet/load generator (LG), sink and monitor, with an Endace Dag 10X4-P card (which gives us accurate and precise hardware timestamps) [20]. The link between the LG and DUT, and DUT and sink were monitored via a passive optical network tap connected to the Dag card. Each receive stream of the Dag card was allocated 4 GB to receive packets. The Host, vswitch VM and tenant VMs used the Linux kernel 4.4.0-116-generic, Mellanox OFED linux driver 4.3-1.0.1.0, OvS-2.9.0 and DPDK 17.11. Libvirt 1.3.1 was used with QEMU 2.5.0. In the tenant VMs, we adapted the DPDK-17.11 $l2fwd$ app to rewrite the correct destination MAC address when using *MTS*, and used the default $l2fwd$ drain-interval (100 microseconds) and burst size (32) parameters. For the Baseline, we used the default linux bridge in the tenant VMs as using DPDK in the tenant without being backed by QEMU and OvS (e.g., dpdkvhostuserclient) is not a recommended configuration [41]. For network performance measurements, we used Endace dag-5.6.0 software tools (dagflood, dagbits, and dagsnap).

4.1 Throughput

Our first performance tradeoff is evaluating the forwarding throughput. This will shed light on the packets per second (pps) processing performance of *MTS* compared to the Baseline. It also uncovers packet loss sooner than measuring the bandwidth [32]. We measure the aggregate throughput with a constant stream of 64 B packets replayed at line rate (14 Mpps) by the LG and collected at the sink. Since we fixed the number of tenants to 4, the stream of packets comprises 4 flows, each to a respective tenant VM identified by the destination MAC and IP address. At the monitor we collect the packets forwarded to report the aggregate throughput. Each experimental run lasts for 110 seconds and measurements are made from the 10-100 second marks.

Results. The throughput measurement data for the shared mode is shown in Fig. 5(a). In Fig. 5(d) we can see the data for the isolated mode and in Fig. 5(g) the data for Level-3 in the isolated mode is shown. From Figures 5(a) and (d) we can see that nearly always MTS *had either the same or higher aggregate throughput than the Baseline*. The improvement in throughput is most obvious in the p2v and v2v topologies as vswitch-to-tenant communication is via the PCIe bus and NIC switch, which turns out to be faster than Baseline's memory bus and software approach. Sharing the physical core for multiple compartments (Fig. 5(a)) in the p2v and v2v scenarios can offer 4x isolation (Level-2 with 4 compartments) and a 2x increase in throughput (nearly .4 Mpps and .2 Mpps) compared to the Baseline (nearly .2 Mpps and .1 Mpps).

Fig. 5(d) is noteworthy as multiple cores for vswitch VMs and the Baseline functions as a load-balancer when isolating the CPU cores. In the p2p scenario, the aggregate throughput increases roughly from 1 Mpps to 2 Mpps to 4 Mpps as the number of cores increase. We observe that *MTS* is slightly more than the Baseline in the p2p, however, in the p2v and v2v scenarios *MTS* offers higher aggregate throughput. As expected, using DPDK can offer an order of magnitude better throughput (Fig. 5(g)). In the p2p topology, we were able to nearly reach line rate (14.4 Mpps) with four DPDK compartments as the packets were load-balanced across the multiple vswitch VMs, while the Baseline was able to saturate the link with 2 cores. With *MTS*, the throughput saturates (at around 2.3 Mpps) in the p2v and v2v topologies because several ports are polled using a single core and packets have to bounce off the NIC twice as much compared to the Baseline where we observe nearly twice the throughput for 2 and 4 cores. Nevertheless, we can see a slight increase in the throughput of *MTS* as the vswitch VMs increase, because the number of ports per vswitch VM decreases as the number of vswitch VMs increase. Due to the limited physical cores on the DUT, we could not evaluate 4 vswitch VMs in the v2v topology as it required more cores and ram than available.

Key findings. The key result here is that *MTS* offers increasing levels of security with comparable, if not increasing levels of throughput in the shared and isolated resource modes, however, the Baseline's throughput with user-space packet processing (DPDK) is better than *MTS*.

4.2 Latency

The second performance tradeoff we evaluated was the forwarding latency, in particular, we studied the impact of packet size on forwarding. We selected 64B (minimum IPv4 UDP packet size), 512B (average packet), 1500B (maximum MTU) packets and 2048B packets (small jumbo frame). As

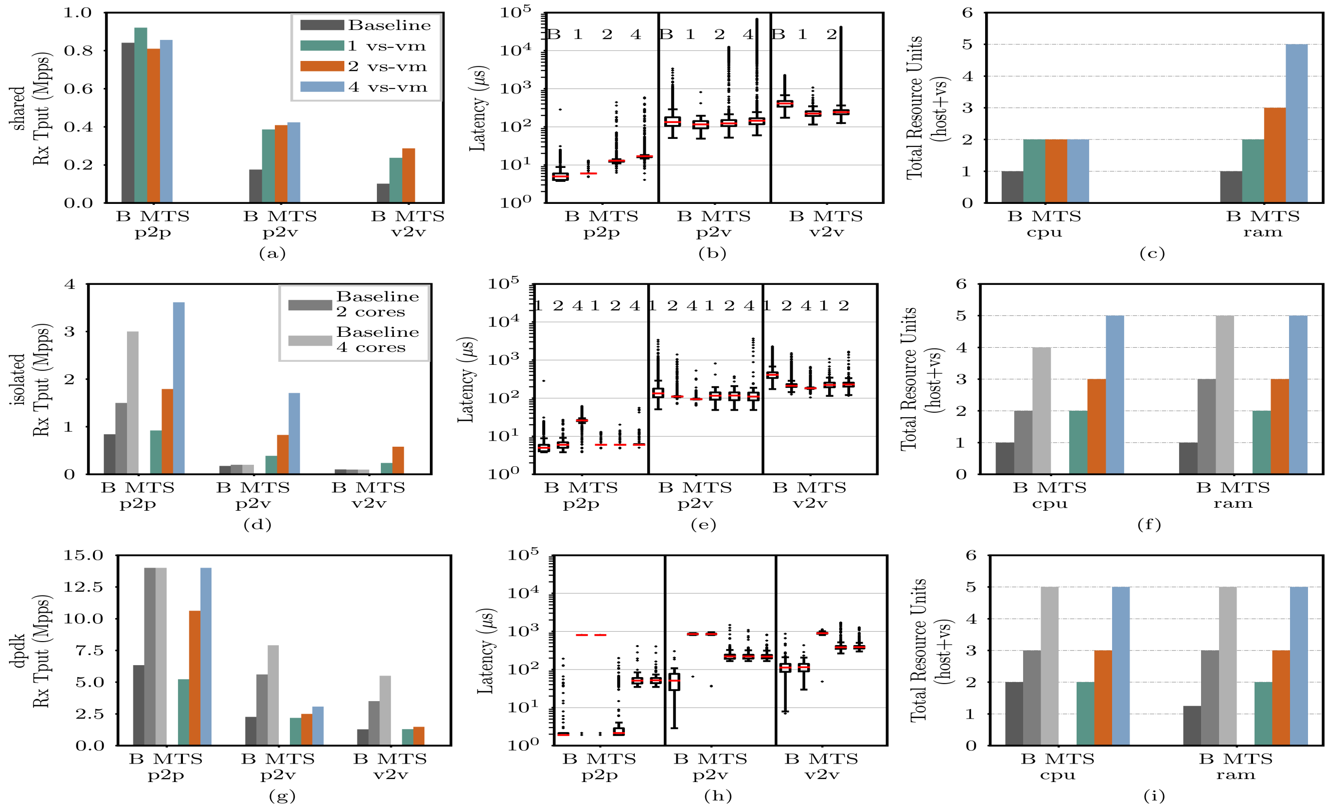

Figure 5: The security, throughput, latency and resource tradeoff comparison of *MTS*. The rows indicate the resource mode. The columns are ordered as throughput, latency and resources. The security levels used are shown in the legend. Note the bottom row is for security Level-3 in the isolated resource mode combined with other security levels.

in the throughput experiments, we used 4 flows, one to each tenant. For each experimental run, we continuously sent packets from the LG to the sink via the DUT at 10 kpps for 30 seconds. Note that is the aggregate throughput sent to the NIC and not to the vswitch VM. To eliminate possible warm-up effects, we only evaluated the packets from the 10-20 second mark.

Results. For brevity the latency distribution only for 64 *B* packets is reported here. Fig. 5(b) shows the data for the shared mode, while Fig. 5(e) is for the isolated mode. Level-3 latency data is shown in Fig. 5(h). Although the p2p scenarios shows that *MTS* increases the latency (Fig. 5(b), (e) and (h)), the p2v and v2v scenarios show that *MTS* is slightly faster than the Baseline. This is for two reasons. First, packets between the vswitch and the tenant VMs pass through the SR-IOV NIC (PCIe bus) rather than a software only vswitch (memory bus). Second, when using the Baseline the tenant uses the Linux bridge. The exception to this can be seen with user-space packet processing (Fig. 5(h)), where the Baseline with a single core for dpdk (2 in total) is always faster than *MTS*. As mentioned in Section. 4.1, due to resource limitations we could not evaluate the 4 vswitch VMs in v2v.

The variance in latency increases as more compartments share the same physical core (Fig. 5(b)). Isolating the vswitch VM cores leads to more predictable latency as seen in Fig. 5(e). When using DPDK (Fig. 5(h)) we make two observations: i) *MTS* takes longer to forward packets than without using DPDK; ii) the latency for Baseline with 2 and 4 cores for dpdk (3 and 5 in total) is unexpectedly high (around 1 ms). Regarding the former, we conclude that *MTS* with OvS and DPDK requires further tuning as we used the default OvS-DPDK parameters for the drain interval, batch size and huge pages: There is an inherent tradeoff between high throughput and average per-packet latency when using a shared memory model where a core is constantly polling [17]. For the latter, we observe that the throughput of 10 kpps is too low to drain the multiple queues on the DPDK ports. At 100 kpps and 1 Mpps, we measured an approximately 2 microsecond latency for the p2p scenario.

Key findings. We observe that for the shared mode, and 4x compartmentalization (Level-2), the latency is comparable to the Baseline (p2v) with a lot of variance whereas when isolated the latency is more predictable.

4.3 Resources

In Fig. 5(c), (f) and (i) we see the total CPU and memory consumption for Baseline and *MTS*. Note that across all the

figures, one core and at least one Huge page is always dedicated for the Host OS. In the case of the (single core) Baseline, the vswitch (OvS) runs in the Host OS and hence shares the Host's core and ram. However, for the single vswitch VM in the shared, isolated and DPDK modes, the Host OS consumes one core and the vswitch VM consumes another core making the total CPU cores two. Similarly, the 2 and 4 vswitch VMs in the shared mode, also consume the same number of cores as the single vswitch VM but a linear increase in ram. In the isolated mode, *MTS* consumes only one extra physical core relative to the Baseline, and in DPDK, *MTS* and Baseline consume equal number of cores. With respect to the memory consumption, we note that *MTS*'s and Baseline's memory consumption in the isolated and DPDK modes are the same.

Hence, we conclude that for one extra physical core, *MTS* offers multiple compartments, making the shared resource allocation economically attractive. The resource cost goes up when user-space packet processing is introduced or isolating cores, making it relatively expensive for multiple vswitch VMs.

Key findings. (i) High levels (2x/4x) of virtual network isolation per server can be achieved with an increase in aggregate throughput (2x) in the shared mode; (ii) for applications that require low and predictable latency, vswitch compartments should use the isolated mode; (iii) although user-space packet processing using DPDK offers high throughput, it is expensive (physical CPU and energy costs).

5 Workload-based Evaluation

We also conducted experiments with real workloads, to gain insights on how cloud applications such as web servers and key-value stores will perform as tenant applications are the end hosts of the virtual networks.

Methodology. For simplicity we focus our workload-based evaluation only on TCP applications as our previous measurements dealt with UDP. In general, we use a similar methodology to the one described in Section 4. For all the TCP-based measurements, we configured the tenant VMs to run the respective TCP server and from the client (LG) we benchmark the server to measure the throughput and/or response time. The topologies, resources and setup used to make these measurements are slightly nuanced which we highlight next.

Traffic scenarios. Only the p2v and v2v patterns are evaluated with workloads as we want to understand the performance of applications hosted in the server.

Resources. The ingress and egress ports for all the traffic are on the same physical NIC port unlike in the previous section where the ingress and egress ports were on separated physical ports of the NIC. Hence, each tenant's vswitch VM was given 1 VF for In/Out and 1 tagged Gw VF. Each tenant VM was given 1 VF.

Setup. The applications generating the load are standard TCP, Apache and Memcached benchmarking tools respectively Iperf3 v3.0.11 [31], ApacheBench v2.3 (ab) [2] and libMemcached v1.0.15 (memslap) [43]. Instead of the Endace card we used a similar Mellanox card at the LG.

5.1 Workloads and Results

Iperf: To compare the maximum achievable TCP throughput, we ran Iperf clients for 100 s with a single stream from the LG to the respective Iperf servers in the DUT's tenant VM. The aggregate throughput was then reported as the sum of throughput for each client-server. We collected 5 such measurements for each experimental configuration and report the mean with 95% confidence.

Webserver: To study workloads from webservers (a very common cloud application), we consider the open-source Apache web server. Using the ApacheBench tool from the LG, we benchmarked the respective tenant webservers by requesting a static 11.3 KB web page from four clients (one for each webserver). Each client made up to 1,000 concurrent connections for 100 s after which we collected the throughput and latency statistics reported by ApacheBench. In the v2v scenario, we used only two client-servers as one of the tenant VMs simply forwarded packets using the DPDK $l2fwd$ app. We collected 5 such repetitions to finally report the average throughput and latency for each experimental configuration with 95% confidence.

Key-value store: Key-value stores are also commonly used cloud applications (e.g., with with webservers). We opted for the open-source Memcached key-value store as it also has an open-source benchmarking tool libMemcached-memslap. We used the default Set/Get ratio of 90/10 for the measurements. The methodology and reporting of the measurements are the same as the webserver.

Results. The data for the Iperf measurements in the shared mode is shown Fig. 6(a). The data for the isolated mode is shown in Fig. 6(f) and Fig. 6(k) depicts the throughput for Level-3. As seen in Section 4.1, here too we observe that *MTS* has a higher throughput (more than 2x in the shared mode) than the Baseline except when DPDK is used in the v2v topology. *MTS* saturated the 10G link in the p2v scenario when isolated and DPDK modes were used.

The data from the throughput measurements for the Apache webserver and Memcached key-value store are first reported in the shared mode in Fig. 6(b) and (c) respectively. For the isolated mode they are shown in Fig. 6(g) and (h). Level-3 throughput is shown in Fig. 6(l) and (m). The three main results from the throughput measurements for Apache and Memcached are the following. *MTS* can offer nearly 2x throughput and 4x isolation (Level-2) in the shared mode. Apache's and Memcached's throughput saturated with *MTS*: we expected the throughput to increase as the vswitch VMs increase when the compartments have isolated cores, how-

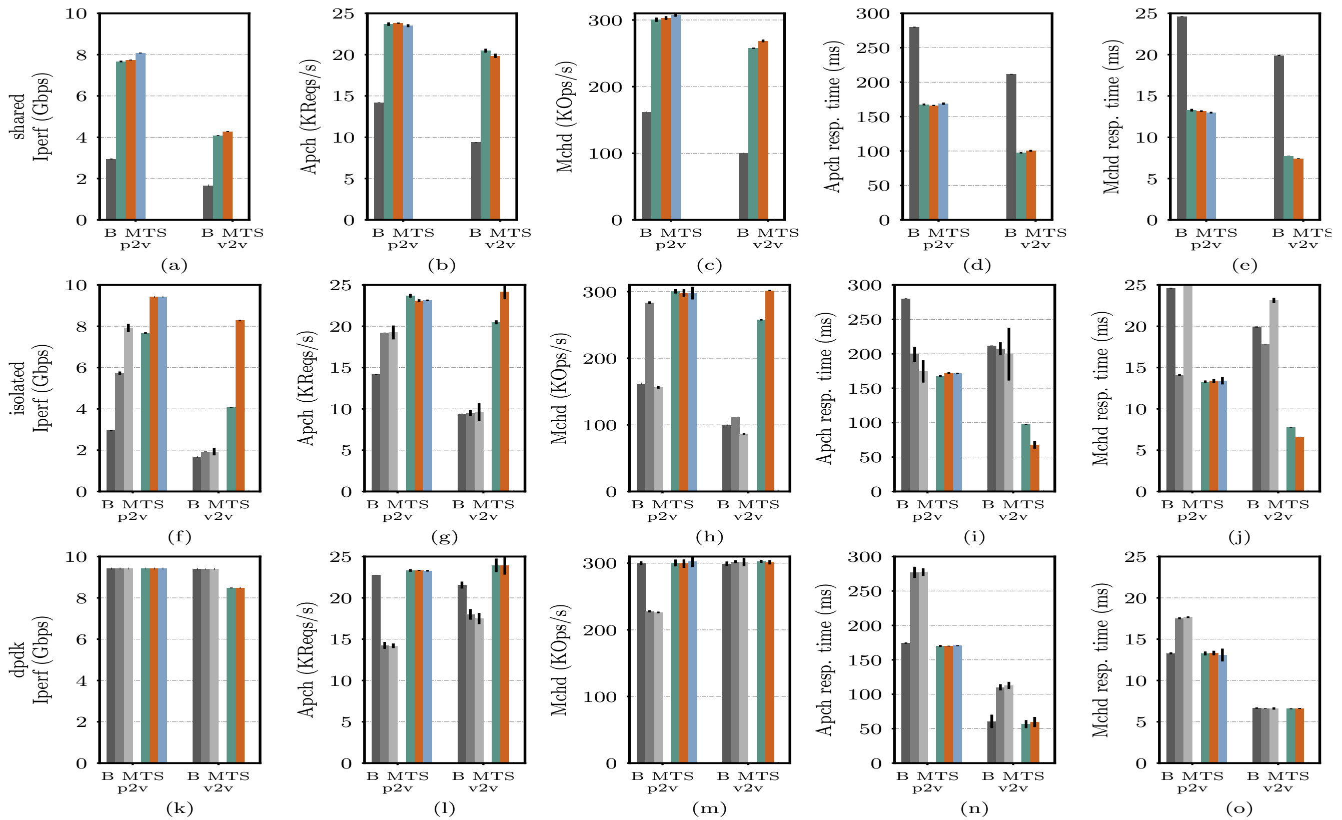

Figure 6: Iperf throughput, Apache and Memcached throughput and latency (shown in the columns) comparison of *MTS*. The rows indicate the resource mode where the bottom row is for security Level-3 in the isolated resource mode combined with the other security levels. The legend is the same as in Figure 5.

ever, we do not observe that. This is further validated when using DPDK. Apache's and Memcached's throughput are highly sensitive when the Baseline uses multiple cores in the isolated and DPDK modes which means that using 2 or more cores requires workload specific tuning to the Host: the DPDK parameters, e.g., drain interval, and the workload VMs, e.g., allocating more cores, which may not always be necessary with *MTS*.

The data from the response time measurements for the Apache webserver and Memcached key-value store are first reported in the shared mode in Fig. 6(d) and (e) respectively. For the isolated mode they are shown in Fig. 6(i) and (j). Level-3 throughput is shown in Fig. 6(n) and (o). Regarding the latency, we again discern that *MTS* can offer multiple levels of isolation and maintain a lower response time (approximately twice as fast) than the Baseline.

Key findings. Our webserver and key-value store benchmarks reveal that application throughput and latency of real application are improved by *MTS*. However, for user-space packet processing, the resource costs go up for a fractional benefit in throughput or latency. Hence, biting the bullet for shared resources, offers 4x isolation and approximately 1.5-2x application performance compared to the Baseline.

6 Discussion

Centralized control, accounting and monitoring. *MTS* introduces the possibility to realize multi-tenant virtual networks which can expose tenant/compartment specific interfaces to a logically centralized control/management plane. This opens up possibilities for full network virtualization, how to expose the interface, and also how to integrate *MTS* into existing cloud management systems in an easy and usable way. Furthermore, controllers may need to manage more device, topology and forwarding information, however, the computations (e.g., routing) should remain the same. From an accounting and billing perspective, we strongly believe that *MTS* is a new way to bill and monitor virtual networks at granularity more than a simple flow rule [24]: CPU, memory and I/O for virtual networking can be charged.

SR-IOV: a double-edged sword. If an attacker can compromise SR-IOV, she could violate isolation and in the worst case get access to the Host OS via the PF driver. Hence, a rigorous security analysis of the SR-IOV standard, implementations and SR-IOV-NIC drivers can reduce the chance of a security vulnerability. Compartmentalizing the PF driver is a promising approach [10]. Furthermore, when a vswitch VM is shared among tenants, performance isolation issues

could lead to covert channels [6] or denial-of-service attacks [64, 75]. Although not yet widely supported, VM migration with SR-IOV can be introduced [45]. SR-IOV NICs have limited VFs and MAC addresses which could limit the scaling properties of *MTS*, e.g., when using containers as compartments instead of VMs.

Evaluation limitations. The results from our experiments are from a network and application performance perspective using a 10 Gbps NIC. For a deeper understanding of the performance improvement we obtained in this paper using SR-IOV, further measurements are necessary, e.g., using the performance monitoring unit (PMU) to collect a breakdown of the packet processing latencies. Such an understanding is important and relevant when dealing with data center applications that require high NIC bandwidth, e.g., 40/100 Gbps.

As described by Neugebauer et al. [48], the PCIe bus can be a bottleneck for special data center applications (e.g., ML applications): A *typical* x8 PCIe 3.0 NIC (with a maximum payload size of 256 bytes and maximum read request of 4096 bytes) has an effective (usable) bi-directional bandwidth of approximately 50 Gbps. Hence, the usability of *MTS* with PCIe 3.0 and 8 lanes can indeed be a limitation which we did not observe in this paper. Nevertheless, increasing the lanes to x16 is one potential workaround to double the effective bandwidth to around 100 Gbps. Furthermore, with chip vendors initiating PCIe 4.0 devices [11], the PCIe bus bandwidth will increase to support intense I/O applications.

7 Related Work

There has been noteworthy research and development on isolating multi-tenant virtual networks in cloud (datacenter) networks: tunneling protocols have been standardized [73, 25], multi-tenant datacenter architectures have been proposed [38], and real cloud systems have been built by many companies [22, 16]. However, most of the previous work still co-locates the vswitch with the Host as we discussed in Section 2.1. Hence, here we discuss previous and existing attempts specifically addressing the security weakness of vswitches.

To the best of our knowledge, in 2012 Jin et al. [34] (see Research prototype in Table 1) were the first to point out the security weakness of co-locating the virtual switch with the hypervisor. However, the proposed design, while ahead of its time, (i) lacks a principled approach which this paper proposes; (ii) has only a single vswitch VM whereas *MTS* supports multiple vswitch compartments making it more robust; (iii) is resource (compute and memory) intensive as the design used shared memory between the vswitch VM and all the tenant VMs while *MTS* uses an inexpensive interrupt-based SR-IOV network card for complete mediation of tenant-vswitch-VM and tenant-host networking; (iv) requires considerable effort, expertise and tuning to integrate into virtualization system whereas *MTS* can easily be scripted into existing cloud systems.

In 2014 Stecklina [65] followed up on this work and proposed sv3, a user-space switch, which can enable multi-tenant virtual switches (see sv3 in Table 1). sv3 adopts user-space packet processing and also supports compartmentalization, i.e., the Host can run multiple vswitches. However, it is still co-located with the Host, partially adopts the security principles outlined in this paper, lacks support for *real* cloud virtual networking, and requires changes to QEMU. Our system on the other hand moves the vswitch out of the Host, supports production vswitches such as OvS and does not require any changes to QEMU.

Between 2016 and 2017, Panda et al. [51] and Neves et al. [49] took a language-centric approach to enforce data plane isolation for virtual networks. However, language-centric approaches require existing vswitches to be reprogrammed/annotated which reduces adoption. Hence the solution of using compartments and SR-IOV in *MTS* allows existing users to easily migrate using their existing software. Shahbaz et al. [63] reduced the attack surface of OvS by introducing support for the P4 domain specific language which reduces potentially vulnerable protocol parsing logic.

In 2018, Pettit et al. [53] proposed to isolate virtual switch packet processing using eBPF: which is conceptually isolating potentially vulnerable parsing code in a kernel-based runtime environment. However, the design still co-locates the virtual switch and the runtime with the Host.

8 Conclusion

This paper was motivated by the observation that while vswitches have been designed to enable multi-tenancy, today's vswitch designs lack strong isolation between tenant virtual networks. Accordingly, we presented a novel vswitch architecture which extends the benefits of multi-tenancy to the virtual switch, offering improved isolation and performance, at a modest additional resource cost. When used in the *shared* mode (only one extra core), with four vswitch compartments the forwarding throughput (in pps) is 1.5-2 times better than the Baseline. The tenant workloads (webserver and key-value stores) we evaluated also receive a 1.5-2 times performance (throughput and response time) improvement with *MTS*.

We believe that *MTS* is a pragmatic solution that can enhance the security and performance of virtual networking in the cloud. In particular, *MTS* introduces a way to schedule an entire core for tenant-specific network virtualization which has three benefits: (i) application and packet processing performance is improved; (ii) this could be integrated into pricing models to appropriately charge customers on-demand and generate revenue from virtual networking for example; (iii) virtual network and Host isolation is maintained even when the vswitch is compromised.

StreamBox-TZ: Secure Stream Analytics at the Edge with TrustZone

Heejin Park[1], Shuang Zhai[1], Long Lu[2], and Felix Xiaozhu Lin[1]

[1]Purdue ECE [2]Northeastern University

Abstract

While it is compelling to process large streams of IoT data on the cloud edge, doing so exposes the data to a sophisticated, vulnerable software stack on the edge and hence security threats. To this end, we advocate isolating the data and its computations in a trusted execution environment (TEE) on the edge, shielding them from the remaining edge software stack which we deem untrusted.

This approach faces two major challenges: (1) executing high-throughput, low-delay stream analytics in a single TEE, which is constrained by a low trusted computing base (TCB) and limited physical memory; (2) verifying execution of stream analytics as the execution involves untrusted software components on the edge. In response, we present StreamBox-TZ (SBT), a stream analytics engine for an edge platform that offers strong data security, verifiable results, and good performance. SBT contributes a data plane designed and optimized for a TEE based on ARM TrustZone. It supports continuous remote attestation for analytics correctness and result freshness while incurring low overhead. SBT only adds 42.5 KB executable to the TCB (16% of the entire TCB). On an octa core ARMv8 platform, it delivers the state-of-the-art performance by processing input events up to 140 MB/sec (12M events/sec) with sub-second delay. The overhead incurred by SBT's security mechanism is less than 25%.

1 Introduction

Many key applications of Internet of Things (IoT) process a large influx of sensor[1] data, i.e. telemetry. Smart grid aggregates power telemetry to detect supply/demand imbalance and power disturbances [76], where a power sensor is reported to produce up to 140 million samples per day [16,17]; oil producers monitor pump pressure, tank status, and fluid temperatures to determine if wells work at ideal operating points [55,60], where an oil rig is reported to produce 1–2 TB of data per day [43]; manufacturers continuously monitor vibration and ultrasonic energy of industrial equipment for detecting equipment anomaly and predictive maintenance [104, 120], where a monitored machine is reported to generate PBs of data in a few days [77].

[1]Recognizing that IoT data sources range from small sensors to large equipment, we refer to them all as *sensors* for brevity.

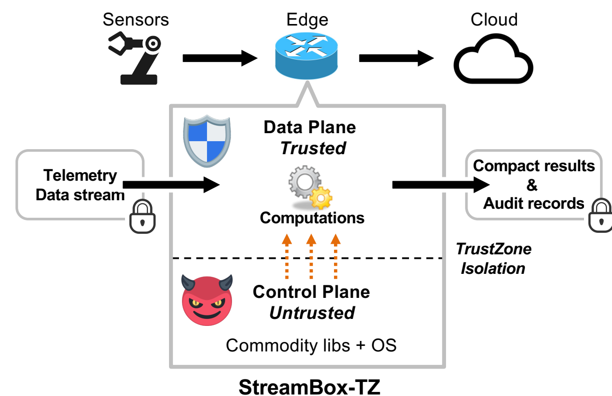

Figure 1: An overview of StreamBox-TZ

The large telemetry data streams must be processed in time. The high cost and long delay in transmitting data necessitate edge processing [98, 100]: sensors send the data to nearby gateways dubbed "cloud edge"; the edge runs a pipeline of continuous computations to cleanse and summarize the telemetry data and reports the results to cloud servers for deeper analysis. Edge hardware is often optimized for cost and efficiency. According to a 2018 survey [45], modern ARM machines are typical choices for edge platforms. Such a platform often has 2–8 CPU cores and several GB DRAM.

Unfortunately, edge processing exposes IoT data to high security threats. i) Deployed in the wild, the edge suffers from common IoT weaknesses, including lack of professional supervision [58, 118], weak configurations [108, 117], and long delays in receiving security updates [58, 114]. ii) On the edge, the IoT data flows through a set of sophisticated components that expose a wide attack surface. These components include a commodity OS (e.g. Linux or Windows), a variety of user libraries, and a runtime framework called *stream analytics engine* [37, 42, 83]. They reuse much code developed for servers and workstations. Their exploitable mis-

configurations [121] and vulnerabilities [23, 35, 109] are not uncommon. iii) With data aggregated from multiple sources, the edge is a high-value target to adversaries. For these reasons, edge is even more vulnerable than sensors, which run much simpler software with narrower attack surfaces. Once attackers compromise the edge, they not only access confidential data but also may delete or fabricate data sent to the cloud, threatening the integrity of an entire IoT deployment.

Towards secure stream analytics on an edge platform, our goal is to safeguard IoT data confidentiality and integrity, support verifiable results, and ensure high throughput with low output delay. Following the principle of least privilege [95], we protect the analytics data and computations in a trusted execution environment (TEE) and limit their interface; we leave out the remaining edge software stack which we deem untrusted. By doing so, we shrink the trusted computing base (TCB) to only the protected functionalities, the TEE, and the hardware. We hence significantly enhance data security.

We face three challenges: i) what functionalities should be protected in TEE and behind what interfaces? ii) how to execute stream analytics on a TEE's low TCB and limited physical memory while still delivering high throughput and low delay? iii) as both trusted and untrusted edge components participate in stream analytics, how to verify the outcome?

Existing solutions are inadequate: pulling entire stream analytics engines to TEE [22, 27, 112] would result in a large TCB with a wide attack surface; the systems securing distributed operators [53, 99, 124] often lack stream semantics or optimizations for efficient execution in a single TEE, which are crucial to the edge; only attesting TEE integrity [65] or data lineages [50, 99, 102, 124] is inadequate for verifying stream analytics. We will show more evidences in the paper.

Our response is StreamBox-TZ (SBT), a secure engine for analyzing telemetry data streams. As shown in Figure 1, SBT builds on ARM TrustZone [2] on an edge platform. SBT contributes the following notable designs:

(1) Architecting a data plane for protection SBT provides a data plane exposing narrow, shared-nothing interfaces to untrusted software. SBT's data plane encloses i) all the analytics data; ii) a new library of low-level stream algorithms called *trusted primitives* as the only allowed computations on the data; iii) key runtime functions, including memory management and cache-coherent parallel execution of trusted primitives. SBT leaves thread scheduling and synchronization out of TEE.

(2) Optimizing data plane performance within a TEE In contrast to many TEE-oblivious stream engines that operate numerous small objects, hash tables, and generic memory allocators [32, 82, 122], SBT embraces unconventional design decisions for its data plane. i) SBT implements trusted primitives with array-based algorithms and contributes new optimizations with handwritten ARMv8 vector instructions. ii) To process high-velocity data in TEE, SBT provides a new abstraction called uArrays, which are contiguous, virtually unbounded buffers for encapsulating all the analytics data; SBT backs uArrays with on-demand paging in TEE and manages uArrays with a specialized allocator. The allocator leverages hints from untrusted software for compacting memory layout. iii) SBT exploits TrustZone's lesser-explored hardware features: ingesting data straightly through trusted IO without a detour through the untrusted OS; avoiding relocating streaming data by leveraging the large virtual address space dedicated to a TEE.

(3) Verifying edge analytics execution SBT supports cloud verifiers to attest analytics *correctness*, result *freshness*, and the untrusted hints received during execution. SBT captures coarse-grained dataflows and generates audit records. A cloud verifier replays the audit records for attestation. To minimize overhead in the edge-cloud uplink bandwidth, SBT compresses the records with domain-specific encoding.

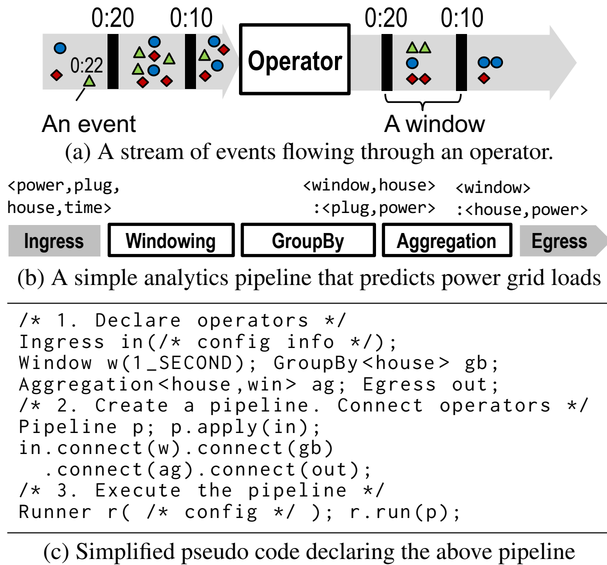
Our implementation of SBT supports a generic stream model [1] with a broad arsenal of stream operators. The TCB of SBT contains as little as 267.5 KB of executable code, of which SBT only constitutes 16%. On an octa core ARMv8 platform, SBT processes up to 12M events (144 MB) per second at sub-second output delays. Its throughput on this platform is an order of magnitude higher than an SGX-based secure stream engine running on a small x86 cluster with richer hardware resources [53]. The security mechanisms contributed by SBT incur less than 25% throughput loss with the same output delay; decrypting ingress data, when needed, incurs 4%–35% throughput loss with the same output delay. While sustaining high throughput, SBT uses up to 130 MB of physical memory in most benchmarks.

The key contributions of SBT are: i) a stream engine architecture with strongly isolated data and a lean TCB; ii) a data plane built from the ground up with computations and memory management optimized for a single TrustZone-based TEE; iii) remote attestation for stream analytics on the edge with domain-specific compression of audit records. To our knowledge, SBT is the first system designed and optimized for data-intensive, parallel computations inside ARM TrustZone. Beyond stream analytics, the SBT architecture should help secure other important analytics on the edge, e.g. machine learning inference. The SBT source can be found at `http://xsel.rocks/p/streambox`.

2 Background & Motivation

2.1 ARM for Cloud Edge

As typical hardware for IoT gateways [45], recent ARM platforms offer competitive performance at low power, suiting edge well. Most modern ARM cores are equipped with TrustZone [2], a security extension for TEE enforcement. TrustZone logically partitions a platform's hardware resources, e.g. DRAM and IO, into a normal (insecure) and a secure world. CPU cores independently switch between two worlds. A TEE



(a) A stream of events flowing through an operator.

(b) A simple analytics pipeline that predicts power grid loads

```
/* 1. Declare operators */
Ingress in(/* config info */);
Window w(1_SECOND); GroupBy<house> gb;
Aggregation<house,win> ag; Egress out;
/* 2. Create a pipeline. Connect operators */
Pipeline p; p.apply(in);
in.connect(w).connect(gb)
  .connect(ag).connect(out);
/* 3. Execute the pipeline */
Runner r( /* config */ ); r.run(p);
```

(c) Simplified pseudo code declaring the above pipeline

Figure 2: Example stream data, operators, and a pipeline

atop TrustZone owns dedicated, *trusted IO*, a unique feature that other TEE technologies such as Intel SGX [81] lack.
Trusted IO is a unique feature of ARM TrustZone, implemented through hardware components including TrustZone Address Space Controller (TZASC) and TrustZone Protection Controller (TZPC). TZASC allows privilege software to logically partition DRAM between the normal and the secure worlds. Similarly, TZPC allows to configure IO peripherals accessible to either world. Any peripheral owned by the secure world is completely enclosed in the secure world. We use trusted IO to support the trusted source-edge links on the cloud edge (§3.1).

2.2 Stream Analytics

Stream Model We target stream analytics over sensor data. A data stream consists of sensor events that carry timestamps defined by event occurrence, as illustrated in Figure 2(a). Programmers specify a pipeline of continuous computations called *operators*, e.g. `Select` and `GroupBy`, that are extensively used for telemetry analytics [62, 90]. As data arrives at the edge, a stream analytics engine ingests the data at the pipeline ingress, pushes the data through the pipeline, and externalizes the results at the pipeline egress.

We follow a generic stream model [14, 32, 69, 85, 122]. Operators execute on event-time scopes called *windows*. Data sources emit special events called *watermarks*. A watermark guarantees no subsequent events in the stream will have event times earlier than the watermark timestamp. A pipeline's *output delay* is defined as the elapsed time starting from the moment the ingress receives the watermark signaling the completion of the current window to the moment the egress externalizes the window results [82]. A pipeline may maintain its internal states organized by windows at different operators. See prior work [20] for a formal stream model.

Analytics example: Power load prediction Figure 2(b-c) shows an example derived from an IoT scenario [62]: it predicts future household power loads based on power loads reported by smart power plugs. The example pipeline ingests a stream of power samples and groups them by 1-second fixed windows and by houses. For each house in each window, it aggregates all the loads and predicts the next-window load as an exponentially weighted moving average over the recent windows. At the egress, the pipeline emits a stream of per-house load prediction for each window.

Stream analytics engines Stream pipelines are executed by a runtime framework called a stream analytics engine [37, 42, 46, 82, 83, 90]. A stream analytics engine consists of two types of function: *data functions* for data move and computations; *control functions* for resource management and computation orchestration, e.g. creating and scheduling tasks. The boundary between the two is often blurry. To amortize overheads, control functions often organize data in *batches* and invoke data functions to operate on the batches.

2.3 Security Threats & Design Objectives

The edge faces common threats in IoT deployment. i) IT expertise is weak. Edge platforms are likely managed by field experts [58, 114, 118] rather than IT experts. Such lack of professional supervision is known to result in weak configurations [108, 117]. ii) The infrastructure is weak. Deployed in the field, the edge often sees slow uplinks [84, 114] and hence much delayed software security updates. For cost saving, edge analytics may need to share OS and hardware with other high-risk, untrusted software such as web browsers [114].

Besides the common threats, existing edge software stacks entrust IoT data with commodity OSes, analytics engines, and language runtimes (e.g. JVM). However, these components are incapable of offering strong security guarantees due to their complexity and wide interfaces. Each of them easily contains more than several hundreds of KSLoC [116]. Exploitable vulnerabilities are constantly discovered [3, 6, 23, 35, 38], making these components untrusted in recent research [36, 54, 79, 80]. By exploiting these vulnerabilities, a local adversary as an edge user program may compromise the kernel through the wide user/kernel interfaces [11, 12] or attack an analytics engine through IPC [7]; a remote adversary, through the edge's network services, may compromise analytics engines [4] or the OS [10]. A successful adversary may expose IoT data, corrupt the data, or covertly manipulate the data. Taking the application in Figure 2(b) as an example, the adversary gains access to the smart plug readings, which may contain residents' private information, and injects fabricated data.

Objectives We aim three objectives for stream analytics over telemetry data on an edge platform: i) confidentiality and integrity of IoT data, raw or derived; ii) verifiable correctness

and freshness of the analytics results; iii) modest security overhead and good performance.

3 Security Approach Overview

3.1 Scope

IoT scenarios We target an edge platform that captures and analyzes telemetry data. We recognize the significance of mission-critical IoT with tight control loops, but do not target it. Our target scenario includes source sensors, edge platforms, and a cloud server which we dub "cloud consumer". All the raw IoT data and analytics results are owned by one party. The sensors produce trusted events, e.g. by using secure sensing techniques [49, 73, 97]. The cloud consumer is trusted; it installs analytics pipelines to the edge and consumes the results uploaded from the edge. We consider *untrusted* source-edge links (e.g. public networks) which requires data encryption by the source, as well as *trusted* source-edge links (e.g. direct IO bus or on-premise local networks), and will evaluate the corresponding designs (§9). We assume untrusted edge-cloud links, which require encryption of the uploaded data.

In-scope Threats We consider malicious adversaries interested in learning IoT data, tampering with edge processing outcome, or obstructing processing progress. We assume powerful adversaries: by exploiting weak configurations or bugs in the edge software, they already control the entire OS and all applications on the edge.

Out-of-scope Threats We do not protect the confidentiality of stream pipelines, in the interest of including only low-level compute primitives in a lean TCB. We do not defend the following attacks. i) Attacks to non-edge components assumed trusted above, e.g. sensors [111]. ii) Exploitation of TEE kernel bugs [8, 9, 56]. iii) Side channel attacks: by observing hardware usage outside TEE, adversaries may learn the properties of protected data, e.g. key skew [72]. Note that controlled-channel attack [119] cannot be applied to ARM TrustZone as it has separate page management within a separate secure OS unlike Intel SGX. iv) Physical attacks, e.g. sniffing TEE's DRAM access [18, 28]. Many of these attacks are mitigated by prior work [39, 66, 123, 124] orthogonal to SBT.

Note that TEE code authenticity and integrity are already ensured by the TrustZone hardware, i.e. only code trusted by the device vendor can run in TrustZone and its integrity is protected by TrustZone.

3.2 Approach and Security Benefits

As shown in Figure 3, SBT protects its data functions in a trusted *data plane* in TEE. SBT runs its untrusted *control plane* in the normal world. The control plane invokes the data plane through narrow, shared-nothing interfaces. The engine's

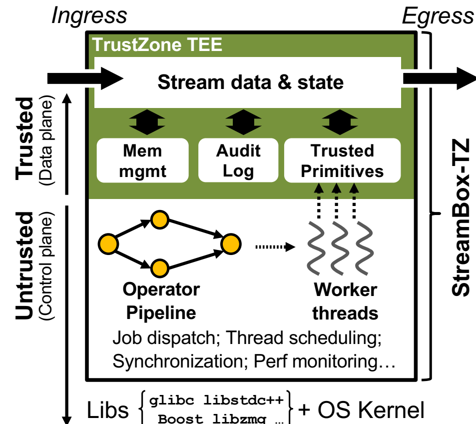


Figure 3: StreamBox-TZ on an edge platform with ARM TrustZone. Bold arrows show the protected data path.

TCB thus only consists of the TEE (including the data plane) and the hardware.

Streaming data always flows in TEE. The data plane ingests the data through TrustZone's trusted IO. After ingestion, it returns *opaque references* of the data batches to the control plane. In turn, the control plane requests computations on the protected data by invoking the data plane with the opaque references. The data plane generates opaque references as long, random integers. It tracks all live opaque references, validates incoming opaque references, and only accepts ones that exist. At the pipeline egress, the data plane encrypts, signs, and sends the result to the cloud.

The analytics execution is continuously attested. SBT captures complete and deterministic dataflows of the stream analytics as well as execution timing, and periodically reports to the cloud server. The cloud server verifies if all ingested data is processed according to the pipeline (correctness), and if the edge incurs low delay (freshness).

Thwarted attacks SBT defeats the following attacks. ***i) Breaking IoT data confidentiality or integrity.*** As the raw and derived data enters and leaves the edge TEE through trusted IOs, adversaries on the edge cannot touch, drop, or inject data. When the data is off the edge transmitted over untrusted networks, it is protected by encryption against network-level adversaries. ii) ***Breaking the data plane integrity.*** Any fabricated opaque reference passed to the data plane will be rejected, since all opaque references are validated before use. Through the data plane's interface, an adversary may exploit bugs in the data plane and compromise it. By minimizing the date plane codebase and hardening its interface, SBT substantially reduces the data plane's attack surface and potential bugs that can be exploited. iii) ***Breaking analytics correctness.*** A compromised control plane may request computations deviating from pipeline declarations or the stream model. For instance, it may invoke trusted computations on partial data, wrong windows, or valid but undesirable opaque references. SBT defeats these attacks through attestation: since the cloud verifier possesses complete knowledge on ingested data and

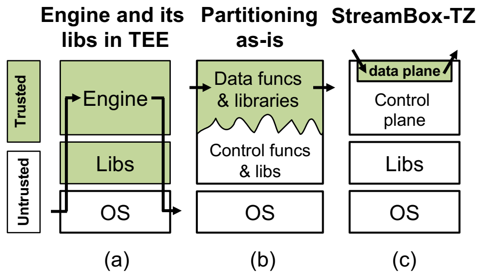

Figure 4: Among alternative architectures for secure stream analytics, StreamBox-TZ (c) leads to the smallest TCB and the most optimized data plane. Arrows indicate data flows.

System	TEE	Analytics	SG	Compute in TEE	Memory	Attestation
VC3 [99]	SGX	Batch	`CIVA-`	Mapper/reducer	Heap	Data lineage
Opaque [124]	SGX	Batch	`CIVAO`	Query plans	unreported	Data lineage

pipelines, it detects such correctness violation and rejects the edge analytics results. ***iv) Attacks on analytics performance or availability.*** A compromised control plane may delay or pause invoking of trusted computations, violating the freshness guarantee. As the execution timing of trusted computations is attested, the cloud verifier detects the attacks and can choose to prompt further investigation. ***v) Attempting to trigger data race or deadlock.*** By design, data race and deadlocks will never happen inside the data plane: the trusted computations do not share state concurrently and all locking happens outside of the TEE.

4 Design Overview

4.1 Challenges

Our approach raises three challenges. i) ***Architecting the engine with a proper protection boundary***. This hinges on a key trade-off among TEE functional richness, overhead of TEE entry/exit, and TCB size. ii) ***Optimizing data functions within a TEE***. Processing of high-velocity data in a TEE strongly favors simple algorithms and compact memory. Yet, existing stream engines often operate numerous short-lived objects indexed in hash tables or trees [32, 69, 82, 90, 122], e.g. for grouping events by key. They manage these objects with generic memory allocators [82] or garbage collectors [87, 122]. Such designs poorly fit a TEE's small TCB and limited DRAM portion, e.g. typically tens of MB for TrustZone TEE and up to 128 MB for Intel SGX enclave [31]. iii) ***Verifying stream analytics results***. This requires to track unbounded data flows in stream pipelines, validate if operators respect the temporal properties, e.g. windows, and minimize the resultant overhead in execution and communication.

Why are existing systems inadequate? First, many TEE-based systems [22, 27, 112] pull entire user applications and libraries to the TCB, as shown in Figure 4(a). However, as we described in Section 2.2, a modern analytics engine and its libraries are large, complex, and potentially vulnerable. Second, partitioning applications to suit a TEE, as shown in Figure 4(b) [71, 93, 101], is unsuitable for existing stream engines: partitioning does not change their hash-based data structures and algorithms, which by design mismatch a TEE. Similarly, recent secure processing engines disfavor partitioning [89, 91]. Third, recent systems use TEE to protect data in analytics or in network packet processing. As summarized in Table 1, they lack support for stream analytics, key computation optimizations, or specialized memory allocation, which we will demonstrate as vital to our objective.

Attesting TEE integrity [65, 91] is insufficient to assert analytics correctness. VC3 [99] and Opaque [124] verify correctness of *batch* analytics by checking the history of compute results, i.e. their data lineage [50, 102]. Without tracking data being continuously ingested and lacking a stream model, data lineages cannot assert whether *all* ingested data is processed according to pipeline declarations, watermarks, and temporal windows, which are critical to stream analytics.

4.2 StreamBox-TZ in a Nutshell

SBT builds on TrustZone [2] due to ARM's popularity for the edge and trusted IO benefiting stream analytics (§2).

Programmability Programming SBT is similar to programming commodity engines such as Spark Streaming [122] and Flink [19]. Analytics programmers assemble pipelines with high-level, declarative operators as exemplified in Figure 2(c). SBT provides most of the common operators offered by commodity engines, as summarized in Table 2. These stream operators are widely used for analytics over telemetry data [62, 90]. SBT supports User Defined Functions (UDFs) that are certified by a trusted party, which is a common requirement in TEE-based systems [91].

SBT architecture As shown in Figure 3, SBT's data plane incarnates as a TrustZone module. SBT runs its control plane as a parallel runtime in the normal world. The control plane invokes the data plane through a narrow interface (details in Section 9). The control plane orchestrates the execution of analytics pipelines. It creates plentiful parallelism among and within operators. It elastically maps the parallelism to a

pool of threads it maintains. At a given moment, all threads may simultaneously execute one operator as well as different operators over different data.

Data plane & design choices SBT's data plane consists of only the trusted primitives and a runtime for them.

i) Trusted primitives are stateless, single-threaded functions that are oblivious to synchronization. We do not enclose whole stream pipelines in the data plane, because a stream pipeline must be scheduled dynamically for parallelism and handling high-velocity data. We do not enclose whole declarative operators in the data plane, because one operator instance has internal thread-level parallelism and hence requires thread management logic. Our choice keeps the data plane lean, leaving out all control functions including scheduling and threading. This contrasts to many other engines pulling whole analytics to TEE as shown in Table 1.

Although exporting low-level primitives entails more TEE switches, the costs are lower on modern ARM [25, 56] and can be amortized by data batching, as will be discussed soon.

ii) The data plane incorporates minimum runtime functions: memory management and paging, which are critical to TEE integrity; cache coherence of parallel primitives, which is critical to parallelism. The data plane is agnostic to declarative operators and pipelines being executed.

For attestation, the data plane generates audit records on data ingress/egress, watermarks, and primitive executions. It reduces overhead via data batching and record compression.

Coping with secure memory shortage When compute cost or data ingestion rate is high, SBT may run short of secure memory. To avoid data loss in such a situation, SBT adds backpressure to source sensors, slowing down data ingestion. In the current implementation, SBT triggers backpressure when ingestion exceeds a user-defined threshold; we leave as future work automatic flow control, i.e. tuning the threshold online per available secure memory and backlog.

5 Trusted Primitives and Optimizations

Parallel execution inside a TEE SBT exploits task parallelism without bloating the TEE with a threading library. The control plane invokes multiple primitives from multiple worker threads, which then enter the TEE to execute the primitives in parallel. All trusted primitives share one cache-coherent memory address space in TEE, which simplifies data sharing and avoids copy cost. This contrasts to existing secure analytics engines that leave task parallelism untapped in a single TEE [53, 99].

Array-based algorithms to suit TEE Unlike many popular stream engines using hash-based algorithms for lower algorithmic complexity, we make a new design decision. We strongly favor algorithms with simple logic and low memory overhead, despite that they may incur higher algorithmic complexity. Corresponding to contiguous arrays as the universal data containers in TEE, most primitives use sequential-access algorithms over contiguous arrays, e.g. executing Merge-Sort over event arrays and scanning the resultant array to calculate the average value per key.

Trusted primitives and vectorization SBT's trusted primitives are generic. They constitute most declarative stream operators, often referred to as Select-Projection-Join-GroupBy (SPJG) families, shown in Table 2. These operators are considered representative in prior research [44].

To speed up the array-based algorithms inside TEE without TCB bloat, our insight is to map their internal data parallelism to vector instructions of ARM [21]. Despite their well-known performance benefit, vector instructions are rarely used to accelerate data analytics *within* TEEs, to our knowledge. Vectorization incurs low code complexity as the performance gain comes from a CPU feature that is already part of the TCB.

Our optimization focuses on Sort and Merge, two core primitives that dominate the execution of stream analytics according to our observation. Inspired by vectorized sort and merge on x86 [26, 64], we build new implementations for SBT by hand-writing ARMv8 NEON vector instructions. Our sort outperforms the ones in the C/C++ standard libraries by more than 2×, as will be shown in evaluation. This optimization is crucial to the overall engine performance.

6 TEE Memory Management

Facing high-velocity streams in a TEE, SBT's memory allocator addresses two challenges: *space efficiency*: it must create compact memory layout and reclaim memory timely due to limited physical memory; *lightweight*: the allocator must be simple to suit a low TCB. The challenges disqualify popular engines that organize events in hash tables (e.g. for grouping events by key) and rely on generic memory allocators [32, 69, 82, 90, 122]. The reasons are two: a hash table's principle of trading space for time mismatches TEE's limited memory; generic allocators often feature sophisticated optimizations, adding tens of KSLoC to TCB [41, 59].

SBT specializes memory management for stream computations: it supports unbounded buffers as the universal memory abstraction (§6.1); it places data by using (untrusted) consumption hints and large virtual address space (§6.2).

6.1 Unbounded Array

We devise contiguous, virtually unbounded arrays called *uArrays*, a new abstraction as the universal data containers used by computations in TEE. uArrays encapsulate all the data in a pipeline, including data flowing among trusted primitives as well as operator states traditionally kept in hash tables.

An uArray is an append-only buffer in a contiguous memory region for same-type data objects. Their lifecycles closely

map to the producer/consumer pattern in streaming computations. One uArray can be in three states. *Open*: after an uArray is created, it dynamically grows as the producer primitive appends data objects to it. *Produced*: the data production completes and the end position of the uArray is finalized. uArray becomes read-only and no data can be appended. *Retired*: the uArray is no longer needed and its memory is subject to reclamation. The memory allocator places and reclaims uArrays regarding their states, as will be discussed in Section 6.2.

Types uArrays fall into different types depending on their scopes and enclosed data. A *streaming uArray* encapsulates data flowing from a producer primitive to a consumer primitive. A *state uArray* encapsulates operator state that outlives the lifespans of individual primitives. A *temporary uArray* live within a trusted primitive's scope.

Low abstraction overhead An uArray spans a contiguous virtual memory region and grows transparently. The growth is backed by the data plane's on-demand paging that completely happens in the TEE. For most of the time, growing an uArray only requires updating an integer index. Compared to manually managed buffers, this mechanism waives bounds checking of uArray in computation code and hence allows the compiler to generate more compact loops. uArrays always grow in place. This contrasts to common sequence containers (e.g. C++ `std::vector` and `java.util.ArrayList`) that grow transparently but require expensive relocation. We will experimentally compare uArray with `std::vector` in Section 9.

6.2 Placing uArrays in uGroups

Co-locating uArrays The memory allocator co-locates multiple uArrays as a uGroup in order to reclaim them consecutively. Spanning a contiguous virtual memory region, a uGroup consists of multiple *produced* or *retired* uArrays and optionally an *open* uArray at its end, as shown in Figure 5. The grouping is purely physical: it is at the discretion of the allocator, orthogonal to stream computations, and therefore transparent to the trusted primitives and the control plane.

With the grouping, the allocator reclaims *consumed* uArrays by always starting from the beginning of an uGroup, as shown in Figure 5. To place a new uArray, the allocator decides whether to create a new uGroup for the uArray, or append the uArray to an existing uGroup. In doing so, the allocator seeks to i) ensure that each uGroup holds a sequence of uArrays to be consumed consecutively in the future; ii) minimize the total number of live uGroups, in order to compact TEE memory layout and minimizes the cost in tracking uGroups. To this end, our key is to guide placement with the control plane's data consumption plan, as will be presented below.

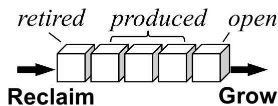

Figure 5: The uArrays in one uGroup

Consumption hints Upon invoking a trusted primitive T, the control plane may provide two optional hints concerning the future consumption order for the output of T:

- *Consumed-in-parallel* ($\|_k$): the control plane will schedule k worker threads to consume a set of uArrays in parallel.
- *Consumed-after* ($b_1 \Leftarrow b_2$): the control plane will schedule worker threads for consuming uArray b_2 after uArray b_1. The *consumed-after* relation is transitive. uArrays may form multiple *consumed-after* chains.

The control plane may specify these relations between new output uArrays (yet to be created) and existing uArrays.

Hint-guided placement The hints assist the data plane to generate compact memory layout and reclaim memory effectively. Upon allocating a uArray, the allocator examines the existing hints regarding to the uArray.

($\Leftarrow$) prompts the allocator to place the uArrays on the same *consumed-after* chain in the same uGroup. Starting from the new uArray b under question, the allocator tracks back on its consumed-after chain, and places b after the first uArray that is both in state *produced* (i.e. its growth has finished) and is located at the end of an uGroup. If no such uArray is available on the chain, the allocator creates a new uGroup for b.

($\|_k$) prompts the allocator to place uArrays $b_{1..k}$ in separate uGroups, so that delay in consuming any of the uArrays will not block the allocator from reclaiming the other uArrays. Our rationale is that despite $b_{1..k}$ are created at the same time, they are often consumed at different moments in the future: i) since SBT's control plane threads independently fetch new uArrays for processing as they become available (§4), the starting moments for processing $b_{1..k}$ may vary widely, especially when the engine load is high; ii) even when k worker threads start processing $b_{1..k}$ simultaneously, straggling workers are not uncommon, due to non-determinism of a modern multicore's thread scheduling and memory hierarchy [24].

The impacts of misleading hints SBT detects misleading hints in retrospect through remote attestation (§7). As the hints only affect TEE memory placement *policy* on the edge, misleading hints never result in data loss (§4.2) or violation of data security and TEE integrity. Yet, such hints may slow down analytics and therefore violate result freshness.

Managing virtual addresses All uGroups grow *in place* within one virtual address space. To avoid collision and expensive relocation, the allocator places them far apart by leveraging the large virtual address space dedicated to a TrustZone TEE. The space is 256TB on ARMv8, 10,000× larger than the physical DRAM (a few GBs). Hence, the allocator simply reserves for each uGroup a virtual address range as large as the total TEE DRAM. We will validate this choice in Section 9.

7 Attestation for Correctness and Freshness

SBT collects evidences for cloud consumers to verify two properties: *correctness*, i.e. all ingested data is processed ac-

Field	Description	Length
Ts	Data plane timestamp	32 bits
Op	Primitive type, including ingress/egress	16 bits
WinNo	Monotonic window sequence number	16 bits
Data	An uArray ID or a watermark value	32 bits
Hint	An optional consumption hint	64 bits
Count	Number of data/hint fields that follow	16 bits

In/Egress	Op	Ts	Data					
Windowing	Op	Ts	Data	WinNo	Data			
Execution	Op	Ts	Cnt	Data...	Cnt	Data...	Cnt	Hints...

Figure 6: Audit records: fields (top) and layout (bottom)

cording to the stream pipeline declaration; *freshness*, i.e. the pipeline has low output delays.

The above objective has several notable aspects. i) We verify the behaviors of untrusted control plane, i.e., *which* primitives it invokes on *what* data and at *what* time. We do not verify trusted primitives, e.g. if a Sort primitive indeed produces ordered data. ii) Verifying data lineages at the pipeline's intermediate operators or egress [50, 102] is insufficient to guarantee correctness, i.e. all data ingested so far is processed according to the stream pipeline. iii) The windows of stream computations and watermarks triggering the computations must be attested, which are keys to stream model (§2). iv) As the volume of evidences can be substantial, evidences must be compacted to save uplink bandwidth [84, 114].

Therefore, SBT provides the following verification mechanism. Agnostic to the pipeline being executed, the data plane monitors dataflows among primitive instances at the TEE boundary, and then generates audit records. For low overhead, it eschews building data lineages on-the-fly unlike much prior work [50,74,99]. The data plane compresses audit records and flushes to the cloud both periodically and upon externalizing any analytics result. We describe details below.

Audit records As being invoked by the control plane, the data plane generates *audit records*. As illustrated in Figure 6, the records track i) ingested and externalized uArrays, ii) associations between uArrays and windows, and iii) primitive executions (with optional hints supplied by the control plane) which establish *derived-from* relations among uArrays. The records further include ingested watermark values, which are crucial for determining output delays as will be discussed below. The data plane timestamps all the records. It generates monotonically increasing identifiers for recorded uArrays. We will evaluate the overhead of audit records in Section 9.

Attesting analytics correctness The cloud verifier checks if all ingested uArrays flow through the expected trusted primitives. Such dataflows are deterministic given the arrivals of input data (including their windows), the watermarks, and the pipeline declaration. Hence, the verifier replays all ingestion records on its local copy of the same pipeline. It checks if all the records resulting from the replay match the ones reported by the edge (except timestamps). The replay is symbolic without actual computations and hence fast.

Note that the verification works for stateful operators as well. The state of a stream operator (e.g. temporal join) is only determined by all the inputs the operator has ever received. Since the cloud can verify that all the ingested uArrays correctly flow through the expected trusted primitives and thus stream operators, it knows that the operator's current state must be correct, and then all results derived from the operator state must be correct.

Attesting result freshness The key for the verifier to calculate the delay of an output result R is to identify the watermark that triggers the externalization of R, according to the delay definition in Section 2.2. From the egress record of R, the verifier traces *backward* following the *derived-from* chain(s) until it reaches an execution record indicating that a watermark W triggers the execution. The verifier looks up the ingress record of W. It calculates the difference between W's ingress time and R's egress time to be the delay of R.

Example In Listing 1, an uArray with identifier 0xF0 is ingested and segmented into two uArrays (0xF1 and 0xF2) for window 0 and 1 respectively. Sort consumes uArray 0xF1 and produces uArray 0xF3. A watermark with value 100 arrives and completes window 0. Triggered by the watermark, SUM consumes uArray 0xF3 of window 0 and produces uArray 0xF5 as the result of window 0.

```
ts= 1  INGRESS data=0xF0
ts= 5  WND data_in=0xF0 win_no=0 data_out=0xF1
ts=10  SORT data_in=0xF1 data_out=0xF3
ts=15  INGRESS data=0xF4 (watermark=100)
ts=25  SUM data_in=0xF3,0xF4 data_out=0xF5
ts=28  WND data_in=0xF0 win_no=1 data_out=0xF6
ts=30  EGRESS data=0xF5
```

Listing 1: Sample audit records for the pipeline in Figure 2. Format is simplified. ts means processing timestamp.

The cloud verifier replays the ingress records on its local pipeline copy and learns that uArray 0xF1 is processed adhering to the pipeline declaration while uArray 0xF2 is yet to be processed. It will assert analytics incorrectness if 0xF2 remains unprocessed until a future watermark completes window 1 (not shown). To verify result freshness, the verifier traces result 0xF5 backward to find its trigger watermark 0xF4 and calculates the output delay to be 15 ($30-15$).

Columnar compression of records The data plane compresses audit records by exploiting locality within one record field and known data distribution in each field. The data plane produces raw audit records in memory (with the format shown in Figure 6) and in a row order, i.e. one record after the other. Before uploading a sequence of records, it separates the record fields (i.e. columns) and applies different encoding schemes to individual columns: i) Huffman encoding for primitive types and data counts, the two columns likely contain skewed values; ii) delta encoding for timestamps, uArray identifiers, and window numbers, which increment monotonically. Our compression is inspired by columnar databases [107]. We will evaluate the efficacy of compression in Section 9.

8 Implementation

We build SBT for ARMv8 and atop OP-TEE [70] (v2.3). SBT reuses most control functions of StreamBox [82], an open-source research stream engine for x86 servers. Yet, as StreamBox mismatches a TEE (§4.1), SBT contributes a new architecture and a new data plane. SBT communicates with source sensors and cloud consumers over ZeroMQ TCP transport [57] which is known for good performance. The new implementation of SBT includes 12.4K SLoC.

Input batch size, a key parameter of SBT, trades off between delays in executing individual primitives, the rate of TEE entry/exit, and attestation cost. We empirically determine it as 100K events and will evaluate its impact (§9). **Opaque references** for uArrays are 64-bit random integers generated by the data plane. It keeps the mappings from references to uArray addresses in a table, and validates opaque references by table lookup. This incurs minor overhead, as live opaque references are often no more than a few thousands.

9 Evaluation

We answer the following questions through evaluation:

- Does SBT result in a small TCB? (§9.1)
- What is SBT's performance and how is it compared to other engines? What is the overhead? (§9.2)
- How do our key designs impact performance (§9.3)?

9.1 TCB Analysis

TCB size Table 4 shows a breakdown of the SBT source code. Despite a sophisticated control plane, the data plane only adds 5K SLoC to the TCB. SBT's memory management is in 740 SLoC, 9× fewer than glibc's `malloc` and 20× fewer than `jemalloc` [41]. The size of data plane is 42.5 KB, a small fraction (16%) of the entire OP-TEE binary.

TCB interface The SBT's data plane exports only four entry functions: two for data plane initialization/finalization, one for debugging, and one shared by all 23 trusted primitives. The last function accepts and returns opaque references (§4). No state is shared across the protection boundary.

Comparison with alternative TCBs Compared to enclosing whole applications in TCB [22, 27, 112], SBT keeps most of the engine out, shrinking the TCB by at least one order of magnitude. Compared to directly carving out [71, 93] the original StreamBox's data functions for protection, SBT completely avoids sophisticated data structures (e.g. AtomicHashMap [47] used by StreamBox) that mismatch TCB. Compared to VC3 [99] that implements Map/Reduce operators in a TCB with ∼9K SLoC, SBT supports much richer stream operators within a 2× smaller TCB.

9.2 Performance & Overhead

Methodology We evaluate SBT on a HiKey board as summarized in Table 3. We chose HiKey for its good OP-TEE support [70] and that it is among the few boards with TrustZone programmable by third parties. We built *Generator*, a program sends data streams over ZeroMQ TCP transport [57] to SBT. We run the cloud consumer on an x86 machine. Data streams are encrypted with 128-bit AES.

In the face of HiKey's platform limitations, we set up the engine ingestion as follows. i) Although Gigabit Ethernet on edge platforms is common [5, 88], Hikey's Ethernet interface (over USB) only has 20MB/sec bandwidth. We have verified that the interface is saturated by SBT with 4 cores. Hence, we report performance when SBT and *Generator* both run on HiKey communicating over ZeroMQ TCP, which still fully exercise the TCP/IP stack and data copy. ii) Although HiKey's TEE is capable of directly operating Ethernet interface as trusted IO, our OP-TEE version lacks the needed drivers. Hence, we emulate SBT's direct data ingestion to TEE by running the ingestion in a privileged process in the normal world, and bypassing data copy across the TEE boundary. Our test harness continuously replays pre-allocated secure memory buffers populated with events.

As summarized in Table 5, we test SBT as well as three modified versions: ***SBT ClearIngress*** ingests data in cleartext; this is allowed if source-edge links are trusted as defined in our threat model (§3). ***SBT IOviaOS*** does not exploit TrustZone's trusted IO: the untrusted OS ingested (encrypted) data and copies the data across TEE boundary to the data plane. ***Insecure*** completely runs in the normal world with ingress and egress in cleartext, showing native performance. This is basically StreamBox [82] with SBT's optimized stream computations (§5). We report the engine performance as its maximum input throughput when the pipeline output delay (defined in §2.2) remains under a target set by us.

Benchmarks We employ six benchmarks of processing sensor data streams from prior work [32, 62, 63, 67, 82]. They

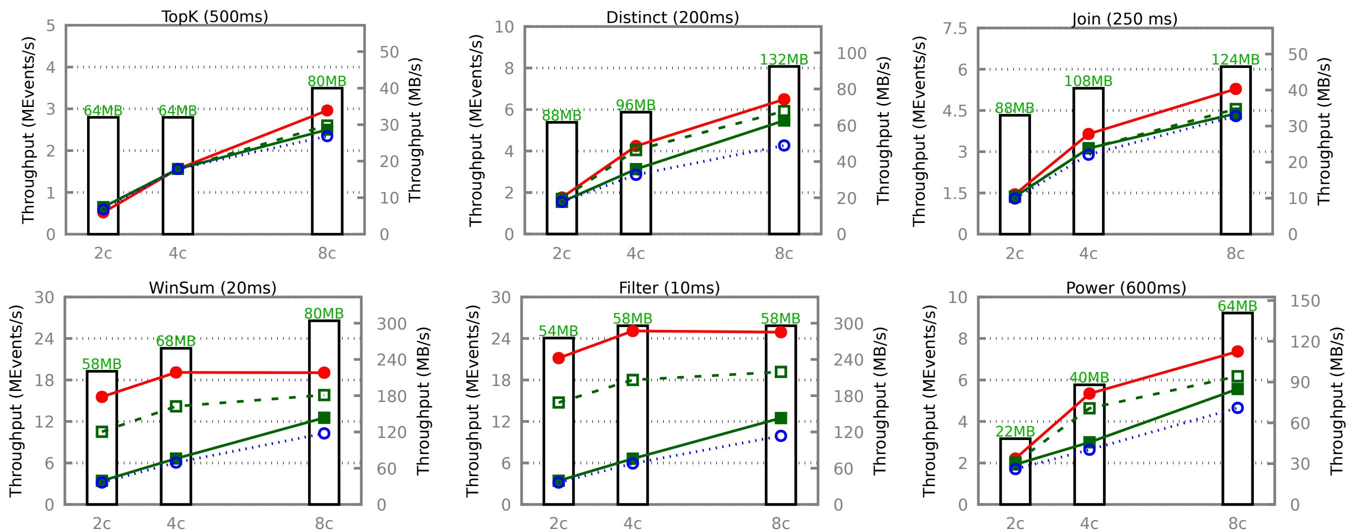

Figure 7: StreamBox-TZ throughput (lines, left/right y-axes) as a function of CPU cores (x-axis) under given output delays (above each plot). Steady consumptions of TEE memory as columns with annotated values. See Table 5 for legends and explanations.

Legend & Version	Data Plane	In/Egress Path	Ingress Data	Egress Data

Table 5: Engine versions for comparison (plots in Figure 7)

cover major stream operators and a variety of pipelines. We use fixed windows, each encompassing 1M events and spanning 1 second of event time. Each event consists of 3 fields (12 Bytes) unless stated otherwise. (1) **Top Values Per Key (TopK)** groups events based on keys and identifies the K largest values in each group in each window. (2) **Counting Unique Taxis (Distinct)** identifies unique taxi IDs and counts them per window. For input events, we use a dataset of taxi trip information containing 11 K distinct taxi IDs [63]. (3) **Temporal Join (Join)** joins events that have the same keys and fall into same windows from two input streams. (4) **Windowed Aggregation (WinSum)** aggregates input values within each window. We use the Intel Lab Data [75] consisting of real sensor values as input. (5) **Filtering (Filter)** filters out input data, of which field falls into to a given range in each window. We set 1% selectivity as done in prior work [67]. (6) **Power Grid (Power)**, derived from a public challenge [62], finds out houses with most high-power plugs. Ingesting a stream of per-plug power samples, it calculates the average power of each plug in a window and the average power over all plugs in all houses in the window. For each house, it counts the number of plugs that have a higher load than average. It emits the houses that have most high-power plugs in the window. The event for this benchmark is composed of 4 fields (16 Bytes).

Benchmark 2, 4, and 6 use real-world datasets; others use synthetic data sets of which fields are 32-bit random integers. Note that SBT's `GroupBy` operator bases on sort and merge and is insensitive to key skewness [15].

End-to-end performance Figure 7 shows the throughputs of all benchmarks as a function of hardware parallelism. SBT can process up to multiple millions of events within sub-second output delays (labeled atop each plot). For simpler pipelines such as WinSum and Filter, SBT processes around 12M events/sec (140 MB/sec). This throughput saturates one GbE link which is common on IoT gateways [88]. Overall, SBT can use all 8 cores in a scalable manner.

SBT's absolute performance is state of the art. We test three popular, insecure stream engines: Flink [19], designed for distributed environment and known for good single-node performance [68]; Esper [46], designed for a single machine; SensorBee [90], designed for sensor data processing on a single device. As shown in Figure 8, on the same hardware (HiKey) and the same benchmark (WinSum), we have measured that SBT's throughput is at least one order of magnitude higher than the others. This is because i) our *Insecure* baseline has high performance for its rich task parallelism (inherited from StreamBox [82]) and native, vectorized stream computations (new contributions); ii) SBT only imposes modest security overhead, as will be shown later.

Comparison to secure stream engines The comparison is challenged by that TrustZone was rarely exploited for protecting data-intensive computations. To our knowledge, i) no analytics engines use TrustZone for data protection and ii) no systems can partition an insecure stream engine for TrustZone. Note that popular secure analytics engines, e.g. VC3 [99] and Opaque [124], not only require SGX but also target batch processing instead of stream analytics. To this end, we qualitatively compare SBT with SecureStreams [53], the closest system we are aware of. Designed for an x86 cluster, SecureStreams uses SGX to protect stream operators and targets strong data security. On a benchmark similar to WinSum it

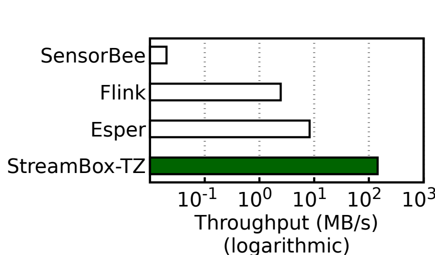

Figure 8: StreamBox-TZ achieves much higher throughput than commodity insecure engines [19, 46, 90] on HiKey. Benchmark: windowed aggregation; target output delay: 50ms.

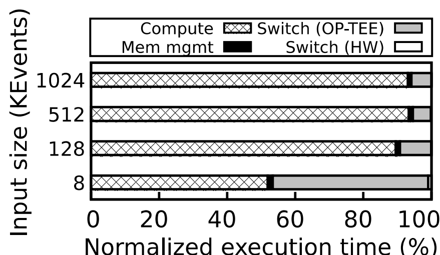

Figure 9: Run time breakdown of operator `GroupBy` under different input batch sizes. The control plane runs 8 threads to execute `GroupBy` in parallel. Total execution time is normalized to 100%.

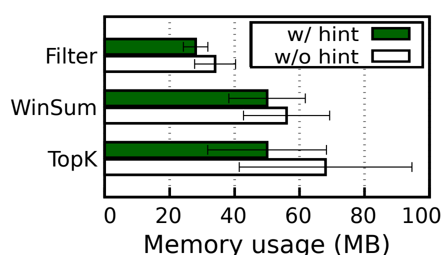

Figure 10: Without consumption hints, the allocator uses more TEE memory. Since memory usage fluctuates at run time, the error bars show two standard deviations below and above the average.

was reported to achieve 10 MB/sec, one magnitude lower than SBT on WinSum. Furthermore, SecureStreams achieved such performance on a small x86 cluster which has much richer resource than HiKey: the former has faster CPUs (8x i7-6700@3.4GHz versus 8x Cortex-A53@1.2GHz), larger DRAM (16 GB versus 2 GB), higher power (130W versus 36W), and higher cost ($600 versus $65).

SBT's advantage comes from i) data exchange via coherent memory inside one TEE, instead of exchanging encrypted messages among workers; ii) memory management specialized for streaming, and iii) vectorized computations.

Security overhead We investigate the overhead of the new security mechanism contributed by SBT – its isolated data plane. We assess the overhead as the throughput loss of *SBT ClearIngress* as compared to *Insecure* (i.e. native performance as StreamBox [82] invoking SBT's stream computations), both paying same costs for data ingress. The target output delays are the same (labeled atop each plot in Figure 7). The security overhead is less than 25% in all benchmarks. This is similar to or lower than the reported overhead (20–70%) in recent TEE systems [22, 71, 112]. ***Overhead analysis:*** The security overhead mostly comes from world switch, among operators and inside each operator. To understand the switch cost within an operator, we profile `GroupBy`, one of the most costly operators. We test different input batch sizes, which have a strong impact on TEE entry/exit rates and hence isolation overhead (§4). Figure 9 shows a run time breakdown. When each input batch contains 128K (close to the value we set for SBT) or more events, more than 90% of the CPU time is spent on actual computations in TEE. The CPU usage of TEE memory management is as low as 1–2%. In the extreme case where each input batch contains as few as 8K events, the overhead of world switch starts to dominate. Most of the world switch overhead comes from OP-TEE instead of the CPU hardware (a few thousand cycles per switch), suggesting room for OP-TEE optimization.

Impact of decrypting ingress data Decrypting ingress data is needed if source-edge links are untrusted (§3) and source must send encrypted data. It has substantial performance impact. By comparing SBT to *SBT ClearIngress*, turning on/off ingress decryption leads to 4% – 35% throughput difference when all 8 cores are in use. The performance gap is more pronounced for simple pipelines, which has higher ingestion throughput leading to higher decryption cost.

TEE memory usage While sustaining high throughput, SBT consumes a moderate amount of physical memory, ranging from 20 MB to 130 MB as shown in Figure 7. The memory usage is as low as 1–6% of the total system DRAM. The virtual memory usage is also low, often 1–5% of the entire virtual address space in OP-TEE. The memory usage increases with the throughput, since there will be more in-flight data. On the same platform, Flink's memory consumption is 3× higher, due to its hash-based data structures and the use of JVM. This validates our choice of uArrays.

Attestation overhead Attestation incurs minor overhead to both the edge and the cloud. We measured that SBT produces 300–400 audit records per second across all our benchmarks, and spends a few hundred cycles on producing each record. Compressing such record streams on HiKey consumes 0.2% of total CPU time. Our consumer written in Python on a 4-core i7-4790 machine replays 57K records per second with a single core, suggesting a capability of attesting near 500 SBT instances simultaneously. We will evaluate the efficacy of record compression in Section 9.3.

9.3 Validation of Key Design Features

Exploitation of trusted IO As shown in Figure 7, a comparison between SBT and *SBT IOviaOS* demonstrates the advantage of directly ingesting data into TEE and bypassing the OS: SBT outperforms the latter by up to 20% in throughput due to reduction in moving ingested data.

Trusted primitive vectorization (§5) Our optimizations with ARM vector instructions are crucial. To show this, we examine `GroupBy`, one of the top hotspot operators. When we replace the vectorized Sort that underpins `GroupBy` with two popular implementations (qsort() from the the OP-TEE's libc and std::sort() from the standard C++ library), we measured the throughput of `GroupBy` drops by up to 7× and 2×,

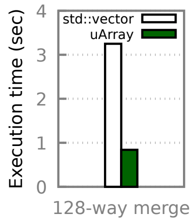

Figure 11: On-demand growth of uArrays vs. std::vector

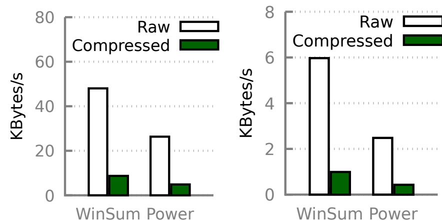

(a) 10K events/batch (b) 100K events/batch

Figure 12: Compression of audit records saves uplink bandwidth substantially.

respectively. We have similar observation on other operators.

Efficacy of hint-guided memory placement (§6.2) We compare to an alternative design: the modified allocator acts based on the heuristics that all the uArrays produced by the same primitive belong to the same *generation* and are likely to be reclaimed altogether. Accordingly, the modified allocator places these uArrays in the same uGroup. As shown in Figure 10, in three benchmarks, the modified allocator increases memory usage by up to 35%. This is because, without hints, it cannot place uArrays based on future consumption.

uArray on-demand growth (§6.1) We compare uArray to std::vector, a widely used C++ sequence container with on-demand growth. We run a microbenchmark of N-way merge, an intensive procedure in trusted primitives. It iteratively merges 128 buffers (uArrays or vectors), each containing 512 KB (128K 32-bit random integers) until obtaining a monolithic buffer; as merge proceeds, buffers grow dynamically. As shown in Figure 11, uArrays is 4× faster than std::vector, because the allocation and paging in TEE that back uArray growth is much faster than that of a commodity OS.

Compression of audit records (§7) The compression significantly saves the uplink bandwidth. We test two benchmarks (WinSum and Power) on two extremes of the spectrum of computation cost, and test two very different input batch sizes. This is because simpler computations and smaller batch sizes generate audit records at higher rates. Figure 12 shows that SBT compresses audit records by 5×–6.7×. In an offline test using gzip to compress the same records, we find our compression ratios are 1.9× higher than gzip. 2–40 KB/sec of uplink bandwidth is saved, which is significant compared to the uploaded analytics results, which are 144 bytes/sec for WinSum and 400 bytes/sec for Power.

10 Related Work

Secure data analytics DARKLY [61] protects sensor data by isolating computations in an OS process, resulting in a large TCB. VC3 [99] and SecureStreams [53] use SGX to protect the operators in distributed analytics. They lack optimizations for parallel execution in one TEE on the edge. To process data confidentiality, STYX [106] computes over encrypted data, a method likely prohibitively expensive to edge platforms. Opaque [124] protects data access patterns of distributed operators, targeting a threat out of our scope.

TCB minimization Minimizing TCB is a proven approach towards a trustworthy system. Flicker [80] directly executes security-sensitive code on baremetal hardware. Trustvisor [79] shrinks its TCB to a specialized hypervisor. Sharing a similar goal, SBT addresses unique challenges in supporting data-intensive computation on a minimal TCB.

Trusted Execution Environments Much work isolates security-sensitive software components. Terra [48] supports isolation with a virtual machine. Many systems used TrustZone and SGX [81] for TEE. Some systems enclose in TEE whole applications [22, 27, 51, 112], while others partition existing programs for TEE [71, 93, 101]. These approaches often result in larger TCBs and/or higher overhead than SBT and are thus less desirable for SBT. TEE also sees various novel usage, including protecting mobile app classes [96], enforcing security policies [30], remote attestation of application control flows [13], and controlling data access [34]. None addresses data-intensive computation as SBT does.

Edge processing evolves from a vision [98, 100] to practice [37, 42, 83]. Most works focused on programming paradigms [94], developing and deploying application [29, 52, 114], and resource management [86]. Complementary to them, SBT focuses on secure analytics on the edge.

Stream processing systems, in response to big data challenges, evolve from single-threaded [33, 40, 78, 105, 110] to massive parallel systems [14, 69, 85, 92, 92, 113, 122]. The existing systems focus on challenges, such as fault tolerance [122], fast reconfiguration [115], high parallelism [32, 82], and the use of GPUs [67]. Few systems achieve data security and performance simultaneously as SBT does.

11 Conclusions

This paper presents StreamBox-TZ (SBT), a secure stream analytics engine designed and optimized for a TEE on an edge platform. SBT offers strong data security, verifiable results, and competitive performance. On an octa core ARM machine, SBT processes up to tens of millions of events per second; its security mechanisms incur less than 25% overhead.

Abstract

Hardware secure enclaves are increasingly used to run complex applications. Unfortunately, existing and emerging enclave architectures do not allow secure and efficient implementation of custom page fault handlers. This limitation impedes in-enclave use of secure memory-mapped files and prevents extensions of the application memory layer commonly used in untrusted systems, such as transparent memory compression or access to remote memory.

CoSMIX is a **Co**mpiler-based system for **S**ecure **M**emory **I**nstrumentation and e**X**ecution of applications in secure enclaves. A novel *memory store* abstraction allows implementation of *application-level secure page fault handlers* that are invoked by a lightweight enclave runtime. The CoSMIX compiler instruments the application memory accesses to use one or more memory stores, guided by a global instrumentation policy or code annotations without changing application code.

The CoSMIX prototype runs on Intel SGX and is compatible with popular SGX execution environments, including SCONE and Graphene. Our evaluation of several production applications shows how CoSMIX improves their security and performance by recompiling them with appropriate memory stores. For example, unmodified Redis and Memcached key-value stores achieve about 2× speedup by using a self-paging memory store while working on datasets up to 6× larger than the enclave's secure memory. Similarly, annotating a single line of code in a biometric verification server changes it to store its sensitive data in Oblivious RAM and makes it resilient against SGX side-channel attacks.

1 Introduction

Virtual Memory is integral to modern processor architectures. In addition to its primary role in physical memory management, it empowers developers to *extend* the standard memory layer with custom data storage mechanisms in software. For example, the memory-mapped file abstraction, which is broadly used, e.g., in databases [10, 5], relies on the OS's page fault handler to map a frame and populate it with the contents of a file. Replacing accesses to physical memory with file accesses requires no application code changes. Therefore, the ability to override page fault behavior has been essential for implementing a range of system services, such as memory compression [44], disaggregation [39, 75], distributed shared memory [36, 46] and heterogeneous memory support [37].

With the emergence of Software Guard Extensions (SGX) for Trusted Execution in Intel CPUs [16, 55], applications are increasingly ported to be entirely executed in *hardware-enforced enclaves* [58, 45, 23, 25]. The enclave hardware protects them from attacks by a powerful privileged adversary, such as a malicious OS or a hypervisor. A number of recent systems facilitate the porting to SGX by shielding unmodified applications in an enclave [21, 81, 18]. Unfortunately, these systems do not allow secure overriding of page fault handling in enclave applications. This drawback complicates porting a large class of applications that use memory-mapped files to SGX. Further, it prevents SGX applications from using security and performance enhancements, such as efficient memory paging [61] and Oblivious RAM (ORAM) side-channel protection [67, 11, 88] without intrusive application modifications. Our goal is to eliminate these constraints.

For example, consider the task of running an SQLite database that uses memory-mapped files in the enclave. The database file must be encrypted to ensure data confidentiality. Enabling in-enclave execution of SQLite therefore requires support for encrypted memory-mapped files, which in turn implies that the *page fault handler must be executed securely* as well. Unfortunately, hardware enclaves available today do not support secure page faults. Instead, existing solutions use workarounds, such as eagerly reading and decrypting the whole mapped file region into trusted enclave memory [18]. This solution does not scale to large files and lacks the performance benefits of on-demand data access.

We argue that the problem is rooted in the fundamental limitation of SGX architecture, which does not provide the mechanism to define *secure* page fault handlers. The upcoming SGX-V2 [54, 86, 43] will not solve this problem either. Moreover, we observe that existing and emerging secure enclave architectures [28, 4, 34] suffer from similar limitations(§2).

In this work, we build **CoSMIX**, a compiler and a lightweight enclave runtime that overcomes the SGX architectural limitations and enables secure and efficient extensions to the memory layer of *unmodified* applications running in enclaves. We introduce a *memory store, (*m*store)*, a programming abstraction for implementing custom memory management extensions for enclaves. The CoSMIX compiler automatically instruments application code to allocate the selected

variables and memory buffers in the *m*store, replacing the accesses to enclave memory with the accesses to the *m*store. The *m*store logic runs in the enclave as part of the application. The CoSMIX runtime securely invokes the *m*store memory management callbacks, which include custom page fault handlers. The page faults are semantically equivalent to hardware page faults yet are triggered by the CoSMIX runtime.

An *m*store can implement the missing functionalities that require secure page fault handlers. For example, it may provide the secure `mmap` functionality by implementing the page fault handler that accesses the file and decrypts it into the application buffer. A more advanced *m*store may add its own in-memory cache analogous to an OS page cache, to avoid costly accesses to the underlying storage layer. CoSMIX supports several types of *m*stores, adjusting the runtime to handle different *m*store behaviors while optimizing the performance.

CoSMIX allows the use of *multiple* m*stores* in the same program. This can be used, for example, to leverage both secure `mmap` *m*store and an ORAM *m*store for side-channel protection. Additionally, CoSMIX supports *stacking* of multiple *m*stores to enable their efficient composition and reuse. We design and prototype three sophisticated *m*stores in §3.2.5, and demonstrate the benefits of stacking in §4.5.

CoSMIX's design focuses on two primary goals: (1) minimizing the application modifications to use *m*stores and (2) reducing the instrumentation performance overheads. We introduce the following mechanisms to achieve them:

Automatic inference of pointer types. CoSMIX *does not* require annotating every access to a pointer. Instead, it uses inter-procedural pointer analysis [17] to determine the type of the *m*store (or plain memory) to use for each pointer. When the static analysis is inconclusive, CoSMIX uses *tagged pointers* [47, 74, 13] with the *m*store type encoded in the unused Most Significant Bits, enabling runtime detection (§3.3.1).

Locality-optimized translation caching. The *m*store callbacks interpose on memory accesses, which are part of the performance-critical path of the application. To reduce the associated overheads, we employ static compiler optimizations to reduce the number of runtime pointer type checks and *m*store accesses. These include loop transformations and a software *Translation Lookaside Buffer (TLB)* (§3.3.4). These mechanisms reduce the instrumentation overheads by up to two orders of magnitude (§4.2).

Our prototype targets existing SGX hardware and is compatible with several frameworks for running unmodified applications in enclaves [81, 1, 18]. However, CoSMIX makes no assumptions about enclave hardware. The CoSMIX compiler is implemented as an extension of the LLVM framework [48].

We prototype three *m*stores: Secure User Virtual Memory (SUVM) for efficient paging in memory-intensive applications [61], Oblivious RAM [78] for controlled side-channel protection, and a secure `mmap` *m*store that supports access to encrypted/integrity-protected memory-mapped files. We evaluate CoSMIX on the Phoenix benchmark suite [66], as well as on unmodified production servers: `memcached`, Redis, SQLite, and a biometric verification server [61]. The compiler is able to correctly instrument all of these applications, some with hundreds of thousands of lines of code (LOC), *without the need to manually change the application code*.

Our microbenchmarks using Phoenix with SUVM and secure `mmap` *m*stores show that CoSMIX instrumentation results in a low geometric mean overhead of 20%.

For the end-to-end evaluation, we run `memcached` and Redis key value stores on 600 MB datasets – each about 6× the size of the secure physical memory available to SGX enclaves. In this setting, SGX hardware paging significantly affects the performance. The SUVM [61] *m*store aims to optimize exactly this scenario. To use it, we only annotate the item allocator in `memcached` (a single line of code) and compile it with CoSMIX. Redis is compiled *without* adding annotations. The instrumented versions of both servers achieve about 2× speedup compared to their respective vanilla SGX baselines.

In another experiment, we evaluate a biometric verification server with a database storing 256 MB of sensitive data. We use the ORAM *m*store to protect it from SGX controlled side-channel attacks [87] that may leak sensitive database access statistics. We annotate the buffers containing this database (one line of code) to use ORAM. The resulting ORAM-enhanced application provides security guarantees similar to other ORAM systems for SGX, such as ZeroTrace [67], yet without modifying the application source code. ORAM systems are known to result in dramatic performance penalties of several orders of magnitude [26]. However, our hardened application is only 5.8× slower than the vanilla SGX thanks to the benefits of selective instrumentation enabled by CoSMIX.

To summarize, our contributions are as follows:

- Design of a compiler and an *m*store abstraction for transparent secure memory instrumentation (§3.2).
- Loop transformation and loop-optimized caching techniques to reduce the instrumentation overheads (§3.3.4).
- Seamless security and performance enhancement for unmodified real-world applications running in SGX, by enhancing them with the SUVM, ORAM and secure `mmap` *m*stores (§4).

2 Motivation

Enabling the use of custom page fault (PF) handlers in enclaves would not only facilitate porting of existing applications that rely on such functionality, but also enable a range of unique application scenarios, as we discuss next.

SUVM. The authors of Eleos [61] proposed Software User-space Virtual Memory (SUVM), which implements *exit-less memory paging in enclaves* and significantly improves the performance of memory-demanding secure applications. It keeps the page cache in the enclave's trusted memory, while the storage layer resides in untrusted memory whose contents are encrypted and integrity-protected.

ORAM. Oblivious RAM (ORAM) obfuscates memory access patterns by shuffling the physical data locations and re-encrypting the contents upon every access. As a result, an adversary observing the accessed locations learns nothing about the actual access pattern to the data [38]. Multiple ORAM schemes have been proposed over time [38, 84, 78, 88, 67, 33], and, ORAM was recently used to manually secure applications executing in SGX enclaves against certain side-channel attacks [88, 67, 33].

Both ORAM and SUVM are generic mechanisms that could be useful in many applications. Unfortunately, integrating them with the application logic requires intrusive code modifications. With the support for efficient and secure in-enclave PF handlers, we could add these mechanisms to existing unmodified programs, as we show in the current work.

Other applications include transparent compression for in-enclave memory, `mmap` support for encrypted and integrity-protected files, and inter-enclave shared memory, as well as various memory-management mechanisms [39, 75, 37].

Unfortunately, existing enclave hardware provides no adequate mechanisms to implement efficient and secure user-defined PF handlers, as we describe next.

2.1 Background: page-faults in enclaves

There are several leading enclave architectures: Intel SGX [16, 43], Komodo for ARM Trust Zone [34, 15], Sanctum [28], and Keystone [4]. Among these, only Intel SGX and Sanctum published support for paging. We briefly describe them below.
Intel SGX [16, 43, 55] supports on-demand paging between secure and untrusted memory. SGX relies on Virtual Memory hardware in X86 CPUs. When a PF occurs, the enclave *exits* to an *untrusted* privileged OS which invokes the SGX PF handler. The enclave execution resumes (via `ERESUME`) after the swapping is complete.

Since the PF handler is untrusted, the SGX paging is secured via SGX paging instructions. Specifically, `EWB` encrypts and signs the page when swapping the page out, whereas `ELDU` validates the integrity and decrypts when swapping it in. These instructions cannot be modified to perform other operations. They cannot change the internal SGX encryption key or modify the swapped page. In other words, they cannot act as a general-purpose secure PF handler.
Sanctum [28] supports per-enclave page tables and secure PF handlers. It uses a security monitor that runs at a higher privilege level than the OS and the hypervisor. Upon a PF, the enclave exits to the security monitor, which triggers the in-enclave secure PF handler.

2.2 Limitations of existing enclaves

Signal handling in SGX. Page fault handlers can be customized in userspace by registering a signal handler. SGX supports signal handlers in enclaves and works according to the following scheme (Figure 1): when an interrupt occurs, the enclave exits to the OS ❶. The OS takes control and performs an up-call to an untrusted user-space trampoline in the enclave's hosting process ❷. The trampoline re-enters the enclave by invoking the in-enclave signal handler ❸. After the signal handler terminates, the enclave exits ❹ and resumes execution of the last instruction ❺ via `ERESUME`.

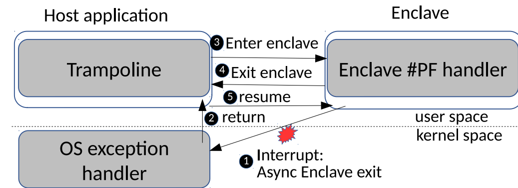

Figure 1: Execution of a signal handler in SGX

SGX: No secure page fault handlers. The SGX signal handling mechanism cannot guarantee secure execution of the handler itself. When the enclave is resumed after the PF, `ERESUME` replays the faulting memory access. Therefore, the enclave *cannot validate* that the signal handler was indeed executed correctly, or was executed at all. To the best of our knowledge, this problem will not be resolved in the next version of SGX [54, 86, 43].
SGX: Performance overheads. Even with hardware support for the secure signal handler, SGX has inherent architectural properties that will lead to significant performance penalties, rendering this mechanism unsuitable for customized application memory management. The architecture relies on the OS to manage the enclave's virtual memory. Furthermore, SGX may only run userspace code. Since the OS is untrusted, any secure page fault handling would inevitably follow the signal handling scheme depicted in Figure 1, namely, double enclave transition between the trusted and untrusted contexts.

We measure the latency of an empty SGX PF handler (access to a protected page) to be *11*μsec, which is more than 6$\times$ the latency of a signal handler outside SGX. For comparison, CoSMIX's software page fault handler is only 0.01 μ second, the cost of a single function call, which is three orders of magnitude faster than in SGX.

Further analysis shows that the signal latency is dominated by the latency of enclave transitions, which we measure to be 5.3μsec each [1] and stems from costly validation, register scrapping, TLB and L1 cache flushes [82, 43].
Other enclave architectures. Enclave transition overheads are pertinent to other enclave architectures. Komodo reports exit latency of 0.96μs [34]. Sanctum and Keystone do not disclose their enclave transition penalties, yet they describe similar operations performed when such transitions occur.

We conclude that *secure page fault handlers are not supported in SGX, and are likely to incur high-performance costs in other enclave architectures due to transition overheads.*

[1] This value is almost double the one reported in prior works [61, 85] because of the firmware update to mitigate the Foreshadow [82] bug.

2.3 Code instrumentation for enclaves

Instrumenting application memory accesses with the desired software PF handling logic is a viable option to achieve the functionality equivalent to the hardware-triggered PF handlers. Unfortunately, existing instrumentation techniques are not sufficient to achieve our goals, as we discuss below.

Binary instrumentation. Dynamic binary instrumentation tools [51, 57, 24, 52, 71], such as Intel PIN [51], enable instrumentation of memory accesses. Unfortunately, these tools have significant drawbacks in the context of in-enclave execution. For example, for PIN to work, all its libraries should be included in the enclave's Trusted Computing Base (TCB). Moreover, PIN requires JIT-execution mode to instrument memory accesses. Therefore, the enclave code pages should be configured as writable, which might lead to security vulnerabilities. Removing the write access permission from enclave pages will be supported in SGX V2, but doing so will require costly enclave transitions [43].

Static binary instrumentation tools do not suffer from these shortcomings. However, compared to the compiler-based techniques we propose in this work, they do not allow using comprehensive code analysis necessary for performance optimizations. Therefore, we decided against the binary instrumentation design.

Compiler-based instrumentation. The main advantage of this method is the ability to aggressively reduce the instrumentation overheads by using advanced source code analysis. On the other hand, the source code access requirement limits the applicability of this method. However, this drawback is less critical in the case of SGX enclaves because many SGX execution frameworks, such Panoply [77] and SCONE [18], require code recompilation anyway. Therefore, we opt for compiler-based instrumentation in CoSMIX.

3 CoSMIX Design

CoSMIX aims to facilitate the integration of different *m*stores efficiently into SGX applications. Our design goals are:

- **Performance.** Low overhead memory-access and software address translation.
- **Ease-of-use.** Annotation-based or automatic instrumentation without manual application code modification.
- **General memory extension interface.** Easy and modular development of application-specific memory instrumentation libraries.
- **Security.** Keep SGX security guarantees and small TCB.

Threat Model. CoSMIX is designed with the SGX threat model, where the TCB includes the processor package and the enclave's code. Additionally, we assume that the code running in an enclave does not contain memory vulnerabilities.

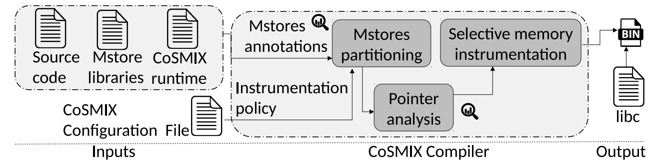

Figure 2: CoSMIX compilation overview. The compiler is guided by code annotations and global instrumentation policy.

3.1 Design overview

Compiler-based instrumentation. CoSMIX enables SGX developers to build custom *memory stores,* m*stores* that redefine the memory layer functionality of an instrumented program. To integrate one or more *m*stores into an application, the CoSMIX compiler automatically instruments the program (Figure 2). The developer may selectively annotate static variables or/and memory allocations to use different *m*stores, or define a global instrumentation policy. The compiler automatically instruments the necessary subset of memory accesses with the accesses to the corresponding *m*stores, and statically links *m*store libraries with the code.

The CoSMIX configuration file defines the instrumentation behavior. It specifies annotation symbols per *m*store, *m*store type (§3.2) and the instrumentation policy(§3.3).

3.2 *M*store abstraction

At a high level, an *m*store implements another layer of virtual memory on top of an abstract *storage layer*. An *m*store operates on pages, m*pages*, and keeps track of the *m*page-to-data mappings in its internal *m*page table. When an application accesses memory, the runtime invokes the *m*store's software *page fault handler*, retrieves the contents (e.g., for the secure `mmap` *m*store, it would read data from a file and decrypt), and makes it accessible to the application.

We distinguish between *cached* and *direct-access* *m*stores. A cached *m*store maintains its own *m*page cache to reduce accesses to the storage layer, whereas a direct-access *m*store does not cache the contents.

Figure 3 shows the execution of an access to a cached *m*store. The pointer access ❶ triggers the runtime call, which chooses the appropriate *m*store ❷ and checks the translation cache ❸. If the translation is not in the cache, the runtime invokes the *m*page fault handler ❹. The *m*store translates the pointer ❺, and either fetches the referenced *m*page from the page cache ❻, or retrieves it from the storage layer and updates the *m*page and translation caches ❼.

3.2.1 *M*store callbacks

Table 1 lists the callback functions *m*stores must implement.

Initialization/teardown. The *m*store is initialized at the beginning of the program execution and torn down when the pro-

Callback	Purpose
`mstore_init(params)/mstore_release()`	Initialize/tear down
`void* alloc(size_t s, void* priv_data)/free(void* ptr)`	Allocate/free buffer
`size_t alloc_size(void* ptr)`	Allocation size
`size_t get_mpage_size()`	Get the size of the *m*page
Direct-access *m*store	
`mpf_handler_d(void* ptr, void* dst, size_t s)`	*m*page fault on access to `ptr`, store the value in `dst`
`write_back(void* ptr, void* src, size_t size)`	Write back value in `src` to `ptr`
Cached *m*store	
`void* mpf_handler_c(void* ptr)`	*m*page fault on access to `ptr`, return pointer to *m*page
`flush(void* ptr, size_t size)`	Write the *m*pages in the range `ptr:ptr+size` to *m*store
`get_mstorage_base()/get_mpage_cache_base()`	Gets the base address of mstorage/*m*page cache
`notify_tlb_cached(void* ptr) / notify_tlb_dropped(void* ptr, bool dirty)`	The runtime cached/dropped the `ptr` translation in its TLB

Table 1: Compulsory *m*store callback functions

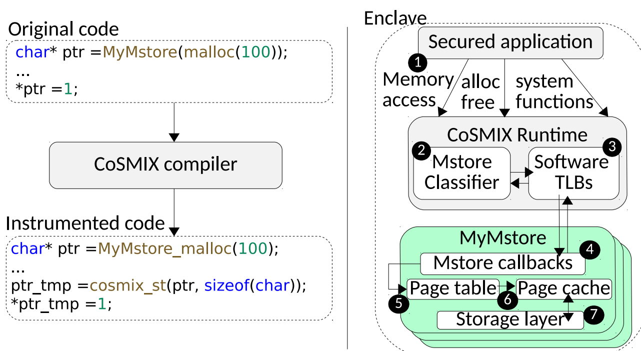

Figure 3: CoSMIX: code transformation and execution flow of access to a cached *m*store. See the text for explanation.

gram terminates. Importantly, the runtime flushes the *m*page cache when tear-down of cached *m*stores is called.

Memory allocation. The runtime delegates the memory allocation calls of the original program to the *m*store `alloc`.

3.2.2 Pointer access and *m*page faults

When the instrumented code accesses the *m*store, the runtime incurs an equivalent of a page fault, and invokes the respective callback in the *m*store, as discussed below.

Cached *m*stores. A cached *m*store *translates* the pointer to the *m*page inside its cache. `mpf_handler_c` returns the pointer into the *m*page that holds the requested data, allowing direct access from the code. For cross-page misaligned accesses, the runtime creates a temporary buffer and populates it by calling the `mpf_handler_c` for every page separately. For store access, the updates are written to both pages.

When the runtime determines that the code is accessing the same *m*page multiple times, it may *cache* the pointer to that *m*page in its private *TLB*. This avoids the address translation overheads for all but the first access to the page. To ensure that the *m*page is not swapped out by the *m*store logic, the runtime notifies the *m*store to pin the *m*page in the *m*page cache via `notify_tlb_cached`. The page is unpinned by `notify_tlb_dropped` when its translation is evicted from the TLB (see §3.3.4 for more details).

There can be multiple cached *m*stores in the same program, each with its own *m*page size. The runtime can query an *m*store page size using the `get_mpage_size` call, for example, to determine accesses to the same *m*page in the TLB.

A cached *m*store must implement the `flush()` callback to synchronize its *m*page cache with the storage layer. This callback is used, for example, to implement the `msync` call.

Direct-access *m*stores. Direct-access *m*stores have no cache and thus are easier to implement. The input pointer provided to the `mpf_handler_d` callback may be used without address translation, and at finer granularity not bound to the *m*page size. The runtime provides a thread-local intermediate buffer to store the accessed data. For loads, the program uses this buffer. For stores, the runtime writes the updated contents back to the *m*store using the `write_back` callback.

3.2.3 Thread safety and memory consistency

CoSMIX allows multiple threads to access the same *m*store, as long as the *m*store implementation is thread-safe.

For cached *m*stores, CoSMIX does not change the *m*store memory consistency model as long as the accesses are inside the same *m*page, and the *m*page size is 4KB or larger. The CoSMIX runtime does not introduce extra memory copies for such accesses and effectively inherits the *m*store memory consistency. In addition, the *m*store itself must ensure that the storage layer is accessed only via its *m*page cache, thereby preventing different threads from seeing inconsistent data.

This guarantee does not hold for direct-access *m*stores and misaligned cross-*m*pages. The primary implication is that hardware atomics will not work for such accesses.

We believe that this limitation does not affect most practical cases. The lack of cross-*m*page atomics support does not affect race-free programs synchronized via locks. This is because the intermediate buffer is written back to the *m*store immediately after the original store operation and thus will be protected by the original lock. We observed no cases of cross-*m*page atomics in the evaluated applications.

Today, the problem of misaligned cache accesses deserves special handling in compilers. For example, LLVM translates such accesses into the `XCHG` instruction [43]. CoSMIX must rely on a software solution, e.g., using readers-write locks per-*m*page. We defer this to future work.

3.2.4 Memory vs. file-backed *m*stores

The *m*store abstraction described so far instruments memory accesses alone. However, it is insufficient to enable implementation of memory-mapped files. For example, consider a program that uses `mmap` to access a file, and then calls `fsync`. It will not work correctly because `fsync` is not aware of the *m*store's internal cache. Specifically, all the I/O operations on files managed by a file-backed *m*store must interact with its *m*page cache to avoid data inconsistency.

We define a *file-backed* cached *m*store type, which implements all the callbacks of memory-backed *m*stores, but additionally overrides the POSIX file API that interacts with the page cache, e.g., `open, close, read, write, msync` (§3.3). Direct-access *m*stores do not have internal caches; thus they can be used with files without overriding file I/O operations other than `mmap` itself.

3.2.5 *M*store examples

CoSMIX provides a set of reusable building blocks for *m*stores, such as a slab memory allocator, spinlocks, a generic *m*page table, and an *m*page cache, all with multi-threading support, which we use to implement the *m*stores below.

SUVM *m*store. SUVM allows exit-less memory paging for enclaves by keeping a page table, page cache and a fault handler as part of the enclave. We implement SUVM from scratch as a cached memory-backed *m*store, using CoSMIX's generic *m*page table and *m*page cache. The `alloc` function returns a pointer to the storage layer in untrusted memory. Upon `mpf_handler_c`, the *m*store checks whether the needed *m*page is already cached in the *m*page table. If not, it reads the *m*page's contents from the storage layer, decrypts and verifies its integrity using a signature maintained for every *m*page, and finally copies it to the *m*page in the page cache. When the *m*page cache is full, the *m*store evicts pages back into the storage layer.

Secure `mmap` *m*store. This *m*store enables the use of memory-mapped encrypted and integrity-protected files in enclaves. We support private file mapping only and leave cross-enclave sharing support for future work. This is a cached file-backed *m*store that maintains its own *m*page table and *m*page cache.

The `alloc` callback is invoked by the runtime upon the `mmap` call in original code. `alloc` records the mapping start offset in the file and the access flags in an internal table. It then returns a pointer with the requested offset from a unique file base address. This address is internally allocated by the *m*store and used as isolated address space for each file.

The `mpf_handler_c` callback translates the given pointer to the respective file. If the contents are not available in the *m*page cache, the data is fetched from the file using a `read` system call, followed by decryption and integrity check.

Oblivious RAM *m*store. ORAM obfuscates memory access patterns by shuffling and re-encrypting the data upon every data access. The ORAM *m*store streamlines the use of ORAM in enclaves. It allows the developer to allocate and access the buffers that store sensitive data in an ORAM, thereby protecting the program against controlled side-channel attacks [87].

We implement a direct-access memory-backed ORAM *m*store. This is because if it were cached, the accesses to the cache would be visible to the attacker, compromising the ORAM security guarantees. Our ORAM *m*store addresses a threat-model similar to ZeroTrace [67], yet without leakage protection in the case of enclave shutdowns. Specifically, all the instrumented memory accesses destined to the ORAM *m*store become oblivious, such that an adversary cannot learn the actual memory access pattern. We implement the Path ORAM algorithm [78] and ensure oblivious accesses to its position map and stash using the *cmovz* instruction.

We store the Path-ORAM tree in a contiguous buffer within the enclave trusted memory. This eliminates the need to implement block encryption and integrity checks as part of the ORAM *m*store since SGX hardware does exactly that.

The `alloc` function allocates the requested number of blocks in ORAM and registers them with the ORAM module. It returns an address from a linear range with a hard-coded base address, which is used only to compute the block index.

The `mpf_handler_d` callback translates the address to the requested block index and invokes the ORAM algorithm to obliviously fetch the requested memory block to a temporary buffer. Loads are issued from this buffer and stores are appended with the `write_back` callback.

3.2.6 Stacking *m*stores

The *m*store abstraction makes it possible to *stack* different *m*stores. Stacking allows one *m*store to invoke another *m*store recursively. We denote by A→B an *m*store A that internally accesses its memory via *m*store B.

Consider, for example, ORAM→SUVM. The motivation to stack is when the ORAM *m*store covers a region that is larger than the enclave's physical memory. Since SUVM optimizes the SGX paging mechanism, stacking ORAM on top of SUVM improves ORAM's performance (§4.5).

To create a new A→B *m*store, the developer simply annotates A's storage layer allocations with B's annotations. CoSMIX instruments all these accesses appropriately.

Stacking the ORAM *m*store on top of any *m*store that maintains data confidentiality does not compromise the ORAM access pattern obfuscation guarantees, as ORAM protocols consider the backing store to be untrusted [78]. Therefore ORAM→SUVM would maintain data-oblivious access.

However, the stacking → operator is *not commutative* from the security perspective: SUVM→ORAM would result in the SUVM *m*store caching *m*pages fetched obliviously by the ORAM *m*store, thereby leaking the access patterns to these *m*pages and compromising ORAM's security guarantees.

3.3 CoSMIX compiler and runtime

The instrumentation compiler modifies the application to use *m*stores and is guided by code annotations or/and a global instrumentation policy. The compiler needs to instrument four different types of code: (1) memory accesses; (2) memory management functions; (3) file I/O operations for file-backed *m*stores; (4) `libc` library calls.

Instrumentation policy. A developer may annotate any static variable declaration or memory allocation function call. Annotations allow instrumentation of a subset of the used buffers to reduce instrumentation overheads. Alternatively, a global instrumentation policy specifies compile-time rules applied to the whole code base (e.g., instrument all calls to `malloc`), or run-time checks injected by the compiler (e.g., using *m*store for large buffers above a certain threshold). A global policy serves for bulk operations on large code bases, such as adding SUVM *m*store to Redis sources with over 130K LOC (§4.4).

Similarly, for file-backed *m*stores, a global policy may limit the use of the *m*store to specific files or directories.

3.3.1 Pointer access instrumentation

Static analysis. The compiler uses static build. Therefore, it can conservatively determine the subset of operations that must be replaced with *m*store-related functions at compile time and eliminate the instrumentation overhead for such cases. Trivially, the compiler may replace an annotated call to `malloc` with the `alloc` callback of the requested *m*store. A much more challenging task, however, is to determine *the type of the* m*store (if any) to use for every pointer in the program*.

For this purpose, we use Andersen's analysis [17] to generate inter-procedural point-to information. In a nutshell, CoSMIX first parses all instructions and generates a graph with pointers as nodes and their constraints (e.g., assignment or copy) as edges. The graph is then processed by a constraint solver which outputs the set of points-to-information.

When instrumenting memory accesses, CoSMIX can use this information to determine whether the pointer may alias to a specific *m*store pointer.

Runtime checks and tagged pointers. CoSMIX's pointer analysis is sound but incomplete; therefore it requires runtime decisions for ambivalent cases. We use tagged pointers [47, 13, 74, 31] to determine pointer type at runtime. Each *m*store is assigned a unique identifier, stored in unused most significant bits of the pointer virtual address. For instrumented allocations, the runtime adds this identifier to the returned address from the *m*store allocation. For external function calls and memory accesses, the runtime checks the tag, strips it from the pointer, and invokes the callback of the respective *m*store if necessary.

Tagged pointers vs. range checks. One known limitation of tagged pointers is that the application code might reset the higher bits of a pointer. Prior work [47] and our own experience suggest that this is rarely the case in practice. An alternative approach is to differentiate between *m*stores by assigning a unique memory range to each. Using tagged pointers turned out to be faster in our experience because the range check requires additional memory accesses.

3.3.2 Memory management and file I/O calls

The compiler replaces all the memory management operations selected by the instrumentation policy with the calls to the runtime that invokes the appropriate *m*store callbacks.

Similarly, file I/O operations are replaced with runtime wrappers. On `open`, the runtime determines whether to use an *m*store with the current file and registers its file descriptor. An I/O call using this file descriptor will be redirected to the respective *m*store.

3.3.3 `libc` support

Invoking an uninstrumented function on an *m*store pointer would result in undefined behavior. We assume that most application libraries are available at compile time. However, `libc` is not instrumented and we provide wrappers instead, similarly to other works [47, 59].

There are two main reasons to not instrument `libc`. First, doing so would create a bootstrapping problem since *m*stores might use `libc` calls. Second, SGX runtimes such as SCONE [18] use proprietary, closed-source versions of `libc`. Wrapping `libc` functions allows CoSMIX to be portable across multiple enclave execution frameworks.

CoSMIX provides wrappers for most popular `libc` functions (about 80), which suffices to run the large production applications we use in our evaluation. Adding wrappers for more functions is an ongoing effort.

In addition to stripping the pointer tag, these wrappers must guarantee access to virtually contiguous input/output buffers from uninstrumented code, instead of using *m*store *m*pages. Thus, where necessary, the wrappers use a temporary buffer in regular memory to stage the *m*store buffer before the library call and write it back to the *m*store after the call.

3.3.4 Translation caching

Minimizing the instrumentation overhead is a fundamental requirement for CoSMIX. The overheads are caused mainly by runtime checks of the pointer type and invocation of the *m*store logic on memory accesses.

To reduce these overheads, CoSMIX first runs aggressive generic code optimizations, reducing memory accesses. It

also avoids invoking *m*store page fault handlers for recurrent accesses to the same *m*page.

Opportunistic caching. We introduce a small (one cache line) TLB stored in the thread-local memory. This TLB is checked upon each access to the *m*store. The runtime pins the page in the *m*store while the *m*page translation is cached, and unpins when it is flushed. To support multiple threads, the TLB notification callbacks use a reference counter for each *m*page. The *m*page can be evicted if the counter drops to zero, eliminating the need for explicit TLB invalidation. We choose small TLB size (5) for its low lookup times. Increasing the size did not improve performance in our workloads.

Translation caching in loops. The TLB captures the locality of accesses quite effectively, but in loops, the performance can be further improved by transforming the code itself to use the *m*page base address without checking the TLB.

For example, in the case of an array allocated in an *m*store and sequentially accessed in a tight loop, most accesses to the *m*store are performed within the same *m*page. Therefore, replacing the code in the loop to check the TLB only at m*page boundaries* would result in near-native access latency.

To perform this optimization, CoSMIX has to (a) determine the iterations in which the same *m*page gets accessed, and (b) determine the pointer transformation across the iterations. For (b), CoSMIX uses the scalar evolution analysis [83] in the compiler to find predictable affine transformations for the pointers used in the loop. For (a) it injects a code that determines the number of iterations where the cached translation hits the same *m*page, recomputing the new base pointer and dropping the translation from the TLB when crossing into a new *m*page. Finally, it replaces the original accesses to the *m*store with the accesses to the *m*page's base pointer with the offset, which is updated across the loop iterations according to the determined transformation.

3.4 Discussion

Security guarantees. CoSMIX itself does not change the security of SGX enclaves. Its runtime neither accesses untrusted memory nor leaks secret information from the enclave. However, the security of *m*stores depends on their implementation: SUVM has the same security as SGX paging [61] and the ORAM *m*store introduces a controlled side-channel [87] protection mechanism not available in the bare-metal SGX [67]. We note, however, that CoSMIX does not guarantee that the code using an *m*store will indeed maintain that *m*store's security properties. For example, in case of the ORAM *m*store, user code must not use sensitive values read from ORAM in a data/control dependent manner because doing so might break the data pattern obfuscation [65].

Other *m*store applications. *M*stores are general and can be used to implement many other useful extensions. For example, implementing bounds checking for 32-bit address space enclaves as in SGXBounds [47] becomes easy. All it takes is adding an extra 4 bytes for each buffer allocation to store the lower bounds of the object and tag the pointer's highest 32 bits with its lower bounds' address. Then, every memory access is instrumented to check these bounds. The SGXBounds *m*store can implement this logic in its callback functions.

Another useful application is transparent inter-enclave shared memory, which may enable execution of multi-socket enclaves and support for secure file sharing.

Eleos vs. CoSMIX. The starting point of our design was Eleos [61]. There, the authors introduce *s*pointers, which are similar to C++ smart pointers. In Eleos all necessary memory accesses are replaced with *s*pointers and translations are cached in the *s*pointers themselves. On every access, *s*pointers perform bound checking, to make sure that pointer arithmetic on the *s*pointer did not cross to a new page. However, the *m*page bound check impacts performance greatly, even when the caching is limited to the scope of a function. Second, maintaining static translation for *m*store pointers complicated the design. For example, pointer-to-integer casts had to be invalidated, forcing a reverse mapping in *m*stores.

A key lesson from CoSMIX is that *caching the translations only in cases of high access locality is enough to leverage the performance benefits and simplify the design.*

Limitations. Inline assembly snippets, while quite rare, cannot be easily supported. CoSMIX considers them as an opaque function call. It injects code to check whether passed arguments are *m*store pointers. If so, CoSMIX aborts the program and notifies that manual instrumentation is necessary.

Hardware extensions. We hope that CoSMIX will motivate hardware developers to support *secure in-enclave fault handling*. This functionality would allow enclaves to control the execution flow of the page faults. For example, an enclave might refuse to resume execution after a fault unless a correct secure fault handler has been invoked. As a result, secure page faults would allow extending enclaves with cached *m*store functionality, such as the secured `mmap` provided by CoSMIX, albeit at a significantly higher performance costs due to transitions to/from untrusted mode. Moreover, hardware support for secure fault handlers would enable paging of code pages not supported by CoSMIX.

However, direct *m*stores such as ORAM cannot be supported in the same way, since they invoke the fault handler for every memory access. Therefore, good performance could be achieved only by much more intrusive modifications that would avoid enclave mode transitions. Additionally, enclave hardware evolves slowly. For example, the SGX2 specification was published in 2014, yet is still not publicly available in mainstream processors [20]. CoSMIX on the other hand, can be used to enhance enclaves' functionality today.

4 Evaluation

Implementation. CoSMIX implementation closely follows its design [2]. The compiler prototype is based on the LLVM 6.0 framework and is implemented as a compile-time module pass, consisting of 1,080 LOC. We compile applications using the Link-Time Optimization (LTO) feature of LLVM and pass them as inputs to the compiler pass.

CoSMIX uses the SVF framework [79, 80] to perform Andersen's pointer analysis with type differentiation. CoSMIX runtime is written in C++ and consists of 1,600 LOC. CoSMIX's configuration file is `JSON` formatted and CoSMIX uses JsonCpp [3] to parse it. All *m*stores are written in C++. Their implementation follows the design described in Section 3. The implementations of SUVM, ORAM and `mmap` *m*stores are 935 LOC, 551 LOC, and 1,108 LOC respectively. `mmap` *m*store leverages the SCONE file shields, which override the `read/write` calls in `libc` to implement integrity checks and encryption for file I/O operations. This is one of the examples when our design choice to use `libc` wrappers rather than `libc` instrumentation pays off.

Setup. Our setup comprises two machines: server and client. The client generates the load for the server under evaluation. The client and the server are connected back-to-back via a 56Gb Connect-IB operating in IP over Infiniband [27] (32Gbps effective throughput) to stress the application logic and avoid network bottlenecks.

For the server, we use Dell OptiPlex 7040, with Intel Skylake i7-6700 4-core CPU with 8 MB LLC, 16 GB RAM, and 256 GB SSD drive, Ubuntu Linux 16.04 64-bit, Linux 4.10.0-42, and Intel SGX driver 2.0 [2]. We use LLVM 6.0 to compile the source code. As recommended by Intel, we apply L1TF microcode patches [9]. The client runs on a 6-core Intel Xeon CPU E5-2620 v3 at 2.40GHz with 32GB of RAM, Ubuntu 16.04 64-bit, Linux 4.4.0-139.

Methodology. Unless otherwise specified, we run all the workloads in SGX using SCONE [18]. We run each test 10 times and report the mean value, with the standard deviation below 5%. We compile all workloads as follows: (1) compile to LLVM IR with full optimizations (-O3) and invoke LLVM's IR linker to link all IR files; (2) invoke CoSMIX LLVM pass for code instrumentation; (3) use the SCONE compiler to generate an executable binary linked with its custom libc. We skip step (2) when compiling the baseline.

Summary of workloads. We evaluated several production applications and benchmarks, detailed in Table 2. CoSMIX successfully instruments large code bases using only *a few or no code annotations, and no source code changes*.

[2]CoSMIX source code is publicly available at `https://github.com/acsl-technion/cosmix`.

Workload	LOC	Changed LOC	*m*store
`memcached` [35]	15,927	1	SUVM
Redis [8]	123,907	0	SUVM
SQLite [62]	134,835	2	secure `mmap`
Phoenix suite [66]	1,064	1/bench	SUVM ‖ secure `mmap`
Face verification [61]	700	1	SUVM → ORAM

Table 2: Summary of the evaluated workloads. ‖ - side-by-side, → - stacked. LOC includes all statically linked libraries.

Data size	Baseline	SUVM	ORAM
16 MB	0.7μsec	0.9μsec ($-1.28\times$)	32.3μsec ($-46.1\times$)
256 MB	14.4μsec	1.5μsec ($9.6\times$)	590.6μsec ($-41\times$)
1GB	19.9μsec	1.6μsec ($12.4\times$)	1.23*m*sec ($-61.8\times$)

Table 3: *m*store latency to fetch a 4 KB page. Baseline is native memory access.

4.1 *M*store performance

First, we measure the latency of random accesses to *m*stores and compare them to native memory accesses in the enclave. We evaluate scenarios with small and large memory usage where the latter causes SGX page faults. We report the results for SUVM and ORAM *m*stores and exclude the `mmap` *m*store because it is similar to SUVM. We measure the average latency to access random 4 KB pages over 100k requests.

Table 3 shows the results. For small datasets, SUVM incurs low overhead compared to regular memory accesses. However, for large data sets which involve SGX paging, it is about $10\times$ faster. This is because SUVM optimizes the enclave paging performance by eliminating enclave transitions [61]. As expected, ORAM *m*store access is between $30\times$ to $60\times$ slower than the baseline, even when covering a small range of 16 MB. This result indicates that selective instrumentation for ORAM is essential to achieve practically viable systems.

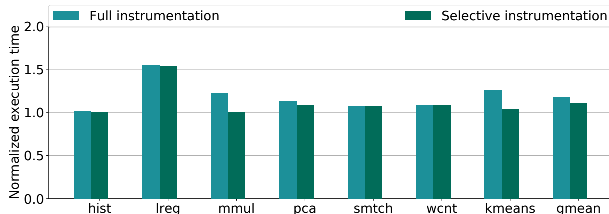
4.2 Instrumentation and *m*store overheads

We instrument all seven benchmarks in the Phoenix suite [66] to measure CoSMIX's instrumentation overheads. Each benchmark is small, making the results easier to analyze.

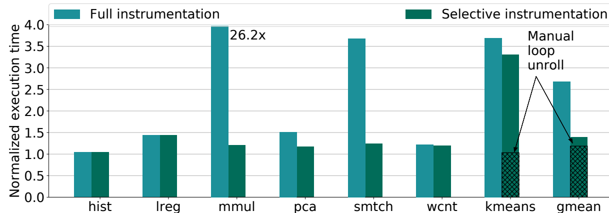
We evaluate 4 configurations: (1) Full automatic instrumentation using SUVM and `mmap` *m*store. Both *m*stores are run side-by-side because Phoenix uses both dynamic allocations and memory-mapped files. (2) Same but with an *empty m*store. All the pointers are instrumented, but the *m*store logic is not invoked. (3) Selective instrumentation where we manually annotate only the inputs. (4) Same but with an empty *m*store. For benchmarks that use `mmap`, the baseline reads the entire input file to memory.

Measuring an empty *m*store allows us to distinguish between overheads of pointer instrumentation and *m*stores.

To focus solely on the CoSMIX overheads, we use the small dataset shipped with Phoenix so no paging operation will occur. The only exception is the histogram benchmark, for which we synthetically resize the dataset to 25 MB. We exclude *m*store initialization and preload all the datasets into



(a) Instrumentation-only cost (empty mstores).



(b) Full cost with mstores.

Figure 4: CoSMIX instrumentation overheads for the Phoenix suite running in the enclave normalized to the execution of non-instrumented binaries. Lower is better.

SGX memory, both in the baseline and in CoSMIX measurements, to stress the runtime components of the system.

Often *m*stores can be tuned to reduce the translation overhead, by increasing the *m*store page size. As a result, the accesses in a loop might touch fewer pages, enabling more efficient use of CoSMIX's TLB. Therefore, we manually tune the page size, setting it to 256 KB for kmeans, 16 MB for word count, 64 MB for lreg, and 4 KB for the rest of the benchmarks, as in all the other experiments.

Figure 4 shows the results. Figure 4b shows the overhead for both CoSMIX's instrumentation and *m*store logic. Figure 4a excludes the *m*store logic. In each figure, the rightmost bar refers to the selective instrumentation of accesses to the input data alone, and the other bar refers to full instrumentation of all dynamic allocations and `mmap` calls.

Instrumentation overheads. The runtime overheads excluding *m*stores are relatively small, with an average (geomean) of 17% for full instrumentation and 10% for the input instrumentation alone, with the worst case of 50% in lreg.

Full instrumentation. With the full instrumentation, *m*store logic dominates the runtime overheads, ranging from almost none for histogram to 26× for matrix multiplication. Such variability stems from the different ways memory is accessed. Specifically, if the program exhibits poor access locality, or the CoSMIX compiler fails to capture the existing locality in a loop, the runtime will not be able to optimize out the calls to the *m*store inside the loop, resulting in high overheads.

Selective instrumentation. Instrumenting only the input buffers results in dramatically lower overheads, ranging from 5% to 15%. The only pathological case is kmeans, where the CoSMIX compiler fails to optimize accesses to the multidimensional input array because the inner array is too short. Unrolling this loop reduces the overhead to about 5%. We plan to add automatic optimizations for this case in the future.

	CoSMIX secure `mmap`	`read` **no cache**	`read` **1 MB cache**	`read` **16 MB-60 MB cache**
Query latency	2.4μsec	10.7μsec	4.5μsec	1.7μsec
Speedup		4.4×	1.8×	−1.4×

Table 4: SQLite performance with secure `mmap` *m*store.

Contribution of CoSMIX optimizations. We measure the performance of the *selective* instrumentation while disabling the runtime TLB and compiler loop optimizations (§3.3.4). We find that these two features *are essential* to make CoSMIX practical and keep the instrumentation overheads low. The slowdown ranges from 4× for word count and kmeans to 55× for histogram and 197× for lreg, making the system unusable. In comparison, the optimized version brings the overheads down to 4% and 44% for histogram and lreg. The geomean of the unoptimized selective instrumentation is 16.4× compared to 20% with the optimizations enabled.

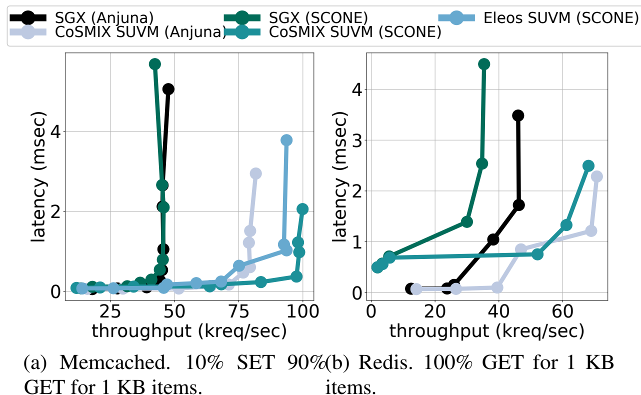
CoSMIX overheads for non-enclave execution. For completeness we perform the same experiment with Phoenix but now outside the enclave. As expected, the relative overheads increase as compared to the in-enclave execution, with up to 50% geometric mean slowdown when using selective instrumentation with SUVM and `mmap` *m*stores and up to 25% when using an empty *m*store. We attribute this discrepancy to SGX's memory encryption engine [40], which provides confidentiality and integrity to memory accesses and therefore offsets the CoSMIX instrumentation overheads.

4.3 Secure `mmap` with SQLite

SQLite is a popular database, but running it in SGX with `mmap` while providing encryption and integrity guarantees for the accessed files is not possible today. To run SQLite with `mmap` support, we use the secure `mmap` *m*store. We configure the *m*page size to be 4 MB. We use SQLite v3.25.3, and evaluate it with kvtest [10], shipped with SQLite to test read access latency to DB BLOBs. We use a database stored in a 60 MB file holding 1 KB BLOBs. The database is sized to fit in SGX physical memory. This allows us to focus on the evaluation of the file access logic rather than SGX paging (refer to §4.4 for paging evaluation).

As a baseline, we evaluate SQLite with its internal backend that uses `read/write` calls instead of memory-mapped files. In this configuration, SQLite implements its own optimized page cache for data it reads from files. In the evaluation, we vary the SQLite page cache size from disabled (1 KB) to 60 MB (no misses). We measure the average latency of 1 KB random read requests over 1 million requests.

Results. CoSMIX enables execution of an unmodified SQLite server that uses `mmap` to access encrypted and integrity-protected files. Such execution was not possible without CoSMIX. Moreover, as we see in Table 4, the secure *m*store enables 4.4× faster queries compared to the SQLite without



(a) Memcached. 10% SET 90% GET for 1 KB items.

(b) Redis. 100% GET for 1 KB items.

Figure 5: Performance improvement using the SUVM *m*store in production key-value stores, each using a 600 MB database (6× the size of SGX secure memory)

page cache. This case illustrates the CoSMIX performance benefits for applications that do not implement their own optimized page cache.

On the other hand, enabling the SQLite page cache allows us to evaluate the instrumentation overheads. This is, in fact, a conservative estimate, because the baseline is hand-optimized and implements the necessary functionality by itself, versus the general instrumentation and generic CoSMIX's page cache. Even in this worst-case scenario, CoSMIX is only about 40% slower than SQLite.

4.4 Optimizing memory-intensive workloads with the SUVM *m*store

To demonstrate CoSMIX's support for different SGX execution frameworks, we run the following experiments both in SCONE [18] and Anjuna [1].

We use CoSMIX to accelerate SGX execution of applications with a large memory footprint. We choose Redis and `memcached` key-value stores as representatives. Both run with data sets of 600 MB – about 6× larger than the SGX enclave-accessible physical memory. These applications experience a significant slowdown due to SGX paging overheads. The goal is to reduce these overheads using the SUVM *m*store.

Memached. `memcached` uses a slab allocator to manage its memory. We annotate a *single line of code* where the memory is allocated, making SUVM *m*store manage all items.

We evaluate `memcached` v1.4.25 [35] using the memaslap load generator shipped with libmemcached v1.0.18 [6]. Our workload consists of 10% SET and 90% GET requests for 1 KB items (key+value) as used in prior works [61], with requests uniformly distributed to stress the memory subsystem.

We compare the instrumented `memcached` with SUVM to native SGX execution. In addition, we run a *manually optimized* version of `memcached` with the SUVM used in Eleos [61]. Notably, in Eleos, the authors changed `memcached` internals to create a shadow memory buffer for the slab allocator. This is an intrusive change that CoSMIX eliminates completely. All runs are performed on 4 cores. Figure 5a shows that SUVM *m*store boosts the throughput by 1.9× and 2.2× compared to native SGX execution in Anjuna and SCONE respectively. The difference between the frameworks correlates with the relative time each of them spends resolving page faults. Interestingly, the CoSMIX version is about 7% *faster* than Eleos thanks to its compiler optimizations.

Redis. Manually annotating Redis with its 130 KLOC would be too tedious. Further, its memory management involves too many allocations, making annotation challenging. Therefore, we use automatic instrumentation *without code changes*.

To achieve high performance, we leverage CoSMIX's ability to perform conditional instrumentation. Specifically, CoSMIX introduces *runtime checks* that determine whether to allocate a buffer in an *m*store or in regular memory based on the requested allocation size. In Redis, we configure the policy to redirect all allocations in the range of 1 KB-10 KB to the SUVM *m*store. The intuition is to use SUVM only for keys and values and keep native memory accesses for the rest.

We use Redis v5.0.2 [8], and evaluate it using the memtier v1.2.15 official RedisLab load generator [7]. We configure memtier to generate uniformly distributed GET requests for 1 KB items as used in prior works [18].

Figure 5b shows that Redis with CoSMIX achieves about 1.6× and 2× higher throughput compared to native SGX execution in Anjuna and SCONE respectively. *These results demonstrate the power of CoSMIX to improve the performance of an unmodified production system.*

4.5 Protecting data with the ORAM *m*store

Selective instrumentation capabilities in CoSMIX are particularly useful when using heavyweight *m*stores such as ORAM. ORAM is known to dramatically affect performance (Table 3).

We use ORAM to protect a face verification server [61] against controlled side-channel attacks [87] on its data store.

The server mimics the behavior of a biometric border control server. It stores a database with sensitive face images. When a person passes through border control, the client at the border kiosk queries the server whether the image of the person in the database matches the one taken at the kiosk.

The implementation stores the images in an array. The server fetches the image from the array and compares it with the input image, using the LBP algorithm [12]. This implementation is vulnerable to controlled channel attacks which leak the access pattern to SGX memory pages. Thus, an attacker may observe page access frequency and learn when a person passes through border control. Note that existing defenses against controlled channel attacks would be ineffective since they cannot handle legitimate demand paging [76, 60].

We use a database with 1,024 256 KB images from the Color FERET dataset [63], totaling 256 MB of sensitive data. We annotate the allocation of the database array to use ORAM

	Native SGX	ORAM	ORAM→SUVM
Throughput(req/sec)	203.1	23.4	34.7
Slowdown		8.6×	5.8×

Table 5: Selective instrumentation of face verification server.

(1 LOC) and compile with CoSMIX. As a result, the application accesses the sensitive data obliviously. In the experiments we configure the server to use 1 thread and the load generator to issue random requests, saturating the server.

We report the throughput achieved in Table 5. It shows that the ORAM *m*store introduces an 8.6× slowdown. We note that for a dataset of 256 MB, the ORAM *m*store overhead is about 41× more than native access, as reported in Table 3. This shows that selective instrumentation may make ORAM an attractive solution for some systems. However, with CoSMIX we can further reduce paging penalties.

ORAM→SUVM stacking. Although the application data is only 256 MB, PathORAM consumes about 860 MB due to its internal storage overheads. As a result, the SGX paging significantly affects the performance.

To optimize, we create a new ORAM→SUVM *m*store by stacking ORAM on top of SUVM. Only 1 LOC in the ORAM *m*store is annotated. The use of the combined ORAM→SUVM *m*store improves the overall performance by 1.5× compared to the ORAM *m*store alone (Table 5). Overall, selective instrumentation and *m*store stacking result in a relatively low, 5.8× slowdown of the oblivious system compared to native SGX execution. This performance might be acceptable for practical ORAM applications and requires no code changes.

5 Related Work

Enclave system support. Recent works proposed systems to protect unmodified applications using enclaves [18, 21, 77, 81]. Other works proposed enclave enhancements [72, 47, 49], such as memory safety, ASLR, and enclave partitioning. Complementary to these works, CoSMIX provides system support for modular extensions to unmodified enclave applications.

Trusted execution environments. Previous works proposed different systems to protect applications from a malicious OS [30, 29, 42, 16, 15]. InkTag [42], for example, offers secured `mmap` service to applications; however, it relies on a trusted hypervisor with para-verification. CoSMIX puts its root of trust in hardware enclaves to implement in-enclave secure fault handlers.

Controlled side-channel mitigation. Previous works suggested the use of ORAM in SGX to improve its security [65, 67, 33, 88, 11, 50]. We believe that CoSMIX will allow the use of ORAM in many more applications via lightweight annotations. More efficient systems for mitigating the controlled side-channel attack have been proposed [22, 60, 76, 30]. For example, Apparition [30] uses Virtual Ghost [29], a compiler-based virtual machine, to restrict OS access to the page table. However, these systems do not support demand paging. CoSMIX protects applications that rely on demand paging from both a malicious OS and physical bus snooping attacks using the ORAM *m*store.

Customizing applications via paging mechanisms. Previous systems proposed using page faults to improve performance and enable quality of service functionality in OS, GPUs, and enclaves [41, 61, 74, 14]. CoSMIX enables using similar enhancements in secure enclave systems.

Recent works take advantage of the RDMA infrastructure to enable efficient and transparent access to remote memory by customizing the OS page fault handler [39, 75, 53, 37]. For example, LegoOS [75] uses paging to simulate an *ExCache* for disaggregated memory support. CoSMIX takes a similar approach for extending secure enclaves.

Software-based distributed shared memory systems were proposed to customize memory access logic across remote machines [68, 69, 70, 64, 19, 56, 32]. These systems either use the page fault handler, runtime libraries or instrumentation of applications. CoSMIX is inspired by these systems; however, the *m*store abstraction is more general and can support different memory access semantics, mixed or stacked in the same application.

Memory instrumentation. Much work has been done on instrumenting memory accesses using binary instrumentation tools [51, 24, 57, 52, 71] and compiler-based instrumentation [73, 47, 13, 31]. CoSMIX enables low-overhead selective memory instrumentation, specifically tailored for enclaves.

6 Conclusions

CoSMIX is a new system for modular extension of the memory layer in unmodified applications running in enclaves. It sidesteps the lack of hardware support for efficient and secure page fault handlers in existing architectures. CoSMIX enables low-overhead and selective instrumentation of memory accesses via a simple yet powerful *m*store abstraction.

We show how compilation with CoSMIX both speeds up execution and adds protection to production applications. We believe that *m*stores may become a useful tool for facilitating the development of new secured systems.

Secured Routines: Language-based Construction of Trusted Execution Environments

Adrien Ghosn James R. Larus Edouard Bugnion
EPFL, Switzerland

Abstract

Trusted Execution Environments (TEEs), such as Intel SGX enclaves, use hardware to ensure the confidentiality and integrity of operations on sensitive data. While the technology is available on many processors, the complexity of its programming model and its performance overhead have limited adoption. TEEs provide a new and valuable hardware functionality that has no obvious analogue in programming languages, which means that developers must manually partition their application into trusted and untrusted components.

This paper describes an approach that fully integrates trusted execution into a language. We extend the Go language to allow a programmer to execute a `goroutine` within an enclave, to use low-overhead channels to communicate between the trusted and untrusted environments, and to rely on a compiler to automatically extract the secure code and data. Our prototype compiler and runtime, GOTEE, is a backward-compatible fork of the Go compiler.

The evaluation shows that our compiler-driven code and data partitioning efficiently executes both microbenchmarks and applications. On the former, GOTEE achieves a 5.2× throughput and a 2.3× latency improvement over the Intel SGX SDK. Our case studies, a Go `ssh` server, the Go `tls` package, and a secured keystore inspired by the go-ethereum project, demonstrate that minor source-code modifications suffice to provide confidentiality and integrity guarantees with only moderate performance overheads.

1 Introduction

Our era is defined by the emergence of a digital society in which established notions of privacy, confidentiality, and trust are undercut by the shortcomings of today's technology, which is increasingly reliant on cloud computing. In the cloud, developers and users implicitly trust the cloud provider but are still susceptible to: (1) hardware and firmware flaws, such as the recent Meltdown [41] and Spectre [36] attacks, (2) vulnerabilities within the hypervisor [3], (3) exploits in libraries and Software as a Service (SaaS) infrastructures [1,2,4,5], (4) malicious employees with physical and administrative access to both computer and storage resources, and (5) intrusive or extra-territorial government surveillance [10,12,18].

To address these concerns, processor vendors, following ARM's lead [9], introduced Trusted Execution Environments (TEEs), a hardware mechanism based on memory encryption and attestation that isolates program execution and state from the underlying operating system, hypervisor, firmware, I/O devices, and even people with physical access to a machine. TEEs have been portrayed as *the* solution to the problem of trust in the cloud [16,17,39,51]. In particular, Intel SGX [6] partitions hardware and software into two mutually distrustful domains: a CPU, trusted user code, and a specified region of memory form the *trusted* domain, while the remainder of the hardware and software form the *untrusted* domain. SGX *enclaves* execute trusted user code in a trusted domain. Entering an enclave guarantees, through hardware, the confidentiality and integrity of the enclave's code, data, and execution.

Despite SGX's availability on current-generation processors, uptake has been slow, probably due to the absence of support on server-grade CPUs, the difficulty of programming enclaves, their performance overhead, and the need to refactor applications. The private messaging application Signal [43] is one of the few applications that appears to use enclaves, and Microsoft Azure only recently offered the first cloud solution to expose SGX features [42,45]. A major challenge is that this new technology lacks a clear programming model. Previous solutions fall into two broad categories: (1) run complete user applications in the trusted domain [16,17] and (2) separate the portions of a program that require trusted execution [7,8,40]. Solutions in the first category provide an abstraction, such as an operating system [17] or a container [16], to execute unmodified applications in an enclave. The other alternative requires a developer to identify and partition [7,8,46], or provide annotations that a program analysis tool can use to partition [40], an application into trusted and untrusted components. None of these prior approaches integrates the TEE into language-specific abstractions and semantics.

This paper describes an approach that fully integrates trusted execution into a modern programming language in an appropriate manner. We extend the Go language to allow a programmer to execute a `goroutine` within an enclave, to use low-overhead channels to communicate between the trusted and untrusted environments, and to rely on the compiler to automatically extract the code and data necessary to run the enclave. Our solution provides language support for trusted execution that is idiomatically compatible with the Go programming language.

We introduce *secured routines*, a new language-based feature that hides the hardware intricacies with little overhead. A secured routine is a user-level thread that executes a closure, *i.e.,* a function call, in the enclave at the request of untrusted code. The secured routine abstraction cleanly distinguishes trusted and untrusted code. Communications between the two domains are possible solely via *cross-domain channels*, an extension to native Go channels that deep-copies values to prevent cross-domain pointer references.

GOTEE extends the Go programming language with a single keyword, `gosecure`, to identify secured routines. GOTEE is an open-source fork of `golang/go` [15]. Starting from `gosecure` calls, the compiler identifies the minimal code required within the enclave and extracts it into a statically-linked trusted binary. Trusted and untrusted domains have their own runtime, memory management, and scheduler. GOTEE coordinates interactions between trusted and untrusted code, replaces control transfers between these domains with inexpensive synchronized data transfers using strongly-typed cross-domain channels.

Our contributions include:

- A language-based, expressive, strongly-typed, high-performance, remote-execution model for TEEs that strengthens isolation between trusted and untrusted code.
- A practical implementation of these ideas using the Go programming language and runtime. Our evaluation using microbenchmarks demonstrates that an enclave core serving secured routines can achieve 5.2× the throughput of domain-crossing control transfers.
- A demonstration that secured routines provide an expressive model to implement secured applications: we partitioned the `tls` module (a built-in Go library), protected a full ssh server, and extended the go-ethereum keystore (a popular cryptocurrency client) to isolate all operations that access private keys and certificates without a significant loss of performance.

We describe the necessary background (§2), the secured routine abstraction (§3), the implementation of GOTEE (§4), and evaluate it using both microbenchmarks and three security-sensitive applications (§5). Finally, we discuss possible architectural improvements in §6, related work in §7, and conclude in §8.

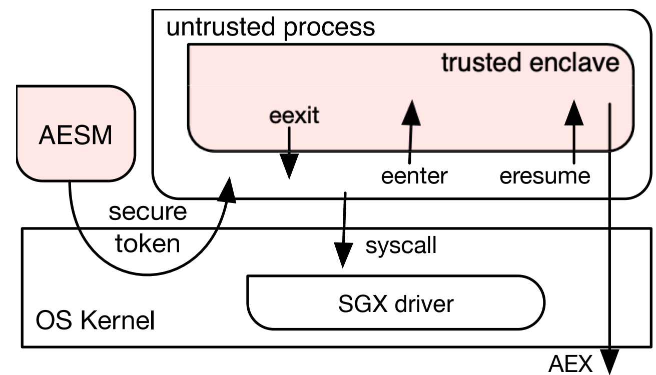

Figure 1: Trusted Execution Environments with Intel SGX; the enclaves and trusted parts are colored.

2 Background

2.1 Intel Software Guard Extension

Intel Software Guard Extension (SGX) [6], introduced in 2015 with Intel's sixth generation Skylake processor, allows user-level creation of *enclaves*. These are contiguous regions of virtual memory, protected against outside access and modification, even by software running at high privilege levels or by I/O devices.

Figure 1 illustrates the partition of a process between secure, trusted code and data and non-secure, untrusted code and data. SGX enforces an asymmetric trust model: the enclave has access to the entire memory, while untrusted code is unable to access or modify enclave memory. SGX further ensures that control from the untrusted domain enters the enclave only at pre-approved entry points. In SGX, Intel provides the root of trust through the `aesm` module that cryptographically ensures the validity of the initial state of the enclave.

SGX reserves, at boot time, a contiguous portion of physical memory, called the *Processor Reserved Memory* (*PRM*), with a maximal size of 128 MB. A 94 MB subset of this region, called the *Enclave Page Cache* (*EPC*), is used to allocate enclave memory pages. The integrity of the EPC is ensured through Merkle trees implemented in hardware [11]. The EPC size is a hard limitation on the amount of code and data that can be loaded into an enclave without incurring expensive page evictions to regular DRAM [17, 53]. The CPU's Memory Management Engine (MME) ensures confidentiality by encrypting cache lines evicted to memory and by decrypting them as they are brought into the CPU running in enclave mode; this reduces the available memory bandwidth by 4× [53].

Creation of an enclave requires the execution of a complex instruction sequence using new instructions such as `ecreate`, `eadd`, `eextend`, and `einit` that respectively create the enclave; define its resources together with their initial state and

access rights; and finally initialize the enclave. The number of concurrent threads allowed inside the enclave corresponds to the number of `eadd`ed Thread Control Structures (*TCS*) and is fixed at enclave initialization.

After enclave initialization, user-level software uses the `eenter` instruction to perform an `ecall`, a control transfer to a pre-defined location within the enclave (Figure 1). The `eexit` instruction allows to perform `ocalls`, *i.e.,* a voluntary control transfer to untrusted code. SGX also supports asynchronous enclave exits (AEX) to service interrupts and exceptions, which is necessary since the enclave forbids privileged instructions. An AEX saves the current state of the enclave within the EPC, restores the untrusted context, and transfers control to the operating system handler. The untrusted code resumes enclave execution by performing an `eresume`.

Finally, SGX provides a remote attestation mechanism that allows developers to verify the integrity of the software in the enclave. As part of enclave creation, developers need to provide a *measurement* of the enclave, *i.e.,* a signed hash of the SGX instructions and arguments used to instantiate the enclave, as well as of selected portions of the enclave's code and data. A remote party can compare this measurement with its expected, precomputed value and proceed with the enclave's execution only if the two values match.

2.2 Building Secured Systems

One approach to utilizing SGX is to run all of an application in the enclave. The literature contains examples of complex abstractions—including an entire operating system, Haven [17]; a library operating system, Graphene [23]; and a container platform, SCONE [16]—running in SGX. While convenient for developers and effective at reducing expensive enclave crossings [53], this approach has significant drawbacks: (1) it greatly expands the amount of code running inside the enclave, which puts pressure on system resources and incurs pervasive memory decryption overheads and (2) it brings into the enclave code and third-party libraries—not necessarily used, understood, or validated—which can facilitate attacks on the enclave (*e.g.,* ROP [47]).

Another approach necessitates a deeper understanding of an application, as it requires splitting the application's code and data into trusted and untrusted portions, following the *Intel SGX Software Development Kit* (*SDK*) [7] model. This SDK is a set of C/C++ libraries and tools that enable programmers to create and deploy enclaves. The Intel SGX SDK exposes an API similar to the SGX instructions. Trusted and untrusted code and data reside within distinct source files. A configuration file describes the required *ecall*s and *ocall*s functions. The compilation process first invokes an IDL compiler to generate boilerplate code and then compiles the enclave code as a position-independent binary with all dependencies statically linked, invokes a signing tool on this `.so` to meter the enclave's code, and finally compiles the untrusted application code as a regular executable.

SCONE [16] and Eleos [44] both rely on message passing to implement asynchronous system calls and avoid expensive enclave exits. Following the same approach, Intel recently published `switchless` [14], a (under-development) mini-framework that provides a simple C++ messaging mechanism on top of the SDK.

Asylo [31] is a C++ framework, compatible with gRPC [32], that abstracts TEE technologies behind a concise API and a set of C++ classes. From a practical point-of-view, Asylo is an improved version of Intel's SDK that exposes a smaller API, requires less boilerplate code, supports different TEE implementations, and provides transparent support to perform system calls from the enclave.

Glamdring [40] automates code partitioning, as it only requires a developer to mark data that needs to be protected. It then relies on static analysis to determine the portion of code that accesses this data and needs to run within the enclave. As an optimization, Glamdring uses heuristics to enlarge the trusted code base and limit the number of expensive enclave crossings. This can help balance a trade-off between EPC memory consumption and the number of domain crossings. Glamdring provides less fine-grained control over code partitioning than the Intel SGX SDK, but hides the technology's intricacies and exposes a very simple programming model.

2.3 SGX Limitations

The SGX technology, and its implementation on current Skylake processors, presents major performance challenges: while the magnitude of these overheads may change in the future with refinement of the processor's micro-architecture, or by adding dedicated silicon, these overheads are, to some extent, tied to the mechanisms providing confidentiality and integrity in the SGX design.

The limited EPC working set and the reduced memory bandwidth are inherent in the design. Similarly, the control-flow transitions between the trusted and untrusted execution (*i.e.,* ecalls, ocalls, and AEX) are expensive because of TLB shootdowns, CPU state changes, and cache flushes needed to mitigate foreshadow attacks [22]. These domain crossings are an order of magnitude more expensive than a system call [53], between $\sim$2µs [53] and $\sim$3.5µs on our hardware. This corresponds to a throughput of less than 1M enclave entries per second with four cores performing `ecalls` in parallel (see §5.2). Keep in mind that system calls within an enclave require a domain crossing, as SGX is limited to user-level execution, and as a consequence these calls also become an order of magnitude more expensive.

Put together, these limitations require a programmer to worry about the size of the trusted code base and the trusted working set, to reduce the exposed attack surface as well as the frequency of EPC page evictions; to optimize the application for cache locality; to understand precisely the threading model

of the application; and to minimize domain crossings, system calls, interrupts, and signals.

3 Design

The *secured routine* extension to Go enables GOTEE to partition an application's code, data, and execution between trusted and untrusted domains, while *cross-domain channels* reinforce memory isolation and enable cross-domain communication and cooperation. This section presents a high-level description of the design and semantics of GOTEE's extensions.

3.1 Threat Model

We follow the threat model of other work in SGX [16, 17, 23, 40] in which an adversary tries to access confidential data or to damage the SGX enclave's integrity. The attacker has administrative access to the machine and control over both hardware and software, and may modify any code or data in untrusted memory, including the operating system and the hypervisor. We consider Iago attacks [24] for GOTEE's runtime and system call interposition mechanism in Section 4.3.

Denial-of-service attacks, a known limitation of SGX [26], and hardware side channels (*e.g.,* based on caches, page faults, or branch shadowing) are out of scope. We assume a correct underlying implementation of SGX that provides confidentiality and integrity for enclave code and data.

3.2 Quick Overview of `Golang`

The Go programming language (`golang`) is a modern, memory-safe, garbage-collected, structurally-typed, compiled, systems programming language. Go supports concurrency based on the Communicating Sequential Processes (CSP) model [33]. The unit of execution within a Go program is called a *goroutine*, a user-level thread executing a closure that is created by prefixing a function call with the `go` keyword. Goroutines are multiplexed and scheduled on a pool of operating system threads, using a cooperative scheduling model implemented by the Go runtime. Goroutines communicate and synchronize using *channels*, which are synchronized, typed message queues with copy and blocking read/write semantics.

3.3 Secured Routines & Cross-domain Channels

From a programming point of view, a secured routine provides a simple and familiar abstraction that allows a programmer to execute a goroutine within an enclave and to use cross-domain channels to communicate between the trusted and untrusted environments.

```
1 var secretKey *Key
2 func generateSymKey(*io.Reader) *Key {...}
3
4 func InitSymKey(done chan bool){
5     fmt.Println(``Creating a new secret key``)
6     secretKey = generateSymKey(rand.Reader)
7     done <- true
8 }
9
10 func EncryptServer(request, reply chan []byte){
11     for {
12       msg := <- request
13       reply <- secretKey.Encrypt(msg)
14     }
15 }
16
17 func TrustedEncryption(msg []byte) []byte{
18     done := make(chan bool)
19     gosecure InitSymKey(done)
20     _ = <- done
21     request := make(chan []byte)
22     reply := make(chan []byte)
23     msg := []byte(``The quick brown fox...``)
24     gosecure EncryptServer(request,reply)
25     request <- msg
26     res := <- reply
27     fmt.Println(``Encryption done``)
28     return res
29 }
```

Listing 1: Using secured routines to isolate a secret key within the TEE.

Listing 1 presents a sample program that secures a secret encryption key, `secretKey`, within the enclave. The `TrustedEncryption` function uses the `gosecure` keyword to spawn a secured routine that creates the key within the enclave. A subsequent `gosecure` call spawns an encryption server, `EncryptServer`, within the enclave. The untrusted code sends the message to the server (line 25) and gets back the encrypted result (line 26).

The programmer relies on `gosecure` to inform the compiler how to partition the code between trusted and untrusted domains. The compiler determines the functions that can be reached by the execution within the enclave, in this example `InitSymKey`, `EncryptServer` and their dependencies `fmt.Println`, `generateSymKey`, `*Key.Encrypt`, *etc.* GOTEE compiles these functions into a statically-linked executable.

Unlike prior work [7, 8, 40], secured routine's code partitioning does not require disjoint trusted and untrusted code. Functions can exist in both environments, *e.g.,* the function `fmt.Println` in Listing 1.

GOTEE hardens memory isolation between trusted and untrusted domains, as compared with the SGX hardware model, in three ways. First, each domain manages its own set of symbols, data, and global variables independently, allowing them to have distinct copies of data and globals. This also differs from Glamdring [40], where the trusted and untrusted

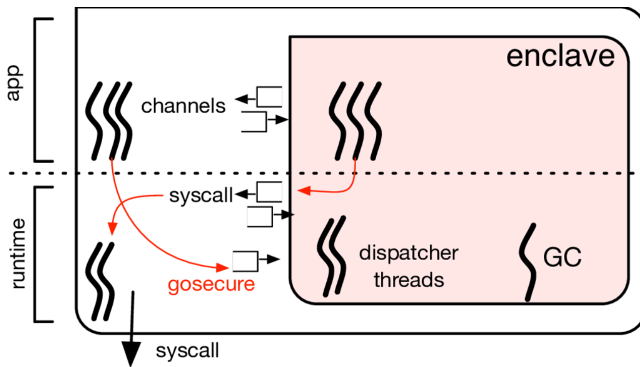

Figure 2: Channel-based cooperation between runtimes.

namespaces cannot overlap.

Second, GOTEE allows only *cross-domain channel*s across the trusted boundary. Cross-domain channels are an extension to the native Go channels allowing secured communications across domains with *deep-copy* semantics. Cross-domain channels are declared and used like regular go channels. However, they provide deep-copy semantics to prevent pointers from crossing a domain boundary. For example, in Listing 1, the `msg` byte slice received at line 12 is an in-enclave copy of the untrusted one sent at line 25.

Third, function arguments passed to secured routines, with the exception of cross-domain channels, are deep-copied inside the enclave by GOTEE's runtime. The deep-copy mechanism can be seen as a marshalling step similar to the one needed to send complex objects or structures over a network. GOTEE emits compilation warnings if a deep-copy, due to a secured routine or a cross-domain channel, requires to dereference a pointer.

While more restrictive than the original SGX model, GOTEE's design ensures that enclave code cannot be subverted or leak secrets by inadvertently dereferencing or writing to an unsafe memory location. All data that leaves the enclave does so by being explicitly sent over a cross-domain channel, while all data referenced by the application's trusted code resides in the enclave.

3.4 Runtime Cooperation

The secured routine abstraction requires mutually distrustful domains to cooperate. More specifically, it allows the untrusted domain to trigger execution of a closure within the trusted one. For example, when the untrusted execution reaches line 19 in Listing 1, the trusted runtime spawns a new routine that invokes the `InitSymKey(done)` closure.

Figure 2 presents the general overview of runtime cooperation. Both domains have their own code and data, their own thread pools to multiplex execution, and their own managed memory regions that are separately garbage collected. Between the two domains, dedicated cross-domain channels are used by the runtimes to trigger the execution of secured routines and to enable enclave system calls. Specifically, and unlike a normal `go` closure, a secured routine is implemented by passing its arguments on a dedicated channel not visible to `golang` programmers. The trusted runtime verifies the validity of the closure's entry point before scheduling it within the enclave. System call interposition operates in a similar manner: the trusted runtime copies the system call's arguments into a dedicated, hidden channel; the untrusted runtime then reissues the system call asynchronously and returns the result over a private channel.

Since full copy semantics are enforced between the two domains, each garbage collector can safely manage its own memory space without synchronizing with the other one.

3.5 Compatibility With SGX

The secured routine abstraction and its design are compatible with the SGX technology and its performance model:

Minimum trusted code: The code loaded into the trusted domain is automatically extracted by the compiler and is minimal. This is both security- and resource-efficient as it reduces the number of EPC pages consumed by the enclave as well as its attack surface.

Control transfers: Control transfers between the two domains are replaced with inexpensive, synchronized, and typed data transfers via cross-domain channels for both application-level communication as well as runtime synchronization. The expensive SGX domain crossings are only necessary in the initialization phase, to block threads when they are idle or in the stop-the-world GC phase, and to service an EPC miss.

Defensive programming: Cross-domain channels, used to launch closures and to invoke system calls, perform memory copies and sanitize arguments. Moreover, they are the single point of interaction between mutually distrustful domains and are therefore easy to augment with defensive programming techniques.

Thread multiplexing: The SGX environment chooses, at enclave creation time, the number of threads that can execute simultaneously within the trusted domain. The Go thread pool size can be fixed at the beginning of the execution to match the number of TCS in the enclave. This, however, does not impose any limitation on the number of concurrently executing secured routines, which means that concurrency is not bounded by this SGX limitation.

System call interposition: The use of channels to communicate and synchronize between the two runtimes simplifies system call interposition. The runtime detects system calls from trusted code, performs argument sanitization, copies arguments to untrusted memory buffers, and sends the system call to the untrusted runtime. Once the system call is serviced, the enclave runtime can perform additional checks to validate the result before delivering it to the application.

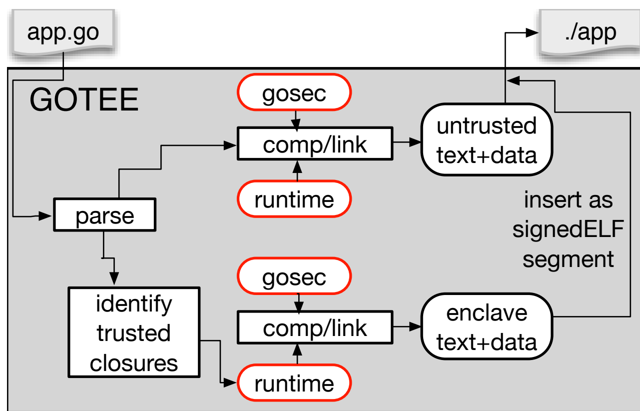

Figure 3: The GOTEE compilation pipeline.

No global variables or cross-domain references: secured routines reinforce the isolation between the two domains by prohibiting shared global variables and cross domain memory references. This forces data sharing to be explicit and passed through either typed communication channels or typed function arguments, with deep-copy semantics. This design eliminates implicit sharing and cross-domain references, which pose the risk of mistakenly leaking data and violating confidentiality.

Secured routines do not provide any guarantee or protection with regards to denial of service attacks. As with previous work [16,23,40], we consider the challenge of bringing secrets into the enclave to be out-of-scope for this paper. These are known, fundamental limitations of the SGX technology that GOTEE does not ameliorate.

Compatibility with other TEE designs: The secured routine abstraction is not tied to the SGX model. From a high-level point-of-view, secured routines and cross-domain channels allow cooperation between two (memory-isolated) peer environments that communicate solely via specific channels. The GOTEE compiler can be extended to support other TEE implementations without requiring application code modifications.

4 Implementation

The GOTEE compiler and runtime extend the Go system. This section describes the changes to the compiler, a new library written in Go that provides SGX support, and the changes to the runtime environment.

4.1 Compiler Support for `gosecure`

The GOTEE compiler is responsible for partitioning code and data according to the design of §3.3. GOTEE is a backward-compatible extension of the standard Go compiler with a new keyword `gosecure`, and an extension to Go channels, *cross-domain channels*. The changes are small, consisting of ∼400 modified lines and ∼2000 lines of new code written in pure Go.

Figure 3 illustrates the process: GOTEE compiles each instance of `gosecure` by type-checking and validating the closures at compile time. The generated code differs slightly from the standard goroutine support. On the caller side, the closure arguments are sent over a cross-domain channel. On the callee side, within the enclave, the runtime library pulls the in-enclave copy of the closure arguments and a function identifier from the channel, validates the target function, spawns the corresponding routine with the arguments, and then schedules it. Compared to a standard goroutine, GOTEE adds a level of indirection, with a write to and read from a cross-domain channel, and the deep-copy of each argument.

GOTEE records functions with the `gosecure` keyword as valid targets for the secured routine abstraction within the enclave. GOTEE then initiates a full compilation for enclave code, using the Go compiler's analysis to determine the minimum transitive closure of code reachable from these functions, as well as the global variables used by this code. The compiler also creates a `main` function for the enclave that serves as the `eenter` entry point and that initializes the runtime servers for cross-domain cooperation. The result of this compilation step is a statically-linked, non-relocatable binary to be loaded into the enclave as the trusted code.

GOTEE implements restrictions on the enclave code. First, the compiler detects channels passed via arguments to secured routines and ensures that these are declared as cross-domain channels. Second, the compiler inspects secured routine's target signatures as well as cross-domain channel types and emits warnings if their deep-copying requires dereferencing pointers. Third, GOTEE does not allow function pointers as arguments to secured routines or cross-domain channels. Finally, GOTEE only allows pure Go code within the enclave and rejects dependencies on C code and shared libraries.

GOTEE also compiles the untrusted code using the standard Go compiler, without these restrictions. As a final step, GOTEE packages the statically linked trusted executable into an ELF segment of the untrusted binary.

GOTEE can optionally generate a signed measurement of the enclave at compile time and store it within a dedicated ELF section of the untrusted binary, so as to perform remote attestation upon deployment. If not done by the compiler, the measurement and signature of the trusted code can be performed at run time.

4.2 `gosec` – an SGX Library in Go

The GOTEE compiler includes an SGX library, completely implemented in Go, as a standard Go package called `gosec`. It contains ∼1000 lines of code.

Loading an enclave: `gosec` mirrors the Intel SGX API in that it provides functions to (1) create an enclave, (2) load

a static binary into the enclave, (3) take a measurement of the enclave, and (4) perform `eenter` and `eresume` to the enclave. The `gosec` package communicates with the Intel SGX Linux kernel driver via `ioctl` to execute the privileged SGX instructions, *i.e.,* `ecreate`, `eadd`, and `einit`. It also communicates with the Intel `aes` module [26] that delivers the token required to perform the initialization (`einit`, see §2.1). The `gosec` package implements step (2) by parsing the ELF binary and extracting the enclave code. At run time, the package spawns a new, untrusted, operating system thread to execute an `eenter` instruction that starts the enclave. The number of concurrent threads allowed inside the enclave can be selected by setting an environment variable. By default, the loader adds only two TCS to the enclave: one to execute the user code, the other to support garbage collection.

Measuring an enclave: Measuring an enclave is a series of distinct steps that involve the SGX driver (to execute privileged instructions), the SGX daemon (to retrieve a cryptographic token), the measurement byte array generated by the `gosec` library while creating the enclave [26] (§4.1), and the enclave binary itself. First, the enclave's memory boundaries are determined by reading the ELF sections of the trusted binary. This information is used to perform the `ecreate` call. Then, individual page contents are registered via the driver, which performs the `eadd` and `eextend` accordingly. At the same time, `gosec` builds the corresponding measurement byte array, which is then used to retrieve a token from the SGX `aes` module daemon. Finally, `gosec` issues the `einit` driver call, using the token, to finalize the enclave.

AEX handler: Asynchronous exits from the enclave, *e.g.,* faults and exceptions, are first passed to the operating system. Then, a user-space AEX handler, implemented in `gosec`, is called. The handler runs outside of the enclave and plays a fundamental role in the debugging process. The `gosec` AEX handler reads a shared region of memory where the GOTEE runtime dumps information before performing a panic or throwing an exception. This, of course, is reliable only for debugging purposes. If no GOTEE runtime cause for the AEX is found, the `gosec` AEX handler performs an `eresume` to return in the enclave.

4.3 GOTEE Runtime

The third component of GOTEE is the runtime library that is statically linked to the enclave code. It consists of the Go runtime modified to run in an enclave, including its cooperative user-level thread scheduler and garbage collector, and extensions to allow trusted and untrusted code to cooperate. It supports cross-domain channels as the *sole* means of communications with untrusted code. The code patch consists of ~760 lines of new code and ~300 modified ones.

Enclave runtime initialization: GOTEE replaces most of the Go runtime initialization steps. The `gosec` package preallocates all trusted heap, thread local storage, and memory pools during the enclave creation as part of the load and initialization sequence. This is necessary because of the SGX metering requirements. As a result, the entry point of the enclave simply switches execution onto a protected stack that is part of the enclave and skips over most of the Go runtime memory allocation steps. After this, the enclave runtime shares most of the Go runtime, with minor changes to avoid enclave-disallowed instructions such as `cpuid` or `rdtsc`.

Allowing multiple trusted threads: GOTEE lazily spawns enclave threads. During the execution, when a new thread is required, the current enclave thread first atomically acquires a TCS from the pool. It then performs an enclave exit and a clone system call before resuming its enclave execution. While exits and entries are expensive, these are bounded by the maximal number of TCS allocated for the enclave. The newly created thread performs an `eenter` and jumps to the pre-defined enclave entry point to initialize its state before serving secured routines.

Securing untrusted channels: The channel implementation, as well as the goroutine structure, were extended to support a secured communication mechanism between the trusted and untrusted environments. To pass copies of values to and from secured routines, GOTEE uses buffers allocated within the unprotected memory region. Upon performing a blocking operation, the trusted runtime allocates an unprotected buffer that will either hold the value that it writes, thereby allowing an untrusted routine to access it, or be used to receive the value produced by an untrusted routine's write to the channel. When unblocked, the secured routine copies the content of the buffer to the appropriate memory location within the enclave. For complex types, the enclave performs a deep-copy. This adds an extra step for secured routines compared to standard Go, which allows direct read/write to the blocked goroutine's enqueued address, *e.g.,* a stack, a heap, or a data variable. GOTEE automatically identifies and instruments cross-domain channels at runtime, hence limiting the effort required to port existing applications. Communications within the same domain are unaffected.

Cross-domain synchronization: The two runtimes, and in particular their schedulers, must cooperate to synchronize access to channels across domains to ensure the timely delivery of messages. In Go, a blocking operation on a channel deschedules the routine and wraps it within a special datastructure along with a pointer to the read (write) memory location. In the case of a cross-domain channel, the wrapper must be accessible from both runtimes. GOTEE's enclave runtime manages a private untrusted memory area from which such wrappers are allocated. A secured routine that needs to enqueue itself will therefore allocate a wrapper, along with an untrusted memory buffer, and then enqueue itself in the untrusted cross-domain channel.

The unblocking operations on cross-domain channels

also required changes. An untrusted routine cannot directly reschedule a trusted routine, and vice versa. Instead, unblocking a routine enqueues it in a ready queue that belongs to the appropriate domain. These queues are polled by the corresponding runtime's scheduler. The scheduler ensures that the address of the goroutine is valid, *i.e.,* that it was registered at creation and is still live, before executing it. Note that this extra step only applies to cross-domain communications.

Memory management: The GOTEE runtime restricts the amount of available heap memory because of SGX memory-size limitations. The standard Go runtime assumes a 64-bit address space with gigabytes of memory and places its runtime heap, spans, and bitmap for memory management accordingly. During runtime initialization, and throughout code execution, the Go runtime `mmaps` portions of the address space corresponding to these regions and frequently extends them. An enclave's maximum memory live working-set is 94 MB, and even less if we want to avoid page evictions. As a result, GOTEE uses a fixed-size heap whose address and size are computed as a fixed offset from the code and data. The heap size can be set either at compile time if a measurement is generated or at run time before loading the enclave.

Thread Local Storage: Go relies on thread local storage (*TLS*) to quickly access runtime values such as the current routine (*G*) or the current machine abstraction (*M*). Go normally allocates *M* in the heap and sets it as the TLS base. SGX, on the other hand, requires a TCS to declare its TLS at creation time. GOTEE circumvents the SGX limitations by preallocating *M*s into the enclave's `.bss` segment. As all `.bss` data structures are part of the garbage collector's root set (unlike an arbitrary location in memory), this approach allows the enclave to use the unmodified Go garbage collector.

Garbage collection and Stack shrinking: Go performs mark and sweep concurrent garbage collection. The GC requires a short pause time with all threads blocked at a safe point for mark and sweep terminations. As a result, secured routines need a way to exit the enclave and perform a blocking `futex` sleep. Other than that, the original Go GC is unmodified, and it executes independently from the untrusted domain's runtime. Untrusted memory buffers are allocated and managed by an in-enclave allocation library and are not traced by either GCs. The trusted runtime keeps references to secured routines blocked on cross-domain channels, which both allows a safety check when they are rescheduled and keeps them in the live-set of objects during garbage collection.

Goroutine stacks can shrink and stack frames can be relocated in memory when the goroutine is blocked on a channel. In standard Go, the destination location of channel data may be on the stack, and therefore handled as part of stack relocation. In GOTEE, when a secured routine is blocked on a cross-domain channel, the destination address points to a location in untrusted memory, *i.e.,* not on the stack, while the stack pointer used as the final recipient of the deep-copy is the one updated during stack shrinking.

Mitigating SGX limitations: The current version of SGX disallows several instructions in the enclave, such as `syscall`, `cpuid`, and `rdtsc`. While these have to be completely avoided during the runtime initialization, due to the limited environment at that time (no heap or channels during the early init phases), they can later be emulated. The system call interposition mechanism allows the enclave to forward system calls to the untrusted runtime. The same mechanism can be used to execute a `rdtsc`, with the communication overhead reducing its accuracy. For the `cpuid` call, most of the information provided by the instruction is fixed at enclave creation, which simplifies its emulation.

Go relies on `futex` calls to implement locking within the runtime. These are optimistic locks, performing a limited amount of spinning before sleeping. In an enclave, a `futex sleep` would require to exit the enclave and re-enter upon a `futex wake up`, with high overheads. Instead, in GOTEE, a secured routine that needs to obtain a cross-domain channel lock will spin until it acquires the lock. Upon an unlock, GOTEE checks if any unsafe thread is sleeping on the `futex`. If so, it spawns a dedicated routine to use the system call interposition to perform the unblocking `futex wake up` system call. This approach is similar to the one used by standard Go for blocking system calls, except that GOTEE relies on routines rather than operating system threads.

Network support: The Go runtime relies on `epoll` calls, as part of the scheduler's logic, for network events. GOTEE extends the scheduler's implementation to ensure that a single idle thread at a time is allowed to exit the enclave and perform the `epoll` call.

Iago Attacks: GOTEE's runtime is hardened against Iago attacks and only relies on 4 syscalls: `mmap` to allocate unsafe memory, checked against enclave boundaries and known unsafe areas; `futex` calls for idle threads, which are used to reduce CPU utilization, not mutual exclusion; and `epoll` calls performed by idle threads as described above.

On the application side, GOTEE provides a single point of system call interposition which relies on channels with deep-copy semantics for memory isolation. This currently performs system call filtering and safety checks on both arguments and results, and could be extended, in the future, to allow user-defined filtering policies.

Debugging: Debugging code within an enclave is challenging as the AEX user-space exception handler provides little information to identify the cause of an asynchronous exit from the enclave. GOTEE has an optional flag that allows a program to run in a simulation environment with identical memory layout and run time behavior as the SGX program, but without the SGX protection mechanisms.

	Workload	Text	Data	RO-data	Total	Main Package Dependencies	Application LOC
GOTEE	runtime only	493	25	273	793	-	-
	hello world	+72	+1	+16	+91	++ fmt, syscall, strconv, os, io, reflect, runtime, unicode	13
	enclave-cert	+174	+1	+45	+221	++ crypto/rsa, math, bytes, hash, unicode	75
	ssh	+1036	+4	+291	+1332	++ golang.org/x/crypto/*, crypto, gnet, encoding	71
	keystore	+1165	+ 4	+329	+1499	++ crypto/ecdsa, crypto/elliptic, crypto/aes	474
SDK	runtime only	67	2	4	75	-	-
	hello world	+49	+0	+1	+51	-	355

Table 1: Per case-study enclave TCB breakdown in KB, package dependencies, and application lines of code (LOC). **+** and **++** are, respectively, an increase over the baseline `runtime only`, and over all previous table entries.

5 Evaluation

Our experiments were performed on a Microsoft Azure Cloud Confidential Computing server, with an Intel(R) Xeon(R) E-2176G CPU @ 3.70GHz with 4 physical cores, configured with Ubuntu 18.04 LTS running Linux kernel 4.15.0-1036-azure. GOTEE operates with the standard Intel SGX 2.0 Linux kernel driver (`sgx2`) and attestation daemon (`aesm`). All GOTEE experiments were run with garbage collection enabled and a single thread servicing secured routines in the enclave.

The purpose of our evaluation is to validate: (1) the effectiveness of secured routines as a way to partition code (§5.1); (2) the performance, latency, and throughput of secured routines and their cost in comparison to the crossing-oriented approach of the Intel SDK (§5.2); (3) with three case studies, GOTEE's usability and ability to hide critical secrets within the enclave by executing a full application in the enclave(§5.3), by performing a fine-grained partitioning of a standard Go package(§5.4), and by extending a real-world application with a TEE-specific implementation(§5.5).

5.1 Code Size

We first evaluate the impact of secured routines on the enclave code size. To this end, we add a baseline `hello world` benchmark that invokes `fmt.Println` in the enclave, and compare it to the Intel SDK C++ `hello world` code sample.

Table 1 shows, for each case study, (1) the size of the enclave code measured as an increase on the baseline size of GOTEE runtime for the enclave, (2) the main Go package dependencies, and (3) the application lines of code. Entries in the table are sorted such that each case study only reports extra packages imported compared to previous lines.

First, we observe that both the Go runtime and the generated code are larger than the C++. Second, the `ssh-server` is responsible for the greatest increase, in TCB size, over the runtime baseline, due to its numerous dependencies. This result is expected as this particular case study does not leverage the fine-grain partitioning provided by GOTEE and simply puts the entire application code inside the enclave. The `keystore` prototype only adds a few crypto subpackages to the TCB dependencies.

On the other hand, Table 1 also shows the difference in source-code level complexity between GOTEE and the Intel SDK. In `hello world`, the lack of transparent forwarding of system calls in the SDK requires a programmer to forgo `printf` in the enclave and instead: (1) call `sprintf` to write to an intermediate buffer, (2) define and `ocall` with the IDL compiler, and (3) use it to issue a `write` system call. Additionally, programmers are still responsible for properly implementing all the boilerplate code required to define, create, and load the enclave. As a result, the C++/SDK `hello world` consists of 355 LOC, 13 files, requires 85 lines of configuration, and 161 lines of `Makefile`.

By comparison, the GOTEE 13 lines of code `hello world` compiles with the `gotee build` command.

5.2 Microbenchmarks

This evaluation uses the following microbenchmarks:

- `syscall`-lat: from within a trusted closure, execute a `getuid()` system call in a loop; report the mean latency.
- `gosecure+block`-lat: spawn a trusted closure and wait for a response over a private cross-domain channel; report end-to-end median latency.
- `gosecure-server`-lat: a single secured routine performs blocking writes to a cross-domain channel in a loop. An untrusted routine measures the latency of performing a read on the same channel. The difference between this measurement and `gosecure+block`-lat corresponds to the runtime overhead required to trigger a secured routine.
- `gosecure`-tput: multiple untrusted goroutines concurrently spawn a trusted closure and wait for a response over a private cross-domain channel.

bench-name	Go	GOTEE	SDK
syscall (getuid)	0.23	1.35	3.69
gosecure+block	0.30	1.5	3.50
gosecure-server	0.20	0.60	-

Table 2: Latency microbenchmarks in µs.

- gosecure-server-tput: a single trusted closure receives requests on a public cross-domain channel from multiple concurrent untrusted goroutines and replies individually on private channels, effectively bypassing the runtime cooperation required to spawn new secured routines.

GOTEE latencies: Table 2 compares the latencies of basic operations in Go, GOTEE, and, when applicable, the equivalent C++ implementation with the Intel SGX SDK. All experiments report the median (mean for syscall-lat) over 500K iterations.

The latency to spawn a secured routine and have it write to a private channel is 1.5µs. The equivalent standard Go program has a latency of 0.30µs, suggesting that GOTEE runtime cooperation and SGX memory overheads have an impact of ∼1.2µs (5.0×). We believe that the implementation can be optimized to reduce contention on cross domain events and runtime cooperation overheads. Still, GOTEE shows a 2.3× improvement over the Intel SDK latency, which requires a full crossing (eenter followed by eexit).

For a trivial system call, that requires going through the syscall interposition mechanism over channels, GOTEE is able to achieve a 2.7× improvement over the Intel SDK crossing-oriented approach.

GOTEE throughput: The throughput experiments consist of multiple concurrent requests to the enclave. For the Intel SDK, different threads perform *ecall*s in parallel, yielding a throughput of 281 Kops for one thread and 938 Kops for all four cores.

For GOTEE, Figure 4 presents two variants, running with a single thread inside the enclave: (1) gosecure-tput, the closest in behavior to the Intel SGX SDK, and (2) gosecure-server-tput. The former shows a throughput improvement of 5.2× (1.46 Mops) over the SDK for a single core running in the enclave. GOTEE can allow a single enclave thread to achieve 1.6× the throughput of four cores executing the Intel SDK. GOTEE's throughput depends on the number of concurrent untrusted goroutines (multiplexed on a single thread) performing gosecure calls. For fewer than three untrusted goroutines, the runtime cooperation requiring to reschedule the secured routines dispatcher is the main bottleneck. After that, there are enough concurrent goroutines to avoid blocking the dispatcher.

The second GOTEE experiment shows the benefit of avoiding the secured routine creation overheads. Its performance degrades, however, as contention on the cross-domain channel increases; both runtimes compete to obtain the lock and must cooperate to reschedule unblocked routines. Vanilla Go, which is not subjected to our cooperation overhead or SGX performance costs, achieves over 4.1Mops.

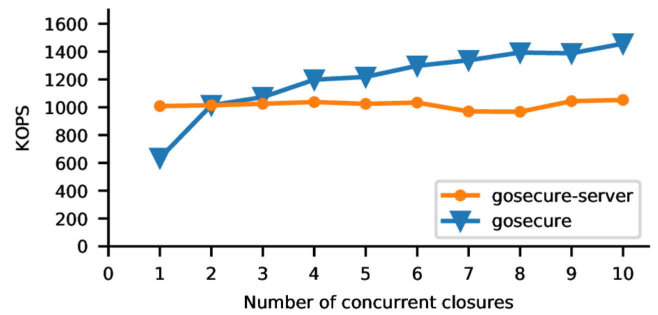

Figure 4: Synchronous closure execution rate for secured routine multiplexed on top of a single enclave thread.

The garbage collector's impact on these microbenchmarks is negligible. The Go memory statistics show that for the full throughput experiment, 21 GC cycles were completed inside the enclave, with a median pause time of 13µs. However, the total GC pause time only accounts for 0.033% of the application's available CPU time. In the latency microbenchmark, we measured a similar median for 2 completed cycles, which accounts for 0.015% of the benchmarks CPU time.

5.3 A full in-enclave ssh server

GOTEE can be used to port a full application to the enclave. The enclave size breakdown is reported in Table 1. The Go programming language provides, under golang.org/x/crypto/ssh, a fully functional implementation of an ssh-server. This implementation relies on the default net package. While *none* of the application logic code for the server was changed, this port required a few modifications to the net package, which relies on C bindings for socket structures in order to stay compatible with the Linux kernel headers. As GOTEE allows only pure Go code inside the enclave, we created gnet, a new package that redefines relevant C structures (*e.g.,* struct_sockaddr, struct_in_addr, struct_addrinfo) and constants in pure Go. This package adds 70 LOC to the native net package.

5.4 Webserver with enclave-cert

The loss or leakage of an SSL private certificate can have serious reputational consequences. However, a private certificate must reside in the memory of the process that handles an SSL connection. Our case study designs and implements the enclave-cert package, which isolates within an enclave the two operations that require access to an SSL certificate's private key: signing the handshake hash and decrypting the client's symmetric session key.

We modified the native Go `tls` package to allocate the server's private certificate key within the enclave and to perform these operations in the trusted environment. The `enclave-cert` package uses channels to pass encryption and decryption requests to the enclave. A single secured routine is spawned by the user application when a certificate is loaded or created. The secured routine then waits on the request channel, performs the requested decryption, and notifies the untrusted requester.

The code patch consists of 9 additional LOC that add optional request channels to the TLS certificate structure. The enclave code is in `enclave-cert`, a new package of 35 LOC that defines the operations on the private key. The `http` package is unmodified. Any webserver application that uses `enclave-cert` operates like a corresponding Go webserver application.

The separation of functionality between the `tls` package (which does not depend on GOTEE or `gosec`) and `enclave-cert` eliminates circular dependencies and ensures backward compatibility when SGX is not available.

In this experiment, we have an `apache-bench` client connect repeatedly over `https://localhost` to a simple webserver and request a single page load per session. The workload is totally dominated by the TLS handshakes.

We compare the built-in Go `http` and `tls` packages with the modified `enclave-cert`. The built-in server achieves an average of 400 reqs/sec, while `enclave-cert` achieves 353 reqs/sec (*i.e.,* 88% of native). The `apache-bench` output shows they have the same mean for connection and processing time, but `enclave-cert` has a higher (6×) standard deviation. In fact, the run time cooperation between trusted and untrusted domains is a source of variability that impacts the system's stability and tail latency. A similar experiment with Glamdring [40] reported only 60% of native throughput due to the cost of frequent enclave crossings.

5.5 Keystore based on go-ethereum

The go-ethereum [29] project is the official implementation of the Ethereum protocol [13] in Go. A particular feature of the project is the ability to manage ethereum signature keys (ECDSA) as part of a `keystore`. The go-ethereum project allows safely encrypting keys with a passphrase before storing them on disk. The keystore is responsible for loading and decrypting the keys using the user-provided passphrase. To reduce the window of vulnerability, go-ethereum zeroes-out, in memory, decrypted keys after signing a hash or a transaction.

As a proof-of-concept, we implemented a simplified version of this keystore with GOTEE. The keystore executes in the enclave and enables: (1) loading an encrypted private key from the disk in the enclave, (2) decrypting the private key using a user-provided passphrase (e.g., via a secured ssh connection), and (3) signing a hash if the user validates it. Our keystore is 500 lines of Go code. The primary benefit of this approach is the elimination of the window of vulnerability. The keystore can safely keep private keys cached in secure memory. It took a single developer one day to implement this simplified secured keystore.

The enclave size break down is reported in Table 1. The amount of code loaded in the enclave, more than 1MB, is large compared to other experiments. This is mostly due the embedded ssh server, the cryptographic libraries, *e.g.,* elliptic curves and AES, and the encoding libraries, required to unmarshal decrypted private keys.

Along the TLS benchmark, this implementation validates that GOTEE can support popular Go cryptographic libraries (RSA, AES, and ECDSA) without modifying these packages.

6 Discussion

GOTEE demonstrates that language support for TEEs can alleviate SGX limitations and that the GOTEE programming model can be used to effectively increase the integrity and confidentiality of sensitive server-side computations. At the same time, the viability of SGX, beyond simple use cases in digital-rights management, as a foundational *trust* technology is doubtful given the large number of SGX vulnerabilities found to date and the complexity of the current architecture. SGX is a complex extension to a complex instruction set with an optimized implementation. Verifying the correctness of this extension and of its interactions with the large number of existing instructions is challenging [11, 26]. SGX has already been shown to be vulnerable to side-channel attacks based on caches [20], page faults [49], branch shadowing [38], and processor side-channel attacks ("Foreshadow" [22], a variant of Spectre [36] and Meltdown [41]).

GOTEE's increased isolation and decoupling between trusted and untrusted code, as well as the channel abstraction as the sole mean of communication, allows GOTEE applications to remain agnostic to the underlying technology's programming model. GOTEE seems ideally suited to provide a programming model for more radical TEE designs, that better protect trusted code in isolated environments comprising dedicated cores, TLBs, and (larger) dedicated, encrypted DRAM. One such TEE design could allocate processors and memory at kernel boot time. With a reserved co-processor, its TLB could be dedicated to an enclave and the responsibility of managing the virtual address space could shift from the operating system kernel to a kernel driver, with a small and verifiable implementation. A robust solution would also partition the cache hierarchy to avoid cache-based side-channel attacks.

7 Related Work

A GOTEE-compiled program results in side-by-side execution of two peer environments that communicate over type-

checked, message-passing channels. Using language-based message passing to isolate parts of a program is similar to the Singularity operating system [35], which used strongly typed channels as its only communication mechanism among processes and the kernel.

Program partitioning has been used to transform programs to run sensitive computations on isolated or secure processors. The Jif/split [50] system used security types and information-flow analysis to partition programs so that secure computations could be distributed and executed on trusted processors. Swift [25] partitioned a web app to run its trusted computation on a server. Wedge [19] was a Linux extension that supported least-privileged partitioning and execution of programs. The Crowbar tool used static program analysis to partition programs so that operations could be performed with least privilege. Privtrans [21] partitioned a program to enforce privilege separation. GOTEE, inspired by these systems, provides a language-base, compiler-driven code and data partitioning for TEEs that presents a simple programming model and which could be extended to support other TEE hardware, as well as secured co-processor or remote execution setups.

TrustScript [30] provides language support for running TypeScript (JavaScript) code in an enclave. Similar to GOTEE, it relies on keyword annotation of trusted code and uses asynchronous message passing between the trusted and untrusted runtimes. Unlike GOTEE's automated, fine-grain partitioning, TrustScript developers must implement all trusted code in an annotated namespace, and the TrustScript's security model is unclear.

Glamdring [40] uses data-driven code partitioning between an SGX enclave and an untrusted environment. The compiler and toolchain try to reduce the number of enclave crossings by bringing more code into the enclave. GOTEE takes a different approach, as it provides programmers with fine-grained control over the TCB, a stricter memory isolation between the two domains, and replaces enclave crossings with channel communications.

The debate on the relative merits of the crossing-oriented abstractions of the Intel SDK and the communication-oriented abstraction of GOTEE is of course a new twist on the duality of shared memory and message passing [37]. While numerous systems have been built with the domain-crossing approach embodied in the Intel SDK (§2.2) [8, 17, 40], the current implementation of SGX favors an asynchronous, communication-oriented model, as demonstrated by GOTEE and Intel's own recent `switchless` [14]. Other mentioned solutions [14, 16, 23, 30, 31, 44] rely *internally* on message passing to avoid enclave crossings. GOTEE, however, leverages Go channels, an abstraction that is part of a language, type-safe, and widely used. The cross-domain channels extend the general channel programming abstraction and enable developers to use *explicit* cross-domain communication at the application-level. Internally, this single point of interaction allows to perform both static and dynamic safety checks in concordance with the language semantics.

As a general result, GOTEE shows that programming language support, with an appropriate abstraction and programming model, combines the best of previous approaches, *i.e.,* the fine-grained automatic partitioning, the message passing model precluding enclave crossings, as well as a higher level of isolation between the two domains, and provides an interesting testbed for future extensions, such as information flow control or user-defined system call filtering.

Microsoft used SGX in conjunction with machine-code modification and verification to ensure a property called information release confinement that guarantees that attackers can only see encrypted data [48]. Although their C++ programming model is crossing oriented, GOTEE would provide a better starting point as they impose and verify safety restriction on the C++ enclave code that would be unnecessary for a safe language such as Go. Similarly, the Microsoft VC3 [46] map-reduce system requires and checks at run-time an even stronger set of control-flow and memory-safety properties, which again are easily satisfied by Go programs.

Finally, there exist software solutions which rely on layered virtualization to remove any trust dependency from the operating system [27, 28, 34] or the cloud hypervisor [52]. GOTEE could provide a complementary application-level isolation.

8 Conclusion

What comes first, the processor or the programming model? Intel's SGX made a TEE generally available, and its SDK provides a thin veneer that exposes its hardware features as the programming model. As systems are constructed on SGX, it has become increasingly clear that the most effective use of this TEE is to have it execute only trusted operations and to run the bulk of an application outside of the enclave. This paper explores a new programming model to support this style of use. GOTEE provides language support for TEEs. It extends the Go programming language and uses the Go routine mechanism to invoke a function within the enclave. Our compiler uses a single annotation to distinguish trusted code and automatically partition a program and establish cross-domain communication.

GOTEE treats the enclave as a distinct computing entity and uses message passing to copy arguments to functions, which then execute securely in a distinct, secure domain. This alternative model has the advantage of not requiring expensive cross-domain control transfers, resulting in significantly higher performance than the standard option. Equally important, it reduces the close coupling between the trusted and untrusted domains and opens the possibility of new, more easily verified hardware implementations that can better isolate TEE cores and run faster.

Abstract

Bolted is a new architecture for bare-metal clouds that enables tenants to control tradeoffs between security, price, and performance. Security-sensitive tenants can minimize their trust in the public cloud provider and achieve similar levels of security and control that they can obtain in their own private data centers. At the same time, Bolted neither imposes overhead on tenants that are security insensitive nor compromises the flexibility or operational efficiency of the provider. Our prototype exploits a novel provisioning system and specialized firmware to enable elasticity similar to virtualized clouds. Experimentally we quantify the cost of different levels of security for a variety of workloads and demonstrate the value of giving control to the tenant.

1 Introduction

There are a number of security concerns with today's clouds. First, virtualized clouds collocate multiple tenants on a single physical node, enabling malicious tenants to launch side-channel and covert channel attacks [21, 51, 54, 55, 66, 69, 80] or exploit vulnerabilities in the hypervisor to launch attacks both on tenants running on the same node [49, 64] and on the cloud provider itself [73]. Second, popular cloud management software like OpenStack can have a trusted computing base (TCB) with millions of lines of code and a massive attack surface [38]. Third, for operational efficiency, cloud providers tend to support *one-size-fits-all* solutions, where they apply uniform solutions (e.g. network encryption) to all customers; meeting the specialized requirements of highly security sensitive customers may impose unacceptable costs for others. Finally, and perhaps most concerning, existing clouds provide tenants with very limited visibility and control over internal operations and implementations; the tenant needs to fully trust the non-maliciousness and competence of the provider.

While bare-metal clouds [27, 46, 48, 63, 65] eliminate the security concerns implicit in virtualization, they do not address the rest of the challenges described above. For example, OpenStack's bare-metal service still has all of OpenStack in the TCB. As another example, existing bare-metal clouds ensure that previous tenants have not compromised firmware by adopting a one-size-fits-all approach of validation/attestation or re-flashing firmware. The tenant has no way to programmatically verify the firmware installed and needs to fully trust the provider. As yet another example, existing bare-metal clouds require the tenant to trust the provider to scrub any persistent state on the physical machine before allocating the machine to other tenants.[1]

These issues are a major concern for "security-sensitive" organizations, which we define as entities that are both willing to pay a significant price (dollars and/or performance) for security and that have the expertise, desire, or requirement to trust their own security arrangements over those of a cloud provider. Many medical, financial and federal institutions fit into this category. Recently, IARPA, who represents a number of such entities, released an RFI [12] that describes their requirement for using future public clouds; to "*replicate as closely as possible the properties of an air-gapped private enclave*" of physical machines. More concretely[2] this means a cloud where the tenant trusts the provider to make systems available but where confidentiality and integrity for a tenant's *enclave* is under the control of the tenant who is free to implement their own specialized security processes and procedures.

By our definition the majority of computing demands are not highly security-sensitive, thus providing a high-security option within a commercially-viable future cloud must not

*Mosayyebzadeh, Mohan, and Tikale contributed equally.

[1]See, for example, IBM Cloud's security policy for scrubbing local drives here https://tinyurl.com/y75sakn4. Note that scrubbing local disks can require hours of overhead on transferring computers between tenants; dramatically impacting the elasticity of the cloud.

[2]Per private communications with RFI authors.

impact the efficiency of providing service to other tenants. Is this possible? Can we make a cloud that is appropriate for even the most security sensitive tenants? Can we make a cloud where the tenant does not need to fully trust the provider? Can we do this without performance impact on tenants who are happy with the security levels of today's clouds?

The Bolted architecture and prototype implementation, described in this paper, demonstrates that the answer to these questions is "yes." The fundamental insight is that to implement a bare metal cloud only a minimum *isolation service* need to be controlled by the provider; all other functionality can be implemented by security-sensitive tenants on their own behalf, with provider-maintained implementations available to tenants with more typical security needs.

Bolted defines a set of micro-services, namely an *isolation service* that uses network isolation technologies to isolate tenants' bare-metal servers, a *provisioning service* that installs software on servers using network mounted storage, and an *attestation service* that compares measurements (hashes) of firmware/software on a server against a whitelist of allowed software. All services can be deployed by the provider as a one-size-fits-all solution for the tenants that are willing to trust the provider.

Security sensitive tenants can deploy their own provisioning and attestation service thereby minimizing their trust in the provider. The tenant's own software executing on machines (already trusted by the tenant), can validate measurements of code to be executed on some newly allocated server against her expectations rather than having to trust the provider. Further, the tenant's attestation service can securely distribute keys to the server for network and disk encryption. Using the default implementation of Bolted services, a tenant's enclave is protected from previous users of the same servers (using hardware-based attestation), from concurrent tenants of the cloud (using network isolation and encryption), and from future users of the same servers (using network mounted storage, storage encryption, and memory scrubbing). Further, a tenant with specialized needs can modify these services to match their requirements; the provider does not sacrifice operational efficiency or flexibility for security-sensitive customers with specialized needs since it is the tenant and not the provider responsible for implementing complex policies.

Key contributions of this paper are:

An **architecture** for a bare-metal cloud that: 1) enables security-sensitive tenants to control their own security while only trusting the provider for physical security and availability while 2) not imposing overhead on tenants that are security insensitive and not compromising the flexibility or operational efficiency of the provider. Key elements of the architecture are: 1) disk-less provisioning that eliminates the need to trust the provider for disk scrubbing (as well as the huge cost), 2) remote attestation (versus validation or re-flashing) to provide the tenant with a proof of the firmware and software running on their server and 3) secure deterministically built firmware that allows the tenant to inspect the source code used to generate the firmware.

A **prototype implementation** of the Bolted architecture where all its components are made available by us open-source, including the isolation service (Hardware Isolation Layer [5, 36]), a deterministic Linux-based minimal firmware (LinuxBoot [6,39], a disk-less bare-metal provisioning service (Bare Metal Imaging [7, 57]), a remote attestation service (Keylime [9, 72]), and scripts that interact with the various services to elastically create secure private enclaves. As we will discuss later, only the microservice providing isolation (i.e., Hardware Isolation Layer) is in the TCB and we show that this can, in fact, be quite small; just over 3K LOC in our implementation.

A **performance evaluation** of the Bolted prototype that demonstrates: 1) elasticity similar to today's virtualized cloud ($\sim$3 minutes to allocate and provision a physical server), 2) the cost of attestation has a modest impact $\sim$25% on the provisioning time, 3) there is value for customers that trust the provider in avoiding extra security (e.g.,$\sim$200% for some applications), while 4) security-sensitive customers can still run many non-IO intensive applications with negligible overhead and even I/O intensive BigData applications with a relatively modest (e.g., $\sim$30%) degradation.

2 Threat Model

We describe the threats to the victim, a tenant renting bare-metal servers from the cloud, and describe approaches taken by Bolted to safeguards against them. We consider external entities (hackers), malicious insiders in the cloud provider's organization and all other tenants of the server—both past and future—as potential adversaries to the victim. We assume that the goal of the adversary is to steal data, corrupt data, or deny services to the victim by gaining access to the victim's occupied servers or network. Our goal is to empower the tenant with the ability to take control of its own security; it is up to the tenant to make the tradeoff decision between the degree to which it relies on the provider's security systems versus the harm that it may suffer from a successful attack.

The cloud provider is always trusted with the physical security of the datacenter, thus any attacks involving physical access to the infrastructure, including power and noise analysis, bus snooping, or decapping chips [33, 34, 74] are out of scope of a tenant's control. The provider is also trusted for the availability of the network, node allocation services, and any network performance guarantees. We assume that the cloud itself is vulnerable to exploitation by external entities (hackers) or a malicious insider (e.g., a rogue systems administrator) but we trust the cloud provider's organization to have necessary systems and procedures in place to detect and limit the impact of such events. For example, the provider can enforce sufficient technical separation of duties (e.g., two-person rule) such that a single malicious insider or hacker cannot both re-flash all the node firmware in a data center and change what

hashes the provider publishes for attestation, have both physical and logical access to a node, or make unreviewed changes to the provider's deployed software, etc. Further, we assume that all servers in the cloud are equipped with a Trusted Platform Module (TPM) - a dedicated cryptographic coprocessor required for hardware-based authentication [11].

We categorize the threats that the tenant faces into the following phases:

Prior to occupancy: Malicious (or buggy) firmware can threaten the integrity of a server, as well as that of other servers it is able to contact. A tenant server's firmware may be infected prior to the tenant using it, either by the previous tenant (e.g., by exploiting firmware bugs) or by the cloud provider insider (e.g., by unauthorized firmware modification). If a server is not sufficiently isolated from potential attackers there is also a threat of infection between the time it is booted until it is fully provisioned and all defenses are in place.

During occupancy: Although many side-channel attacks are avoided by disallowing concurrent tenants on the same server, if the server's network traffic is not sufficiently isolated, the provider or other concurrent tenants of the cloud may be able to launch attacks against it or eavesdrop on its communication with other servers in the enclave. Moreover, if network attached storage is used (as in our implementation) all communication that is not sufficiently secured between server and storage may be vulnerable. Finally, there is a threat to the tenant from denial of service attacks.

After occupancy: Once the tenant releases a server, the confidentiality of a tenant may be compromised by any of its state (e.g, storage or memory) being visible to subsequent software running on the server.

3 Design Philosophy

The key goals of Bolted are: (1) to minimize the trust that a tenant needs to place in the provider, (2) to enable tenants with specialized security expertise to implement the functionality themselves, and (3) to enable tenants to make their own cost/performance/security tradeoffs – in bare-metal clouds. These goals have a number of implications in the design of Bolted.

First, Bolted differs from existing bare metal offerings in that most of the component services that make up Bolted can be operated by a tenant rather than by the provider. A security sensitive tenant can customize or replace these services. All the logic that orchestrates how different services are used to securely deploy a tenant's software is implemented using scripts that can be replaced or modified by the user. Most importantly, the service that checks the integrity of a rented server can be deployed (and potentially re-implemented) by the tenant.

Second, while we expect a provider to secure and isolate the network and storage of tenants, we only rely on the provider for availability and not for the confidentiality or integrity of the tenant's computation. For tenants that do not trust the provider, we assume that Bolted tenants will further encrypt all communication between the their servers and between those servers and storage. Bolted provides a (user-operated) service to securely distribute keys for this purpose.

Third, we rely on attestation (measuring all firmware and software and ensuring that it matches known good values) that can be implemented by the tenant rather than just validation (ensuring that software/firmware is signed by a trusted party). This is critical for firmware which may contain bugs [24, 35, 40, 41, 70, 77] that can disrupt tenant security. Attestation provides a time-of-use proof that the provider has kept the firmware up to date. More generally, the whole process of incorporating a server into an enclave can be attested to the tenant. In addition, the tenant can continuously attest when the server is operating, ensuring that any code loaded in any layer of software (OS, applications and etc., and irrespective of who signed them) can be dynamically checked against a tenant-controlled whitelist.

Fourth, we have a strong focus on keeping our software as small as possible and making it all available via open source. In some cases, we have written our own highly specialized functionality rather than relying on larger function rich general purpose code in order to achieve this goal. For functionality deployed by the provider, this is critical to enable it to be inspected by tenants to ensure that any requirements are met. For example, previous attacks have shown that firmware security features are difficult to implement bug-free – including firmware measurements being insufficient [26], hardware protections against malicious devices not being in place [59], and dynamic root of trust (DRTM) implementation flaws [79]. Further, our firmware is deterministically built, so that the tenant can not only inspect it for correct implementation but then easily check that this is the firmware that is actually executing on the machine assigned to the tenant. For tenant-deployed functionality, small open source implementations are valuable to enable user-specific customization.

Finally, servers are assumed to be stateless with all volumes accessed on-demand over the network. This removes confidentiality or denial of service attacks by the provider or subsequent tenants of server inspecting or deleting a tenants disk state. Bare-metal clouds that support stateful servers need to either give the tenant the guarantee that a node will never be preempted (problematic in a pay-for-use cloud model) or ensure that the provider scrubs the disks (trusting the provider and potentially requiring hours with modern disks). As we will see, stateless servers also dramatically improve the elasticity of the service.

4 Architecture

Bolted enables tenants to build a secure enclave of bare-metal servers where the integrity of each server is verified by the tenant before it is allowed to participate in the tenant's enclave. During the allocation process, a server transitions through the following states: **free**, or not allocated, **airlock**, where

the integrity of the server is checked, after which it is either **allocated** to a tenant's secure enclave if it passes the integrity check or **rejected** if it fails. In this section, we discuss the Bolted components; their operations; the process of server allocation, attestation, and the degrees of freedom in deploying Bolted components to support different security requirements and use cases.

4.1 Components

Bolted consists of four components which operate independently and (in the highest-security and lowest-trust configurations) are orchestrated by the tenant rather than the provider.

Isolation Service: The Isolation Service exposes interfaces to (de)allocate servers and networks to tenants, and isolate and/or group the servers by manipulating a provider's networking infrastructure (switches and/or routers). Using the exposed interfaces, the servers are moved to *free* or *rejected* state as well – ensuring the servers are not part of any tenant-owned network. These interfaces are also used to move the servers to the *airlock* state (to verify if they have been compromised) or the *allocated* state (where they are available for the tenant).

The Isolation Service uses network isolation techniques instead of encryption-based logical isolation in order to enforce guarantees of performance and to provide basic protection against traffic analysis attacks. Since the operations performed by these interfaces (on the networking infrastructure) are privileged, the isolation service needs to be deployed by the provider; if a tenant does not trust the provider, it can further encrypt network traffic between their servers.

Secure Firmware: Secure firmware is crucial towards improving tenant's trust of the public cloud servers; it should consist of following properties. First, it should be open-source, so that it benefits from large community support in improving its features and fixing any bugs and vulnerabilities. Second, it should be deterministically built so that a tenant can build the firmware from verified source code and independently validate the provider-installed firmware. Third, it must scrub server memory prior to launching a tenant OS – if the server was preempted from a previous tenant, it must guarantee that the previous tenants' code and data is not present in the memory. Finally, it must provide an execution environment for the attestation agent in the airlock state.

We note that it is challenging to replace computer firmware; even major providers are often forced to install huge binary blobs signed by the hardware manufacturer with no access to the source code. When firmware cannot be replaced, we use the installed firmware for the minimum amount of time in order to download our own secure firmware – and the servers' pre-installed firmware must support trusted boot [20].

While the overall Bolted architecture design supports the attestation and security of both system firmware (e.g., BIOS or UEFI) and peripheral firmware (e.g., GPU, network card, etc.), there are no standardized and implemented methods to attest those peripheral firmware to an external party. Early attempts at standardization are underway, and we expect Bolted can leverage them when they mature [67].

Provisioning Service: This service is broadly responsible for three things – (1) initial provisioning of the server with the software stack (i.e. secure firmware and attestation agent) responsible for its attestation during the *airlock* state, (2) provisioning of the server during the *allocated* state (i.e. the server was successfully verified that it was not compromised) with the intended software stack i.e. the operating system and the relevant software packages, and (3) saving and/or deleting the servers' persistent state when a server is released.

The Provisioning Service can be deployed either by the provider or by tenants themselves. The latter option is valuable for security-sensitive tenants who do not want to trust the provider with their operating system images or who want to use their own (e.g., legacy) provisioning systems. The provisioning service must provision the servers in a stateless manner so that the tenants do not have to rely on (and trust) the provider to remove any persistent state after the server is released.

Attestation Service: The Attestation Service consists of two parts: an attestation agent that executes on the server to be attested, and an attestation server that maintains a prepopulated database of known reliable hash measurements of allowed firmware/software (i.e., a whitelist). This service is used during the *airlock* and *allocated* states. The Attestation Service can be deployed either by the provider or by the tenant.

During the *airlock* state, the attestation agent (downloaded from the Provisioning Service during initial provisioning) is responsible for sending *quotes*[3] of the firmware and any other software involved during the boot sequence to the attestation server to be matched against the whitelist. Depending on the attestation result obtained from the attestation server, the state of the attested server is changed to allocated or rejected. In the case when the computer firmware cannot be replaced, the trusted boot sequence measurement (until the secure firmware is executed) must be supplied by the provider. Obtaining this measurement is a one-time operation for each server, and this whitelist can be published publicly by the provider.

In the *allocated* state, the attestation agent (installed on the tenants' OS) can continuously verify the software stack running against the whitelist present on the attestation server (also referred as *Continuous Attestation*). For continuous attestation to work, the software stack should be configured such that it saves new measurements to the cryptoprocessor upon observing any change/modification/access. The attestation agent periodically sends the new hash measurements of software and configuration registered in the cryptoprocessor to the attestation server; if attestation fails (i.e., when any malicious activity is observed), the attestation server alerts the

[3] Hash measurements obtained from and signed by a secure cryptoprocessor such as TPM.

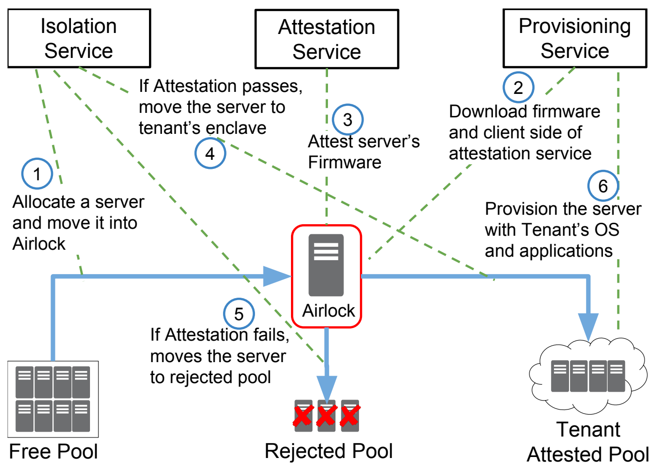

Figure 1: Bolted's Architecture: Blue arrows show state changes and green dotted lines shows the actions during a state change.

attestation agent. Continuous attestation protects tenants both against unauthorized execution of executables and against malicious reboots into unauthorized firmware, bootloader, or operating system. Note that continuous attestation is fundamentally more challenging in a provider-deployed attestation service, as the runtime whitelist (e.g., hashes of approved binaries allowed to be run on the node) must be tenant-generated; we assume continuous attestation is only used by security-sensitive tenants that deploy their own attestation service.

4.2 Life Cycle

The different Bolted components do not directly interact with each other, but instead, are orchestrated by user-controlled scripts. Figure 1 shows the **life-cycle of a typical secure server** (in the case of security-sensitive tenant), which progresses through six steps: (**1**) The tenant uses the Isolation Service to allocate a new bare metal server, create an airlock network, and move the server to that airlock, shared with the Attestation and the Provisioning networks; we need to isolate servers in the airlock state from other servers in the same state so that a compromised server cannot infect other uncompromised servers. (**2**) The secure firmware is executed (if stored in system flash) or provisioned onto the server along with a boot-loader, attestation software agent, and any other related software. With these in place, (**3**) the Attestation Service attests the integrity of the firmware of this server. Once initial attestation completes, (**4**) the tenant again employs the Isolation Service to move the server from the airlock network. If firmware attestation failed (**5**) it is moved into the Rejected Pool, isolated from the rest of the cloud; if attestation was successful, the server is made part of the tenant's enclave by connecting it to the tenant networks. In order to make use of the server, further provisioning is required (**6**) so the tenant again uses the Provisioning Service to install the tenant operating system and any other required applications.

4.3 Use Cases

Figure 2 demonstrates the flexibility of Bolted using three examples of users, namely; 1) Alice, a graduate student, who wants to maximize performance and minimize cost and does not care about security, 2) Bob, a professor, who does not trust other tenants (e.g., graduate students) but is willing to trust the provider, and 3) Charlie, a security-sensitive tenant, who not only does not trust other tenants but wants to minimize his trust in the provider.

Alice and Bob are willing to trust the provider's network isolation and storage security, and do not need to employ runtime encryption and will not incur its performance burden; nor will they need to expend the effort to deploy and manage their own services[4]. Alice, further, uses scripts that do not even bother using the provider's attestation service, further improving the speed that she can start up servers as well as her costs if the provider charges her for all the time a server is allocated to her.

Security-sensitive tenant Charlie deploys his own, potentially modified, provisioning and attestation service. He does not have to rely on the provider's network isolation to protect his confidentiality and integrity but can implement runtime protections such as network and disk encryption. Moreover, the attestation service can be used not only to protect him from previous tenants, but also to maintain a whitelist of applications and configuration, and to quickly detect any compromises in an ongoing fashion. The one area where Bolted requires Charlie to trust the provider is for protecting against denial of service attacks since only the provider can deploy the isolation service that allocates servers and controls provider switches. Trusting a provider, in this case, is unavoidable with current networking technology, as the provider controls all networking to the datacenter.

In addition to the cloud use cases, Bolted was designed to be flexible enough to handle the use case of co-location facilities [1, 4, 8] where the datacenter tenants temporarily "loan" computers to each other to handle fluctuations in demand; and this use case is, in fact, the primary one for which Bolted is going into production currently. In this case, a single party may be both provider and tenant. As an example, one party might have a high demand on their HPC cluster, while another party has spare capacity in their IaaS cloud; the isolation service from the second party (the provider) could be used to provision servers for loan to the first party, with attestation and provisioning services (including provisioning-associated storage) provided by the first party (the user).

Since the different Bolted services are independent, being orchestrated by tenant scripts, it is straightforward for a tenant to use capacity from multiple isolation services. The attestation of Bolted is important to enable supporting untrusted environments (e.g., research testbeds) alongside production services. For tenants that use the standard Bolted provisioning

[4] Or mismanage, a more significant risk for less security-literate users.

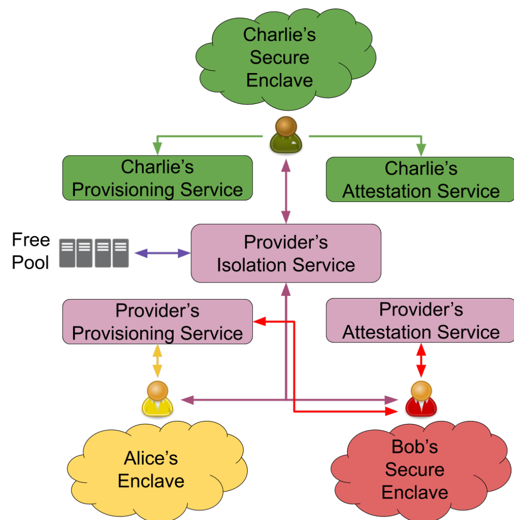

Figure 2: Bolted deployment examples; purple boxes are provider-deployed and greens are tenant-deployed. Alice and Bob trust the provider-deployed infrastructure, while security-sensitive Charlie deploys its own.

service, the use of network mounted storage by Bolted enables them to use their own storage for persistence, making storage encryption unnecessary. Because Bolted enables tenants to deploy their own provisioning service, some tenants can use custom provisioning services which install to local storage.[5] When using their own infrastructure, the tenant and provider are in the same organization. In this case, tenants trust the provider, and hence network encryption is unnecessary. Tenants are willing to make agreements with trusted partners from whom they will be using servers; trusting the partner's isolation service makes network encryption unnecessary for communication with servers obtained from it.

5 Implementation

We describe our implementation of the Isolation Service (HIL [36]), Firmware (LinuxBoot [6]), Attestation Service (Keylime [72]), and Provisioning Service (BMI [57]), and explain how they work together as Bolted. All of these constituent services of Bolted are open-source packages and can be modified by tenants or providers to meet their specific requirements.

Hardware Isolation Layer: The fundamental operations Hardware Isolation Layer (HIL) provides are (i) allocation of physical servers, (ii) allocation of networks, and (iii) connecting these servers and networks. A tenant can invoke HIL to allocate servers to an enclave, create a management network between the servers, and then connect this network to any provisioning tool (e.g., [15, 19, 57, 62]). It can also let tenants create networks for isolated communication between servers and/or attach those servers to public networks made available by the provider. HIL controls the network switches of the cloud provider and provides VLAN-based [45] network isolation mechanism. HIL also supports a simple API for Baseboard Management Controller (BMC) operations like power cycling servers and console access; ensuring that users cannot attack the BMC. HIL cannot be deployed by tenants and must be deployed by the provider and is the only component shared by tenants, that is not attested to. In our effort to minimize this TCB we have worked hard to keep HIL very simple (approximately 3000 LOC).

Because the provider is trusted for physical isolation and security, it also acts as the source of truth for information on servers in two ways. First, it maps each server's HIL identity to a TPM identity by exporting the TPM's public Endorsement Key (EK) through administrator-modifiable metadata per server, ensuring that the tenant is able to confirm that the tenant she received is indeed the one she reserved thus protecting the tenant from any server spoofing attack. Second, HIL exposes the provider-generated whitelist of TPM PCR measurements, i.e., ones that relate to the platform components like BIOS/UEFI firmware and firmware settings.

LinuxBoot: LinuxBoot is our firmware implementation and bootloader replacement. It is a minimal reproducible build of Linux that serves as an alternative to UEFI and Legacy BIOS. LinuxBoot retains the vendor PEI (Pre-EFI environment) code as well as the signed ACM (authenticated code modules) that Intel provides for establishing the TEE (trusted execution environment). LinuxBoot replaces the DXE (Driver Execution Environment) portion of UEFI with open source wrappers, the Linux Kernel, and a flexible initrd based runtime. Advantages over stock UEFI include: 1) LinuxBoot's open-source Linux devices drivers and filesystems have had significantly more scrutiny than the UEFI implementations, 2) its deterministic build enables easy remote attestation with a TPM; a tenant can independently confirm that the firmware on a server corresponds to source code that they compile themselves, 3) it can use any Linux-supported filesystem or device driver, execute Linux shell scripts to perform remote attestation over secure network protocols and mount encrypted drives, simplifying integration into services like Bolted, 4) it is significantly faster to POST than UEFI; taking 40 seconds on our servers, compared to about 4 minutes with UEFI.

We chose LinuxBoot over alternatives like Tianocore [10] – an open source implementation of UEFI because unlike Tianocore it does not depend on hardware drivers provided by motherboard vendors. In addition to the driver dependency Tianocore also needs support of Firmware Support Package (FSP) from processor vendors which are closed source binaries or independent softwares like coreboot [2, 3] to function as a complete bootable firmware. LinuxBoot does use FSP however Heads which is our flavor of LinuxBoot is able to establish root of trust prior to executing FSP thus ensuring that FSP blob is measured into TPM PCR's. This protects from attacks that involve replacing a measured FSP with a malicious FSP. Additionally, while LinuxBoot and Tianocore

[5] In this case, provisioning time is much larger and tenants are responsible for scrubbing the local disk.

both are open source projects, LinuxBoot is based on Linux, a much more mature and widely used system with battle tested code.

We have modified LinuxBoot such that it scrubs memory before a tenant can use a server; a tenant that attests that LinuxBoot is installed is guaranteed that subsequent tenants will not gain control until the memory has been scrubbed since the only way for the provider, or another tenant, to gain control (or reflash the firmware) is to power cycle the machine which will ensure that LinuxBoot is executed. Scripts integrated with LinuxBoot download the attestation service's client side agent, download and kexec a tenant's kernel (only if attestation has succeeded), and obtain a key from the attestation service to access the encrypted disk and network.

Keylime: Keylime is our remote attestation and key management system. It is divided into four major components: Registrar, Cloud Verifier, Agent, and Tenant. The registrar stores and certifies the public *Attestation Identity Keys (AIKs)* of the TPMs used by a tenant; it is only a trust root and does not store any tenant secrets. The Cloud Verifier (CV) maintains the whitelist of trusted code and checks server integrity. The Agent is downloaded and measured by the server (firmware or previously measured software) and then passes quotes (i.e., TPM-signed attestations of the integrity state of the machine) from the server's TPM to the verifier. The Tenant starts the attestation process and asks the Verifier to verify the server. The Registrar Verifier and Tenant can be hosted by the tenant outside of the cloud or could be hosted on a physical system in the cloud. Keylime delivers the tenant kernel, initrd and scripts to the server (after attestation success) using a secure connection between the Keylime CV and Keylime agent. The script is executed by the agent to 1) make sure the server is on the tenant's secure network and 2) kexec into tenant's kernel and boot the server.

For tenants that do not trust the provider, Keylime supports automatic configuration for Linux Unified Key Setup (LUKS) [13] for disk encryption and IPsec for network encryption using keys bootstrapped during attestation and bound to the TPM hardware root-of-trust. Also, Keylime integrates with the Linux Integrity Measurement Architecture (IMA) [71] to allow tenants to continuously attest that a server was not compromised after boot. IMA continuously maintains a hash chain rooted in the TPM of all programs, libraries, and critical configuration files that have been executed or read by the system. The CV checks the IMA hash chain regularly at runtime to detect deviations from the whitelist of acceptable hashes.

Bare Metal Imaging: The fundamental operations provided by the Bare Metal Imaging (BMI) are: (i) disk image creation, (ii) image clone and snapshot, (iii) image deletion, and (iv) server boot from a specified image. Similar to virtualized cloud services, BMI serves images from remote-mounted boot drives, with server access via an iSCSI (TGT [76]) service managed by BMI and back-end storage in a Ceph [78] distributed storage system. When the server network-boots, it only fetches the parts of the image it uses (less than 1% of the image is typically used), which significantly reduces the provisioning time [57]. BMI allows tenants to run scripts against a BMI-managed filesystem which we use to extract boot information (kernel, initramfs image and kernel command lines) from images so that they could be passed to a booting server in a secure way via Keylime.

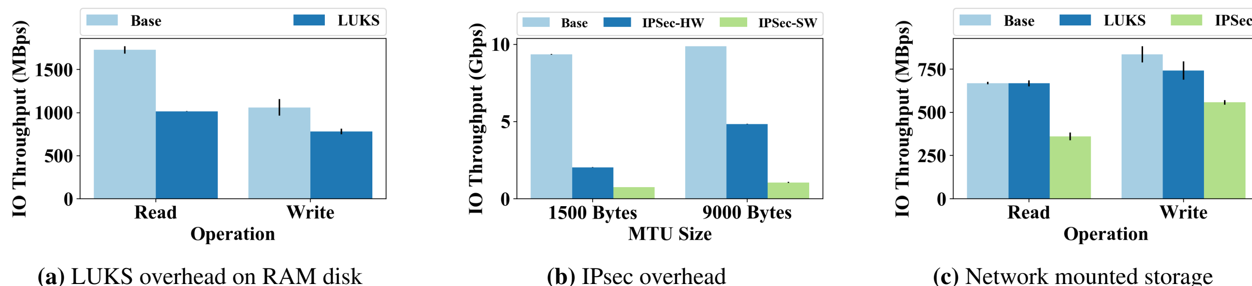
Putting it together: The booting of a server is controlled by a Python application that follows the sequence of steps shown in Figure 1. For servers that support it, we burn LinuxBoot directly into the server's SPI flash. Figure 1 shows another case where we download LinuxBoot's runtime (Heads) using iPXE and then continue the same sequence as if LinuxBoot was burned into the flash. We have modified the iPXE client code to measure the downloaded LinuxBoot runtime image into a TPM platform configuration register (PCR) so that all software involved in booting a server can be attested. When servers pass attestation, the Keylime Agent downloads an encrypted zip file containing the tenant's kernel, initrd, and a script from Keylime server and unzips them. The zip file also includes the keys for decrypting the storage and network. After a server is moved (using HIL) to the tenant's enclave, the Keylime Agent runs the script file. The script stores the cryptographic keys into an initrd file to pass it to the tenant's kernel and then kexecs into the downloaded kernel. After it boots, the kernel uses the keys from the initrd file to decrypt the remote disk and encrypt the network.

Keylime [72] and LinuxBoot [6] were previously created in part by authors of this paper, and modified as discussed above. While previously published, HIL [36] and BMI [57] were designed with the vision of integrating them in the larger Bolted architecture described in this paper.

6 Addressing the Threat Model

Here we discuss how, for security-sensitive tenants, Bolted's architecture addresses the threats in the three phases described in Section 2.

Prior to occupancy: We must protect a tenant's server against threats from previous users of the server and isolate it from potential network-based attacks until a server is fully provisioned. To do this, Bolted uses attestation to ensure that the firmware of the server was not modified by previous tenants, and isolates the server in the airlock state (protected from other tenants) until this attestation is complete. The deterministic nature of LinuxBoot enables tenants to inspect the source code of the firmware, and ensure that it is trusted, rather than just trusting the provider. Further, all communication within the networks in the enclave is encrypted, using a key provided by the tenant's attestation service (e.g., Keylime), ensuring that the server will not be susceptible to attacks by other servers as it is provisioned. Since our current implementation is unable to attest the state of peripheral firmware, there could be malware embedded in those devices that could compromise



(a) LUKS overhead on RAM disk

(b) IPsec overhead

(c) Network mounted storage

Figure 3: Performance Impact of Encryption

the node. Disk and network encryption securely bootstrapped by the TPM mitigate data confidentiality and integrity attacks from malicious peripherals with external access like network interfaces and storage controllers. System level isolation of device drivers, as in Qubes[6], could further be used to mitigate the impact of malicious peripherals mounting attacks against the node [32].

During occupancy: We must ensure that the server's network traffic is isolated so that the provider or other concurrent tenants of the cloud cannot launch attacks against it or eavesdrop on its communication with other servers in the enclave. HIL performs basic VLAN-based isolation to provide basic protection from traffic analysis by other tenants. However, a tenant can choose to both encrypt their network traffic with IPsec and shape their traffic to resist traffic analysis from the provider and not rely on provider's HIL. Keylime securely sends the keys for encrypting networking and disk traffic directly to the node. Disk encryption ensures the confidentiality and integrity of the persistent data even if the storage is under the control of a malicious provider.

Continuous attestation can detect changes to the runtime state of the server (e.g., unauthorized binaries being executed or reboot to an unauthorized kernel) and notify the tenant to take some action to respond. Response actions include revoking the cryptographic keys used by that server for network/storage encryption, removing it from the enclave VLAN, and immediately rebooting the system into a known good state and scrubbing its memory. While IMA only supports load/read-time measurement (i.e., hashing) of files on the system as they are used, most existing runtime protection measures like kernel integrity monitoring [56], control-flow integrity [25], or dynamic memory layout randomization [23] are built into either the kernel image/modules, application binaries, or libraries themselves. Thus, TPM measurements created by IMA at runtime will demonstrate that those protections were loaded.

After occupancy: Once a server is removed from a tenant enclave, we must ensure that the confidentiality of a tenant is not compromised by any of its state being visible to subsequent software running on the server. Stateless provisioning of the servers protects against any persistent state remaining on the server and avoids any reliance on the provider scrubbing the disk if it preempts the tenant. Further, the tenant can deploy its own provisioning service and ensure that the provider has no access to that storage. If the tenant requires the use of the local disks for performance reasons (e.g., for big data applications), the server can use local disk encryption with ephemeral keys stored only in memory. As long as the tenant attests that LinuxBoot is used, it knows that this firmware will zero the server's memory before another tenant will have the opportunity to execute any code.[7]

[6]https://www.qubes-os.org/

[7]Note that we are assuming here that the provider cannot re-flash the firmware remotely over the BMC.

7 Evaluation

We first use micro-benchmarks to quantify the cost of encrypted storage and networking on our system, then examine the performance and scalability of the Bolted prototype, the cost of continuous attestation and finally the performance of applications deployed using Bolted under different assumptions of trust.

7.1 Infrastructure and methodology

Single server provisioning experiments were performed on a Dell R630 server with 256 GB RAM and 2 Xeon E5-2660 v3 2.6GHz processors with 10 (20 HT) cores, using UEFI or LinuxBoot executing from motherboard flash. All the other experiments were conducted on a cluster of 16 Dell M620 blade servers (64 GB memory, 2 Xeon E5-2650 v2 2.60GHz processors with 8 cores (16 HT) per socket) and a 10Gbit switch. The M620 servers do not have a hardware TPM, so for functionality, we used a software emulation of a TPM [43], and for performance evaluation, emulated the latency to access the TPM based on numbers collected from our R630 system.

HIL, BMI, and Keylime servers were run on virtual machines with Xeon E5-2650 2.60GHz CPUs: Keylime with 16 vCPUs and 8GB memory; BMI with 2 vCPUs and 8GB, and HIL with 8 vCPUs and 8GB RAM. The iSCSI server ran on a virtual machine with 8 vCPUs and 32GB RAM. The Ceph cluster (the storage backend for BMI disk images) has 3 OSD servers (each dual Xeon E5-2603 v4 1.70GHz CPUs, 6 cores each) and a total of 27 disk spindles across the 3 machines. The servers were provisioned with Fedora 28 images (Linux

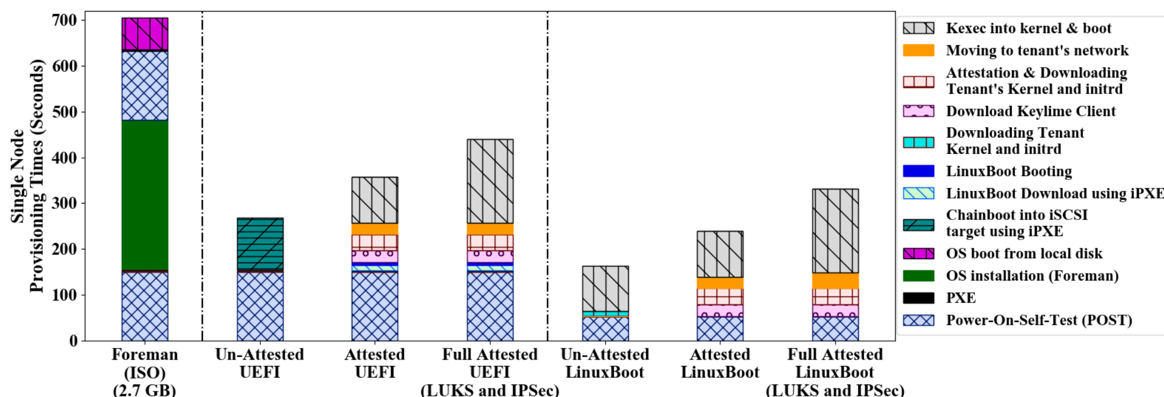


Figure 4: Provisioning time of one server.

kernel 4.17.9-200) enabled with IMA and version 5.6.3 of Strongswan [17] for IPsec. IPsec was configured in 'Host to Host' and Tunnel mode. The cryptographic algorithm used was AES-256-GCM SHA2-256 MODP2048. The authentication and encryption were done through a pre-shared key (PSK). IMA used SHA-256 hash algorithm. Cryptsetup utility version 1.7.0 was used to setup disk encryption based on LUKS – with AES-256-XTS algorithm. Unless otherwise stated, each experiment was executed five times.

7.2 The cost of encryption

For security-sensitive tenants that do not trust a provider, they must encrypt the disk and network traffic. To understand the overhead in our environment, we ran some simple micro-benchmarks.

Disk Encryption: Figure 3a shows the overhead of LUKS disk encryption on a Block RAM disk exercised using Linux's "dd" command. While LUKS introduces overhead in this extreme case, we can see that the bandwidth that LUKS can sustain at 1GB for reads is likely to be able to keep up with both local disks and network mounted storage delivered over a 10Gbit network while write performance may introduce a modest degradation at ∼0.8GB.

Network Encryption: Figure 3b shows the overhead of IPsec using Iperf between two servers using both hardware-based Intel AES-NI (IPsec HW) and software-based AES (IPsec SW) and MTU's of 1500 and 9000. We can see that IPsec has a much larger performance overhead than LUKS disk encryption, with even the best case of HW accelerated encryption and jumbo frames having almost a factor of two degradation over the non-encrypted case (CPU usage on our infrastructure is between 60% and 80% of one processing core for HW accelerated encryption). Additional tuning or specialized IPsec acceleration network interfaces could be used to boost performance [37]. We use hardware accelerated encryption and jumbo frames for all subsequent experiments.

Network mounted storage: In our implementation we boot servers using iSCSI which in turn accesses data from our Ceph cluster. In Figure 3c we show the results of exercising the iSCSI server using "dd". Experimentally, we found that increasing the read ahead buffer size on Linux to 8MB was critical for performance, and we do this on all subsequent experiments (the default size is 128KB). Since Ceph as the backend storage reads data in 4MB chunks, increasing the read ahead buffer size to 8MB results in higher sequential read performance. As expected we find that LUKS introduces small overhead on writes and no overhead on reads, while IPsec between the client and iSCSI server has a major impact on performance.

7.3 Elasticity

Today's bare-metal clouds take many tens of minutes to allocate and provision a server [61]. Further, scrubbing the disk can take many hours; an operation required for stateful bare metal clouds whenever a server is being transferred between one tenant and another. In contrast, virtualized clouds are highly elastic; provisioning a new VM can take just a few minutes and deleting a VM is nearly instantaneous. The huge difference in elasticity between bare-metal clouds and virtualized clouds has a major impact on the use cases for which bare-metal clouds are appropriate. How close can we approach the elasticity of today's virtualized clouds? What extra cost does attestation impose on that elasticity? What is the extra cost if the tenant does not trust the provider and need to encrypt disks and storage?

To understand the elasticity Bolted supports, we first examine its performance for provisioning servers under different assumptions of security and then examine the concurrency for provisioning multiple servers in parallel.

Provisioning time: Figure 4 compares the time to provision a server with Foreman (a popular provisioning system) [30] to Bolted with both UEFI and LinuxBoot firmware under 3 scenarios: *no attestation* which would be used by clients that are insensitive to security, *attestation* where the tenant trusts the provider, but uses (provider deployed) attestation to ensure that previous tenants have not compromised the server, and *Full attestation*, where a security-sensitive tenant that does not trust the provider uses LUKS to encrypt

the disk and IPsec to encrypt the path between the client and iSCSI server. There are a number of important high-level results from this figure. First for tenants that trust the provider, Bolted using LinuxBoot burned in the ROM is able to provision a server in under 3 minutes in the unattested case and under 4 minutes in the attested case; numbers that are very competitive with virtualized clouds. Second, attestation adds only a modest cost to provisioning a server and is likely a reasonable step for all systems. Third, even for tenants that do not trust the provider, (i.e. LUKS & IPsec) on servers with UEFI, Bolted at ∼7 minutes is still 1.6x faster than Foreman provisioning; note that Foreman implements no security procedures and is likely faster than existing cloud provisioning systems that use techniques like re-flashing firmware to protect tenants from firmware attacks.

Examining the detailed time breakdowns in Figure 4; while we introduced LinuxBoot to improve security, we can see that the improved POST time (3x faster than UEFI) on these servers has a major impact on performance. We also see that booting from network mounted storage, introduced to avoid trusting the provider to scrub the disk, also has a huge impact on provisioning time. The time to install data on to the local disk is much larger for the Foreman case, where all data needs to be copied into the local disk. In contrast, with network booting, only a tiny fraction of the boot disk is ever accessed. We also see that with a stateful provisioning system like Foreman, it needs to reboot the server after installing the tenant's OS and applications on the local disk of the server; incurring POST time twice. While not explicitly shown here, it is also important to note that with Bolted a tenant can shutdown the OS and release a node to another tenant and then later restart the image on any compatible node; a key property of elasticity in virtualized clouds that is not possible with stateful provisioning systems like Foreman.

We show in Figure 4 the costs of all the different phases of an attested boot. With UEFI, after POST, the phases are: (i) PXE downloading iPXE, (ii) iPXE downloading LinuxBoot's runtime (Heads), (iii) booting LinuxBoot, (iv) downloading the Keylime Agent (using HTTP), (v) running the Keylime Agent, registering the server and attesting it, and then downloading the tenant's kernel and initrd, (vi) moving the server into the tenant's network and making sure it is connected to the BMI server and finally (vii) LinuxBoot kexec'ing into the tenant's kernel and booting the server. In each step, the running software measures the next software and extends the result into a TPM PCR. Using LinuxBoot firmware, after POST we immediately jump to step (iv) above.

While the steps for attestation where complex to implement, the overall performance cost is relatively modest, adding only around 25% to the cost of provisioning a server.[8] This is an

[8]Moreover, given that performance is sufficient, we have so far made no effort to optimize the implementation. Obvious opportunities include better download protocols than HTTP, porting the Keylime Agent from python to Rust, etc.

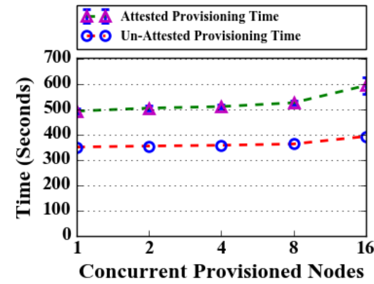

Figure 5: Bolted Concurrency

important result given a large number of bare-metal systems (e.g. CloudLab, Chameleon, Foreman, ...), that take no security measure today to ensure that firmware has not been corrupted. There is no performance justification today for not using attestation, and our project has demonstrated that it is possible to measure all components needed to boot a server securely. For the full attestation scenarios (UEFI and LinuxBoot), two more steps are added to the basic attestation scenarios: (+i) loading the cryptographic key and decrypting the encrypted storage with LUKS (+ii) establishing IPsec tunnel and connecting to the encrypted network. These two steps are incorporated into Kernel boot time in Figure 4. We can see that the major cost is not these extra steps but the slow down in booting into the image that comes from the slower disk that is accessed over IPsec.

Concurrency: Figure 5 shows (with UEFI firmware) how Bolted performs, with and without attestation, as we increase the number of concurrently booting servers (log scale). In both the attested and unattested case performance stays relatively flat until 8 nodes. In our current environment, this level of concurrency/elasticity has been more than sufficient for the community of researchers using Bolted. There is a substantial degradation in both the attested and unattested case when we go from 8 to 16 servers. In the unattested case, the degradation is due to the small scale Ceph deployment (with only 27 disks) available in our experimental infrastructure. For the attested boot, the performance degradation arises from a limitation in our current implementation where we only support a single airlock at a time; attestation for provisioning is currently serialized. While this scalability limitation is not a problem for current use cases in our data center, we intend to address it to enable future use cases of highly-elastic security-sensitive tenants; e.g., a national emergency requiring many computers.

7.4 Continuous Attestation

Once a server has been provisioned, a security sensitive tenant can further use IMA to continuously measure any changes to the configuration and applications. The Keylime Agent will include the IMA measurement list along with periodic continuous attestation quotes. This allows the Keylime Cloud Verifier to help ensure the integrity of the server's runtime state by comparing the provided measurement list with a

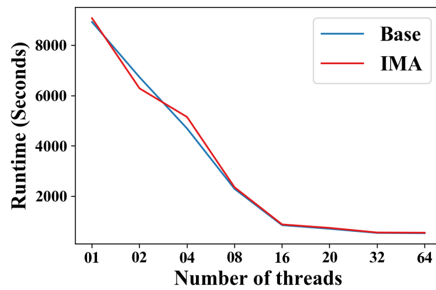

Figure 6: IMA overhead on Linux Kernel Compile

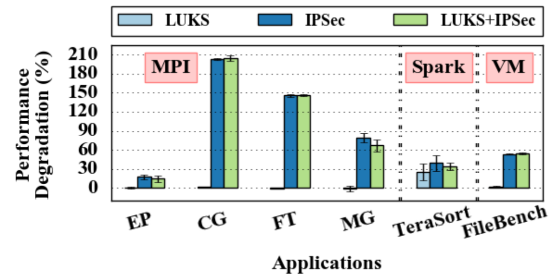

Figure 7: Macro-benchmarks' performance

whitelist of approved values provided by the tenant. In the case of a policy violation, Keylime can then revoke any keys used for network or disk encryption; essentially isolating the server. To evaluate IMA performance, we measured Linux kernel 4.16.12 compile time with and without IMA with a different number of processing threads. We use kernel compilation as a test case for IMA because it requires extensive file I/O and execution of many binaries. The IMA policy we used measured all files that are executed as well as all files read by the *root* user. To stress IMA we ran the kernel compile as root such that all of its activity would be measured.[9] Figure 6 shows the results in log scale; even in this unrealistic stress test IMA does not impose a noticeable overhead.

Keylime can detect policy violations from checking the IMA measurements and TPM quotes in under one second. To simulate a policy violation, we ran a script on the server without having a record of it in the whitelist, resulting in an IMA measurement different than expected. This results in Keylime issuing a revocation notification for the key of the affected server used for IPsec to the other servers in the system; the entire process takes approximately 3 seconds for a compromised server to have its IPsec connections to other servers reset and be cryptographically banned from the network.

7.5 Macro-Benchmarks

Security-sensitive tenants using Bolted rely on network and disk encryption to minimize their trust in the provider. Surprisingly there is little information in the literature what the cost of such encryption is for real applications. Is the performance good enough that we can tolerate a one-size-fits-all solution and avoid ever trusting the provider? Is the performance so poor that it will never make sense for security-sensitive customers to use Bolted?

Figure 7 (MPI) shows performance degradation results for a variety of applications from the NAS Parallel Benchmark [22] version 3.3.1: Embarrassingly Parallel (EP), Conjugate Gradient (CG), Fourier Transform (FT) and Multi Grid (MG) applications class D running in a 16 server enclave. We see overall that these applications only suffer significant overhead for IPsec, ranging from ∼18% for EB, which has modest communication, to ∼200% for CG which is very communication intensive. These results suggest that there are definitely workloads for which not trusting the provider incurs little overhead. At the same time, a one-size-fits-all solution is inappropriate; only tenants that are willing to trust the provider, and avoid the cost of encryption, are likely to run highly communication intensive applications in the cloud.

To understand the performance overhead for more cloud relevant workloads, Figure 7 (Spark) shows the performance of Spark [81] framework version 2.3.1 (working on Hadoop version 2.7.7) running TeraSort on a 260GB data set. The experiment is run in parallel in an enclave of 16 servers. TeraSort is a complex application which reads data from remote storage, shuffles temporary data between servers and writes final results to remote storage. We can see a significant overall degradation, of ∼30% for LUKS+IPsec. While this degradation is significant, we expect that security sensitive tenants would be willing to incur this level of overhead. On the other hand, this overhead is large enough that tenants willing to trust the provider would prefer not to incur it, suggesting that the flexibility of Bolted to provide this choice to the tenant is important.

Our last experiment (Figure 7 (VM)) is based on virtualization. An important application of bare metal servers is to run virtualized software (e.g., an IaaS cloud). In this experiment, we installed KVM QEMU version 2.11.2 on a M620 server as the hypervisor. The virtual machine we run on the hypervisor is CentOS 7 with Linux kernel 3.10.0. It has 8 vCPU cores and 32 GB RAM. This is based on the observation [28] that 90% of virtual machines having $\leq$ 8 vCPU cores and $\leq$ 32 GB RAM. We run Filebench version 1.4.9.1 benchmark [75] on 1000 files with 12MB average size on the virtual machine. We can see that the performance of this benchmark is ∼50% worse in the case of IPsec; a significant performance penalty. While we would expect less of a degradation for regular VMs (rather than ones running a file system benchmark), we can see that a tenant deploying generic services, like virtualization, should be very careful about the kind of workload they expect to use the service.

8 Related Work

Our work on creating a secure bare-metal cloud was motivated by a huge body of research demonstrating vulnerabilities due

[9] This policy and workload are very unlikely to be either useful or manageable from a security perspective. We used them only as a stress test.

to co-location in virtualized clouds including both hypervisor attacks [21,49,64,73,80] and side-channel and cover-channel attacks like the Meltdown and Spectre exploits [51,54,55,66, 69].

There is a large body of products and research projects for bare-metal clouds [27,46,48,63,65] and cluster deployment systems [15, 42, 62, 68] that have many of the capabilities of isolation and provisioning that Bolted includes. The fundamental difference with Bolted is that we strongly separate isolation from provisioning and different entities (e.g. security sensitive tenants) can control/deploy and even re-implement the provisioning service. This structuring clearly defines the TCB that needs to be deployed by the provider.

While it is often unclear exactly which technique each cloud uses to protect against firmware attacks, a wide variety of techniques have been used including specialized hardware [16, 18], using a specialized hypervisor to prevent access to firmware [31], and attestation to the provider [44, 47]. In all cases, there is no way for a tenant to programmatically verify that the firmware is up to date and not compromised by previous tenants. Bolted is unique in enabling tenant deployed attestation for bare-metal servers, where the measurement of the firmware and software are provided directly to the tenant.

The static root of trust (SRTM) approach used by Bolted requires all software to be measured in an unbroken chain of trust. It would have been simpler for us to use dynamic root of trust (DRTM), however, DRTM has additional chip dependencies and, more importantly, been shown to be vulnerable to attacks [79] and work of Kovah et. al has shown that it can be used as an attack vector itself [52].

9 Concluding Remarks

We presented Bolted, an architecture for a bare metal cloud that is appropriate for even the most security sensitive tenants; allowing these customers to take control over their own security. The only trust these tenants need to place in the provider is for the availability of the resources and that the physical hardware has not been compromised. At the same time, by delegating security for security sensitive tenants to the tenants, Bolted frees the provider from the complexity of having to directly support these demanding customers and avoids impact to customers that are less security sensitive.

To enable a wide community to inspect the TCB, all components of Bolted are open source. We designed HIL, for example, to be a simple micro-service rather than a general purpose tool like IRONIC [62] or Emulab [19]. HIL is being incorporated into a variety of different use cases by adding tools and services on and around it rather than turning it into a general purpose tool. Another key example of a small open source component is LinuxBoot. LinuxBoot is much simpler than UEFI. Since it is based on Linux, it has a code base that is under constant examination by a huge community of developers. LinuxBoot is reproducibly built, so a tenant can examine the software to ensure that it meets their security requirements and then ensure that the firmware deployed on machines is the version that they require.

Bolted protects against compromise of firmware executable by the system CPU; however modern systems may have other processors with persistent firmware inaccessible to the main CPU; compromise of this firmware is not addressed by this approach. These include: Base Management Controllers (BMCs) [58], the Intel Management Engine [29,53,60], PCIe devices with persistent flash-based firmware, like some GPUs and NICs, and storage devices [50]. Additional work (e.g. IOMMU based techniques, disabling the Management Engine [14] and the use of specialized systems with minimum firmware) will be needed to meet these threats.

The evaluation of our prototype has demonstrated that we can rapidly provision secure servers with competitive performance to today's virtualized clouds; removing one of the major barriers to bare metal clouds. We demonstrate that the cost of not trusting the provider (network/storage encryption) and of additional runtime security (continuous attestation) varies enormously depending on the application. (In fact, we are not aware of other work that has quantified the cost of network encryption, disk encryption, and continuous attestation with modern servers and implementation.) Results for HPC applications vary from negligible overhead to three times overhead for communication-intensive applications. Clearly the public cloud becomes economically unattractive for applications with three times overhead unless there are no other alternatives. However, we expect that the $\sim$30% degradation we see for TeraSort is likely representative of many applications today. Such overheads suggest that the cost of security is modest enough that security-sensitive customers will find value in using cloud resources. At the same time, the overhead is significant enough that the flexibility of Bolted that enables tenants to just pay for the security they need is justified. One surprising result is that our secure firmware, LinuxBoot achieves dramatically better POST time than existing firmware; this is one of the few times in our experience that additional security comes with performance advantages.

10 Acknowledgment

We would like to acknowledge the feedback of the anonymous reviewers and our shepherd, Dr. Nadav Amit. We would like to thank Red Hat, Two Sigma and NetApp, the core industry partners of Mass Open Cloud (MOC) for supporting this work. This project involved extensive efforts over many years to integrate all the components together. We gratefully acknowledge Jason Hennessey, Gerardo Ravago, Ali Raza, Naved Ansari, Kyle Hogan, and Radoslav Nikiforov Milanov for their significant contributions in development and their assistance in the evaluations. Partial support for this work was provided by the USAF Cloud Analysis Model Prototype project, National Science Foundation awards CNS-1414119, ACI-1440788 and OAC-1740218.

Abstract

Today's ultra-low latency SSDs can deliver an I/O latency of sub-ten microseconds. With this dramatically shrunken device time, operations inside the kernel I/O stack, which were traditionally considered lightweight, are no longer a negligible portion. This motivates us to reexamine the storage I/O stack design and propose an *asynchronous* I/O stack (AIOS), where synchronous operations in the I/O path are replaced by asynchronous ones to overlap I/O-related CPU operations with device I/O. The asynchronous I/O stack leverages a lightweight block layer specialized for NVMe SSDs using the page cache without block I/O scheduling and merging, thereby reducing the sojourn time in the block layer. We prototype the proposed asynchronous I/O stack on the Linux kernel and evaluate it with various workloads. Synthetic FIO benchmarks demonstrate that the application-perceived I/O latency falls into single-digit microseconds for 4 KB random reads on Optane SSD, and the overall I/O latency is reduced by 15–33% across varying block sizes. This I/O latency reduction leads to a significant performance improvement of real-world applications as well: 11–44% IOPS increase on RocksDB and 15–30% throughput improvement on Filebench and OLTP workloads.

1 Introduction

With advances in non-volatile memory technologies, such as flash memory and phase-change memory, ultra-low latency solid-state drives (SSDs) have emerged to deliver extremely low latency and high bandwidth I/O performance. The state-of-the-art non-volatile memory express (NVMe) SSDs, such as Samsung Z-SSD [32], Intel Optane SSD [12] and Toshiba XL-Flash [25], provide sub-ten microseconds of I/O latency and up to 3.0 GB/s of I/O bandwidth [12, 25, 32]. With these ultra-low latency SSDs, the kernel I/O stack accounts for a large fraction in total I/O latency and is becoming a bottleneck to a greater extent in storage access.

[*]Currently at Samsung Electronics

One way to alleviate the I/O stack overhead is to allow user processes to directly access storage devices [6, 16, 27, 28, 49]. While this approach is effective in eliminating I/O stack overheads, it tosses many burdens to applications. For example, applications are required to have their own block management layers [49] or file systems [15, 43, 49] to build useful I/O primitives on top of a simple block-level interface (e.g., BlobFS in SPDK). Providing protections between multiple applications or users is also challenging [6, 16, 28, 43]. These burdens limit the applicability of user-level direct access to storage devices [49].

An alternative, more popular way to alleviate the I/O stack overhead is to optimize the kernel I/O stack. Traditionally, the operating system (OS) is in charge of managing storage and providing file abstractions to applications. To make the kernel more suitable for fast storage devices, many prior work proposed various solutions to reduce the I/O stack overheads. Examples of such prior work include the use of polling mechanism to avoid context switching overheads [5, 47], removal of bottom halves in interrupt handling [24, 35], proposal of scatter/scatter I/O commands [37, 50], simple block I/O scheduling [3, 24], and so on. These proposals are effective in reducing I/O stack overheads, and some of those are adopted by mainstream OS (e.g., I/O stack for NVMe SSDs in Linux).

In our work, we identify new unexplored opportunities to further optimize the I/O latency in storage access. The current I/O stack implementation requires many operations to service a single I/O request. For example, when an application issues a read I/O request, a page is allocated and indexed in a page cache [36]. Then, a DMA mapping is made and several auxiliary data structures (e.g., `bio`, `request`, `iod` in Linux) are allocated and manipulated. The issue here is that these operations occur synchronously before an actual I/O command is issued to the device. With ultra-low latency SSDs, the time it takes to execute these operations is comparable to the actual I/O data transfer time. In such case, overlapping those operations with the data transfer can substantially reduce the end-to-end I/O latency.

To this end, this paper proposes an *asynchronous* I/O

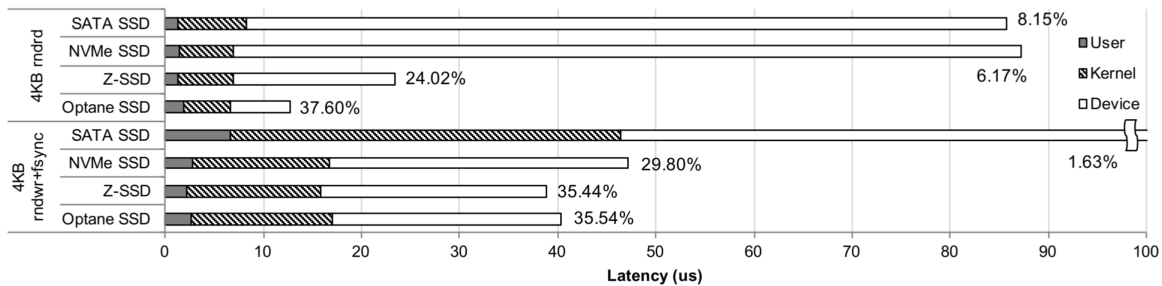

Figure 1: I/O latency and its breakdown with various storage devices. The numbers beside each bar denote the relative fraction of kernel time in the total I/O latency.

stack (AIOS), a low-latency I/O stack for ultra-low latency SSDs. Through a careful analysis of synchronous, hence latency-critical, system call implementations (i.e., `read()` and `fsync()`) in the Linux kernel, we identify I/O-related CPU operations that can be overlapped with device I/O operations and modify the Linux kernel to execute such CPU operations while the I/O device is processing a request. To further reduce the CPU overhead, we also introduce a lightweight block I/O layer (LBIO) specialized for NVMe-based SSDs, which enables the kernel to spend considerably less time in the block I/O layer. Our evaluation demonstrates that AIOS achieves up to 33% latency reduction for random reads and 31% latency reduction for random writes on FIO benchmarks [2]. Also, AIOS enables various real-world applications (e.g., a key-value store, database) to achieve higher throughput. Our contributions are summarized as follows:

- We provide a detailed analysis of the Linux kernel I/O stack operations and identify CPU operations that can overlap with device I/O operations (Section 2).
- We propose the lightweight block I/O layer (LBIO) specialized for modern NVMe-based SSD devices, which offers notably lower latency than the vanilla Linux kernel block layer (Section 3.1).
- We propose the asynchronous I/O stack for read and fsync paths in which CPU operations are overlapped with device I/O operations, thereby reducing the completion time of the read and fsync system calls (Section 3.2 and 3.3).
- We provide a detailed evaluation of the proposed schemes to show the latency reduction of up to 33% for random reads and 31% for random writes on FIO benchmarks [2] and substantial throughput increase on real-world workloads: 11–44% on RocksDB [10] and 15–30% on Filebench [40] and OLTP [18] workloads (Section 4).

2 Background and Motivation

2.1 ULL SSDs and I/O Stack Overheads

Storage performance is important in computer systems as data should be continuously supplied to a CPU to not stall the pipeline. Traditionally, storage devices have been much slower than CPUs, and this wide performance gap has existed for decades [26]. However, the recent introduction of modern storage devices is rapidly narrowing this gap. For example, today's ultra-low latency (ULL) NVMe SSDs, such as Samsung's Z-SSD [32], Intel's Optane SSD [12], and Toshiba's XL-Flash [25], can achieve sub-ten microseconds of I/O latency, which is orders of magnitude faster than that of traditional disks.

With such ultra-low latency SSDs, the kernel I/O stack [11, 38] no longer takes a negligible portion in the total I/O latency. Figure 1 shows the I/O latency and its breakdown for 4 KB random read and random write + `fsync` workloads on various SSDs[1]. The figure shows that ultra-low latency SSDs achieve substantially lower I/O latency than conventional SSDs. Specifically, their device I/O time is much lower than that of the conventional SSDs. On the other hand, the amount of time spent in the kernel does not change across different SSDs. As a result, the fraction of the time spent in the kernel becomes more substantial (i.e., up to 37.6% and 35.5% for the read and write workloads, respectively).

An I/O stack is composed of many layers [17]. A virtual file system (VFS) layer provides an abstraction of underlying file systems. A page cache layer provides caching of file data. A file system layer provides file system-specific implementations on top of the block storage. A block layer provides OS-level block request/response management and block I/O scheduling. Finally, a device driver handles device-specific I/O command submission and completion. In this paper, we target two latency-sensitive I/O paths (`read()` and `write()+fsync()`) in the Linux kernel and Ext4 file system with NVMe-based SSDs, since they are widely adopted system configurations from the mobile [13] to enterprise [33, 51].

2.2 Read Path

2.2.1 Vanilla Read Path Behavior

Figure 2 briefly describes the read path in the Linux kernel. Buffered read system calls (e.g., `read()` and `pread()` without `O_DIRECT`) fall into the VFS function (`buffered_read()` in the figure), which is an entry point to the page cache layer.

Page cache. Upon a cache miss (Line 3-4), the function

[1] The detailed evaluation configurations can be found in Section 4.1. Note that all the tested NVMe SSDs feature a non-volatile write cache, hence showing low write latency.

```
1  void buffered_read(file, begin, end, buf) {
2   for (idx=begin; idx<end; idx++) {
3    page = page_cache_lookup(idx)
4    if (!page) {
5     page_cache_sync_readahead(file, idx, end)
6     page = page_cache_lookup(idx)
7    } else {
8     page_cache_async_readahead(file, idx, end)
9    }
10   lock_page(page)
11   memcpy(buf, page, PAGE_SIZE)
12   buf += PAGE_SIZE
13  }
14 }
15
16 void page_cache_readahead(file, begin, end) {
17  init_list(pages)
18  for (idx=begin; idx<end; idx++) {
19   if (!page_cache_lookup(file, idx)) {
20    page = alloc_page()
21    page->idx = idx
22    push(pages, page)
23   }
24  }
25  readpages(file, pages)
26 }
27
28 void ext4_readpages(file, pages) {
29  blk_start_plug()
30  for (page : pages) {
31   add_to_page_cache(page, page->idx, file)
32   lba = ext4_map_blocks(file, page->idx)
33   bio = alloc_bio(page, lba)
34   submit_bio(bio)
35  }
36  blk_finish_plug()
37 }
```

Figure 2: Pseudocode for Linux kernel read path.

`page_cache_sync_readahead()` is called, in which missing file blocks are read into the page cache. It identifies all missing indices within the requested file range (Line 18-19), allocates pages and associates the pages with the missing indices (Line 20-21). Finally, it requests the file system to read the missing pages (Line 25).

File system. File systems have their own implementation of `readpages()`, but their behaviors are similar to each other. In Ext4 `ext4_readpages()` inserts each page into the page cache (Line 30-31), retrieves the logical block address (LBA) of the page (Line 32) and issues a block request to the underlying block layer (Line 33-34).

Linux batches several block requests issued by a thread in order to increase the efficiency of request handling in the underlying layers (also known as *queue plugging* [4]). When `blk_start_plug()` is called (Line 29), block requests are collected in a plug list of the current thread. When `blk_finish_plug()` (Line 36) is called or the current thread is context-switched, the collected requests are flushed to the block I/O scheduler.

After issuing an I/O request to a storage device, the thread rewinds its call stack and becomes blocked at the function `lock_page()` (Line 10). When the I/O request is completed,

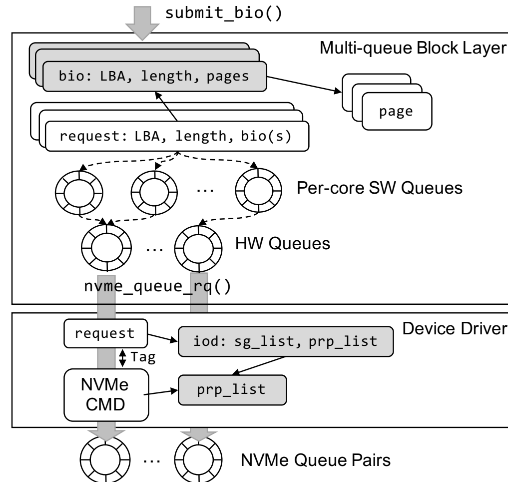

Figure 3: The overview of the multi-queue block layer. The shaded rectangles are dynamically allocated objects.

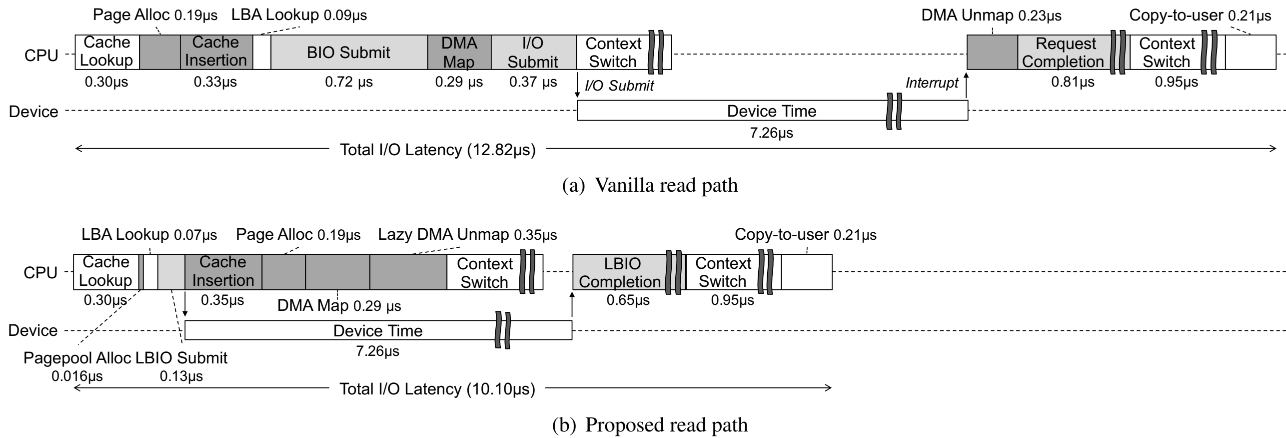
the interrupt handler releases the lock of the page, which wakes up the blocked thread. Finally, the cached data are copied to the user buffer (Line 11-12).

Block layer. Figure 3 shows the overview of the multi-queue block layer, which is the default block layer for NVMe SSDs in the Linux kernel, and the device driver layer. In the block layer, a `bio` object is allocated using a slab allocator and initialized to contain the information of a single block request (i.e., LBA, I/O size and pages to copy-in) (Line 33). Then, `submit_bio()` (Line 34) transforms the `bio` object to a `request` object and inserts the `request` object into request queues, where I/O merging and scheduling are performed [3, 8]. The `request` object passes through a per-core software queue (`ctx`) and hardware queue (`hctx`) and eventually reaches the device driver layer.

Device driver. A `request` is dispatched to the device driver using `nvme_queue_rq()`. It first allocates an `iod` object, a structure having a scatter/gather list, and uses it to perform DMA (direct memory access) mapping, hence allocating I/O virtual addresses (or DMA addresses) to the pages in the dispatched request. Then, a `prp_list`, which contains physical region pages (PRP) in the NVMe protocol, is allocated and filled with the allocated DMA addresses. Finally, an NVMe command is created using the `request` and the `prp_list` and issued to an NVMe submission queue. Upon I/O completion, the interrupt handler unmaps DMA addresses of the pages and calls a completion function, which eventually wakes up the blocked thread. While the above describes the basic operations in the read path, the roles of the block and device driver layers are identical in the write path.

2.2.2 Motivation for Asynchronous Read Path

Figure 4(a) summarizes the operations and their execution times in the read path explained in Section 2.2.1. The main problem is that a single read I/O path has many operations



(a) Vanilla read path

(b) Proposed read path

Figure 4: The operations and their execution times in the read paths during 4 KB random read on Optane SSD. (drawn to scale in time)

that occur synchronously to an actual device I/O operation. This synchronous design is common and intuitive and works well with slow storage devices because in such cases, the time spent on CPU is negligible compared to the total I/O latency. However, with ultra-low latency SSDs, the amount of CPU time spent on each operation becomes a significant portion of the total I/O latency.

Table 1 summarizes the ratio of each operation to the total kernel time. With small I/O sizes, the context switching is the most time-consuming operation. In this case, it is possible to reduce the overhead through the use of polling [5, 47]. The copy-to-user is another costly operation but is a necessary operation when file data is backed by the page cache. If we exclude these two operations, the remaining operations account for 45-50% of the kernel time.

Upon careful analysis of the code, we find that many of the remaining operations do not have to be performed before or after the device I/O time. In fact, such operations can be performed while the device I/O operation is happening since such operations are mostly independent of the device I/O operation. This motivates us to overlap such operations with the device I/O operation as sketched in Figure 4(b) (shaded in dark gray).

Layer	Action	Lines in Figure 2	% in kernel time
Page cache	Missing page lookup Page allocation	Line 18-24	9–10.8%
	Copy-to-user	Line 11-12	4.5–12%
File system	Page cache insertion LBA retrieval `bio` alloc/submit Make `request` from `bio`	Line 30-35	26–28.5%
Block	I/O scheduling (noop)	Line 36	10–11%
Driver	DMA mapping/unmapping NVMe command submit		
Scheduler	Context switch (2 times)	Line 10	25–41.5%

Table 1: Summary of operations and their fractions in kernel time in the read path. (4–16 KB FIO rndrd on Optane SSD)

2.3 Write Path

2.3.1 Vanilla Write Path Behavior

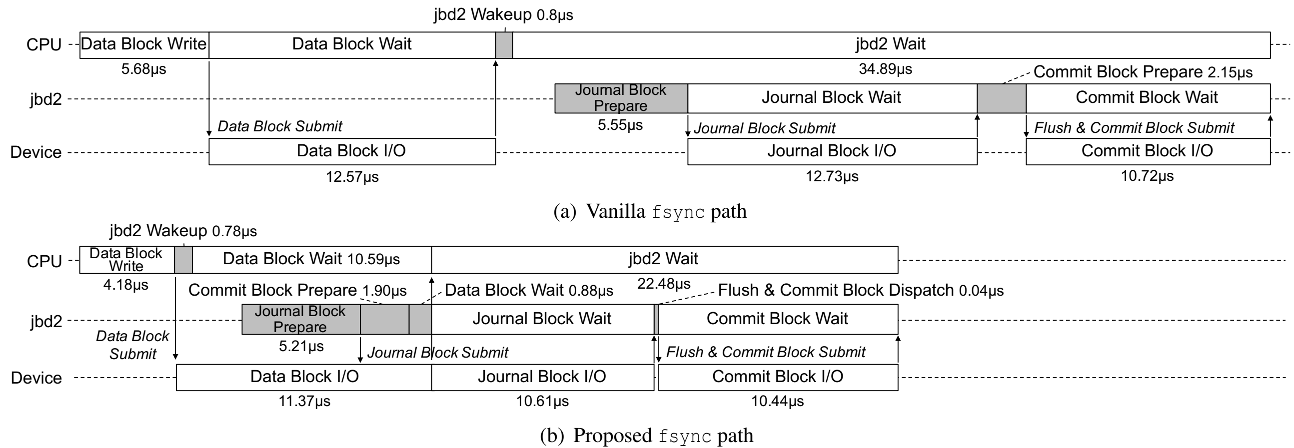
Buffered write system calls (e.g., `write()`) usually buffer the modified data in the page cache in memory. When an application calls `fsync()`, the kernel actually performs write I/Os to synchronize the dirtied data with a storage device.

The buffered write path has no opportunity to overlap computation with I/O because it does not perform any I/O operation. On the other hand, `fsync` accompanies several I/O operations due to the writeback of dirtied data as well as a crash consistency mechanism in a file system (e.g., file system journaling). Since `fsync` most heavily affects the application performance in the write path, we examine it in more detail.

Figure 5(a) shows the operations and their execution times during an `fsync` call on Ext4 file system using ordered journaling. First, an application thread issues write I/Os for dirty file blocks and waits for them to complete. Then, the application thread wakes up a journaling thread (`jbd2` in Ext4) to commit the file system transaction. It first prepares the write of modified metadata (*journal block* in the figure) onto the journal area and issues the write I/O. Then, it waits for the completion of the write. Once completed, it prepares the write of a commit block and issues the write I/O. A flush command is enforced between the journal block write and the commit block write to enforce the ordering of writes [45]. Hence, total three device I/O operations occur for a single `fsync` call.

2.3.2 Motivation for Asynchronous Write Path

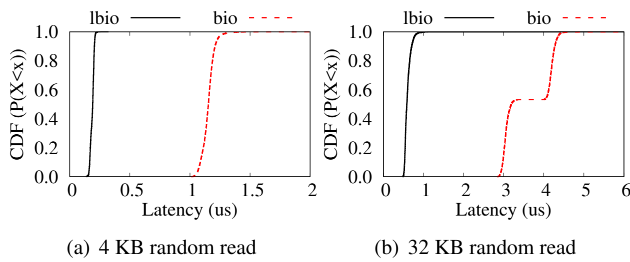
As in the case of the read path, there is also an opportunity to overlap the device I/O operations with the computation parts in the `fsync` path. As shown in Figure 5(a), the journaling thread performs I/O preparation and I/O waiting synchronously. Each I/O preparation includes assigning blocks in the journal area to write on, allocating buffer pages, allo-



(a) Vanilla `fsync` path

(b) Proposed `fsync` path

Figure 5: The operations and their execution times in the `fsync` paths during 4 KB random write with `fsync` on Optane SSD. (drawn to scale in time)



(a) 4 KB random read

(b) 32 KB random read

Figure 6: The CDF of the block I/O submission latency in the Linux block layer (*bio*) and the proposed lightweight block layer (*lbio*) on Optane SSD.

cating/submitting a `bio` object, assigning DMA address, and so forth. If these CPU operations are overlapped with the previous device I/O time, the total latency of the `fsync` system call can be greatly reduced as shown in Figure 5(b).

2.4 Motivation for Lightweight Block Layer

The Linux kernel uses the multi-queue block layer for NVMe SSDs by default to scale well with multiple command queues and multi-core CPUs [3]. This block layer provides functionality like block I/O submission/completion, request merging/reordering, I/O scheduling and I/O command tagging [3]. While these features are necessary for general block I/O management, they delay the submission time of an I/O command to a storage device.

Figure 6 shows the block I/O submission latency, time from allocating a `bio` object to dispatching an I/O command to a device (denoted as *bio*); the figure also includes the same measurement using the proposed lightweight block layer in Section 3.1 (denoted as *lbio*). We use two I/O sizes, 4 KB and 32 KB, to minimize and maximize the number of dynamic memory allocations during I/O submissions, respectively. Considering that the device time for a 4 KB read is around 7.3 μs on ultra-low latency SSDs, the amount of time spent in the block layer is about 15% of the device time, which is a non-negligible portion.

While block I/O submission/completion and I/O command tagging are necessary features, request merging/reordering and I/O scheduling are not significant. The multi-queue block layer supports various I/O schedulers [8] but its default configuration is *noop* since many studies report that I/O scheduling is ineffective for reducing I/O latency for latency-critical applications on fast storage devices [34, 46, 51]. I/O scheduling can also be replaced by the device-side I/O scheduling capability [14]. The effectiveness of request merging/reordering is also questionable in ultra-low latency SSDs because of their high random access performance and the low probability to find adjacent or identical block requests.

Based on these intuitions, we propose to simplify the roles of the block layer and make it specialized for our asynchronous I/O stack to minimize its I/O submission delay.

3 Asynchronous I/O Stack

The proposed asynchronous I/O stack (AIOS) consists of two components: the lightweight block I/O layer (LBIO) and the modified I/O stack that overlaps I/O-related computations with the device I/O operations. This section first explains LBIO and then explains the modified read and write paths.

3.1 Lightweight Block I/O Layer

To minimize the software overheads in the block layer, we design a lightweight block I/O layer (or LBIO), a scalable, lightweight alternative to the existing multi-queue block layer. LBIO is designed for low-latency NVMe SSDs and supports only I/O submission/completion and I/O command tagging. Figure 7 shows the overview of our proposed LBIO.

Unlike the original multi-queue block layer, LBIO uses a single memory object, `lbio`, to represent a single block I/O request, thereby eliminating the time-consuming `bio`-to-`request` transformation in the original block layer. Each

`lbio` object contains LBA, I/O length, pages to copy-in and DMA addresses of the pages. Containing DMA addresses in `lbio` leverages the asynchronous DMA mapping feature explained in the following sections. An `lbio` only supports 4 KB-aligned DMA address with I/O length of multiple sectors to simplify the codes initializing and submitting block I/O requests. This approach is viable with the assumption of using the page cache layer. Similar to the original block layer, LBIO supports queue plugging to batch multiple block I/O requests issued by a single thread.

LBIO has a global `lbio` two-dimensional array whose row is dedicated to each core, and a group of rows is assigned to each NVMe queue pair as shown in Figure 7. For example, if a system has 8 cores and 4 NVMe queue pairs, each `lbio` array row is one-to-one mapped to each core and two consecutive rows are mapped to an NVMe queue pair. When the number of NVMe queue pairs is equal to the number of cores, lockless `lbio` object allocations and NVMe command submissions are possible, as in the existing multi-queue block layer. The index of an `lbio` object in the global array is used as a tag in an NVMe command. This eliminates the time-consuming tag allocation in the original block layer.

Once an `lbio` is submitted, the thread directly calls `nvme_queue_lbio()` to dispatch an NVMe I/O command. Note that LBIO does not perform I/O merging or I/O scheduling, and thus reduces I/O submission delay significantly. Without the I/O merging, it is possible for two or more `lbio`'s to access the same logical block. This potentially happens in the read path and is resolved by the page cache layer (see Section 3.2). However, this does not happen in the write path because the page cache synchronizes writeback of dirty pages.

Figure 6 shows the reduced I/O submission latency with LBIO. On average, a block I/O request in LBIO takes only 0.18–0.60 μs, which is 83.4%–84.4% shorter latency compared to that of the original block layer.

3.2 Read Path

In addition to the introduction of LBIO, our approach reduces the I/O latency of the read path by detaching synchronous operations from the critical path as sketched in Figure 4(b). The following subsections describe each relocated operation and additional work to support the relocation.

3.2.1 Preloading Extent Tree

For a read operation, retrieving LBAs corresponding to the missing file blocks is a necessary step to issue a block request and thus this operation should be in the critical path. Instead of taking this step off the critical path, our proposal focuses on reducing its latency itself. The implementation of the Linux Ext4 file system caches logical to physical file block mappings in memory, and this cache is called extent status tree [19]. When a mapping can be found in the cache, obtaining an LBA takes a relatively short time; however, when the mapping is not found, the system has to issue an I/O request to read the missing mapping block and thus incurs much longer delay.

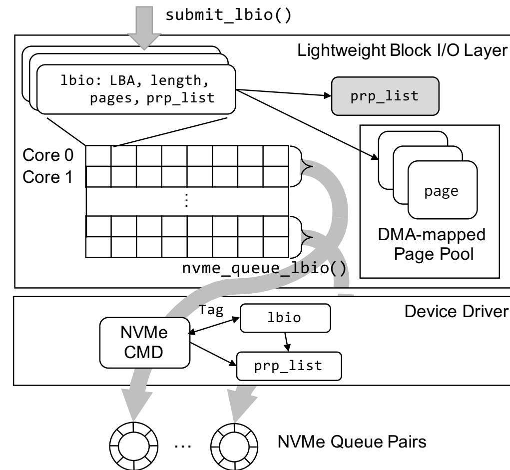


Figure 7: The proposed lightweight block I/O layer (LBIO). Shaded objects are dynamically allocated.

To avoid this unnecessary overhead, we adopt a plane separation approach [28]. In the control plane (e.g., file open), the entire mapping information is preloaded in memory. By doing so, the data plane (e.g., read and write) can avoid the latency delay caused by a mapping cache miss. The memory costs of caching an entire tree can be high; the worst case overhead is 0.03% of the file size in our evaluation. However, when there is little free memory, the extent cache evicts unlikely-used tree nodes to secure free memory [19]. To reduce the space overhead even further, this technique can be selectively applied to files requiring low-latency access.

3.2.2 Asynchronous Page Allocation/DMA Mapping

Preparation of free pages is another essential operation in the read path. In the original read path, a page allocator of the kernel performs this task, and it consumes many CPU cycles. For example, a single page allocation takes 0.19 μs on average in our system as shown in Figure 4(a). Similarly, assigning a DMA address to each page (DMA mapping) takes a large number of CPU cycles (754 cycles or 0.29 μs). Our approach is to take these operations off from the critical path and perform them while the device I/O operation is happening.

To this end, we maintain a small set of DMA-mapped free pages (a linked list of 4 KB DMA-mapped pages) for each core. With this structure, only a few memory instructions are necessary to get free pages from the pool (*Pagepool Alloc* in Figure 4(b)). The consumed pages are refilled by invoking page allocation and DMA mapping while the device I/O operation is occurring. This effectively hides the time for both page allocation and DMA mapping from the application-perceived I/O latency as shown in the figure. Note that, when the number of free pages in the pool is smaller than the read request size, page allocation and DMA mapping happens synchronously as in the vanilla kernel case.

3.2.3 Lazy Page Cache Indexing

Insertion of a page into a page cache index structure is another source of the large kernel I/O stack latency. Our approach is to overlap this operation with the device I/O operation while resolving the potentially duplicated I/O submissions.

In the vanilla kernel, the page cache works as a synchronization point that determines whether a block I/O request for a file can be issued or not. File blocks whose cache pages are successfully inserted into the page cache are allowed to make block requests (Line 31 in Figure 2), and a spinlock is used to protect the page cache from concurrent updates. Consequently, no duplicated I/O submission occurs for the same file block.

However, if we delay the page cache insertion operation to a point after submitting an I/O command to a device, it is possible for another thread to miss on the same file block and to issue a duplicate block request. To be exact, this happens if another thread accesses the page cache after the I/O request is submitted but before the page cache entry is updated.

Our solution is to allow duplicated block requests but resolve them at the request completion phase. Although there are multiple block requests associated with the same file block, only a single page is indexed in the page cache. Then, our scheme marks other pages as *abandoned*. The interrupt handler frees a page associated with the completed block request if it is marked *abandoned*.

3.2.4 Lazy DMA Unmapping

The last long-latency operation in the read path is DMA unmapping that occurs after the device I/O request is completed. The vanilla read path handles this in the interrupt handler, which is also in the critical path. Our scheme delays this operation to when a system is idle or waiting for another I/O request (*Lazy DMA unmap* in Figure 4(b)).

Note that this scheme prolongs the time window in which the DMA buffer is accessible by the storage device. This is essentially an extended version of the deferred protection scheme used in Linux by default [20]. Deferring the DMA unmapping (either in our scheme or in Linux) may potentially create a vulnerability window from a device-side DMA attack. However, with an assumption that the kernel and the device are neither malicious nor vulnerable, the deferred protection causes no problem [20]. If the assumption is not viable, users can disable the lazy DMA unmapping.

3.3 Write and fsync Path

As explained in Section 2.3.1, an `fsync` system call entails multiple I/O operations, and thus it is not possible to reuse the same scheme we proposed for the read path. For example, by the time `fsync` happens, pages are already allocated and indexed in the page cache. Instead of overlapping the I/O-related computation with individual device I/O operation, we focus on applying the overlapping idea to the entire file system journaling process.

Specifically, we overlap the computation parts in the journaling thread with the previous I/O operations in the same write path. As shown in Figure 5(a), there are two I/O preparation operations: journal block preparation and commit block preparation. Each preparation operation includes allocating buffer pages, allocating a block on the journal area, calculating the checksum and computation operations within the block and device driver layers. Since these operations only modify in-memory data structures, they have no dependency on the previous I/O operation in the same write path. Note that, at any given time, only a single file system transaction can be committed. While a transaction is in the middle of commit, no other file system changes can be entangled to the current transaction being committed. Hence, if the ordering constraint, which allows the write of a commit block only after the data blocks and journal blocks are made durable on the storage media, is guaranteed, our approach can provide the same crash consistency semantic provided by the vanilla write path.

To this end, we change the `fsync` path as shown in Figure 5(b). Upon an `fsync` system call, an application thread issues the writeback of dirty data pages first. Then, it wakes up the journaling thread in advance to overlap the data block I/Os with the computation parts in the journaling thread. The application thread finally waits for the completion of the writeback I/Os as well as the completion of the journal commit. While the data block I/O operations are happening, the journaling thread prepares the journal block writes and issues their write I/Os. Then, it prepares the commit block write and waits for the completion of all the previous I/O operations associated with the current transaction. Once completed, it sends a flush command to the storage device to make all the previous I/Os durable and finally issues a write I/O of the commit block using a write-through I/O command (e.g., FUA in SATA). After finishing the commit block write, the journaling thread finally wakes up the application thread.

When an `fsync` call does not entail a file system transaction, it is not possible to overlap computation with I/O operation. In this case, the use of LBIO reduces its I/O latency.

3.4 Implementation

The proposed scheme is implemented in the Linux kernel version 5.0.5. A new file open flag, `O_AIOS`, is introduced to use the proposed I/O stack selectively. The current implementation supports `read()`, `pread()`, `fsync()`, and `fdatasync()` system calls. For now, other asynchronous or direct I/O APIs are not supported.

The LBIO layer shares the NVMe queue pairs used in the original block layer. The spinlock of each queue pair provides mutual exclusion between LBIO and the original block layer. The most significant bit of a 16-bit tag is reserved to distin-

	Object	Linux block	LBIO
128 KB block request	`(l)bio` + `(l)bio_vec`	648 bytes	704 bytes
	`request`	384 bytes	
	`iod`	974 bytes	
	`prp_list`	4096 bytes	4096 bytes
	Total	6104 bytes	4800 bytes
Statically allocated (per-core)	`request` pool	412 KB	
	`lbio` array		192 KB
	free page pool		256 KB

Table 2: Memory cost comparison

Server	Dell R730

Table 3: Experimental configuration

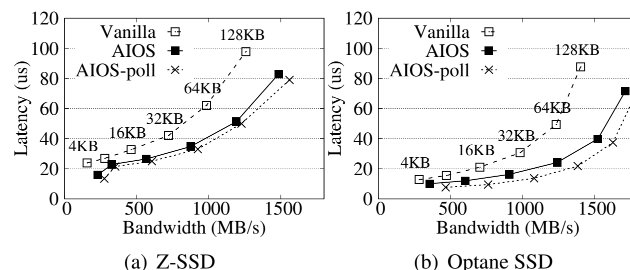

Figure 8: FIO single-thread random read latency and throughput with varying block sizes.

guish the two block layers. Since the NVMe SSDs used for evaluation supports 512 or 1024 entries for each queue, the remaining 15 bits are sufficient for command tagging.

Table 2 summarizes the memory cost of our scheme and the original block layer. To support a single 128 KB block request, both layers use a comparable amount of memory for `(l)bio`, `(l)bio_vec`, and `prp_list` objects. However, the original block layer requires two additional memory objects: `request` and `iod`, and thus requires extra memory compared to LBIO.

As for the cost of statically allocated memory, the original block layer maintains a pool of `request` objects (1024 objects with 1024 I/O queue depth), which requires 412 KB memory per core. LBIO replaces the per-core request pool with the per-core `lbio` row of size 192 KB. Meanwhile, our scheme also maintains a pool of DMA-mapped free pages. We maintain 64 free pages for each free page pool, hence consuming additional 256 KB memory per core.

In order to implement the AIOS `fsync` path, the `jbd2` wakeup routine in `ext4_sync_file()` is relocated to the position between data block write and data block wait. The function `jbd2_journal_commit_transaction()` is also modified to implement our scheme. The routine to prepare a commit block is moved to the position before the waiting routine for the journal block writes. The waiting routine for data block writes (using `t_inode_list`) is also relocated to the position before the waiting for journal block writes. The routine to issue commit block write I/O (i.e., `submit_bh()` in the vanilla path) is split into two routines: one for allocating an `lbio` and mapping DMA address, and the other for submitting an I/O command to a device (i.e., `nvme_queue_lbio()`). With this separation, AIOS can control the time to submit the commit block I/O so that it can satisfy the ordering constraints, while allowing the overlap of block request-related computations (e.g., DMA mapping) with the previous I/O operations.

4 Evaluation

4.1 Methodology

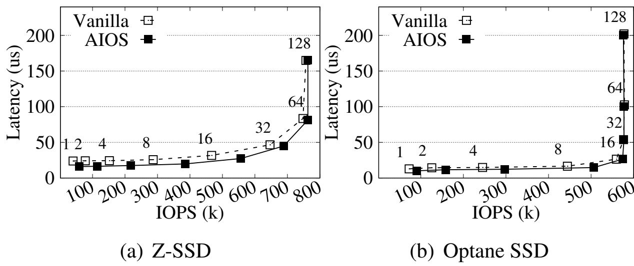
We use Dell R730 Server machine with Intel Xeon E5-2640 CPU and 32 GB DDR4 memory for our experiments. For the ultra-low latency storage devices, we evaluate both Samsung Z-SSD and Intel Optane SSD; both integrate a non-volatile write cache, which ignores flush and FUA commands in the block layer. We implement our proposed scheme AIOS on Linux kernel 5.0.5, denoted as *AIOS*. The baseline is the vanilla Linux kernel 5.0.5 using the Ext4 file system, denoted as *vanilla*. Table 3 summarizes our experimental setup.

For evaluation, we utilize both the synthetic microbenchmark and real-world workloads. For the synthetic microbenchmark, we use FIO [2] using the *sync* engine with varying I/O request sizes, I/O types, the number of threads and so forth. For real-world workloads we utilize various applications such as key-value store (RocksDB [10]), file-system benchmark (Filebench-varmail [40]), and OLTP workload (Sysbench-OLTP-insert [18] on MySQL [22]). Specifically, we run *readrandom* and *fillsync* workloads of the DBbench [30] on RocksDB; each representing a read-intensive case and `fdatasync`-intensive case, respectively. Filebench-varmail is `fsync`-intensive, and Sysbench-OLTP-insert is `fdatasync`-intensive.

4.2 Microbenchmark

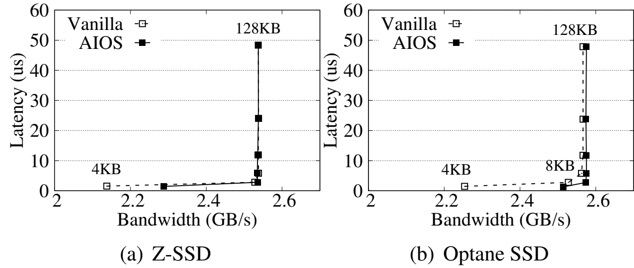
4.2.1 Read Performance

Random read latency. Figure 8 shows the effect of AIOS on FIO random read latency and throughput with varying block sizes. The figure shows that AIOS reduces random read latency by 15–33% when compared to the vanilla kernel on both Z-SSD and Optane SSD. In general, a larger block size results in greater latency reduction because a larger portion of the read-related kernel computation gets overlapped with the device I/O operation (see Figure 4). One important note is that AIOS achieves single-digit microseconds latency for a 4 KB random read on Optane SSD, which was previously not possible due to substantial read path overheads.



(a) Z-SSD (b) Optane SSD

Figure 9: FIO 4 KB random read latency and throughput (in IOPS) with varying the number of threads.



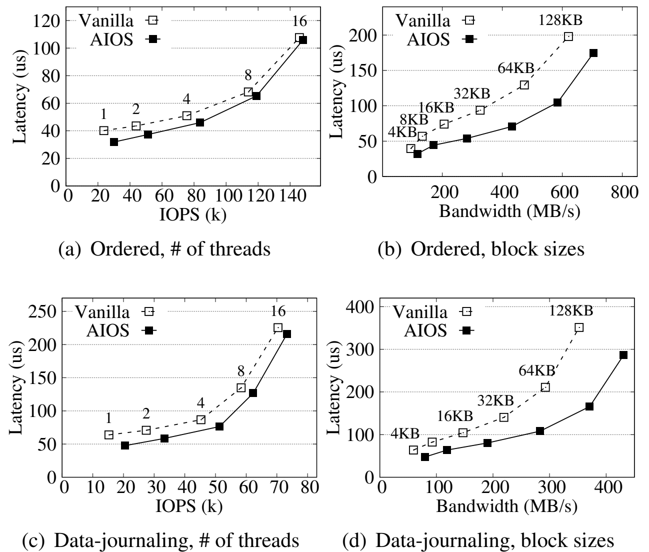
(a) Z-SSD (b) Optane SSD

Figure 10: Single-thread FIO sequential read latency and bandwidth with varying block sizes.

Polling vs. interrupt. Figure 8 also shows the impact of I/O completion scheme to the read latency. In the figure, *AIOS-poll* denotes the AIOS scheme using not interrupt but polling as its I/O completion method. In general, polling is better than interrupt in terms of latency because it eliminates context switches [47]; Table 1 has shown that context switches account for the largest fraction in kernel time. With small I/O sizes, the latency reduction from polling is comparable to that from AIOS. However, with large I/O sizes, the latency reduction from AIOS is greater than that from polling because of I/O-computation overlap to a greater extent. Please note that the interrupt mode is used by default in the rest of this section.

Random read throughput. Figure 9 shows the FIO 4 KB random read latency and throughput in I/O operations per second (IOPS) with varying the number of threads. Here, each thread is set to issue a single I/O request at a time (i.e., queue depth is one). In this setting, a large number of threads means that a large number of I/O requests are outstanding, hence mimicking high queue-depth I/O. As shown in the figure, both Z-SSD and Optane SSD achieve notably higher IOPS (i.e., up to 47.1% on Z-SSD and 26.3% on Optane SSD) than the baseline when the number of threads is less than 64. From that point, the device bandwidth gets saturated, and thus AIOS does not result in additional performance improvement.

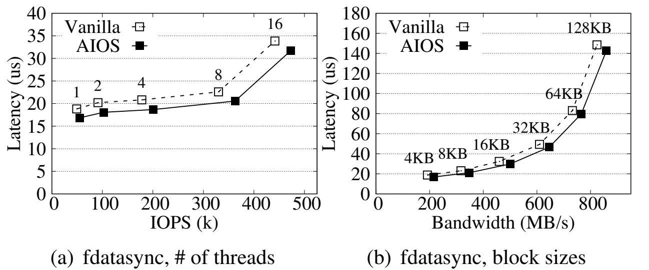
Sequential read bandwidth. Figure 10 shows the effect of AIOS on a single-thread sequential read workload with varying block sizes. Because the workload uses buffered reads, the readahead mechanism in Linux prefetches data blocks with large block size (128 KB) into the page cache. This results in high sustained bandwidth. In both Z-SSD and Optane SSD



(a) Ordered, # of threads (b) Ordered, block sizes

(c) Data-journaling, # of threads (d) Data-journaling, block sizes

Figure 11: Fsync performance with different journaling modes, number of threads and block sizes on Optane SSD.



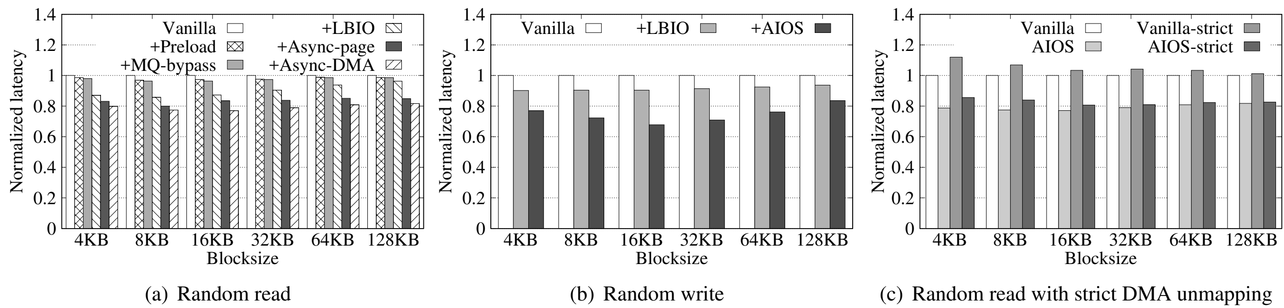
(a) fdatasync, # of threads (b) fdatasync, block sizes

Figure 12: Fdatasync performance with ordered mode with varying the number of threads and block sizes on Optane SSD.

cases, AIOS enables higher sustained bandwidth usage only for 4 KB block reads. For 16–128 KB blocks, AIOS does not result in any bandwidth improvement because the baseline scheme already reaches peak bandwidth.

4.2.2 Write Performance

Fsync performance. Figure 11 shows the performance impact of AIOS on FIO 4 KB random write followed by fsync workload. Here, we evaluate two journaling modes: ordered mode and data-journaling mode. With a single thread, our scheme shows IOPS improvement by up to 27% and 34% and latency reduction by up to 21% and 26% in the ordered mode and data journaling mode, respectively. With increasing the number of threads, natural overlap between computation and I/O occurs, thereby diminishing the performance benefit of our scheme. With large block sizes, the long I/O-computation overlapping happens, thereby widening the absolute performance gap between our scheme and the baseline. In the data-journaling mode, the length of the overlapped portion is longer than that of the ordered mode, and thus its latency advantage



(a) Random read (b) Random write (c) Random read with strict DMA unmapping

Figure 13: Normalized Latency of FIO 4 KB random read or write workloads with varying optimization levels on Optane SSD.

is slightly larger than that of the ordered mode.

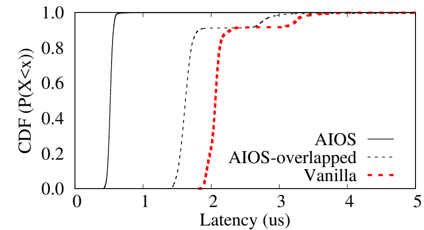
Fdatasync performance. Figure 12 shows the performance impact of AIOS on FIO 4 KB random write followed by fdatasync under the ordered mode. Unlike fsync, fdatasync does not journal metadata if the metadata has not changed; hence showing fewer performance gains than the fsync cases. Our AIOS presents up to 12% IOPS increase with a single thread. AIOS shows up to 10.5% latency decrease on the 4 KB random write workload using a single thread.

4.2.3 Performance Analysis

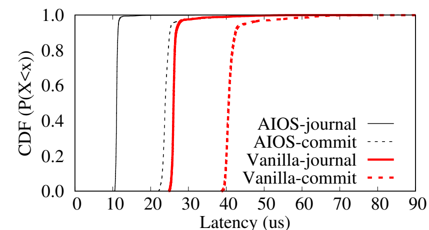
Read latency. Figure 13(a) compares the 4 KB random read latency on Optane SSD with varying optimization levels. The leftmost bar represents the baseline, and the next five bars represent the latency with cumulatively applying the optimizations presented throughout the paper. First, the preloading of extent tree (*+Preload*, Section 3.2.1) shows up to 3.1% latency reduction. Second, bypassing the block multi-queue scheduling (*+MQ-bypass*) provides 1.1% of additional latency reduction. The complete use of LBIO (*+LBIO*, Section 3.1) reduces I/O latency additionally by up to 12.5% because of its low overhead. By overlapping only cache indexing (Section 3.2.3) and page allocation (Section 3.2.2) with device I/O operation, the latency is reduced by up to 11.9% (*+Async-page*). Finally, the asynchronous DMA mapping/unmapping (*+Async-DMA*, Section 3.2.4) further reduces the I/O latency by up to 7.8%. The latency benefit of LBIO is similar across different block sizes. The benefit of the asynchronous operations, however, increases as the block size increases.

Write latency. Figure 13(b) compares the 4 KB random write+fsync latency on Optane SSD with varying optimization levels. For the write operation, the use of LBIO (*+LBIO*) shows up to 9.8% of latency reduction. Our asynchronous write path (*+AIOS*, Section 3.3) achieves additional latency reduction by up to 24.4%.

Cost of safety. Figure 13(c) shows the latency penalty of disabling the deferred DMA unmapping (i.e., unmapping DMA addresses immediately after I/O completion). *AIOS-strict* denotes our scheme without the lazy DMA unmapping (Section 3.2.4). For a fair comparison, we also measured the performance of the baseline without the deferred DMA unmapping [20] (denoted as *Vanilla-strict*). As shown in the figure, the use of strict DMA unmapping incurs a slight increase in I/O latency for both schemes by 1.2–11.9%.



(a) Latency from `read` entry to I/O cmd. submit

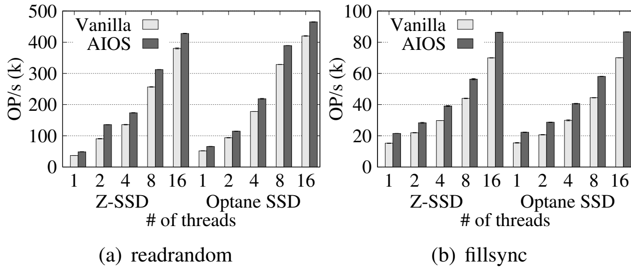


(b) Latency from `fsync` entry to each I/O cmd. submit (journal block and commit block)

Figure 14: CDF of I/O command submission latencies in 4 KB random read and 4 KB random write+fsync workloads on Optane SSD.

Overlapping analysis. One of our key ideas is to overlap computations with I/O so that the I/O command can be submitted as early as possible. To clarify this behavior, we measured the latency to submit I/O command(s) to a storage device and present the cumulative distribution function (CDF) of latencies. Figure 14(a) shows the time between the `read` system call entry and the I/O command submission. We also show the time to complete the overlapped operations in our scheme (denoted as *AIOS-overlapped*). As shown in the figure, the I/O submission latency is greatly reduced to 1.63 μs on average (75% reduction compared to the baseline). Also, note that the time to complete the overlapped operations is earlier than the I/O submission latency in the baseline. This is because of the additional latency reduction achieved by LBIO.

Similar measurement is also made on the write paths. Figure 14(b) shows the time between the `fsync` system call entry and the I/O command submission for journal block(s) and commit block (denoted as *-journal* and *-commit*, respectively).



(a) readrandom (b) fillsync

Figure 15: DBbench on RocksDB Performance (IOPS) with varying the number of threads.

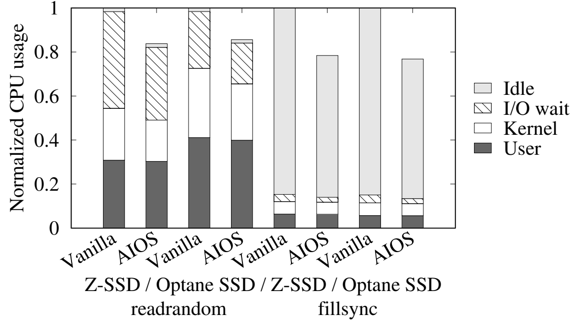


Figure 16: Normalized CPU usage breakdown for DBbench (*readrandom* and *fillsync*) on RocksDB using eight threads.

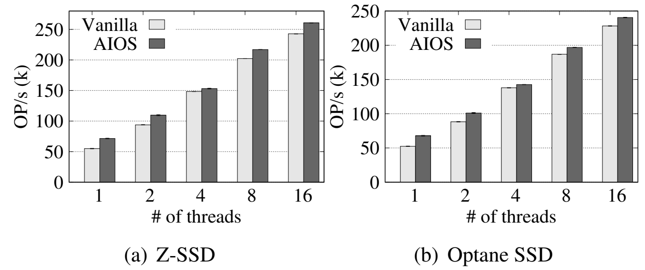
As shown in the figure, our scheme brings the I/O command submission times forward. Interestingly, the time to submit commit block I/O in AIOS is even earlier than the time to submit journal block I/O in the baseline.

4.3 Real-world Applications

4.3.1 Key-value Store

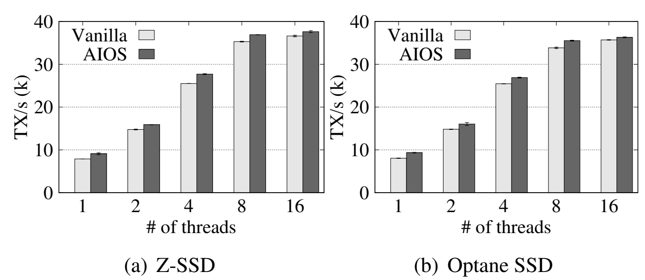
Performance. Figure 15 demonstrates the performance result of DBbench on RocksDB. Specifically, we evaluate the *readrandom* (64 GB dataset, 16-byte key and 1000-byte value) and *fillsync* (16 GB dataset) workloads in DBbench, each representing the random read-dominant case and the random write (and `fdatasync`)-dominant case. Overall, AIOS demonstrates notable speedups on the readrandom workload by 11–32% and the fillsync workload by 22–44%. Recall that AIOS allows duplicated I/Os because of the lazy page cache indexing feature (Section 3.2.3). Duplicated I/Os happen in this experiment. However, the frequency of such events is extremely low (e.g., less than once in 10 million I/Os on the readrandom workload).

CPU usage breakdown. Figure 16 shows the normalized CPU usage breakdown analysis of each workload using eight threads. Overall, AIOS reduces the CPU time spent on I/O wait and kernel. This indicates that AIOS effectively overlaps I/O operation with kernel operations without incurring extra overhead and LBIO effectively reduces the block I/O management overhead. Furthermore, by providing a low random read and write latency, AIOS reduces the overall runtime as well. The trend is similar in both Z-SSD and Optane SSD.



(a) Z-SSD (b) Optane SSD

Figure 17: Filebench-varmail performance with varying the number of threads.



(a) Z-SSD (b) Optane SSD

Figure 18: Sysbench-OLTP-insert performance with varying the number of threads.

4.3.2 Storage Benchmark and OLTP Workload

Figure 17 and Figure 18 show the Filebench-varmail (default configuration) and Sysbench-OLTP-insert (10 GB DB table size) performance with varying the number of threads. On the single thread cases of Filebench-varmail, utilizing AIOS results in 29.9% and 29.4% of improved throughput on Z-SSD and Optane SSD, respectively. Similarly, on the single thread cases of Sysbench-OLTP-insert, AIOS achieves 15.4% and 16.2% performance increase with Z-SSD and Optane SSD, respectively. In general, the use of multi-threading diminishes the benefits of our scheme because of the natural overlap of computation with I/O happens.

5 Related Work

Many prior works aim to alleviate the overheads of the kernel I/O stack, some of which are deployed in commodity OS kernels (e.g., Linux). Multi-context I/O paths can increase the I/O latency due to the overhead of context switching [5, 35]. Today's I/O path design for NVMe SSDs reduces this overhead by eliminating the bottom half of interrupt handling [24]. Using polling instead of interrupts is another solution for removing context switching from the I/O path [5, 47]. Hybrid polling is also proposed to reduce high CPU overheads [9, 21]. Simplified scheduling (e.g., Noop) is effective for reducing I/O latency in flash-based SSDs due to its high-performance random access [46, 51]. Instead of providing I/O scheduling in software, the NVMe protocol supports I/O scheduling on the device side in hardware [14, 24]. Support for differentiated I/O path was introduced to minimize the overhead of I/O path

for high priority tasks [5, 17, 48, 51], which is similar to our LBIO. However, to the best of our knowledge, there is no work applying the asynchronous I/O concept to the storage I/O stack itself.

There are proposals to change the storage interface for I/O latency reduction. Scatter/scatter I/O coalesces multiple I/O requests into a single command, thereby reducing the number of round trips in storage access [37, 42, 50]. DC-express attempts to minimize protocol-level latency overheads by removing doorbells and completion signals [44].

Improving the performance of `fsync` operation is important in many applications as it provides data durability. Nightingale et al. propose to extend the time to preserve data durability from the return of an `fsync` call to the time when the response is sent back to the requester (e.g., remote node) [23]. Using a checksum in the journal commit record can be effective in overlapping journal writes and data block writes [29], albeit checksum collision can become problematic in production systems [41]. OptFS [7] and BFS [45] propose write order-preserving system calls (`osync` and `fbarrier`). With the order-preserving system calls, the overlapping effect in the `fsync` path will be identical. However, when applications need the `fsync` semantic, operations occur synchronously with regard to I/Os.

User-level direct access can eliminate the kernel I/O stack overhead in storage access [6, 16, 28, 49]. The lack of a file system can be augmented by many different approaches from a simple mapping layer [28, 49] to user-level file systems [15, 43, 49]. However, enforcing isolation or protection between multiple users or processes should be carefully addressed [6], and hardware-level support is highly valuable [24]. However, this is not available at the moment.

6 Discussion and Future Work

I/O scheduling. I/O scheduling is necessary for certain computing domains (e.g., cloud computing) [1]. Early versions of the block multi-queue layer provided no I/O scheduling capability [3], but recently, several I/O schedulers have been integrated [8]. Our LBIO eliminates software-level request queues, and thus the current implementation is not compatible with software-level block I/O schedulers. However, the NVMe protocol can support device-side I/O scheduling (e.g., weighted round robin with urgent priority feature [14, 24]), which can augment LBIO. Furthermore, we believe that LBIO can support proper process/thread/cgroup-level I/O scheduling if we relax the static mapping between cores and NVMe queues. We leave this as future work.

File system coverage. Our current implementation is based on the Linux kernel with the Ext4 file system. However, we believe that other journaling file systems (e.g., XFS [39]) or copy-on-write file systems (e.g., Btrfs [31]) may provide similar opportunities for overlapping computation in the I/O path with device access, considering out-of-place updates

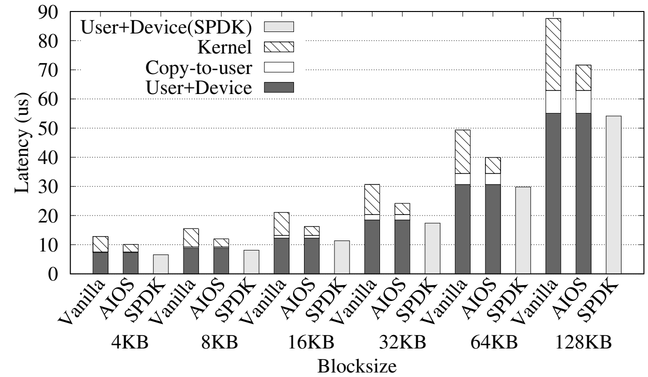


Figure 19: FIO random read latency breakdown in comparison with Intel SPDK on Optane SSD.

employed by these file systems.

Copy-to-user cost. AIOS greatly reduces the I/O stack overhead of the vanilla Linux kernel as shown in Figure 19. However, our proposal does not optimize copy-to-user operations, which remain as a non-negligible source of the overhead, especially when the requested block size is large. Although the in-memory copy is inevitable for buffered reads, we are seeking solutions to take off the memory copy from the critical path so that our proposal can compete with the user-level direct access approach.

7 Conclusion

We propose AIOS, an asynchronous kernel I/O stack customized for ultra-low latency SSDs. Unlike the traditional block layer, the lightweight block I/O (LBIO) layer of AIOS eliminates unnecessary components to minimize the delay in submitting I/O requests. AIOS also replaces synchronous operations in the I/O path with asynchronous ones to overlap computation associated with `read` and `fsync` with device I/O access. As a result, AIOS achieves single-digit microseconds I/O latency on Optane SSD, which was not possible due to high I/O stack overhead. Furthermore, AIOS demonstrates significant latency reduction and performance improvement with both synthetic and real-world workloads on Z-SSD and Optane SSD[2].

M³x: Autonomous Accelerators via Context-Enabled Fast-Path Communication

Nils Asmussen[†] [‡] Michael Roitzsch[†] [‡] Hermann Härtig[†] [‡]
[†] *Technische Universität Dresden, Germany* [‡] *Barkhausen Institut, Dresden, Germany*

Abstract

Performance and efficiency requirements are driving a trend towards specialized accelerators in both datacenters and embedded devices. In order to cut down communication overheads, system components are pinned to cores and fast-path communication between them is established. These fast paths reduce latency by avoiding indirections through the operating system. However, we see three roadblocks that can impede further gains: First, accelerators today need to be assisted by a general-purpose core, because they cannot autonomously access operating system services like file systems or network stacks. Second, fast-path communication is at odds with preemptive context switching, which is still necessary today to improve efficiency when applications underutilize devices. Third, these concepts should be kept orthogonal, such that direct and unassisted communication is possible between any combination of accelerators and general-purpose cores. At the same time, all of them should support switching between multiple application contexts, which is most difficult with accelerators that lack the hardware features to run an operating system.

We present M³x, a system architecture that removes these roadblocks. M³x retains the low overhead of fast-path communication while enabling context switching for general-purpose cores and specialized accelerators. M³x runs accelerators autonomously and achieves a speedup of 4.7 for PCIe-attached image-processing accelerators compared to traditional assisted operation. At the same time, utilization of the host CPU is reduced by a factor of 30.

1 Introduction

The end of Dennard scaling [18] prevents further frequency gains and the prospect of dark silicon [21] hampers general-purpose parallelism. Hardware and system designers thus turn to new architectures to increase performance or reduce power consumption. These new ideas often revolve around specialization through custom accelerators [9, 26, 35, 37, 48, 67, 68] and streamlined communication that bypasses the operating system to avoid overheads [10, 39, 46].

TPUs [27] are a key example of the first approach. By creating a fixed-function accelerator for neural network training and inference, Google managed to increase performance per socket 30-fold and performance per watt 80-fold over a contemporary CPU. The second approach of preferring data fast paths to avoid indirections through the operating system can be observed today with technologies like single root I/O virtualization (SR-IOV) or Infiniband. System designs like M³ [10] and DLibOS [39] have shown that fast-path communication achieves latency reductions of 5× for a file system workload on M³, and 20× for memcached on DLibOS. Furthermore, our previous work M³ demonstrates that this idea can be generalized to provide fast-path communication between all compute units in the system.

Encouraged by these benefits, we expect ongoing development and increased deployment of these solutions. Use-case-driven accelerators will find their place in datacenters, also because of their deterministic execution model which helps to meet tail-latency requirements. We therefore assume that more applications will entail complex interactions between a mix of accelerators and general-purpose cores. Additionally, in multi-tenant cloud environments context switching is essential, because a single user will typically underutilize accelerators. We also envision advantages for small embedded and edge devices. Due to their limited hardware resources, these devices benefit from the power efficiency of accelerators and require context switching to flexibly time-share these resources.

1.1 Problem Statement

We extract three fundamental architectural challenges from our assumptions: First, the system architecture should enable accelerators to run autonomously. Currently, accelerators are often treated as peripheral devices whose execution needs to be assisted by a general-purpose CPU [57]. The TPUs described in Google's paper burden their controlling CPU with 11 – 76% load just to operate the TPU [27]. Our comparison to the traditional usage of accelerators in § 7.6 confirms this experience by showing that even a 3 GHz out-of-order

x86-64 core is 86% loaded to assist three image-processing accelerators attached via PCIe. If accelerators had direct access to data sources and sinks, this overhead would not be necessary. However, such connectedness requires first-party interaction of accelerators with OS services like storage and network. Specialized solutions exist, like GPUfs [58], GPUnet [29], and PTask [52] for GPUs or BORPH [59] and FPGAFS [31] for FPGAs. But there is no general solution that would grant any accelerator first-party access to OS services and also allow direct communication between multiple accelerators without assistance by a general-purpose core.

Second, fast-path communication without OS interaction is important for low-latency data and control transfer, but conflicts with context switching. This problem applies to communication channels involving general-purpose cores as well as accelerators. If communication partners are pinned and exclusively use dedicated resources, direct communication is easy. However, with context switching, communication needs to consider whether the intended recipient is currently running and how to deliver a message otherwise. A system design needs to answer, how the equivalent of a blocking system call should work on an accelerator that lacks the hardware features to run an operating system. Current solutions like M³ and DLibOS avoid this question and forgo context switching altogether.

Finally, all compute resources in the system — accelerators as well as general-purpose cores — should be accessible via the same communication primitives. The resulting system should enable developers to offload any job to the most suitable compute resource. Such unification was explored in previous work, but only for heterogeneous general-purpose cores [12, 19, 43].

1.2 Scope

We believe that accelerators should not be forced to adapt to operating system requirements, but focus on their main task: a fast and energy-efficient solution to a specific problem. In this paper, we take the extreme position and rethink the system architecture to enable a first-class integration of accelerators without imposing changes on them.

In contrast to conventional architectures, we do *not* build upon coherent shared memory for two reasons: First, providing global cache coherency is challenging for systems that consists of a wide variety of compute units such as general-purpose cores, DSPs, and fixed-function accelerators. Second, the costs of cache coherency in terms of chip area, power, complexity, and performance are expected to increase with an increasing number of compute units [28, 41]. For these reasons, it is still unclear whether and how future systems will support cache coherency. Therefore, we keep cache coherency optional.

Additionally, our long-term goal is to support arbitrary accelerators as first-class citizens. In this paper, we begin to address this challenge by demonstrating our approach for accelerators that are arguably the most difficult to support as first-class citizens: fixed-function accelerators [22, 26, 35, 37, 48, 65] that do not execute software and therefore provide none of the features that are required to run an operating-system kernel. We believe our efforts towards a unified interface for all compute units will generalize to more feature-rich accelerators in the future.

1.3 Contribution

We propose M³x, a solution for the identified issues using a hardware-software co-design approach.

- We explore the design space for fast-path communication and context switching. We explain the fundamental problems, when combining both techniques (§ 2) and discuss solutions in terms of interaction modes (autonomous vs. assisted) and mechanisms (hardware vs. software).
- We converge on a design for M³x that allows fast-path communication without involving the OS kernel and enables accelerators to access data sources and sinks without assistance by a general-purpose core. At the same time, M³x supports context switching on both general-purpose cores and accelerators (§ 4).
- We implement these mechanisms within the M³ OS and hardware architecture (§ 5). M³ already supports fast-path communication within a tile-based architecture and unifies communication among heterogeneous instruction sets [10]. Thus, it constitutes a suitable starting point, which we extend with support for context switching and autonomous accelerators.
- In the evaluation (§ 7), we demonstrate how M³x retains the low overhead of fast-path communication while enabling context switching. We show the performance and utilization benefits of autonomous accelerators using an accelerator benchmark suite and an application scenario that might occur in datacenters.

We rely on gem5 [16] as our simulation platform. Its high accuracy and modularity enable us to experiment with new hardware components. The implementation of M³x[1] and our extensions to gem5[2] are available as open source.

2 Background and Motivation

Traditional communication via UNIX pipes, sockets, or microkernel IPC involves the kernel in every communication. For that reason, the kernel can buffer messages until the recipient is ready to receive them, can schedule recipients based on pending messages, and can easily switch to a different thread if the current thread needs to wait for I/O. Communication that bypasses the kernel offers significant gains in terms of latency and throughput, as has been shown by M³ [10] and DLibOS [39]. We call such communication *fast-path communication* in this paper. Using fast-path

[1] https://github.com/TUD-OS/M3
[2] https://github.com/TUD-OS/gem5-dtu

communication with dedicated cores for the applications is easy, because none of the aforementioned actions are required, which is why M³ and DLibOS chose to omit context switching support altogether. We also believe the still increasing core counts and the dark silicon effect [21, 25] will reduce the context switching frequency and lead to dedicated cores for applications by default. However, in the foreseeable future, provisioning enough hardware resources to handle all load spikes is not feasible. These load spikes therefore require oversubscription of cores and accelerators. Thus, fast-path communication needs to be combined with context switching to use the system as efficiently as possible.

Combining fast-path communication with context switching is a hard problem, though. If the kernel is not involved in the communication, how can we determine whether the recipient is running and how can we deliver the message if it is not running? Even without relying on coherency (see § 1.2), we could buffer all messages in DRAM to cope with non-running recipients. However, this would effectively route all communication over DRAM, which increases latency and DRAM load and is therefore detrimental to the goals of fast-path communication. On the other hand, communicating directly between compute units, without involving the OS, has the consequence that a message cannot be delivered if the designated recipient is not running. The naive solution of waking up the recipient and retrying the fast-path communication is not sufficient. Since these two steps are not atomic, the recipient can be suspended in between, leading to no progress at the sender side. Furthermore, the kernel can no longer make scheduling or placement decisions if it cannot tell whether applications are currently waiting for a message or are doing useful work.

Accelerators typically lack the architectural features to run an OS kernel locally. To avoid the indirection of all communication through a remote kernel, accelerators require fast-path communication to interact with other accelerators [57]. However, as described before, fast-path communication is possible only if the recipient is running. Thus, the combination of fast-path communication and context switching is necessary to run accelerators autonomously, without indirection through the kernel.

3 Related Work

There are industry solutions for accelerator integration such as the coherent accelerator processor interface (CAPI) [6, 62] and the heterogeneous system architecture (HSA) [4, 51]. Both allow the integration of accelerators into a cache coherent virtual memory system, but in contrast to M³x, these hardware solutions do not consider direct access to operating system services by accelerators. Such access is investigated by other works for specific OS services and specific accelerators like GPUs [15, 29, 34, 52, 58, 64, 69] or FPGAs [31, 47, 59]. In contrast, M³x does not target a specific kind of accelerator, but provides a general construction principle for fast-path communication of any accelerator with any OS service or application.

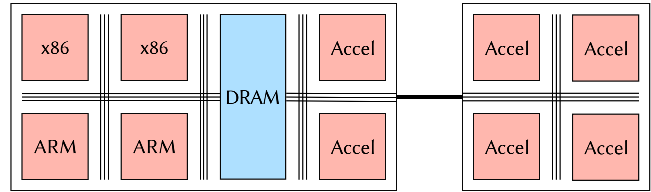

Figure 1: Overview of the system architecture.

K2 [36] and Popcorn Linux [12] demonstrate how the Linux kernel can be extended to support multiple coherence domains and potentially heterogeneous cores. However, heterogeneity in these cases is represented by general-purpose cores with different instruction sets and does not include fixed-function accelerators. Barrelfish [14] introduced the multikernel concept, where message passing is used to communicate between the operating system instances on each core. This concept is close to the design of M³x, but it assumes that all cores offer the architectural features to run an OS kernel. M³x sets out to remove this requirement to integrate fixed-function accelerators as well.

Arrakis [46] and OmniX [57] integrate peripherals and accelerators using SR-IOV. Instead of requiring the architectural features to run a kernel, these works assume the hardware to manage multiple contexts. M³x explores a more lightweight design, yet with enough hardware support to enable context switching and fast-path communication between components. Like NIX [11] or FlexSC [60], M³x adopts the idea of redirecting system calls to kernel cores to reduce the duties of non-kernel cores such as accelerators.

Horizontal system layouts [66] with different services on separate cores were explored in DLibOS [39] and M³ [10]. Both works have shown latency reductions due to the use of fast-path communication between cores, but they do not support context switching due to the problems explained in the previous section. Context switching of accelerators has been explored specifically for GPUs [13, 45], but without considering fast-path communication. M³x combines context-switching with the benefits of fast-path communication.

4 Design

We start this section with an introduction to the basic system architecture and discuss the design space for accelerator integration. Afterwards, we describe how fast-path communication is combined with context switching. Finally, we explain how this combination is used to run accelerators autonomously.

4.1 System Architecture

In this work, we assume a tiled system architecture as depicted in Fig. 1. The system uses an interconnect to communicate between tiles, similar to M³ [10] and DLibOS [39] and also similar to upcoming system architectures based on GenZ [3] or CCIX [2]. The tiles can contain heterogeneous *compute units* (CUs), ranging from general-purpose cores to DSPs

to fixed-function accelerators. These CUs can be part of the host system (left) and can be attached as an expansion card (right). The host system has a shared DRAM. We use the term *activity* to unify the active entities on these CUs. On general-purpose cores, an activity is typically a thread, whereas on accelerators it is the logic operating on a context.

4.2 Accelerator Integration

Adding accelerators into a system design poses the question of how to balance responsibilities between hardware and software. First, there are different ways to support arbitrary data sources and sinks for accelerators. Access to OS services like file systems or network stacks can be performed by software, which is the typical approach today. This approach requires a general-purpose core to assist the accelerator by continuously moving data back and forth. However, if the protocol to access OS services and data is sufficiently simple, it can be implemented in hardware. Such a hardware-friendly protocol allows accelerators to autonomously access arbitrary sources and sinks and removes software from the critical path. We present our protocol in § 4.8.

Second, if a system wants to support multiple activities with different priorities on a single accelerator, a low-latency context switch to the prioritized activity is needed. However, accelerators are typically invoked by software and are not interruptible until the computation is complete. One way to lower the latency is to reduce the amount of data per invocation. Consequently, the compute time per invocation is reduced, but software needs to continuously invoke the accelerator, which causes more CPU utilization and power consumption. Alternatively, the fine-grained invocation can be done in hardware by adding a simple state machine with preemption points next to the accelerator logic, as described in § 4.9.

Finally, to improve the utilization of accelerators, support for multiple contexts is necessary. One solution is to require the accelerator to provide a sufficient number of contexts and multiplex the hardware accordingly (e.g., based on SR-IOV). Alternatively, a combination of hardware and software can be used, which requires only a single context in hardware. To keep the hardware simple, we chose the latter approach: We perform the potentially complex scheduling decisions in software and add a simple state machine to the hardware, which saves and restores contexts.

4.3 Activity-aware Communication

To increase the flexibility and applicability of our system design, we chose not to rely on shared memory. Hence, messages cannot be delivered if the receiving activity is suspended (e.g., by preemption). There are two basic solutions to this problem:

1. *Eagerly* invalidate all incoming communication channels to an activity before suspending it or
2. keep the communication channels alive, but *lazily* detect communication attempts with suspended activities.

The eager approach does not require hardware support, but leads to more context switching overhead that grows linearly with the number of communication channels. In contrast, the lazy approach requires hardware support, but communication channels do not need to be invalidated on context switches. We chose the lazy approach, because our system supports many incoming communication channels (at most $(n-1)*m$ per compute unit with n CUs and m communication endpoints per CU). Furthermore, many communication channels are typically not used while an activity is suspended. To this end, we inform the hardware of the running activity and of the intended recipient activity when communicating (see § 5.5 for details). The hardware compares both and reports an error upon communication attempts with suspended activities.

4.4 Message Forwarding

Independent of eager invalidation or lazy detection, the hardware reports an error to the sender if the intended recipient is not running. Unfortunately, the naive solution of scheduling the recipient and retrying the fast-path communication introduces the following race condition: Since the kernel is not involved in this communication, it does not know when the communication has been completed successfully. If the kernel suspends the recipient before the communication has been finished, the sender does not make progress. The problem is that context switching and communication are decoupled, because the kernel performs the context switching, but activities bypass the kernel when performing fast-path communication. For example, if multiple senders try to communicate with multiple recipients scheduled on the same CU, the kernel could decide to schedule the next recipient before the communication with the current recipient has been finished.

We resolve this race condition by falling back to the traditional kernel-based communication model, if a communication failed due to a suspended activity. The kernel performs both the context switching and the communication: If activity A receives an error after trying to send a message to activity B, it asks the kernel to *forward* this message to B. When receiving the forward request, the kernel will first schedule B and afterwards send the message to B. To guarantee progress, the kernel does not suspend B until the message has been successfully delivered.

4.5 Computing vs. Idling

Another consequence of fast-path communication is that the kernel does not know whether an activity is currently computing or idling, because it waits for a message. We solve this problem by sending an *idle notification* to the kernel, similarly to scheduler activations [8]. Alternatively, the kernel could poll all CUs periodically to check whether the current activity is performing useful work, but we opted against this solution in favor of a less loaded and more scalable kernel.

We employ two optimizations. First, to prevent overeager context switches, we delay the sending of idle notifications

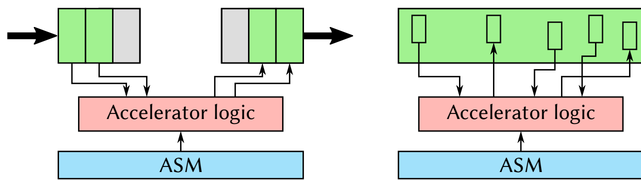

Figure 2: Stream-processing accelerators (left) and request-processing accelerators (right).

by a kernel-defined value called *idle delay*. The idle delay is stored in the address space of the current activity and updated by the kernel. Second, an activity does not need to send idle notifications at all if there is no ready activity that can run on its CU. In this case the idle delay is set to zero.

Note that we cannot force activities to report idling. However, threads on traditional systems can also decide to poll instead of using blocking system calls. On both systems, CPU-hogging activities can be penalized (e.g., priority degradation) and forcefully preempted.

4.6 Gang Scheduling

The concepts described so far allow to suspend activities, resume activities based on communication attempts, and to use the system's resources efficiently by switching to a different activity in case the current activity idles. However, if a set of heavily communicating activities contend with other activities for the same CUs, a systematic scheduling approach is required to maintain good performance. For example, consider a chain of accelerator activities that perform stream processing and therefore exchange messages and data at a high rate. If multiple such chains are contending for the same accelerators, the kernel needs to context switch these activities. However, uncoordinated context switching among the activities of all chains leads to many failed communication attempts when activities of different chains run simultaneously.

We solve this problem by introducing a simple form of gang scheduling [44]. Applications define the gang of a new activity at its creation time and the kernel pins all activities in a gang on different CUs and schedules them at the same time. We use this to run all activities of a single chain simultaneously. As the evaluation shows, multiple sets of heavily-communicating activities can therefore efficiently share the same CUs.

4.7 Accelerator Types

In this work, we consider two types of accelerators, depicted in Fig. 2: *stream-processing accelerators* that process a stream of data in blocks and compute on each block exactly once (e.g., AES encryption) and *request-processing accelerators* that receive the entire data for the computation with a single request and can access all data during the entire computation (e.g., graph processing or garbage collection). The stream-processing accelerators use DMA-based memory access to load a block of data from a source (e.g., a file or network socket), perform the computation on the block, and store the result to a sink. The request-processing accelerators use cache-based memory access to the request data to support large requests while maintaining fine-grained data access. For both accelerators, we add an *accelerator support module* (ASM), implemented as a finite-state machine, to the accelerator logic. The accelerator logic performs the computation, whereas the ASM interacts with other CUs and invokes the accelerator logic. We implemented the ASM as a piece of hardware in the current gem5-based prototype to demonstrate its simplicity.

Running these two types of accelerators autonomously requires access to OS services such as file systems, network stacks, and pipes to load and store data. Furthermore, accelerators need to be interruptible without requiring assistance by a general-purpose core. We describe our solution for both problems in the following sections.

4.8 Access to OS Services

Enabling accelerators to access files or network sockets requires a simple and unified protocol to obtain access to these resources. To this end, we designed a simple protocol for all file-like objects, in the same spirit as UNIX's everything-is-a-file principle. In contrast to UNIX, we implement OS services as microkernel-style servers and support both applications and accelerators as clients.

The *file protocol* uses a fast-path messaging channel between client and server. The server is expected to make the data available in memory and to provide the client with access to the data via a fast-path data channel. This channel enables accelerators to access large amounts of data autonomously, preventing frequent client-server interactions.

The protocol comprises two main requests: `next_in` and `next_out`. The former requests access to the next piece of data to read, whereas the latter requests access to the memory to which the next piece of data should be written. For example, a file-system server will provide the client with access to a fragmented file piece by piece, as described in more detail in § 5.7. After providing the client access to the data, the server returns the offset and size of the piece. Upon receiving this reply, the client can access the data via the fast-path data channel without involving the server again. After finishing the current piece, the client issues another `next_in` or `next_out` request to the server. A piece of length zero from the server denotes end-of-file.

As the client accesses the data on its own, the server does not know how many bytes the client has actually read or written. Therefore, input and output requests need to be *committed*. Each `next_in` and `next_out` request implicitly commits the complete previous piece of input or output data, respectively. Additionally, the `commit(nbytes)` request can be used to explicitly commit the first `nbytes` of the previous input or output request. The commit request is used, for example, if a client wants to stop writing to a file, in which case it might have written less than it got access to.

Finally, some servers support the seek request to change the file position. As described in more detail in § 5.8, the file protocol is implemented within the ASM of the stream-processing accelerators to load input data from arbitrary file-like sources and store the result to arbitrary file-like sinks. Note that request-processing accelerators can access OS services via the file protocol as well, but this has not been implemented. To test the generality of the protocol, we added a POSIX-like API on top and implemented a file system server, pipe server, and virtual terminal.

4.9 Interruptible Accelerators

As discussed in § 4.2, accelerators should be interruptible with low latency, requiring fine-grained invocations. At the same time, accelerators should run autonomously, asking for coarse-grained interactions with software. We achieve both by using the ASM as an indirection. Software performs the coarse-grained invocation of the hardware-implemented ASM, which in turn invokes the accelerator logic in a fine-grained fashion and is interruptible between these invocations. We implemented this scheme for request-processing accelerators, because the considered stream-processing accelerators already perform their computation block-wise with relatively small block sizes.

5 Implementation

Our prototype implementation is based on the hardware and software part of M³ [10]. The hardware platform of M³ exists by now as custom silicon in the Tomahawk 4 chip [24]. To extend the hardware part, we build on top of the already existing gem5 prototype. Both the gem5 prototype platform and the OS are open source and have been extended in this work to support context switching and autonomous accelerators.

5.1 Background on M³

The key idea of M³ is to introduce a new hardware component next to each CU, which serves as an abstraction for the heterogeneity of the CUs and supports fast-path communication between CUs. This hardware component is called data transfer unit (DTU) and is accessible over memory-mapped I/O (MMIO). Each CU is integrated with its DTU as a tile into the network-on-chip. The DTU provides a set of communication endpoints that can be configured as send, receive, or memory endpoints. Send and receive endpoints allow to establish a fast-path messaging channel, whereas memory endpoints are used for fast-path data channels. Data channels provide DMA-like access to a contiguous and byte-granular memory region.

The M³ kernel runs on a dedicated *kernel tile*, because not all tiles can be expected to run an OS kernel. The M³ kernel is different from traditional kernels, because it does not run user applications on the kernel tile. Instead, the kernel runs applications on other tiles, called *user tiles*, and waits for system calls in the form of messages, sent by applications via the DTU. Since only the kernel tile can configure DTU endpoints, applications are isolated from each other by default. The main responsibility of the kernel is to establish communication channels between applications by configuring DTU endpoints remotely. After a communication channel has been established, applications communicate directly with each other, bypassing the kernel.

On M³, the same activity abstraction[3] is used for all types of tiles, because the kernel is only concerned with their DTU state. The M³ kernel uses capabilities to manage the permissions in the system. Each activity has its own address space and capability space and system calls allow to exchange capabilities between activities. Since M³ does not support context switching, an activity is assigned to a free tile on creation and occupies this tile until its termination.

Outside of the kernel, M³ provides servers to host the actual functionality of the OS. M³ offers an in-memory filesystem, called *m3fs*, that organizes the data similarly to classical UNIX filesystems. The important difference is that m3fs grants applications direct access to file data via the DTU. Additionally, M³ offers a pipe server to connect activities via a unidirectional, first-in-first-out communication channel.

5.2 Virtual Memory Support

So far, M³ supports only simple general-purpose cores without virtual memory. Instead, cores have untranslated access to their dedicated scratchpad memory. To support more complex applications and be able to switch between them without first saving their entire memory state to DRAM, we added virtual memory support to M³. However, to prepare for future systems, M³x does not take advantage of cache coherency, but keeps it optional.

As virtual memory is also desirable for the cache-based memory access of request-processing accelerators, we added virtual memory support in two variants. For general-purpose cores, we use their memory management unit (MMU) and run a small helper on the core that receives page faults. For accelerators, we add an MMU to the DTU, consisting of a page table walker and translation lookaside buffer (TLB). In both cases, page faults are resolved by a *pager* in collaboration with the M³x kernel, which updates the page table entries, similar to other microkernel-based systems [33,61]. The pager is a server in M³x that supports copy-on-write and demand loading. On general-purpose cores, the helper sends a message to the pager to resolve page faults. On accelerators, the DTU sends the message to the pager, which is transparent to the accelerator.

5.3 Context Switching Overview

Context switches are performed remotely on the user tiles, initiated by the M³x kernel. This approach is required for accelerators that do not have the architectural features to run an OS kernel, but is optional for general-purpose cores with these features. In other words, the implementation could be extended to perform context switches on general-purpose cores locally.

[3] M³ calls tiles *processing elements* (PEs) and activities *virtual PEs* (VPEs).

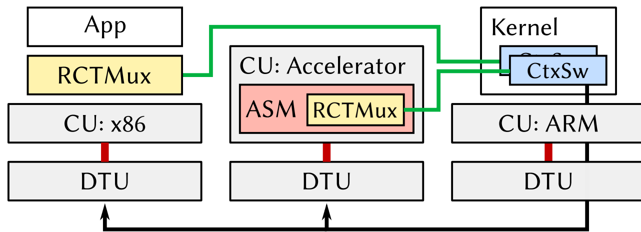

Figure 3: The involved components for context switches and their interfaces, shown on an exemplary assembly of CUs.

A context switch involves four components, depicted in Fig. 3: the CU, the DTU, the *context switcher* (CtxSw) in the M^3X kernel, and a small component on each user tile, called *remotely controlled time multiplexer* (RCTMux). RCTMux saves and restores the CU-state (e.g., CPU registers or the accelerator's local memory) during a context switch. The security-critical DTU-state (e.g., communication endpoints) is saved and restored by the kernel. RCTMux is CU-specific and either a piece of software on programmable CUs or a piece of hardware as part of the ASM for accelerators. The M^3X kernel maintains one context switcher for each user tile and performs scheduling and placement decisions.

These four components have two important interfaces. The first interface between the context switcher and RCTMux (green in Fig. 3) is used by the kernel to request saves and restores from RCTMux and by RCTMux to acknowledge their completion. Second, the DTU-CU interface (red) is used by the kernel to signal the CU about an imminent context switch. Depending on the type of CU, the signal injects an interrupt request into a core or notifies the ASM of an accelerator.

5.4 Kernel Extensions

We incorporated the context switcher module into the M^3 kernel to perform context switches on user tiles. First, the context switcher asks RCTMux to save the CU state. The context switcher then saves the DTU state of the current activity, restores the DTU state of the new activity, and asks RCTMux to restore said activity's CU state. Each of these steps is executed individually to be able to handle other requests (e.g., system calls) in the meantime.

Furthermore, we introduced a system call to forward messages upon communication attempts with suspended activities. The kernel buffers the message to forward, schedules the recipient, and delivers the message to the recipient as soon as it is running. Finally, we added a system call for idle notifications, upon which the kernel switches to the next ready activity or work-steals an activity from another tile in case no activity was ready. For application activities, the kernel sets the idle delay to 20,000 cycles[4]. For server activities, the kernel uses an idle delay of one cycle, because servers are typically only activated on demand. Hence, switching to an application is more beneficial for the system's performance.

To facilitate fast-path communication, the kernel migrates activities in two situations. First, if two activities are scheduled on the same CU and attempt to communicate, the kernel tries to migrate the currently suspended activity to another CU. If migration is not possible (e.g., no other compatible CU is available), the kernel instead performs a context switch from the activity that attempted the communication to the suspended activity. Second, if an activity is idling (see § 4.5), the kernel tries to work-steal a ready activity from a compatible CU.

5.5 DTU Extensions

To detect communication attempts with suspended activities, we equipped the DTU with the ID of the current activity and added the destination activity ID to the message header. If the destination activity ID at the recipient's DTU does not match the current activity ID, the DTU reports an error to the sender. In this case, the sender asks the kernel to forward the message to the recipient via the forward system call.

If the kernel decides to perform a context switch on a user tile, the DTU might currently be busy with a communication. As explained in § 5.1, the DTU supports messaging channels and data channels. Messages need to be delivered exactly once, whereas data accesses can be repeated. To keep the DTU simple, we decided against a complicated protocol to abort potentially ongoing communication. Instead, the DTU has an abort command, which consists of two parts. First, further communication attempts are rejected with an error until re-enabled by the kernel. Second, the DTU waits until all message-based communication is completed, whereas data accesses are aborted with an error and need to be repeated later.

5.6 RCTMux

We implemented RCTMux both for accelerators and for general-purpose cores. As mentioned before, on accelerators, RCTMux receives a signal from the kernel if a context switch is desired. The ASM checks for the signal only at convenient points in time, because the accelerator logic is not assumed to be interruptible. Upon the signal, it saves the ASM's state and the accelerator's local memory via DTU to a previously allocated space in DRAM, uses the DTU's abort command, and notifies the kernel that the state has been saved. Analogously, the state is restored upon a restore request from the kernel.

We also implemented RCTMux for x86-64 as a small piece of software running in ring 0. In this case, RCTMux is activated by an interrupt injection, saves the CPU registers, uses the DTU's abort command, and notifies the kernel. Upon a restore request from the kernel, it restores the CPU registers and resumes a previously aborted data access, if necessary.

5.7 File Protocol Servers

M^3 already features an in-memory file system, called m3fs, and a pipe server. However, since M^3 was only evaluated

[4]This idle delay turned out to be a good trade-off between context switching too often and overly long idle periods.

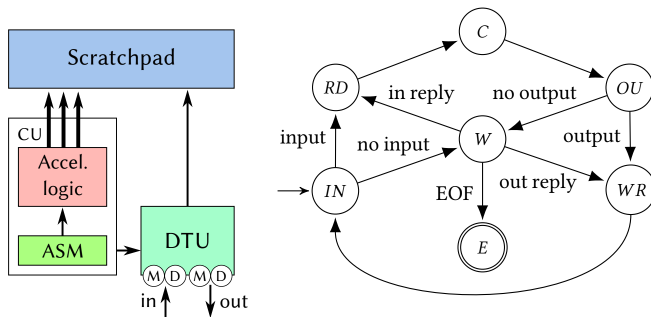

Figure 4: Stream-processing accelerator.

on general-purpose cores (in some cases with instruction extensions), the protocols to access these OS services are not suited for accelerators. First, M3 uses a different protocol for m3fs than for the pipe server, requiring accelerators to implement multiple protocols. Second, m3fs's protocol is based on the exchange of capabilities to obtain access to the data and requires clients to manage the file position. In summary, the existing protocols are too complex to be implemented in hardware. For that reason, we replaced them with the file protocol, as introduced in § 4.8.

On M3x, the file protocol is based on a messaging channel between client and server and a data channel to access the file data. Since m3fs manages the file data in extents, similar to other modern file systems [40, 50], the `next_in` request provides the client with access to the next extent of the file by asking the kernel to establish a corresponding data channel. The file position is managed and advanced by m3fs and can also be changed by the `seek` request. For appends, the `next_out` request allocates new space and provides the client with access to this space. Upon commit, m3fs truncates this space, if necessary, and makes it visible to other clients.

The pipe server uses a single and contiguous shared memory area in DRAM per pipe to exchange data between clients. For that reason, the pipe server asks the kernel to configure the client's data channel only once for the complete area and tells the clients where to read or write next. If no data can be read or written, the pipe server delays its response to the `next_in` or `next_out` request correspondingly.

5.8 File Protocol Clients

On the client side, we implemented the file protocol in software (for general-purpose cores) and in hardware (for accelerators). The software version is part of M3x's standard library and allows applications to use a POSIX-like file API. The library maps this API to the corresponding `next_in`, `next_out`, `commit`, and `seek` requests.

To enable access to file-like resources for stream-processing accelerators, we implemented the file protocol as part of the accelerator support module (ASM). The stream-processing accelerator has an input stream and an output stream, each using one messaging channel (M) to the server and one data channel (D) to access to data, as shown in Fig. 4. Like many other accelerators [17, 38, 55, 56, 63], the computation is performed on scratchpad memory (SPM), because it allows many parallel memory accesses (indicated by the thick arrows) and has predictable access latency.

The ASM loads data via the DTU from the input stream into the accelerator's SPM, activates the accelerator logic, and writes the result to the output stream. The ASM starts in state *IN*, which checks whether the input data channel has data left to read. If so, it directly transitions to state *RD* to read the next block of data into the SPM. Otherwise, it sends an input request (`next_in`) to the input server to request access to new input data and transitions to state *W*. State *W* waits until a message arrives and transitions to *RD* as soon as the reply to the input request has been received. After the next data block has been read into the SPM, the accelerator logic is activated and the ASM transitions to state *C* for the computation. As soon as the computation has been completed, the ASM transitions to state *OU*. Analogously to the input phase, *OU* first checks whether the output data channel has space left for the result of the computation. If so, it directly transitions to *WR* and writes the data. Otherwise it first requests new space from the output server (`next_out`). Afterwards, the ASM transitions back to state *IN*, which repeats the procedure until the reply to an input request indicates end-of-file. In this case, the ASM commits the written data by sending `commit` to the output server, if required, and transitions to state *E*.

6 Discussion

We believe that our architecture provides a good foundation for very heterogeneous systems, but we are aware that CUs will be diverse and have different requirements. This section discusses a few examples of how our current prototype can be extended to support other use cases.

Our context switching mechanism handles the simple save and restore actions on user tiles and the decision making in the M3x kernel. While we show in the evaluation that context switches on fixed-function accelerators have acceptable overhead, the mechanism is probably not a good fit for accelerators that have a large state such as GPUs. General-purpose cores provide native mechanisms to save/restore their state, which are used by the software version of RCTMux. Therefore we believe that large-state accelerators need tailored context-switching mechanisms as already partially supported by modern GPUs.

As described in § 5.4, the M3x kernel currently migrates an activity to a different tile if two activities on the same tile try to communicate. This policy assumes that the communication attempt starts a series of interactions between these activities, which mostly holds true for our current workloads. Clearly this is not the best solution in all cases. For example, if the activities communicate just once, a local communication channel with context switching can be preferable, if supported by the compute unit.

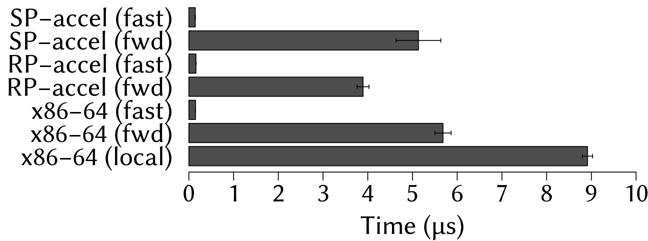

Figure 5: Fast-path vs. forwarded communication.

And finally, our current prototype does not queue messages at the recipient's compute unit if the recipient is suspended, but forwards the message to the recipient via the M³x kernel. We chose this solution to keep the hardware extensions small and, most importantly, minimize the burden on accelerators. If accelerators support message queues or such queues are added externally, the number of kernel involvements can be reduced. Thus, arguably our solution uses a queue size of zero, which can be extended to queue a few messages locally and only resort to the M³x kernel if the queue is full.

7 Evaluation

Our evaluation answers the following questions:

- How does fast-path and forwarded communication perform?
- Do the changes to the file protocol reduce its performance?
- What is the performance impact if activities share tiles?
- What are the benefits of autonomous accelerators?

7.1 Evaluation Platform

We used the gem5-based prototype platform for our evaluation. General-purpose tiles contain a single out-of-order x86-64 core with 32 KiB L1 instruction cache, 32 KiB L1 data cache, and 256 KiB L2 cache. The request-processing accelerators use 32 KiB L1 cache, whereas the stream-processing accelerators use 2 KiB scratchpad memory. General-purpose cores are simulated with a 3 GHz clock frequency, whereas accelerators are clocked with 1 GHz. All DTUs are configured to have 16 endpoints available. We use the `DDR3_1600_8x8` model of gem5 as the physical memory, clocked at 1 GHz. To keep the simulation times manageable, we connect the tiles via a crossbar instead of a full network-on-chip, which was sufficient, because our evaluation does not require large numbers of tiles. Due to the still long simulation times we used representative, but short-running benchmarks.

7.2 Fast-Path vs. Forwarding

M³x combines fast-path communication with context switching. In a first step, we use micro-benchmarks to determine the costs of forwarded communication, requiring a context switch, compared to fast-path communication. We measure the round-trip-time between activities on different CUs. Fig. 5 shows the average time over 16 runs with warm caches. The uppermost two rows show the time for stream-processing accelerators (SP), first if the recipient is running, resulting in fast-path communication, and second if the recipient is suspended, resulting in forwarded communication. The next two rows show the results for request-processing accelerators (RP), followed by two rows for an x86-64 core. The final row shows the time for a core-local round trip, using forwarded communication for both the request and the response.

As the results in Fig. 5 show, fast-path communication is more than one order of magnitude faster than forwarded communication on our system. All forwarded communication requires a forward system call, upon which the kernel performs a context switch to the receiving activity and forwards the message to the recipient. Most of the time is spent with the actual context switch, because it requires multiple steps and is carried out partially by RCTMux and partially by the kernel. Since stream-processing accelerators use a local scratchpad memory, the content needs to be saved and restored, leading to additional overhead. On x86-64, the overhead is larger, because the RCTMux is implemented in software. Finally, the core-local round trip requires two context switches. However, it is not twice as expensive as a single context switch, because the kernel optimizes this case by omitting the idle notification.

7.3 Application-level Benchmarks

As described in § 5.7, we simplified and unified the file protocol to be hardware-friendly. To evaluate whether these changes impact performance, we used the system call tracing infrastructure from M³. It allows to run an application on Linux, trace the system calls including timing information and replay the trace on M³. We used the following applications:

1. *tar*: creates a tar archive from files with sizes between 128 and 8192 KiB and 16 MiB in total,
2. *untar*: unpacks the same archive,
3. *shasum*: computes the SHA256 hash of a 512 KiB file,
4. *sort*: sorts a 256 KiB file with 408 lines,
5. *find*: searches 24 directories with 40 files each,
6. *SQLite*: creates a table and inserts/selects 32 entries, and
7. *LevelDB*: creates a table and inserts/selects 512 entries.

The applications *tar*, *untar*, *shasum*, *sort*, and *find* have been taken from BusyBox 1.26.2 [1]. *SQLite* is an embedded and highly reliable database engine [7]. *LevelDB* is a light-weight and high-performance key-value store, created by Google [5]. We chose these applications to stress the system in different ways: *tar* and *untar* are data intensive, *shasum* and *sort* are compute intensive, *find* performs many small file-system requests, and *SQLite* and *LevelDB* are mixtures of these.

We used these applications to compare the performance between Linux 4.10, M³ with the original file protocol, and M³x using the unified and hardware-friendly file protocol. In this section, M³ and M³x use three dedicated x86-64 tiles (without accelerator tiles) for the application, m3fs, and the pager, whereas Linux uses a single x86-64 core. However, M³ and M³x

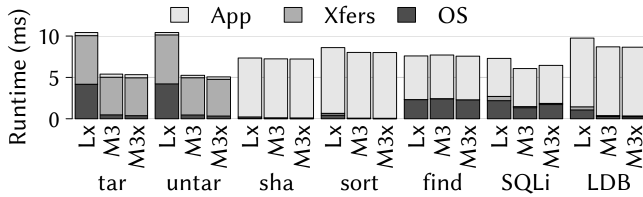

Figure 6: Performance comparison between Linux (Lx), M³, and M³x.

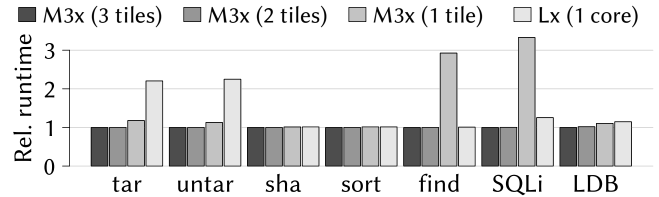

Figure 7: Application performance with a varying number of tiles, relative to the runtime on M³x with 3 tiles.

do not take advantage of multiple tiles, because all cross-tile interactions are synchronous and therefore, at no point in time is useful work done in parallel. On M³ and M³x, we use extents of at most 512 KiB, requiring multiple requests to m3fs to read and write files. On Linux, we use `tmpfs` as the in-memory file system. All file systems use a block size of 4 KiB. Fig. 6 shows the average runtime of 7 runs after one warmup run, broken down into the application time, time for data transfers, and OS overhead. We account Linux's time for the system calls, which are unsupported[5], as application time as well. Since the standard deviation is below 1%, we omit error bars.

In our previous work, we have already shown that data-intensive workloads like tar and untar have significantly less OS overhead on M³ than on Linux when running on simple Xtensa cores. As Fig. 6 shows, these improvements can be seen on x86-64 cores as well. Note however, that the difference is about a factor of two on x86-64 instead of five as on Xtensa, because the Xtensa cores did not have a cacheline prefetcher, resulting in poor performance on Linux [10]. On both architectures, the DTU's data channel can be configured in constant time for any byte-granular and contiguous region of memory, independent of its size. After the channel has been established, applications access the data via DMA with almost no overhead. Therefore, M³ and M³x outperform Linux significantly.

For the remaining applications, computation dominates the runtime, leading to smaller overall performance improvements. Note that SQLite is slightly faster on M³, because the new file protocol in M³x currently does not provide clients with read-write access to data and SQLite often switches between reading and writing of the same file. These switches require a `commit` request and a new `next_in` or `next_out` request, causing additional overhead.

7.4 Tile Sharing

After the performance comparison using three tiles, we show the performance impact when activities share tiles by means of context switching. In the first step, we ran both OS servers (m3fs and pager) on the same tile and in the second step, we ran the OS servers and the application on a single tile.

Fig. 7 shows the average runtime of three runs, preceded by one warmup run, normalized to the average runtime on M³x with three tiles. The standard deviation is less than 2%. As the results show, using the same tile for both servers and a dedicated tile for the application (two tiles in total) has almost no performance impact. Running servers and application on a single tile leads to a performance degradation in some cases. For *tar* and *untar*, the runtime is increased by 17% and 12%, respectively, but M³x is still about twice as fast as Linux. *shasum* and *sort* show almost no performance degradation, whereas *find* and *SQLite* experience a significant slowdown. The reason is, that both *find* and *SQLite* communicate heavily with m3fs, leading to many context switches. The performance of *LevelDB* degrades slightly, but is still better than on Linux. We conclude that some workloads require faster core-local context switches. We could improve M³x by running a kernel with context-switching support directly on the core, in case the necessary hardware features are available.

7.5 Autonomous Request Processing

After the evaluation on general-purpose cores, we want to demonstrate the benefits of autonomous accelerators. In this section, we start with request-processing accelerators. As described in § 4.9, software invokes the ASM, which in turn invokes the accelerator logic. In this section, we evaluate the impact of the invocation granularity on performance and CPU wake-up frequency.

We simulate the accelerators using gem5-Aladdin [56], which is a power-performance accelerator modeling framework that can be used to explore the design space for fixed-function accelerators. gem5-Aladdin simulates the accelerator logic and uses the memory subsystem of gem5 to perform memory accesses. gem5-Aladdin achieves an error of less than 6% for the accelerator's performance compared to real hardware. We adapted gem5-Aladdin to be invoked by the ASM and to notify the ASM of completions.

To use a request-processing accelerator, an application creates an activity for the desired accelerator, creates the memory mappings for the input and output data in the activity's virtual address space, and establishes the communication channel to invoke the ASM. In this case, the input data is stored in files and the output data should be written to files as well. Therefore, these files are mapped into the virtual address space of the accelerator activity.

We use different accelerator workloads from MachSuite [49]. MachSuite has been analyzed by gem5-Aladdin

[5] In these benchmarks, the system calls `access`, `brk`, `chdir`, `chmod`, `chown`, `dup2`, `fchown`, `fcntl`, `fdatasync`, `futex`, `geteuid`, `getpid`, `getrlimit`, `gettimeofday`, `getuid`, `ioctl`, and `utimes` were unsupported on M³/M³x. The sum of the times for the ignored system calls was at most 0.4 ms.

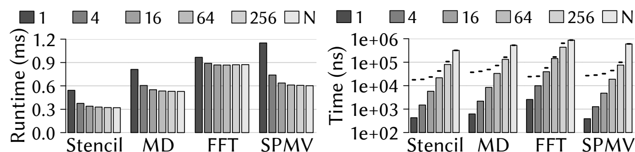

Figure 8: Total runtime (left) and the average (bars on the right) and maximum execution times (lines on the right) for different batch sizes.

with the result that some accelerators benefit from DMA-based memory access and others benefit from cache-based memory access. For this evaluation, we picked the accelerators that benefit from cache-based memory access:

1. Stencil-3D: a three-dimensional stencil computation,
2. MD-KNN: a k-nearest-neighbor computation from molecular dynamics,
3. FFT-1D: a one-dimensional fast Fourier transform, and
4. SPMV: a sparse matrix-vector multiplication.

We adjusted each accelerator to perform a single indivisible step per invocation by the ASM. Multiple such invocations are batched in a single invocation by the CPU. We analyze the spectrum between assisted and autonomous operation by varying the batch size.

Fig. 8 shows the results from three runs after one warmup run with batch sizes of 1 to 256. Performing all invocations in a single batch is shown as 'N', because the total number of invocations depends on the workload. The standard deviation is less than 1%. As can be seen in the left part of the figure, larger batch sizes lead to better performance. More importantly, the right part of the figure shows the average (bars) and maximum (lines) accelerator execution times for each ASM invocation. For example, using the MD workload and a batch size of 16 shows acceptable performance, but leads to a context switching latency of 48 µs and the CPU is woken up every 8 µs on average. High wake-up frequencies are a problem on modern cores, which can only achieve significant power savings in deep sleep states. However, the deeper the sleep state, the longer the time to bring the core back into a functional state (e.g., on Intel's Haswell generation, dozens of microseconds to leave C6 and up to several milliseconds to leave C10 [32, 54]). Hence, deeper sleep states are only beneficial during longer idle periods.

M³X performs all accelerator invocations in a single batch and uses an ASM that is interruptible between invocations to get the best of both worlds: On the one hand, a single batch leads to the best performance. On the other hand, the fine-grained interruptibility allows to context-switch to a more important activity with a low latency. Note that an immediate interruption can be achieved by resetting the accelerator logic, but requires to repeat the last step of the computation. If all invocations are done by the ASM in hardware (*autonomous*), the accelerator needs to repeat only a single indivisible step. If all invocations are done in software (*assisted*), the accelerator needs to repeat as many steps as the performance and energy constraints allow.

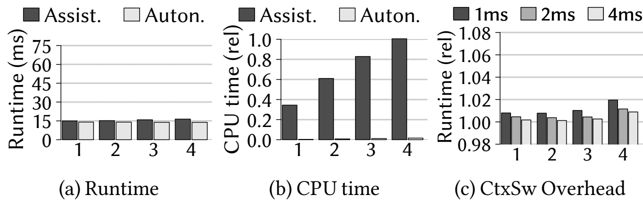
7.6 Autonomous Stream Processing

Finally, we want to show the benefits of autonomous stream-processing accelerators. Stream processing is used in various domains such as mobile communication, image processing, and audio processing. In this work, we consider an image processing scenario as is imaginable in data centers, similar to Google's TPU [27] workloads. The cloud provider offers a set of image-processing accelerators as a service and allows customers to perform large-scale image processing on these accelerators. An efficient method for large images is FFT convolution [42], which first performs a 2D fast Fourier transform (FFT) on the input image, then multiplies the result pointwise with an image filter, and finally performs the inverse FFT. Depending on the filter, FFT convolution can be used, for example, for edge detection or low-pass filtering.

To evaluate this scenario, we use three types of accelerators called FFT, MUL, and IFFT. Each accelerator has 2 KiB (the block size for the 32×32 point FFT) of local scratchpad memory (SPM) and uses the file protocol (see § 5.8) to stream the data block-wise from the input stream via the SPM to the output stream. Due to the deterministic execution model of these accelerators, we did not use gem5-Aladdin to simulate the accelerator logic, but used Aladdin [55] to determine the computation times offline. To get reasonable results, we generated all sensible configurations and picked the sweet spot between performance and the product of chip area and power consumption. We obtained 5,856 cycles for FFT and IFFT and 1,189 cycles for MUL. To put these numbers into perspective, the FFT/IFFT accelerator is about three times as fast as a simple software implementation and Aladdin reports a three orders of magnitude lower power consumption than a typical modern x86 core.

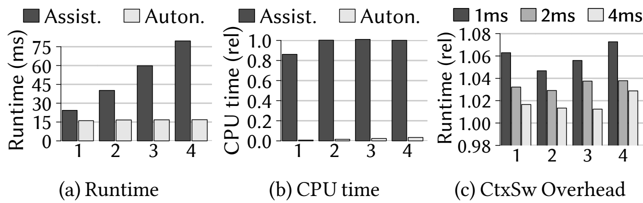
These three types of accelerators run activities that form an FFT-MUL-IFFT chain to process a 4 MiB image file and store the resulting image as a file. In our first experiment, we run 1 to 4 such chains simultaneously without context switching, thus using 1 to 4 instances of each accelerator type. To show the benefits of autonomous accelerators, we compare M³X's autonomous approach with the assisted approach. The assisted approach drives the accelerators from software using a single general-purpose core. Hence, software loads the input data into the SPM, starts the accelerator via a message, and asks the accelerator's DTU to move the result from the SPM to the next accelerator or to the output file. The autonomous variant connects the DTU endpoints of the accelerators as follows: The input of the first and the output of the last accelerator are connected to a file. The output of the first and second accelerator are directly pushed to the successor.

We simulate two ways to attach accelerators to the system: network-on-chip and PCI Express (PCIe). The former leads to superior performance due to lower latency, whereas the latter



(a) Runtime (b) CPU time (c) CtxSw Overhead

Figure 9: Total runtime, CPU time, and context switching overhead for different numbers of accelerator chains when integrating the accelerators into the NoC.



(a) Runtime (b) CPU time (c) CtxSw Overhead

Figure 10: Like Fig. 9, but with PCIe-attached accelerators.

allows a flexible combination of independently developed components. The result for the NoC version is depicted in Fig. 9, whereas the PCIe version is depicted in Fig. 10. We show the overall runtime (a) and the CPU time spent to drive the accelerators (b), depending on the number of accelerator chains using three runs, preceded by one warmup run. The standard deviation is below 3%. We simulate the PCIe-attached add-on card by connecting the accelerators via a bridge with a delay of 500 ns to the host system, which is the typical one-way latency for PCIe gen 3 [20, 23, 30, 53]. In other words, we do not simulate a complete PCIe interconnect, but only the latency PCIe introduces. The one-way latency within the NoC is about 10 ns. In both cases, the DRAM is part of the host system and stores the in-memory file system.

Using the assisted approach leads to slightly worse overall runtime with an increasing number of accelerator chains when integrating the accelerators into the NoC. With PCIe, the overall runtime increases significantly, leading to a slowdown of factor 4.7. In contrast, the autonomous approach always achieves the same runtime, independent of the number of chains. More importantly, the assisted approach keeps the CPU busy most of the time. Within the NoC, the CPU is utilized 100% of the time starting at four accelerator chains, whereas with PCIe, the CPU is already fully utilized starting with two chains. The autonomous approach does not cause significant CPU load in either case. Additionally, Fig. 10 shows that the autonomous approach outperforms the assisted approach for PCIe-based accelerators even if the assisted approach does not fully utilize the CPU. The reason is the 500 ns delay when communicating with the accelerators, which prevents the assisted approach from fully utilizing the accelerators.

Finally, we evaluate the context switching overhead when two chains of activities compete for the same accelerators. In this case, we use only the autonomous approach and put each chain of activities into the same gang to benefit from gang scheduling. Plot (c) in Fig. 9 and Fig. 10 shows the context switching overhead by comparing the runtime of two activity chains running consecutively with the runtime of two chains running interleaved. We vary the time slice length for context switching between 1 ms and 4 ms. As the results show, using a still rather short time slice of 4 ms leads to less than 0.9% overhead with accelerators integrated into the NoC and less than 2.9% overhead when attaching them via PCIe.

Note that the performance can still be improved for both the assisted and the autonomous approach. For the assisted approach, batching could be used to reduce the interaction frequency with the accelerators. However, batching is only possible by increasing the SPM sizes of the accelerators, which is expensive in terms of area and energy and increases the time the accelerator is not interruptible. Additionally, the assisted approach can trade more CPU time for more accelerator performance by using multiple cores to drive the accelerators, until the PCIe bus becomes the bottleneck. The autonomous approach does not suffer from the trade-off between SPM size and CPU utilization and can further improve performance by overlapping data transfers to the DRAM instead of issuing one transfer at a time.

8 Conclusion

In this work, we presented M³x, which combines fast-path communication, bypassing the kernel, with context switching and thereby enables autonomous accelerators. To this end, we re-evaluated the boundary between hardware and software. We found that (1) introducing a hardware-friendly file protocol enables accelerators to autonomously access file systems or network stacks, (2) performing potentially complex scheduling decisions in software and simple save and restore actions in hardware allows to context switch accelerators, and (3) attaching a simple hardware component to the accelerator logic allows to combine autonomous operation and interruptibility.

We demonstrated in our evaluation that M³x retains the performance advantages of M³'s fast-path communication, while using the system's resources more efficiently by performing context switches, if required. Additionally, we have shown that running PCIe-attached image processing accelerators autonomously achieves a speedup of 4.7 and reduces the CPU utilization by a factor of 30.

In future work, we plan to study other types of accelerators such as FPGAs and GPUs and apply our insights from simulation to real hardware.

SmartDedup: Optimizing Deduplication for Resource-constrained Devices

Qirui Yang

Abstract

Storage on smart devices such as smartphones and the Internet of Things has limited performance, capacity, and endurance. Deduplication has the potential to address these limitations by eliminating redundant I/Os and data, but it must be considered under the various resource constraints of the devices. This paper presents SmartDedup, a deduplication solution optimized for resource-constrained devices. It proposes a novel architecture that supports symbiotic in-line and out-of-line deduplication to take advantage of their complementary strengths and allow them to be adapted according to a device's current resource availability. It also cohesively combines in-memory and on-disk fingerprint stores to minimize the memory overhead while achieving a good level of deduplication. SmartDedup is prototyped on EXT4 and F2FS and evaluated using benchmarks, workloads generated from real-world device images, and traces collected from real-world devices. The results show that SmartDedup substantially improves I/O performance (e.g., increases write and read throughput by 31.1% and 32%, respectively for an FIO experiment with 25% duplication ratio), reduces flash writes (e.g., by 70.9% in a trace replay experiment with 75.8% duplication ratio), and saves space usage (e.g., by 45% in a DEDISbench experiment with 46.1% duplication ratio) with low memory, storage, and battery overhead, compared to both native file systems and related deduplication solutions.

1 Introduction

Smart devices such as smartphones and the Internet of Things (IoT) are becoming pervasively used. The high volume and velocity of data produced by the growing applications and sensors on these devices present serious challenges to the on-device flash storage, which has limited performance, capacity, and endurance. Deduplication has the potential to address these limitations by reducing the I/Os and storage caused by duplicate data. But adopting deduplication on smart devices must address their unique resource constraints. In particular, the *limited memory* on the devices presents a difficult trade-off between the speed of deduplication and the amount of duplicates that it can find. The *limited storage performance and endurance* require the deduplication operations to incur minimal additional I/Os. For many devices with *limited power and energy capacity*, the design of deduplication also needs to be aware of its power and energy usage.

To address these challenges, this paper presents SmartDedup, a deduplication solution optimized for smart devices considering their various resource constraints. The architecture of SmartDedup is designed to support the symbiotic in-line and out-of-line deduplication. It employs in-line deduplication in the foreground to reduce redundant writes and runs out-of-line deduplication in the background to find duplicates missed by in-line deduplication. These two techniques work together cooperatively by sharing the fingerprint stores and information (e.g., fingerprints) about the I/O requests.

SmartDedup employs cohesively designed in-memory and on-disk fingerprint stores to minimize memory overhead while achieving a good level of deduplication. The small in-memory fingerprint store provides fast fingerprint lookup and effective write reduction; the on-disk fingerprint store supports complete data deduplication. Fingerprints migrate between the two stores dynamically based on data access patterns. SmartDedup also embodies several techniques to make efficient use of the two fingerprint stores. To further reduce the overhead, both fingerprint stores share the same indexing data structure to save memory usage; fingerprints are evicted from memory in groups to reduce the involved I/Os and wear-

out.

To support this study, we collected file system images and long-term (2-6 months) traces from real-world smartphones. The data confirms that there is a good level of duplication in real-world workloads: the average duplication ratio is 33% in the data from the images, and ranges from 22% to 48% among the writes in the traces. The specific applications and types of files that contribute the most duplicates differ by device, so a holistic system-level deduplication solution is needed to fully exploit these I/O and data reduction opportunities.

We prototyped SmartDedup on OSs (Android and Raspbian) and file systems (EXT4 and F2FS) commonly used by smart devices. We evaluated it on two representative devices, a Nexus 5X smartphone and a Raspberry Pi 3 device, using intensive benchmark (FIO [12]) and realistic workloads generated by DEDISbench [20] from sampling real-world smartphone images and by replaying real-world smartphone I/O traces. The results show that SmartDedup achieves substantial improvements in performance, storage utilization, and flash endurance compared to both the native file systems and related solutions.

For example, on Nexus, SmartDedup outperforms native EXT4 by 16.9% in throughput and 18.5% in 95th percentile latency for writes, and 38.2% in throughput and 18.7% in 95th percentile latency for reads, for intensive FIO workloads with only 25% duplicates; and it improves the write latency by 25.5% for a trace segment with a 47.9% duplication ratio. In terms of space saving, SmartDedup saves 45% of space (after factoring in its own space overhead) compared to EXT4 when the duplication ratio is 46.1% in a DEDISbench experiment. In terms of reducing the wear-out, SmartDedup reduces 70.9% of writes from EXT4 (after factoring in its own write overhead) in a trace replay with a duplication ratio of 75.8%. SmartDedup also outperforms the state-of-the-art related works Dmdedup [16, 23] by 1.5X in throughput and 57.1% in 95th percentile latency in an FIO write experiment with 25% duplicates, and CAFTL [9] by 37.7% in average write latency in a trace replay with 75.8% duplication ratio. All the improvements are achieved with low resource usage. In these experiments, SmartDedup uses less than 3.5MB of memory, and it actually reduces the battery usage by up to 7.7% and 49.2% for intensive workloads on Nexus and Pi, respectively.

2 Analysis of Real-world Device Data

To confirm the potential of deduplication for smart devices, we collected and analyzed I/O traces and file system images from smartphones used by different real users.

ID	Total I/Os (GB)	Read/ write ratio	# of days	Unique addresses (GB)	Unique data (GB)	Duplication ratio (%)
1	2096.8	7.5	173	148.2	192.7	21.9
2	773.6	3.4	85	36.3	96.2	45.3
3	426.7	4.8	73	34.6	56.5	23.2
4	2385.6	5.8	145	101.2	184.2	47.5
5	1119.7	3.4	92	126.7	148.6	41.6
6	765.9	3.4	72	23.9	124.8	28.3

Table 1: File system traces from real-world smartphones. For each trace, the table shows the total amount of data requests (4KB each), the ratio between reads and writes, the total number of days, the total amount of writes with unique addresses, the total amount of writes with unique data, and the total percentage of duplicate writes.

	Top 3 duplicate contributors (file type, % of writes, duplication ratio (%))		
Trace	1	2	3
1	(res, 12, 15)	(db, 10, 15)	(exe, 39, 13)
2	(tmp, 3, 73)	(exe, 36, 65)	(res, 27, 62)
3	(res, 17, 65)	(media, 3, 19)	(db, 11, 17)
4	(exe, 29, 78)	(tmp, 4, 77)	(media, 24, 49)
5	(media, 76, 48)	(res, 2, 34)	(exe, 12, 25)
6	(res, 19, 45)	(exe, 35, 36)	(media, 9, 31)

Table 2: The file types that contribute the most amount of duplicates in the file system traces collected from smartphones used by real users. For each top contributor, the table shows the file type, the percentage of writes that it contributes to the trace's total write volume, and the percentage of duplicate writes within only this type of files.

First, we studied the long-term file system I/O traces [4] collected from six smartphones (from VFS and EXT4 on Android) used by six users from four countries who are between 20 to 40 years old, which recorded the fingerprints of writes when they were flushed from the page cache to flash storage. Commonly used applications include chat (WhatsApp and WeChat), video (Youtube), and social network (Facebook and Weibo) applications. As summarized in Table 1, these traces confirm that: 1) real-world device workloads are indeed quite intensive, and do have a significant impact on the performance and endurance of devices. The average daily I/O volume ranges from 4.2GB to 17.6GB, and the amount of writes ranges from 0.7GB to 3.5GB; and 2) a good level of deduplication can be achieved on the writes captured in the traces. Considering the entire traces, the percentage of duplicate writes ranges from 21.9% to 47.5%; and on a daily basis, on average between 16.6% and 37.4% of writes are also duplicates.

To understand where the duplicates came from, we further analyzed the effectiveness of deduplication within

the writes to each type of files. We classified the files into several categories (*resource* files, *database* files, *executables*, *temporary* files, and *multimedia*), following the methodology in [14]. [1] Table 2 shows that the file types that contribute the most duplicates vary across the traces collected from different users' devices. This observation suggests that applying deduplication only to specific types of files, or even more narrowly, only to specific applications [17], is insufficient. Although not shown in the figure, our results also reveal that whole-file-based deduplication [3] is also insufficient as over 80% of the duplicates are from files that are not completely duplicate.

To complement the above trace analysis, we also studied file system images collected from 19 real-world smartphones, which on average have 10.4GB of data stored on the device and 33% duplicates in the data. The analysis also confirms that there is a good amount of duplicate data stored on the devices. We also analyzed the effectiveness of deduplication on different types of files, and as in the trace analysis, we did not find any pattern—the file types that contribute the most to deduplication differ across the devices. For example, on one image, a large percentage of duplicates is found within database files (69.1%) and apk files (74.8%), but this percentage is low on the other images; on another image, thumbnail files have a duplication ratio of 99.0% whereas on another image this ratio is only 0.9%.

Overall the above analysis of real-world device traces and images shows strong evidence for the potentials of deduplication on devices. They also suggest that a holistic, system-level solution is necessary to fully exploit the deduplication opportunities.

3 Design and Implementation

3.1 Design Overview

Overall the design of SmartDedup is based on the following key principles:

- I The storage on smart devices has limited bandwidth, capacity, and endurance, so deduplication should be applied as much as possible to improve its performance, utilization, and lifetime.
- II The available memory on devices is often limited, so the use of in-memory data structures should be kept as low as possible. To complement the low memory footprint, disk space should also be leveraged to keep additional data structures.
- III Many smart devices are power or energy constrained (e.g., limited battery life), and deduplication should work adaptively according to the current power or energy availability.

While following these general principles, we also cautiously design the data structures and operations used by deduplication so that its overhead is as low as possible. The rest of this section presents first an overview and then details of this design.

Deduplication can be performed at different layers (file system or block layer) of the storage stack. SmartDedup chooses the design of file system level deduplication, which allows it to exploit useful semantics and improve efficiency (e.g., avoid deduplicating unallocated blocks or processing files that have not been modified). Although hints can be passed from the file system to the block layer [16], they may not be sufficient (e.g., for providing the above semantics), and the file system's unawareness of deduplication also leads to inefficiencies. For example, the file system either cannot exploit the space saved by deduplication or has to assume a fixed deduplication ratio which does not always hold for the actual workload.

According to Design Principle I, SmartDedup considers both *in-line* and *out-of-line* deduplication to maximize the effectiveness of deduplication. In-line deduplication removes duplicate writes before they reach the disk, and can thereby quickly reduce the data and avoid the wear-out caused by duplicates. But it needs to run in the I/O path at all times; otherwise, it may miss many deduplication opportunities. Out-of-line deduplication works in the background to remove duplicates already stored on disk, and can use fingerprints stored both in memory and on disk to identify duplicates. Although out-of-line deduplication can be integrated with garbage collection to reduce wear-out [10], it is not as effective as the in-line method which removes duplicates before they reach the disk. Therefore, SmartDedup combines in-line and out-of-line deduplication to take advantage of their complementary strengths, and optimizes their uses for resource-constrained devices. In particular, these two deduplication procedures share the same fingerprint store to reduce the resource overhead (per Design Principle II); and both procedures can be dynamically enabled or disabled and dynamically change the processing rate based on a device's current power or energy status (per Design Principle III).

According to Design Principle II, to address the memory limitations of smart devices, SmartDedup adopts cohesively designed two-level in-memory and on-disk fin-

[1] Our results show that the writes to database-related files account for 21.9% of the total amount of writes, which is much lower than the 90% observed by [14]. We believe that this discrepancy is because the related work considered only writes from Facebook and Twitter, whereas we analyzed system-wide writes.

gerprint stores. The fingerprint store is the core data structure of a deduplication solution: it maintains the fingerprints of existing data so that it can determine whether new data is duplicate or not by comparing the fingerprint to existing ones. In SmartDedup, the *in-memory fingerprint store* supports fast deduplication of commonly used data with low memory cost; the *on-disk fingerprint store* keeps fingerprints that are not in memory and supports more thorough data deduplication; and fingerprints can dynamically migrate between these two stores. Together, these two fingerprint stores support the efficient operation of both in-line and out-of-line deduplication.

The rest of this section explains the various components of SmartDedup and how they function together. Our core designs, including cooperative in-line and out-of-line deduplication and tiered fingerprint stores are applicable to different types of file systems. We use our prototypes for EXT4 [18], which is the *de facto* file system on Android devices, and F2FS [15], a new flash-optimized file system increasingly used by smart devices, to explain SmartDedup.

3.2 Two-level Fingerprint Stores

In-memory Fingerprint Store. SmartDedup uses only a small amount of memory to store important fingerprints (and the corresponding PBNs) and support fast deduplication, while the other less important fingerprints are kept on disk. When the in-memory fingerprint store gets full, some of the fingerprints are demoted to the on-disk fingerprint store to make room for new ones.

To support fast fingerprint search at low memory cost, the store uses a prefix tree (implemented using a Linux radix tree [8]) as the *fingerprint index* (Figure 1). To conserve memory, different from typical indexes which provide direct locations of individual fingerprints, our index provides the locations of fingerprint groups—the fingerprints in each group shares the same prefix. For example, with an 18-bit index, all the fingerprints that share the same 18-bit prefix are grouped together. This design also facilitates the group-based fingerprint eviction and on-disk fingerprint lookup discussed later in this section. Within each group, the fingerprints are indexed by a linked list. The list is sorted by the fingerprints' remaining bits, which allows misses to be determined sooner than using an unsorted list. Moreover, the length of such a list is generally short because 1) the in-memory fingerprint store is typically small, and 2) the cryptographic hash function used for fingerprinting tends to distribute the fingerprints evenly across the different groups. Experiments from replaying our traces confirm that the average length of these lists is 9 (maximum length is 63).

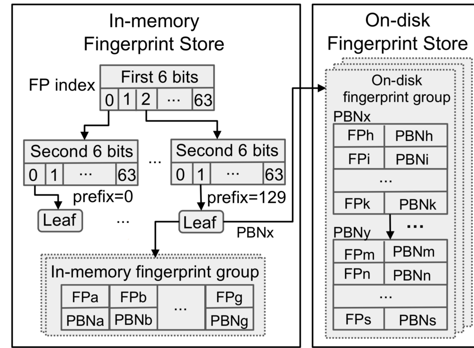

Figure 1: SmartDedup's two-level fingerprint stores.

With the above design, the space overhead of the in-memory fingerprint store is kept low. If we use 1% of the device's memory (40MB of a 4GB memory) to store MD5-based fingerprints, we can take the first 18 bits of each fingerprint as the prefix index and limit the height of the tree to three. Under this setting, the fingerprint index uses 2.03MB of memory. Considering the data structure overhead, the in-memory store can keep 1.3 million fingerprints for 5GB of unique data. For SHA1-based fingerprints, the number of fingerprints that the store can hold is 1.12 million.

The in-memory fingerprint store is used by both in-line and out-of-line deduplication as explained later. By allowing them to share this store, SmartDedup further reduces its memory usage on resource-constrained devices.

On-disk Fingerprint Store. The on-disk fingerprint store maintains the fingerprints that are evicted from memory due to the limited space of the in-memory fingerprint store. It allows SmartDedup to make full use of the existing fingerprints for providing thorough deduplication, and supports the promotion of fingerprints from disk to memory when they become important to the current workload. It is implemented as a sparse file on disk where the fingerprints are stored sequentially along with the PBNs. The size of the sparse file grows and shrinks, block by block, on demand with the number of fingerprints in the store for space efficiency. For 256GB of device storage, the total number of fingerprints that need to be stored on disk is 2^{26} in the worst case, assuming all the data is unique, which requires 2GB of disk space. In comparison, deduplicating merely 1% of 256GB of data saves 2.6GB of space and can already compensate the overhead of the on-disk store.

To enable fast search of on-disk fingerprints, SmartDedup also needs an index in memory, but it reuses the same *fingerprint index*—the prefix tree—described above for the in-memory store to reduce its memory usage (Figure 1). In fact, it adds only an address to each leaf node

of the index, which is the starting PBN of the on-disk group of fingerprints with the same prefix as the fingerprints of the in-memory fingerprint group. Each group of fingerprints is stored in an array on disk, which is sorted by its remaining fingerprint bits and stored sequentially from this PBN address in one or multiple disk blocks. In this way, the same fingerprint index is shared by both in-memory and on-disk fingerprint stores, and each leaf node can point to both an in-memory fingerprint group and an on-disk fingerprint group that share the same prefix. For a three-level tree that indexes an 18-bit prefix, the addition of the PBN in each leaf node adds at most 1MB of memory usage.

This scheme allows efficient operations on on-disk fingerprints. To search for a fingerprint on disk, SmartDedup looks for the corresponding leaf node in the fingerprint index. If the node does not exist in the prefix tree, SmartDedup knows immediately that the fingerprint does not exist on disk. If the node exists and contains a valid PBN, SmartDedup loads the whole group from that address into memory and searches for the given fingerprint in memory using binary search. The I/O overhead for accessing the on-disk groups is small because the size of each group is generally small. Assuming each group shares the 18-bit prefix, for 256GB of device storage with no duplicate data blocks, there are about 256 fingerprints per group, requiring only one to two 4KB blocks to store them. For even larger disks, we can increase the length of the prefix to bound the group size.

As discussed above, our proposed fingerprint index provides the functionality of a Bloom filter; in comparison, employing a separate Bloom filter incurs additional time and space overhead. For example, using a Bloom filter to determine whether a group of fingerprints exists or not would require 0.92MB of memory and applying five hash functions. In addition, it needs to deal with the difficulty of fingerprint deletions [7, 11].

Fingerprint Migration. Fingerprints evicted from the in-memory store are moved to the on-disk store; conversely, when an on-disk fingerprint is matched by new data, it is promoted from disk to memory. When deciding which fingerprints to evict, the in-memory fingerprint store tries to keep the fingerprints that are important to the current workload. Our evaluation results show that a simple policy such as least recently used (LRU) achieves good deduplication ratios (Section 4.2).

But the I/O overhead of fingerprint migrations is an important consideration for devices. Evicting a fingerprint from memory to disk requires two I/Os for loading the corresponding fingerprint group from disk and storing the updated group back to disk. To reduce disk I/O overhead, instead of evicting one fingerprint at a time, SmartDedup evicts a group of fingerprints at a time, so that a number of slots are freed up at once in the in-memory fingerprint store and can be used to store a number of fingerprints from the future requests. With the design of a prefix-tree-based index, the fingerprints linked to the same leaf node share the same prefix and automatically form an eviction group. Note that when migrating fingerprints from disk to memory, SmartDedup still promotes one fingerprint, instead of a whole group, at a time, since there is limited locality within each group. Moreover, with a small group size (9 on average), the deduplication ratio is also not compromised much by evicting the whole group together.

To implement a group-based eviction policy, SmartDedup keeps an LRU list for all the groups in the fingerprint index. Whenever a fingerprint is matched to a new request, its group is brought to the head of the LRU list. When eviction is needed, the entire group of fingerprints that is at the tail of the LRU list is evicted. Since both the in-memory and on-disk fingerprint stores share the same index, fingerprints that are evicted together from the in-memory fingerprint store also belong to the group that shares the same prefix in the on-disk fingerprint store, so they can be inserted into the on-disk group using a single read-merge-write operation.

3.3 Hybrid Deduplication

In-line Deduplication happens when the file system handles a write request, and it removes a duplicate write by modifying the file system's logical block to physical blocks mappings. Specifically, in our prototypes, the write paths of EXT4 and F2FS are modified in the following manner to make sure that the deduplication procedure does not violate the basic design principles of modern file systems. First, SmartDedup achieves deduplication by changing the one-to-one mappings that the file system maintains from logical blocks to physical blocks to many-to-one. Second, SmartDedup performs in-line deduplication when the file system writes back buffered data to disk; by doing so, it saves itself from processing repeated writes to buffered data, which does not hurt either performance or endurance. SmartDedup also handles direct I/Os, but the discussion here focuses on buffered I/Os since they dominate common device workloads.

In-line deduplication may not be able to find a match for a request even if there is a duplicate block on the file system, because the in-memory fingerprint store is not large enough to hold all the existing fingerprints. For such requests, in-line deduplication hands them over to out-of-line deduplication, which searches the on-disk fingerprint store in the background without slowing down the foreground application.

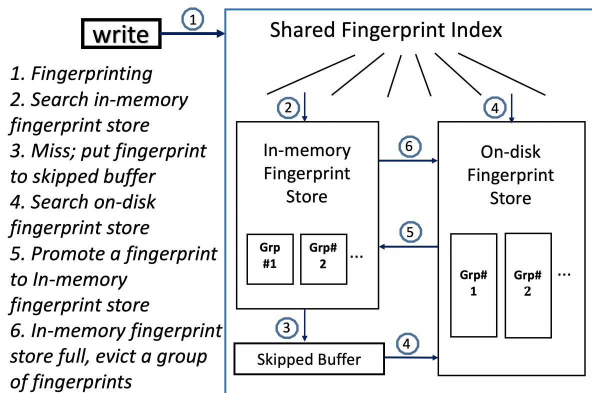

Figure 2: SmartDedup operations.

Out-of-line Deduplication works in the background on data that is not processed by in-line deduplication, which may be still in the page cache waiting to be written back or be already stored on disk. When processing a block of data, it looks for the fingerprint in both the in-memory and on-disk stores. When a match is found for a logical block, it changes the mappings between the logical block and physical block and, if needed, deallocates the redundant physical block to perform deduplication.

For efficiency, SmartDedup avoids processing data blocks that have not been modified since the last time they were processed by either in-line or out-of-line deduplication. It uses an in-memory buffer, called *skipped buffer*, which stores the list of blocks skipped by in-line deduplication, either because the latter is disabled or is enabled but cannot find fingerprint matches in the in-memory store. Each entry in this buffer stores a skipped block's information (inode number, LBN, and fingerprint (if available)) for the out-of-line deduplication to process the block quickly. It is implemented using an array-based hash table, indexed by inode and LBN. When the fingerprint of a data block is updated, the previous content of the hash table entry is replaced by the new one.

The size of the skipped buffer is kept small and is also adjustable depending on the device's current memory availability. For example, with 0.5MB of memory, the skipped buffer can store the information of 22K requests and 65K requests with and without their fingerprints, respectively. If the buffer does get full, SmartDedup converts it to store only the inode numbers of modified files so that out-of-line deduplication processes only these files. As the inode number requires only 4 bytes, the buffer rarely overflows in practice.

3.4 Putting Everything Together

Read and Write Path. When handling a write, SmartDedup fingerprints the request, searches for it in the fingerprint store(s), and deduplicates it if a match is found, as discussed above and illustrated in Figure 2. The read path in the file system is also modified to make use of deduplication to improve read performance. Because the page cache is indexed by each file's LBNs, a read that cannot find its LBN in the page cache cannot be avoided even if the requested data duplicates another logical block that is already in the cache.

To address this limitation, SmartDedup employs a *page cache index* which maps from PBNs to their corresponding pages in the page cache. For a read that cannot find a match in the page cache by its LBN, SmartDedup searches the index using its PBN, before considering it a miss as the native file system does. If a match is found, it means that the requested data already exists in the page cache, and there is no need to perform the actual read I/O. SmartDedup directly copies the data from the duplicate page in the cache. The size of this index is bounded by the size of page cache, and it can be further restricted when SmartDedup indexes only the important set of pages (e.g., the most recently used ones) in the cache.

Handling Data Updates and Deletions. A complication to the above write process is that when handling an update to or deallocation of an existing block, the fingerprint stores need to be consistently updated. SmartDedup needs to find the original fingerprint of the block so that it can update the reference count (the number of logical blocks deduplicated by this fingerprint) and delete the fingerprint if the reference count drops to zero. But SmartDedup does not have the original data's fingerprint; it has only the new request's LBN (and from there the PBN). To address this problem, SmartDedup maintains a *reverse index* (a sparse file) on disk for the fingerprint stores, which maps from a fingerprint's PBN to its corresponding leaf node in the *fingerprint index* of the fingerprint store using an array where the PBN is the index and the entries store the leaf node addresses. The leaf node represents a group of fingerprints either in memory or on disk, and SmartDedup can search this group to quickly locate the fingerprint. Compared to mapping from PBNs directly to the locations of the fingerprints, this design reduces the overhead of the reverse index because when a fingerprint migrates between the in-memory and on-disk stores, the leaf node that the fingerprint belongs to does not change and the index does not have to be updated.

Adaptive Deduplication. To further reduce the overhead of deduplication, SmartDedup can adapt its processing rate based on the current resource availability. For out-of-line deduplication, SmartDedup adapts the number of blocks that it processes per period of time (e.g., every minute). For in-line deduplication, it adapts the process-

ing rate by selectively processing n out of the N write requests that it receives—n/N defines the *selectivity*. Considering CPU and I/O load, SmartDedup automatically reduces its processing rate whenever it detects that the CPU or disk is fully utilized. Considering battery usage, SmartDedup reduces its processing rate proportionally to the remaining battery life, and completely disables deduplication when the device enters low-power mode. Similar policies for other resource constraints can also be easily specified and carried out by SmartDedup using this adaptive deduplication mechanism.

To further reduce resource usage, SmartDedup can also adapt its processing rate (by adjusting the selectivity) based on the level of data duplication observed in the workload. When the observed duplication level is low in the previous time window, SmartDedup gradually reduces its processing rate, but it quickly restores its processing rate when it detects an increasing duplication level in the current workload.

File System Consistency. Because the LBN-to-PBN mapping is already kept consistent by the native file system, the only metadata that SmartDedup needs to safekeep is the reference counts of the fingerprints—it relies on the reference counts to decide when to free a data block and when to perform copy-on-write. SmartDedup stores the reference counts persistently as part of the on-disk reverse index (together with the leaf node addresses of the corresponding fingerprints as described above).

To ensure consistency, on EXT4, SmartDedup journals the modifications to the reverse index as part of the file system journaling. The design of the reverse index helps reduce the overhead from its journaling. The entries in the index are sorted by the PBNs, so consecutive updates to the reference counts of adjacent physical blocks can be aggregated into much fewer updates to the reverse index blocks—a 4KB block stores 512 entries. Experiments using our traces confirm that the amount of additional writes to the reverse index is less than 0.5% of the total write volume. After a crash, the file system can be brought back to a consistent state by replaying the latest valid journal transaction. Similarly, on F2FS, SmartDedup ensures that modifications to the reverse index and on-disk fingerprint store are captured by the file system checkpoint so that they can always be brought to a valid state after the file system's crash recovery. The overhead of recovery is also small as it requires only updating the affected reference counts using the journal or checkpoint.

All other data structures that SmartDedup maintains can be safely discarded without affecting file system consistency. The in-memory fingerprint store will be warmed up again after the system recovers. The page cache index will be reconstructed as the page cache warms up again. The loss of the skipped buffer will make SmartDedup miss the requests that have not been processed by out-of-line deduplication. For a 0.5MB skipped buffer, at most 254MB of data will be missed (assuming that the buffer stores only the inode and LBN of each request). To reduce this impact, SmartDedup periodically checkpoints the inodes and LBNs from the skipped buffer.

	Nexus 5X	*Raspberry Pi 3*
CPU	Qualcomm Snapdragon 808	Broadcom BCM2837

Table 3: Specifications of the testing devices.

4 Evaluation

We evaluated SmartDedup based on prototypes implemented on EXT4 and F2FS. Testing devices include a Nexus 5X phone and a Raspberry Pi 3 device (Table 3). We considered the following workloads to provide a comprehensive evaluation:

- *FIO* [12]: We used FIO to create intensive I/O workloads with different access patterns and levels of duplication.
- *Trace Replay*: We replayed our collected real-world smartphone traces (Table 1), which helps us understand the performance of SmartDedup for real-world workloads of smart devices.
- *DEDISbench* [20]: We used DEDISbench to scan our collected real-world Android images and then generate workloads that reflect the data duplication characteristics (such as the distribution of reference counts) of these images.

We compared SmartDedup to two related solutions: Dmdedup [16, 23] and CAFTL [9]. Dmdedup is a block-level in-line deduplication solution that supports flexible metadata management policies. It can use a copy-on-write B-tree to store metadata and provide a consistency guarantee by flushing metadata periodically. To provide a fair comparison, we further enhanced Dmdedup by passing hints from the file system and allowing it to flush metadata only at journal commit times.

CAFTL implements both in-line and out-of-line deduplication at the flash translation layer (FTL), with several techniques designed for the resource constraints at this layer. Sampling hashing fingerprints only one data

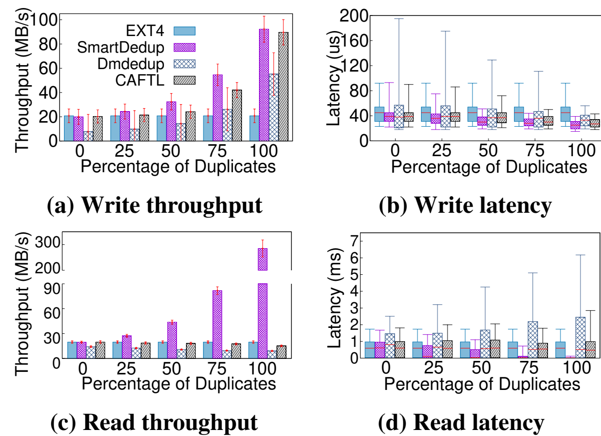
block in a request that has multiple blocks to reduce overhead. Lightweight pre-hashing applies CRC32 to pre-hash data blocks and filter out the unmatched ones to save fingerprinting overhead. Dynamic switches dynamically enable and disable deduplication based on the available cache space. For a fair comparison, we implemented sampling hashing and lightweight pre-hashing in the EXT4 writeback path, but dynamic switches are not necessary because the page cache supports rate limiting.

In all the experiments, the memory usage was capped at 3.5MB for all the evaluated solutions (unless otherwise noted). SmartDedup used 3MB for in-memory fingerprint store, which used a 14-bit prefix, and 0.5MB for the skipped buffer, which stored full information and never overflowed during the experiments. All the experiments were started with empty in-memory and on-disk fingerprint stores. Both in-line and out-of-line deduplication were used in the experiments (unless otherwise noted); adaptive deduplication was enabled and evaluated only in Section 4.4. SmartDedup uses fingerprints generated by cryptographic hash functions [19, 21] to find duplicates. The overhead for fingerprinting one 4KB block of data on Nexus 5X is about 9μs if using SHA1 and 16μs if using MD5, and on Pi is about 30μs for both. Due to limited space, we present only the MD5 results here. Each experiment was repeated at least five times.

4.1 FIO

We ran FIO with three threads, each issuing random 4KB reads or writes, using buffered I/Os (which is what real-world applications typically use). For all FIO experiments, the total read or write size was set to 2GB on Nexus and 1GB on Pi. We varied the percentage of duplicates in the workloads; at 0%, SmartDedup's in-memory fingerprint store can hold 20% and 10% of total fingerprints for the 1GB and 2GB experiments, respectively. The read experiments were performed using random reads on the data written by FIO in the write experiments (after the page cache was dropped).

Nexus 5X Results. Figure 3a and 3b show the write performance on Nexus 5X. The worst case for SmartDedup is when there is no duplicate, where SmartDedup has only 3.8% overhead in throughput and 1.1% overhead in 95th percentile latency compared to EXT4, including all the overhead from fingerprinting and operations on in-memory and on-disk fingerprint stores. In comparison, Dmdedup has a much higher overhead, 62.8% in throughput and 1.1X in 95th percentile latency, which we believe is due to 1) deduplication at the block layer adds another level of LBN-to-PBN mapping and additional overhead; 2) to guarantee consistency, the copy-on-write



(a) Write throughput (b) Write latency

(c) Read throughput (d) Read latency

Figure 3: FIO on EXT4 using Nexus 5X. Figures 3a and 3c show the average write and read throughput, respectively, with the error bars showing the standard deviations. Figures 3b and 3d illustrate the write and read latency results, respectively, using box and whisker plots, where the whiskers indicate the 5th and 95th percentiles.

B-tree requires more metadata I/Os. For this experiment, Dmdedup introduces 75.6% more metadata writes than EXT4, whereas SmartDedup introduces only 9% more. CAFTL has less overhead than SmartDedup (1.4% less in throughput and 3.2% less in 95th percentile latency) because, with no duplicates in the workload, its pre-hashing can save substantial fingerprinting.

As the percentage of duplicates in the workload grows, the performance of SmartDedup quickly improves and exceeds EXT4. With 25% duplicates, SmartDedup already outperforms EXT4 by 16.9% in throughput and 18.5% in 95th percentile latency. Dmdedup has an overhead of 52.8% in throughput and 90.2% in 95th percentile latency. CAFTL outperforms EXT4 by only 3.1% in throughput and 6.5% in 95th percentile latency. We found out that using pre-hashing hurts deduplication performance—since requests are filtered out by pre-hashing, CAFTL does not have their fingerprints and cannot deduplicate future requests that have the same data. To verify this observation, we tried removing pre-hashing from CAFTL and the deduplication ratio indeed increases (by 14% for FIO with 25% duplicates). Without pre-hashing, CAFTL is still slower than SmartDedup (6.7% in throughput and 9.3% in 95th percentile latency), because 1) its out-of-line deduplication works only when the system is idle and cannot help much; 2) its reference-count-based eviction policy cannot exploit temporal locality in fingerprint accesses (further discussed in Section 4.2).

Figure 3c and 3d compare the read performance. Even in the worst case with no duplicates, the overhead of SmartDedup is small, merely 0.6% in throughput and 2.7% in median read latency, which is mainly from main-

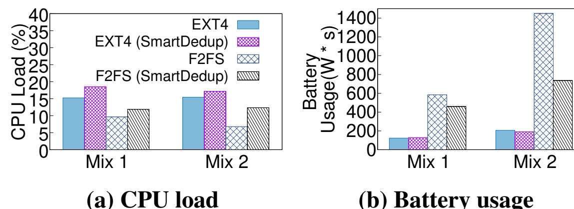
(c) Read throughput **(d) Read latency**

Figure 4: FIO on F2FS using Raspberry Pi. Figure 4a and 4c represent the average write and read throughput, respectively, and the error bars represent the standard deviations. Figure 4b and 4d illustrate the write and read latency results, respectively, using box and whisker plots, where the whiskers indicate the 5th and 95th percentiles.



(a) CPU load **(b) Battery usage**

Figure 5: Resource usage of FIO.

	Write size (MB)	Duplication ratio (%)	Read/Write ratio	Source Trace #
Segment 1	17612.8	75.8	1.5	4
Segment 2	12697.6	47.9	2.2	6
Segment 3	9318.4	26.4	6.8	2
Segment 4	65.8	46.1	51.3	4
Segment 5	78.5	19.4	69.8	4

Table 4: Trace segment statistics.

taining the page cache index. As the percentage of duplicates increases, the performance of SmartDedup rises accordingly, as expected, and SmartDedup substantially outperforms EXT4, improving the throughput by up to 13.4X and reducing the 95th percentile latency by up to 93%, owing to the page cache index which allows SmartDedup to use cached data to satisfy read requests for different logical blocks but with the same content (as discussed in Section 3.4). In comparison, both Dmdedup and CAFTL are slower than EXT4. CAFTL has up to 23% and 64.1% overhead in throughput and 95th percentile latency, respectively, which we believe is due to the fragmentation induced by deduplication [13]. SmartDedup's use of page cache index helps compensate for this overhead; additional techniques [22] can also be adopted to address this problem as discussed in Section 4.5.

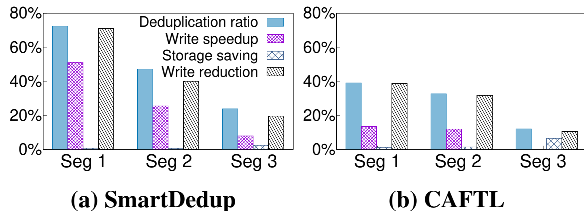
Raspberry Pi Results. Figure 4 compares the FIO performance on Raspberry Pi which has even fewer resources than Nexus 5X. The results show that SmartDedup also achieves substantial improvements compared to the native file system (F2FS) and the related solution (Dmdedup). For example, SmartDedup achieves a speedup of 31.1% and 32% in throughput for the write and read workloads with 25% duplicates, respectively compared to F2FS. Compared to Dmdedup, the throughput improvement is 2.8X and 34.5% for write and read, respectively. Although the improvement of 95th percentile latency is not as significant as in the Nexus results, SmartDedup still improves the 99.5th percentile latency substantially. Compared to F2FS, SmartDedup reduces the write tail latency by 30.4% and the read tail latency by 15.7%; and it outperforms Dmdedup by 85.4% in write and 18.7% in read.

Resource Usage. To understand the resource usage under realistic settings, we used FIO with different mixes of reads and writes to mimic the composition of real-world workloads. In our traces, the percentage of reads varies from 77.4% to 88% and the percentage of duplicates varies from 21.9% to 47.5%. For power measurement, we used the Trepn profiler [24] (for Nexus) and Watts Up Pro [5] (for Pi). Figure 5 shows the results. In Mix 1, the workload has 4GB of I/Os with 50% reads and 25% duplicates. SmartDedup's CPU overhead on EXT4 and F2FS is 3.3% and 2.2%, respectively, which are both reasonably small. For battery usage, SmartDedup has 4% overhead on EXT4 and uses 21.2% less battery on F2FS. In Mix 2, the workload consists of 6GB of I/Os with 66% reads and 25% duplicates. In this setting, SmartDedup's CPU overhead is merely 1.7% on EXT4 and 5.5% on F2FS; but it actually saves 7.7% of battery usage on EXT4 and 49.2% on F2FS because its saving on FIO runtime outweighs its overhead in power consumption. SmartDedup achieves these results while using only 0.2% (3.5MB out of 2GB) of the device's memory. Therefore, it is reasonable to believe that for typical device workloads, SmartDedup does not incur much resource overhead, and can in fact save the battery usage of the devices.

4.2 Trace Replay

The above FIO results give us insight into SmartDedup's performance and overhead under highly intensive settings. In the following two sections, we consider more realistic workloads using traces and images collected from real-world smartphones.

Replay on Real Devices. We replayed several represen-



(a) SmartDedup **(b) CAFTL**

Figure 6: Trace replay on EXT4 using Nexus 5X.

tative segments of the traces as summarized in Table 4 (Segments 1 to 3) using the real implementation of SmartDedup and CAFTL on the Nexus 5X device. These segments have different levels of duplication and all have a substantial amount of writes. Therefore, they can well represent the characteristics of the entire traces.

Figure 6 shows the results of the trace replay, including the achieved deduplication ratio and the speedup and the space and write savings compared to EXT4. The deduplication ratio reported here as well as the rest of the evaluation is computed using only the duplicates discovered by in-line deduplication. SmartDedup delivers a good speedup, up to 51.1%. It also achieves a high level of write reduction, up to 70.9%, after factoring in its own overhead in journaling and managing the on-disk data structures, e.g., 24.8 MB and 127.9 MB data were written to the reverse index and on-disk fingerprint store, respectively, during the replay of Segment 1. But there is not much space saving here, mainly because these trace segments are dominated by updates to existing data on the file system. During the replay of Segment 2, 34.2 MB and 12.5 MB disk space were used by the on-disk fingerprint store and reverse index, respectively. In comparison, CAFTL achieves less improvement (up to 13.4% and 38.7% in speedup and write reduction, respectively).

Since navigation is one of the typical applications on IoT devices [1, 2], we extracted the Google Map I/Os from our smartphone traces and replayed them (Segments 4 and 5 in Table 4) on the Raspberry Pi. As shown in Figure 7, SmartDedup also achieves good write speedup (up to 30.9%) and reduction (up to 47%) on the Pi.

Replay on Simulator. We also replayed three entire traces listed in Table 1 on a simulator of SmartDedup. The simulator implements SmartDedup's data structures and operations in user space and allows us to replay these months-long traces within a reasonable amount of time. Even though it does not model real-time performance, it allows the study of several important aspects of SmartDedup by replaying the entire traces.

First, we used the simulator to study the impact of our group-based fingerprint eviction (*G-LRU*) versus the standard, individual fingerprint eviction (*LRU*). Figure 8 shows that for different traces, *G-LRU* achieves a deduplication ratio that is at most 3% lower than *LRU*, which confirms that group-based eviction does not compromise the effectiveness of deduplication while saving substantial I/O overhead (on average 87%).

Next, we compared our recency-based fingerprint replacement, which replaces the least recently used fingerprint, to CAFTL's reference-count-based replacement, which replaces the fingerprint with the smallest reference count. As discussed in Section 4.1, pre-hashing is detrimental to deduplication ratio; here we considered the modified CAFTL that does not use pre-hashing. The results confirm the importance of exploiting temporal locality which allows SmartDedup to achieve 41.8% higher deduplication ratio than CAFTL.

We also studied the effectiveness of SmartDedup's in-memory fingerprint store design, which uses a prefix tree to index the fingerprints, by comparing its results to Dmdedup, which uses a copy-on-write B-tree as the index. We varied the amount of memory that each solution is allowed to use from 1MB to 40MB. The results show that SmartDedup's memory-conserving designs allow it to achieve higher deduplication ratios (by up to 35.7%), especially when the available memory is limited.

Finally, we evaluated the effectiveness of our two-level fingerprint store design by comparing the deduplication ratio of G-LRU with (*G-LRU*) and without (*G-LRU (in-line only)*) the on-disk fingerprint store. As expected, when the in-memory fingerprint store is small (1MB), the availability of an on-disk store and out-of-line deduplication improves the deduplication ratio from 6.7% to 12.1% (Trace 1). With a larger in-memory fingerprint store, the use of an on-disk fingerprint store still increases the deduplication ratio from 36.7% to 43.1% (Trace 2). These results prove that our designs for synergistic in-line and out-of-line deduplication with two-level fingerprint stores work well for real-world workloads, and they are particularly important for devices with limited memory capacity.

4.3 DEDISbench

In addition to using real traces, we also created additional workloads by sampling real-world smartphone images using DEDISbench [20]. We chose two of the smartphone images that we collected, with duplication ratios of 46.1% and 19.4%, and used DEDISbench to generate workloads that represent the data duplication characteristics of these images. All experiments were done on Nexus 5X using four threads and a total of 2GB of random 4KB reads or writes (SmartDedup's in-memory fingerprint store can

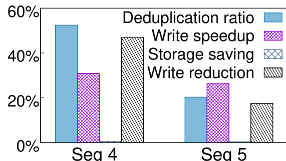


Figure 7: Trace replay on F2FS using Pi

hold 20% of all the fingerprints during these experiments). The write experiment was done in the peak mode (the more intensive mode of DEDISbench) with the hotspot I/O distribution (which DEDISbench uses to model real-world workloads with hotspot regions in their requests). The read experiment was done by reading from what DEDISbench generated in the write experiment (after the page cache was dropped).

Figure 9 shows the deduplication ratio achieved by SmartDedup and its I/O speedups, storage savings, and write reduction compared to EXT4. The write and read speedups are both significant, up to 54.4% and 33.6%, respectively, and largely follow the deduplication ratio of the workload. The read speedup is lower than the write speedup, because not all duplicate data can be found in the page cache due to cache evictions.

The space and write savings are also substantial, up to 45.0% and 41.6%, respectively. Note that these savings are computed after SmartDedup's overhead—the space and writes used for its on-disk data structures (including the on-disk fingerprint store and the reverse index and its journal)—is factored in. These results confirm the effectiveness of our techniques (Sections 3.2 and 3.4) for reducing the I/O overhead of deduplication.

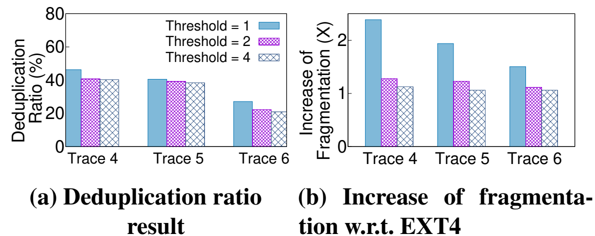
4.4 Adaptive Deduplication

Next, we evaluated the effectiveness of adaptive deduplication described in Section 3.4 by replaying trace segments on Nexus 5X. The first experiment studied the effectiveness of adapting deduplication selectivity based on the level of duplication observed in the workload. Following the general strategy described in Section 3.4, the specific algorithm used by SmartDedup is as follows. It computes the deduplication ratio of the last window—the last 150 write requests—and compares it to the average ratio from the past 30 windows. If the former is lower, it indicates that the current workload has fewer duplicates, and SmartDedup slowly reduces the percentage of requests that it fingerprints in-line in the next window (by 10% until it reaches a lower bound of 30%). But if the deduplication ratio of the last window is higher, SmartDedup quickly increases the percentage of requests that it fingerprints in-line in the next window (by 30% until it is back to 100%). How quickly SmartDedup adjusts its selectivity offers a tradeoff between performance and battery usage. We omit the sensitivity study's results due to lack of space. With the setting mentioned above, SmartDedup reduces its power consumption overhead (compared to EXT4) by up to 14% at the cost of 8% loss in deduplication ratio (as shown in Figure 10).

The second experiment evaluated adaptive deduplication based on the available battery level (Figure 11). We replayed a 12-hour long trace segment and assumed that the device's battery level was 100% (when it was fully charged) at the start of the replay and dropped to 20% (when it entered low-power mode) at the end. With adaptive deduplication, SmartDedup automatically increased the selectivity of fingerprinting as the available battery reduced. The power consumption overhead (compared to EXT4) dropped from 8%, when the battery level is 100%, to 0.3% when the battery level is 20%, at the cost of reducing the deduplication ratio from 51% to 32%.

4.5 Fragmentation Resistance

Deduplication usually brings fragmentation to disk and can hurt I/O performance. Even though flash storage is



(a) Deduplication ratio result **(b) Increase of fragmentation w.r.t. EXT4**

Figure 12: Fragmentation-resistant deduplication.

much less affected by fragmentation than HDDs, Hahn et al. [13] showed that flash devices still suffer from fragmentation due to increased I/O stack overhead. To address fragmentation, we leveraged the filtering technique from iDedup [22], which applies deduplication only to a physically contiguous sequence of writes that are duplicates. It sets a threshold on the length of a duplicate sequence, and filters out all sequences shorter than this threshold.

To evaluate the effectiveness of this filtering technique in SmartDedup, we replayed three complete traces listed in Table 1 on our simulator while varying the value of the threshold from one to four (when the threshold is one, the filtering is essentially disabled). We evaluated the impact on fragmentation, by measuring the total number of extents created by the workload. The results in Figure 12 confirm that by integrating the filtering technique, SmartDedup can reduce fragmentation without hurting the effectiveness of deduplication. For example, as the threshold increases from one to four, the deduplication ratio of SmartDedup drops by 6.0% while the increase in fragmentation (compared to native EXT4) reduces from 1.5X to 1.06X for Trace 6.

5 Related Work

There are several related deduplication solutions designed for resource-constrained systems. As mentioned in Section 4.1, CAFTL includes several techniques designed for deduplication on flash device controllers. The key differences of SmartDedup are its symbiotic use of in-line and out-of-line deduplication and the synergistic combination of in-memory and on-disk fingerprint stores for low-overhead and effective deduplication. In comparison, CAFTL relies mainly on in-line deduplication, while its out-of-line deduplication plays only a minor role and is completely separate from the former.

A recent study [17] proposed per-application, in-line deduplication for smartphones. It groups the fingerprints by applications, loads only the group for the foreground application, and swaps it out to disk when the application is switched to the background. As discussed in Section 2, per-application deduplication can miss many duplicates that exist across different applications. Moreover, migrating applications' entire fingerprint sets between memory and disk can be expensive when they become large. For example, our traces show that commonly used applications such as Gmail and Youtube have over 20MB of fingerprints and Weibo has 40MB. In comparison, SmartDedup supports system-wide deduplication with fine-grained fingerprint migration, and performs well with much lower memory usage.

Hybrid use of in-line and out-of-line deduplication has been studied in other related works. For example, DDFS [6, 25] employs both in-line and out-of-line deduplication for backup systems, and like CAFTL, they are not well integrated as in SmartDedup. DDFS caches fingerprints in memory to reduce on-disk fingerprint lookups, but unlike SmartDedup's in-memory fingerprint store, it is not designed for memory-constrained scenarios. For example, DDFS requires complex data structures to organize fingerprints that are grouped by their spatial locality. This design is important for deduplication on high-performance backup systems, but is unnecessary and costly for deduplicating the primary storage of low-end devices.

6 Conclusions and Future Work

This paper presents a deduplication solution optimized for smart devices. The novelties of this work lie in a new architectural design that synergistically integrates in-line with out-of-line deduplication and in-memory with on-disk fingerprint stores. The entire solution is cautiously designed and optimized considering the various resource constraints of smart devices. An extensive experimental evaluation based on intensive workloads and smartphone images and I/O traces confirms that SmartDedup can achieve substantial improvement in performance, endurance, and storage utilization with low memory, disk, and battery overhead. In our future work, we will further study the effectiveness of SmartDedup in other types of resource-constrained environments such as various Internet of Things and embedded storage controllers.

Data Domain Cloud Tier: Backup here, backup there, deduplicated everywhere!

Abhinav Duggal Fani Jenkins Philip Shilane Ramprasad Chinthekindi Ritesh Shah
Mahesh Kamat
Dell EMC

Abstract

Data Domain has added a cloud tier capability to its on-premises storage appliance, allowing clients to achieve the cost benefits of deduplication in the cloud. While there were many architectural changes necessary to support a cloud tier in a mature storage product, in this paper, we focus on innovations needed to support key functionality for customers. Consider typical customer interactions: First, a customer determines which files to migrate to the cloud by estimating how much space will be freed on the on-premises Data Domain appliance. Second, a customer transfers selected files to the cloud and later restores files back. Finally, a customer deletes a file in the cloud when its retention period has expired. Each of these operations requires significant architectural changes and new algorithms to address both the impact of deduplicated storage and the latency and expense of cloud object storage. We also present analysis from deployed cloud tier systems. As an example, some customers have moved more than 20PB of logical data to the cloud tier and achieved a total compression factor (deduplication * local compression) of 40× or more, resulting in millions of dollars of cost savings.

1 Introduction

Today many customers want options to migrate portions of their data to cloud storage. Object storage in public and private clouds provides cost-effective, on-demand, always available storage. Data protection is a key requirement, and Data Domain [32] has traditionally served as an on-premises data protection product, holding backups of customers' primary data. Data Domain added a deduplicated *cloud tier* to its data protection appliances. Our deduplication system consists of an *active tier* where customers backup their primary data (typically retained for 30-90 days) and a cloud tier where selected backups are transitioned to cloud storage and retained long term (1-7 years). Our recent cloud tier product is currently being used by hundreds of customers.

Adding a cloud tier to a mature storage appliance involved numerous architectural changes to support local and remote storage tiers. We present some of the most novel improvements necessary to support basic capabilities required by customers. First a customer wishes to free up space on their active tier by migrating files to the cloud and wishes to determine how much space will be saved (Section 4). While this is straightforward to calculate in traditional storage systems, deduplication complicates the process because the files may have content that overlaps with other files that will remain on the active tier. We present a new algorithm to estimate the amount of space unique to a set of files. This algorithm builds upon a previous technique using perfect hashes and sequential storage scans [7] for memory and I/O efficiency.

Once a customer selects files for migration to the cloud tier, we wish to transfer the unique content to the cloud tier to preserve the benefits of deduplication during transfer. When a large quantity of data is being initially transferred, we developed a bulk seeding algorithm that also uses perfect hashes to select the set of chunks to transfer (Section 5). For ongoing transfers, we developed a file migration algorithm that leverages metadata that is stored locally to accelerate the deduplication process and avoids the latency of accesses to cloud object storage (Section 6.1). We then describe how files can be efficiently restored to the active tier.

Finally, as a customer deletes files from a cloud tier, unreferenced chunks must be removed to free space and reduce storage costs (Section 7.2). While garbage collection for the active tier has been described [11], we updated the cloud tier version to handle the latency and financial cost of reading data from the cloud back to the on-premises appliance.

From experience with a deployed cloud tier, we have learned lessons about sizing objects stored in private and public object storage systems and trade-offs of performance and cost. After analyzing deployed systems, we found that customers achieve a range of deduplication ratios. Our customers achieved an active tier deduplication ranging between 1× and 848× and cloud tier deduplication ranging between 1× and 66×. The space savings result in cost savings and one customer saved as much as $10 million (Section 8).

Our largest system has a single 1PB active tier and two 1PB cloud units within a single cloud tier. This is the physical capacity before the benefits of deduplication and compression. A cloud unit is a single deduplication domain. Each cloud unit has its own metadata, data and fingerprint

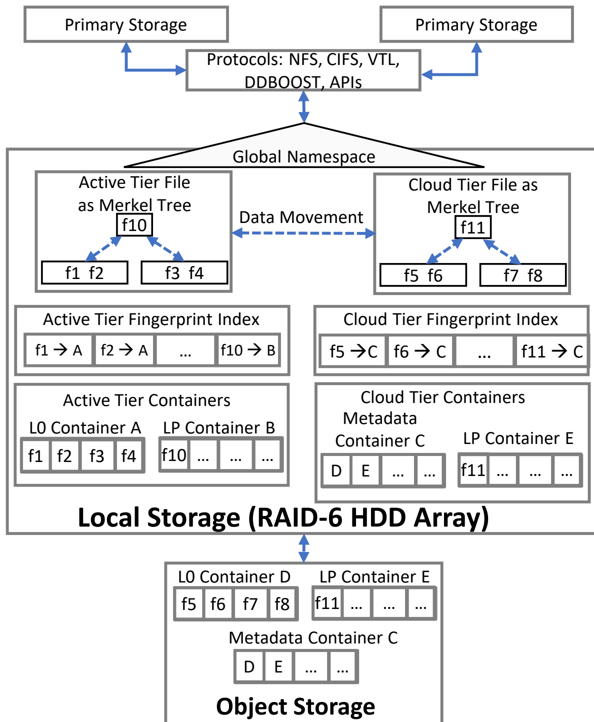

Figure 1: Data Domain with active and cloud tiers

index. For simplicity, we will use *active tier* and *cloud tier* as the terminology when referring to the active and cloud components of our backup appliance. Our cloud tier is designed to work with object storage that is either on-premises or in a public cloud, and we use the terms *object storage* and *cloud storage* interchangeably.

The vast majority of the technology described in this paper is publicly available and used by our customers. The exception is an experimental improvement to our garbage collection algorithm described in Section 7.2 based on microservices for public cloud providers. We believe the following contributions, except the performance results, are applicable to other deduplicated storage systems adding a cloud tier.

1. An architecture for a deduplicated cloud storage tier
2. A space estimation algorithm for files within deduplicated storage
3. Algorithms to seed a cloud tier or perform ongoing file migration
4. A garbage collection algorithm designed for cloud storage properties
5. An evaluation of how customers are using the cloud tier
6. Performance results on internal systems

2 Architecture

We updated our deduplicated storage architecture to support both a local, active tier and a remote, cloud tier. We first review the active tier architecture and then describe changes for a cloud tier as shown in Figure 1.

2.1 Active Tier Architecture

A file in both, active and cloud tiers, is represented by a Merkle tree with user data as variable sized chunks at the bottom level of the tree, referred to as *L0 chunks*. The SHA1 fingerprints of those chunks are grouped together at the next higher level of the tree to form chunks, referred to as L1 chunks. SHA1 fingerprints of L1 chunks are grouped together as L2 chunks, and this continues up to L6 which represents the entire file. The top chunk of the tree is always an L6 chunk, even though it may refer to chunks in a lower numbered level. We refer to chunks above L0 as LP chunks. The L6 chunk of every file is stored in a namespace which is represented as a B+ Tree [11].

Deduplication happens when different files refer to the same L0 and LP chunks. As an example, if two files are exactly the same, they would have the same L6 fingerprint. But if two files only partially overlap in content, then some branches of the tree will be identical (LP and L0 chunks), while other branches will have different fingerprints. Multiple L0 chunks are compressed into 64K-128K sized compression regions, while LP chunks are not compressed as SHA1 fingerprints are quite random and do not compress. If encryption is enabled, the compression regions are also encrypted before they are written to storage containers.

A Data Domain appliance tends to be utilized by a single customer, who typically selects a single encryption key for all of the data. If multiple keys are selected, customers accept a potential loss in cross-dataset deduplication. We have not found customer demand for convergent encryption or stronger encryption requirements for cloud storage than on-premises storage.

All chunks (L0s and LPs) are written into storage containers. On the active tier, containers are 4.5MB in size, while the container size on the cloud tier varies with properties of each cloud storage system (Section 2.3). We segregate the L0 and LP chunks into separate containers, which we refer to as *L0-Containers* and *LP-Containers*, respectively. Creating separate LP-Containers supports various operations like garbage collection that need to process LP chunks. Segregating L0 chunks from LP chunks also ensures that the locality of L0 chunks is preserved which results in better read performance. Both types of containers consist of a data section with the chunks and a metadata section with fingerprints of the chunks. During deduplication, container metadata sections are loaded into a memory cache. This loads 1,000 or more fingerprints into memory, helps to accelerate deduplication, and reduces fingerprint index accesses from disk. During reads, container metadata sections are loaded into the same memory cache and this avoids having to read all subsequent fingerprints in the container from disk [32].

2.2 Cloud Tier Architecture

With the introduction of cloud tier, there is a single namespace, referred to as global namespace. The global namespace spans both, active tier and cloud tier files. The Merkle trees of files in the cloud tier are stored on the local storage of the Data Domain system to facilitate high-speed access of those files. The global namespace which contains the L6 chunks of every file is periodically written to the cloud tier. In this design, files exist in one tier or the other based on a customer's policy. In some cases, customers use the cloud tier as extra capacity, while other customers use it for long term archival of selected data.

For the cloud tier, we introduced a third type of container, which we refer to as *Metadata-Container*. Metadata-Containers store the metadata sections from multiple L0 and LP-Containers. Since the metadata sections of containers are read during deduplication and garbage collection, and require quick access, Metadata-Containers are stored on the local storage as well as in cloud storage.

The SHA1 fingerprints of chunks are stored in an on-disk fingerprint index which consists of a mapping of fingerprint to container number. To avoid these writes and reads to the cloud, the cloud tier fingerprint index is stored on the local storage of the Data Domain system. In the active tier, the fingerprint index contains fingerprint to L0 or LP-Container number mappings, while the cloud tier index contains fingerprint to Metadata-Container number mappings. This is an optimization to load fingerprints from a local Metadata-Container instead of a remote L0 or LP-Container.

Figure 1 shows an active tier file that contains L0 chunks with fingerprints f1, f2, f3, and f4. The L0 chunk fingerprints are stored in an LP chunk with fingerprint f10. The L0 chunks and their fingerprints are stored in an L0-Container A, while the LP chunks and their fingerprints are stored in an LP-Container B. The active tier fingerprint index contains mappings for all the L0 and LP chunks' fingerprints. Figure 1 also shows a cloud tier file. The global namespace contains the location of this file. The file contains L0 chunks with fingerprints f5, f6, f7, and f8. The L0 chunk fingerprints are stored in an LP chunk with fingerprint f11. The L0 chunks and their fingerprints are stored in an L0-Container D, while the LP chunks and their fingerprints are stored in an LP-Container E. L0-Container D is written to object storage in the cloud, while LP-Container E is written to both, object storage in the cloud and local storage. The cloud tier fingerprint index contains mappings for all the L0 and LP chunks' fingerprints, and is stored on local storage.

As explained above, we store critical cloud tier metadata on the local storage of the Data Domain system to improve performance and reduce cost. The majority of this metadata, including the global namespace, is also mirrored to the cloud in order to provide a disaster recovery (DR) functionality. Disaster recovery is needed if a Data Domain system with a cloud tier was lost in a disaster. Such a disaster can result in the loss of active tier and the local cloud tier storage, where cloud tier metadata resides. Disaster recovery is the main reason why the active tier and cloud tier have different deduplication domains. If an active tier is lost, the backup copies migrated to object storage can be recovered.

The DR procedure to recover the cloud tier includes procuring a replacement Data Domain system and initiating an automated recovery process, which involves: creating a new cloud unit, copying the metadata (LP and Metadata-Containers) to the local storage for the cloud tier, rebuilding the cloud tier fingerprint index, and recovering the global namespace. Note that we only recover the metadata from the cloud storage. The data continues to reside in cloud storage, and it is not copied to the Data Domain system. After the DR procedure is completed, the cloud tier is accessible from the new Data Domain system.

To summarize our new architecture, we support an active tier and a cloud tier. Both tiers offer the benefits of deduplication, however each tier is a separate deduplication domain. Chunks are not shared between the active tier and the cloud tier. Note that if the underlying object storage provides deduplication, it would be ineffective since our deduplication algorithm removes the majority of duplicates at 8KB granularity. A global namespace maintains the location of both, active tier and cloud tier files. Each tier has its own metadata, data, and fingerprint index. To eliminate the costly reads and writes from/to the cloud, we copy key cloud tier data structures on the local storage of the Data Domain system. The data structures stored locally are the Metadata-Containers, the LP-Containers, the Merkle trees, and the cloud tier fingerprint index. The Metadata-Containers and LP-Containers are also mirrored to the cloud to facilitate disaster recovery.

2.3 Object Sizes for Cloud Tier

The cloud tier architecture we have chosen allows us to select an optimum object size because we write L0-Containers as individual objects and we have the ability to control the container size, up to 4.5MB. We are not able to write containers larger than 4.5MB without significant changes to our implementation. In the case of cloud tier, we use the terms objects and containers interchangably.

We started with 64KB objects, but evolved to larger sizes in the range of 1-4MB for several reasons. Larger objects result in less metadata overhead at the cloud storage provider because they store per-object metadata. Larger objects also decrease transaction costs as cloud storage providers charge per-object transaction costs. We have also discovered that larger objects perform better. Using an internal tool, we experimented with object sizes ranging between 64K and 4MB. On private cloud storage such as ECS [8], we saw a 6x improvement with 4MB objects compared to 64KB objects. On public cloud storage such as Amazon S3 [3], we saw a 2x

improvement with 4MB objects compared to 64KB objects. Even though the performance does not improve much after 1MB, a higher object size is better as it reduces the cost of transfer. Ultimately, writing larger-sized objects is a better choice for our cloud tier solution, though the exact size we choose varies with properties of each cloud storage system. In some cases certain object sizes align better with the provider's block size. For different providers, we choose different object sizes ranging from 1MB to 4MB.

3 Background on Perfect Hashing and Physical Scanning for the Cloud Tier

In addition to the architecture changes described in Section 2.2, we introduced several new algorithms specific to cloud tier. Since these algorithms utilize the perfect hashing technique from Botelho et al. [7] and the physical scan technique of Douglis et al. [11] as building blocks, we briefly review those works. Perfect hashing and physical scanning provide the basis for building the following cloud tier algorithms: space estimation (Section 4), seeding (Section 5), and cloud tier garbage collection (Section 7.2). Adapting perfect hashing and physical scanning to these cloud tier algorithms was mostly an engineering effort, and the novelty is specific to solving the challenges of the cloud tier algorithms and not necessarily the underlying techniques used.

3.1 Perfect Hashing

For algorithms described below, we need to perform a membership query for our fingerprints. Perfect hashing is a technique that helps us to perform this membership query by representing a fixed key set. We use a *perfect hash* vector which consists of a perfect hash function and a bit vector [7, 11]. A perfect hash function is a collision-free mapping which maps a key to a unique position in a bit vector. To generate the hash functions, a static set of fingerprints under consideration is used to generate a 1:1 mapping of fingerprint to a unique position in the bit vector. The function building process involves hashing the fingerprints into buckets where multiple fingerprints map to one bucket. Then for the fingerprint set in each bucket, we build a perfect hash function. By dividing the fingerprints into these buckets, we can build functions for each bucket in parallel. Once we obtain the function for each bucket, we store the function in a compact way [5, 6, 9]. Without the compactness of the perfect hashing representation, we would not have sufficient memory to reference all fingerprints in the system.

Building the perfect hash functions is quite efficient. For example, on a full 1PB system, we can build the perfect hash functions for 256 billion fingerprints in less than 3 hours with about 2.8 bits needed per fingerprint. The bit value in the perfect hash vector is used to record membership, such as chunk liveness for garbage collection.

3.2 Physical Scanning

As files are deduplicated, new LP chunks are written which refer to lower level LP and L0 chunks. Say two L2's written by two different files refer to the same L1, then these L2s most likely will get written to different containers. Hence these LP chunks get fragmented over time. For algorithms described in the sections below (e.g. garbage collection), we need to walk the LP chunks of all or most of the files in the system.

One way to walk the Merkle trees of LP chunks is to do it in a depth first manner. For every file, walk from L6 chunk, to L5, L4, L3, L2 and down to L1 chunks and get the L0 refererences. There are two problems with this traversal. First is that if two files point to the same LP chunk, then by doing file by file walk in depth-first manner, we will enumerate the same LP twice. The second problem is that since these LP chunks can be in different containers, loading these LP chunks will result in doing a random lookup to first get the location of LP chunk from the fingerprint index and second to read the LP chunk. Over time as deduplication increases, the same LP and L0 chunks get referenced multiple times and the LP fragmentation worsens.

Hence, instead of doing an expensive depth-first traversal, enumeration is done in a breadth first manner. By keeping track of LP chunks we have already enumerated (using a perfect hash vector), we avoid enumerating the same chunk twice. To reduce the random lookups, we first segregated LP and L0 chunks in different containers. By doing this, we converted random lookup for every LP to a random lookup for a group of LPs present in same compression region of the container. Here is a summary of the steps we follow to perform a physical scan of the file system:

Analysis Step: We walk the on-disk fingerprint index to create three perfect hash vectors as described in Section 3.1. Two of the perfect hash vectors are called the *walk vector* and *read vector*, respectively, and are used to assist in the breadth-first walk of the Merkle trees of all the files. These two vectors are only built for LP chunks. The third vector is called the *fingerprint vector*, and is used to record the liveness of a fingerprint. The fingerprint vector has bits for LP and L0 chunks. 97% of chunks are L0s, so the fingerprint vector is the largest.

Enumeration Step: We perform a number of sequential scans of containers to find chunks at specific levels in the Merkle trees. We first walk the namespace and mark all L6 fingerprints in the walk and fingerprint vectors. The top chunk is always a L6 chunk, which may refer to any lower-numbered chunk. Our system has an in-memory structure that records which LP types (L6, L5, ... L0) exist in each container, so we can specifically scan containers with L6 chunks. Figure 2 shows the next two steps of the enumeration process along with how the perfect hash vectors are used. Blue indicates the state of perfect hash vectors in the

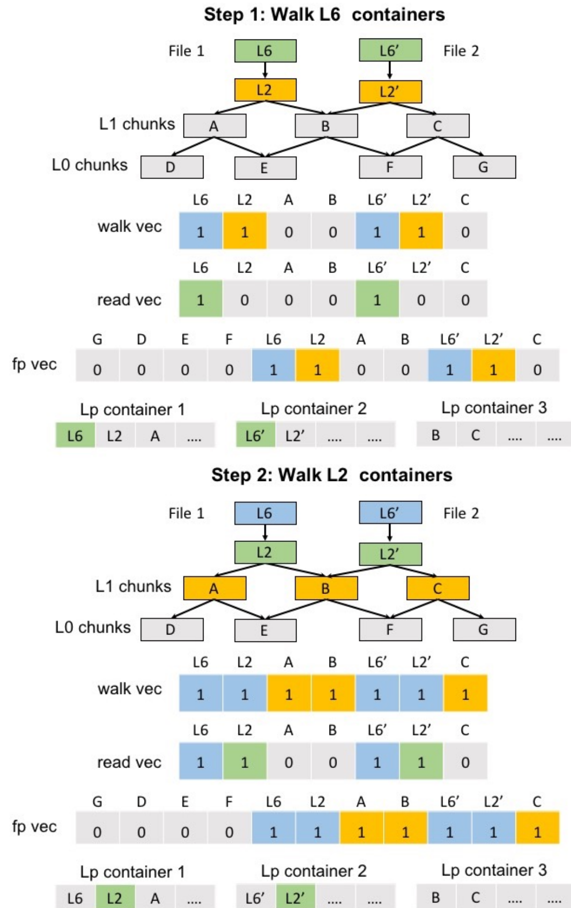

Figure 2: Physical Enumeration process

previous step, green indicates that we are reading containers and setting the read vector and yellow indicates that we are setting the walk and fingerprint vectors and gray indicates that we are yet to process those fingerprints. In step 1, we walk the container set reading L6 chunks and for any L6 fingerprints marked in the walk vector, we mark that L6 in the read vector (green). In this example, the L6 chunks reference L2 fingerprints, so we mark the L2 fingerprints in the walk (yellow) and fingerprint vectors (yellow). In step 2, we walk the container set again reading L2 chunks and for any L2 fingeprints which are marked in walk vector, we mark those L2 fingerprints in read vector (green). We read the L1 fingerprints from the marked L2 chunks and mark those L1 fingerprints in the walk (yellow) and fingerprint (yellow) vectors. For deeper trees, we repeat the steps of reading a level, marking fingerprints in a walk vector and fingerprint vector, and then reading the lower level and marking fingerprints in the walk vector. Finally, in the L1 container set walk, the L1 chunks have a list of L0 fingerprints, which we mark in the fingerprint vector. Parallel I/O is leveraged to read containers from the RAID array, and multiple threads are used for marking the chunks in the walk, read, and fingerprint vectors.

4 Estimate Freeable Space

Deduplication creates a new challenge for customers interested in reducing their active tier footprint. In traditional storage, transferring 10GB of files would reduce the active tier by 10GB. With deduplicated storage, less space may be freed because of content overlap with files that remain on the active tier. So, a customer may end up paying for on-premises capacity as well as object storage capacity despite their intention.

Such customers need a way to evaluate how much space would be freed on the active tier by moving files to the cloud tier. Variants of this problem have been considered for directing content to storage nodes [10, 12, 20] to maximize deduplication and to evaluate the unique space referenced by volumes of block storage [14]. Our system does not maintain reference counts due to the difficulty of maintaining accurate counts under complex error cases, so we implemented an algorithm to calculate the space that would be saved on the active tier if selected files were migrated to the cloud.

Using the perfect hashing (Section 3.1) and physical scanning (Section 3.2) techniques, we walk the files selected for migration in a breadth-first manner through the Merkle tree and mark the chunks in an in-memory perfect hash vector. Then, we walk all the remaining files (those not selected for migration) and repeat the breadth-first traversal again. In the second traversal, we unmark the chunks referenced by these remaining files. After this traversal is complete, the chunks which are still marked in the perfect hash vector are the chunks which are uniquely referenced by files selected for migration to the cloud tier. We perform a walk of the containers and sum up the chunk sizes for any chunks marked in the perfect hash vector.

This gives us an exact count of the bytes that would be freed. It becomes an estimate when new files are written to the active tier after constructing the perfect hash vector and such files deduplicate with selected chunks. In such cases, our algorithm overestimates the number of bytes that would be freed due to migration.

Since space estimation uses perfect hashing, the estimation cannot be done until the perfect hash functions are generated. As discussed in Section 3.1, this process takes nearly 3 hours for 1 PB of physical data. Also, this process gives only a point in time space estimate. As new data gets written to active tier, it can deduplicate against the chunks that will be moved to the cloud storage. As a result the point in time estimate becomes stale. Our customers can run this tool periodically to get the updated estimate. In practice, this has not been an issue.

5 Seeding

When customers started using cloud tier, they faced new challenges with data migration to the cloud. Some customers

had hundreds of TBs of data on the active tier that they wanted to migrate to the cloud tier. Being a deduplication system, migration of large amount of data to the cloud suffered from the same challenges as described in Section 3.2. Hence, we implemented a seeding algorithm based on the perfect hashing (Section 3.1) and physical scanning (Section 3.2) techniques.

We first build an in-memory perfect hash vector for fingerprints in the active tier fingerprint index. Then, for all the files that need to be transferred to the cloud tier, we traverse the Merkle trees in the same breadth first manner and mark the corresponding chunks live in the perfect hash vector. We then walk the containers on the active tier, pick the chunks which are marked live in the perfect hash vector, pack them in destination containers, and write them to cloud tier. This process generates both data containers (L0) and containers for metadata (LP and Metadata-Containers). Once all these containers are written, we update the namespace to indicate that all these files are now located in the cloud tier.

Seeding needs to be resumable because the memory requirements for seeding and GC are high and memory is shared between these processes. Cloud GC and seeding share memory, but until seeding is complete, there is no need to run cloud GC since the cloud tier is nearly empty. Active GC and seeding may need to run at the same time, especially since seeding may take weeks to transfer data depending on WAN speed. To make it resumable, after we mark the chunks that need to be transferred in the perfect hash vector, we persist the perfect hash vector (function and bit vector) to disk and then start active GC. Once active GC finishes, we load the perfect hash vector and resume writing to the cloud.

Seeding guarantees that all the L0 and LP chunks are transferred to the cloud tier before the file's location is changed in the namespace. It uses the perfect hash vector to guarantee that property. As we transfer chunks to the cloud tier, we change the membership bit in the perfect hash vector from 1 to 0. At the end of seeding, all the bits in the perfect hash vector should be 0 to guarantee that all necessary chunks are transferred.

There is an important caveat with seeding. The chunks written to the cloud tier do not pass through the deduplication process. So, seeding is only used to transfer large amounts of data for the first time when a customer buys a cloud tier license. We cannot use the typical fingerprint caching and prefetching approach for deduplication because the seeding process works in physical disk order instead of the logical order of chunks in a file, so caching is ineffective. Another approach is to consider generating a perfect hash vector for data already stored in the cloud tier, but this would double the memory requirements since we would need to generate perfect hash vectors for both the active and cloud tiers. We already use a large perfect hash vector and cloud tier had to be supported on existing active tier systems in the field, so adding more memory for this is not a practical solution.

6 File Migration and Restore

6.1 File Migration

Unlike seeding which is a one time process to transfer a large amount of data from the active tier to a nearly empty cloud tier, file migration is designed to transfer a few files incrementally. File migration reduces the amount of data transferred to the cloud tier by performing a deduplication process relative to chunks already present in the cloud tier.

File migration starts in the active tier by traversing the Merkle trees for selected files in a depth-first search manner. This traversal is performed in parallel for a number of selected files. The traversal ends when we reach the desired L1 chunks, which contain L0 fingerprints. The fingerprints are checked against the cloud tier using the same container metadata prefetching technique used during deduplication to see if identical fingerprints are already present in the cloud tier. If the fingerprints are not present in the cloud tier, then the corresponding chunks are read from the active tier and packed to form new L0-Containers. This process generates both data containers (L0) and containers for metadata (LP and Metadata-Containers). After Metadata-Containers are written, all contained fingerprints are added to the cloud tier fingerprint index. Finally, the namespace is updated to indicate that the file is located in the cloud tier.

To compare seeding and file migration, seeding is designed for bulk transfers such as when first moving files from a full active tier to nearly empty cloud tier. Seeding has the overhead of generating the perfect hash function, which is nearly 3 hours per 1PB of physical capacity. This is acceptable relative to the many days or weeks possibly required to transfer a large dataset to the cloud. Seeding has the advantage of physical enumeration, which uses sequential I/O instead of random I/O. On the other hand, when transferring a small number of files, it is more efficient to perform the random I/O to find the needed chunks for the files than generate the perfect hash function. Newer backup files on the active tier also tend to have better physical locality as our deduplication engine explicitly writes duplicates to keep locality high [2, 25]. Seeding and file migration are experimentally compared in Section 8.

6.2 File Restore

Restoring a file back from the cloud tier involves the reverse process of reading the Merkle trees to the L1 chunks in a depth-first manner. The L1 chunks are read from local storage since the LP-Containers are stored locally. The L0 fingerprints are checked against the active tier fingerprint index, and if present, do not need to be read from cloud tier. For new L0 fingerprints (not present in the active tier), we get the Metadata-Container number from the cloud tier fingerprint index, read the Metadata-Container to get the L0-

Container number, read the L0-Container from object storage, and write the relevant L0 chunks to L0-Containers in the active tier. As L0-Containers are being written to active tier, new Merkle trees for the active tier are formed in a bottom-up manner. This process generates new LP chunks which are written to LP-Containers in the active tier, and the namespace is updated.

To summarize, while performing file migration to the cloud tier, we deduplicate against chunks in the cloud tier, and while restoring files from the cloud tier, we deduplicate against chunks in the active tier.

7 Garbage Collection (GC)

When customers expire backups, some chunks become unreferenced. The Data Domain filesystem is log-structured and garbage collection is responsible for cleaning the unreferenced data asynchronously. Our garbage collection is mark and sweep based and described in our previous work [11]. To briefly summarize the process, we use the physical scanning technique described in Section 3.2 to mark chunks live (referenced from live files) in the perfect hash vector. Then, we perform the sweep operation. Active tier GC and Cloud tier GC differ in the sweep process, and we describe the differences here. Most of our customers run GC on the active tier weekly according to a default schedule, whereas cloud tier garbage collection varies from once every two weeks to once every month to never.

7.1 Active Tier Garbage Collection

After marking chunks live in the perfect hash vector, the sweep process walks the container set to copy live chunks from old containers into newer containers while deleting the old containers. This sweep process is also called copy forward. This process focuses on a subset of the container set which will give us the maximum space back.

During this process we first read the source containers from disk. Then, we check the fingerprints from the metadata sections of these containers against the perfect hash vector to determine which L0 chunks are live. Finally, we decrypt (if encrypted) and uncompress the compression regions inside the source containers, encrypt and compress the live chunks into new compression regions, and pack them into destination containers which are written to disk. The copy forward process for LP Containers does not perform decompression/-compression since LP chunks are not compressed.

7.2 Cloud Tier Garbage Collection

As data is written to the cloud tier, space usage and costs grow. Similar to the active tier, when customers expire files in the cloud, GC needs to clean unreferenced chunks on the cloud tier. The challenge for cloud GC is that L0 containers are not local and reading them from the cloud is expensive. It is also slow in terms of performance as we have to read the container objects over WAN.

From our experience with active tier, we know that a single cycle of GC copies forward 15% of the containers on average, where each container has an average of 50% live data. Hence, for 1PB of physical capacity in a cloud tier, we need to read 150TB of partially-live containers and write 75TB of newly-formed containers, increasing data transfer costs and transactional costs. As an example, based on AWS pricing, we calculated the cost of copy forward for 150TB of data to be nearly $14,000 per GC cycle. The major contributor to this cost is egress data transfer cost, so we needed a way to do garbage collection without reading the L0-Containers from object storage and writing new L0-Containers to object storage. To address this, we defined an API to perform copy forward inside the cloud provider's infrastructure. ECS and VirtuStream cloud providers have implemented this API. The API takes a list of source container objects, a list of offset ranges inside of those container objects, and a destination container object. The offset ranges correspond to live compression regions within the source container objects. Upon receiving the API, the cloud provider copies the live offset ranges from the source container object to a new, destination container object.

In order to perform the chunk level copy forward done by active tier GC, the compression regions need to be decrypted and uncompressed, and the live chunks need to be copied forward to form new compression regions inside new containers. Doing all of this in the cloud provider's infrastructure poses a challenge as we need to expose our container format, compression libraries, and encryption keys to the cloud provider. To address this, the new API we have implemented does not decompress/compress or decrypt/encrypt compression regions. It performs copy forward at the compression region level. We only delete a compression region in a cloud container when it is completely unreferenced. This approach is different from active tier GC where we delete individual chunks. The advantage of treating an entire compression region as live or dead is that the service running inside the cloud does not need to understand the container format or to compress/uncompress or decrypt/encrypt the compression regions. The service just reads offset ranges of where the live compression regions reside in existing container objects and writes a new destination container object. The disadvantage is that we won't delete a compression region until all the chunks inside the compression region are unreferenced. This can reduce our cleaning efficiency. In Section 8.1.2, we present field analysis of how live and dead data is distributed in compression regions and how much cleaning efficiency is lost due to compression region based cleaning instead of chunk based cleaning.

The cloud GC copy forward process works as follows. Once the live chunks have been identified in the per-

fect hash vector using the physical scanning technique described in Section 3.2, cloud tier GC performs a copy forward process of the Metadata-Containers. This process copies the live chunks' metadata from an existing Metadata-Container to a new Metadata-Container, and deletes the old Metadata-Container. The copy forward process of Metadata-Containers occurs on the local storage as Metadata-Containers are stored locally. As part of this process, we create a recipe containing the old L0-Container, the offset ranges of the live compression regions in that L0-Container, and a destination L0-Container which is being generated. Next, we send this recipe to the cloud provider in the form of the new API, and the cloud provider performs the copy forward of compression regions within their infrastructure. We then delete the old container objects.

For public cloud storage like AWS, Azure, and Google Cloud, such an API does not yet exist, so we have created an experimental version (not yet available to our customers) using a microservice that can be deployed and run inside the public cloud provider environment. Our plan is to work with cloud providers to either use a custom API for copy forward or our microservice. The results from the API and microservices based approaches are presented in Section 8.

8 Evaluation

We divide our evaluation into results from deployed systems and results from internal experiments.

8.1 Deployed Systems Evaluation

In this section, we show how our customers are using cloud tier in terms of data written, deduplication, and data deleted. We do not present results for space estimation and seeding in this section as these were recently released and the sample set is statistically small. Those techniques are evaluated on internal systems. We considered results from hundreds of deployed systems, filtered out systems with less than 1TB (post dedup/compression) of data in the cloud tier and inconsistent reports, and randomly selected 200 systems for analysis. Across systems, the age of the cloud tier varied from a few months to over two years.

Figure 3 shows monthly cumulative bytes (before deduplication and compression) sent from active tier to cloud tier for our 200 systems in the last three months. On one end, in 35% of the cases, less than 60TB (before dedup/compression) per month has been moved to cloud tier. On the other end, in 15% of the cases, over 660TB per month was sent to the cloud tier.

Figure 4 shows a scatter plot comparing the amount of data (before deduplication and compression) the deployed systems have moved to cloud tier and the total compression they have achieved. Total compression ratio is defined as deduplication ratio * local compression ratio. The general trend is that as more data is moved to the cloud tier, the more total compression is achieved because the new data deduplicates with older data. But there are some cases where even after moving large amounts of data to the cloud tier, the total compression is low. We further analyzed those systems and discovered that those customers are selecting and moving datasets with low total compression to the cloud tier to reduce their on-premises cost. Interestingly, we also found a few systems that have moved 20PB or more to the cloud tier and achieved a total compression factor of 40× or more. One system in particular achieved 66× total compression after moving 40PB of logical data to the cloud tier, resulting in substantial space and cost savings.

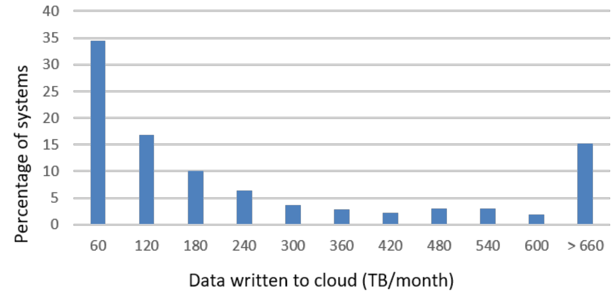

Figure 3: Distribution of TB/month moved to the cloud

Figure 4: Data moved to the cloud versus total compression

To understand the cost savings seen by our customers, we calculated how much money our customers are saving due to deduplication and compression. Even though customers are using various cloud providers, for simplicity, we assume Amazon S3 cost metrics for transaction and storage costs. We calculated total storage costs by calculating a monthly storage cost and accumulating it for all the months. We then calculated the transaction costs based on the total number of transactions performed and the cost of each transaction. Next, we added the storage and transaction costs based on bytes written before and after deduplication and compression, and we calculated the difference of the two. The histogram in Figure 5 shows this difference which represents the cumulative cost savings due to deduplication and compression in thousands of dollars on a log scale. Some of our customers saved nearly $10 million due to deduplication and

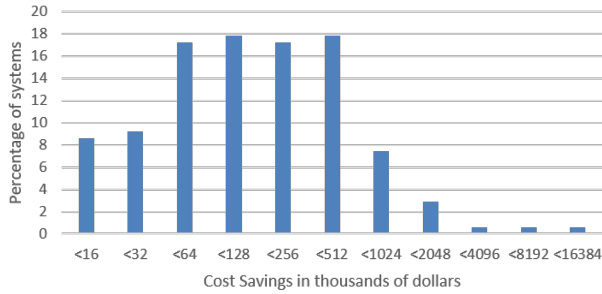

Figure 5: Histogram of cumulative cost savings in thousands of dollars due to deduplication and compression

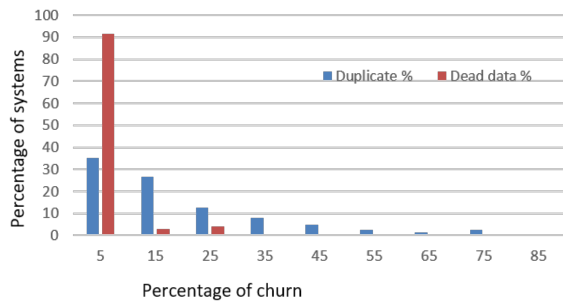

Figure 6: Comparison of physical churn due to file deletes and duplicates

compression. As customers retain the cloud tier data for a longer time period or write more data, their savings due to deduplication and compression will further increase.

8.1.1 Field GC Analysis

To understand how customers are deleting data and how much churn is really generated, we looked at customers who ran GC at-least once (40% of our selected 200 systems). As customers delete files in the cloud tier, data becomes unreferenced and needs to be cleaned. As mentioned in Section 7.2, our system writes some duplicates to improve restore performance. In turn, our GC algorithm retains the most recent version of a duplicate (written to the newest container) and removes older duplicates to reclaim space. Hence there are two types of chunks that can be freed from our system: unreferenced chunks due to file deletions and duplicate chunks. Figure 6 presents the percentage of physical churn (bytes deleted within a time period) that is dead due to file deletions and due to duplicates relative to total capacity of the system. Results from the last three months are included for systems that have run cloud GC at least once.

The churn due to file deletions is relatively low-90% of the systems had less than 5% of space reclaimed for dead chunks, because deduplication creates many references to chunks and because customers tend to retain their cloud data for long periods. There are some cases where the churn due to file deletions is over 25%, suggesting some customers delete a large fraction of their cloud tier periodically. In the steady state, most customers continue to delete the oldest backups as newer backups are stored. This graph also shows that while most of the systems have less than 30% of their churn as duplicates, in some cases the duplicates are very high (up to 75%). We looked at those systems and found that some of those customers have never run GC or have not run GC recently, so duplicates have not yet been removed. In contrast, active tier GC runs each week, so duplicates do not accumulate. We have learned that retention policies differ between active and cloud data, and we have provided an option to customers to control the amount of duplicates they want to write to cloud tier in case they infrequently run GC.

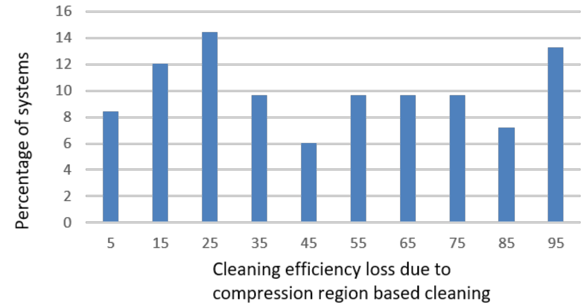

Figure 7: Percentage of cleaning efficiency loss

8.1.2 Cleaning Efficiency Loss due to Compression Region Cleaning

We analyzed the 200 systems to understand how much cleaning efficiency we lose with compression region-based cleaning for the cloud tier relative to possibly running chunk-level cleaning. Figure 7 shows the percentage of bytes that cannot be deleted by compression-region level cleaning but could have been deleted by chunk-level cleaning. As we can see, the cleaning efficiency loss is almost 100% in some cases. In such cases, compression-region level cleaning won't delete anything. We looked at some of these systems closely and found that this happens because the churn (bytes deleted within a time period) in the cloud tier is low. Even though there are a lot of duplicates that can be removed, these duplicates reside in the same compression regions as chunks that are still live, and this prevents us from deleting the compression region. In contrast, chunk-level cleaning is able to delete the duplicates while keeping only the live chunks. Further analysis of this observation is needed as the frequency and pattern of deletions and deduplication can result in different amounts of cleaning efficiency loss. In cases where we are not able to free up any space using compression-region level cleaning, we offer a chunk-level cleaning option, which performs the traditional algorithm of reading and writing container objects over the WAN. We also plan to augment our API and microservice based cleaning services to perform chunk level cleaning in the future.

Hardware	DD-Mid	DD-High
Memory	192GB	384GB
CPU(cores * GHz)	8 * 2.4GHz	24*2.5GHz
Active tier capacity	288TB	720TB
Cloud tier capacity	576TB	1440TB

Table 1: Data Domain hardware for experiments

8.1.3 Deployed Systems Summary

Here are findings from our cloud tier deployments:

1. Some customers are writing 500TB logically per month while others are writing 100TB or less.
2. Customer data is achieving a broad range of total compression ratios, from less than 4× to 100×, because customers are using a cloud tier in different ways. Some are writing highly redundant data to cloud tier (their total compression factor on the cloud and active tiers are both high). Such customers may accumulate more metadata than we originally anticipated and this can affect the runtime of GC and other algorithms. Other customers are writing non-redundant data to the cloud tier. It is likely that such customers are choosing low-deduplication data to migrate to the cloud tier. Other customers have not written much data to the cloud tier yet, so their total compression factor is lower.
3. Some customers have more data written to the cloud tier than to the active tier, so these customers are trying to reduce their on-premises storage cost.
4. Churn on the cloud tier (0-5% per month) is substantially lower than churn on the active tier (10% per week) because customers are not deleting much data. This finding is aligned with our expectation that cloud tier is used for long term retention.
5. Most customers are running cloud tier GC infrequently or not at all and have accumulated a high number of duplicates. Modifications to internal parameters can reduce the number of duplicates in these situations.

8.2 Experiments on Internal Systems

In this section, we focus on results from internal systems experiments. For all experiments, we used two cloud storage systems, Amazon S3 (public cloud) and ECS (private cloud). We used two Data Domain systems shown in Table 1, with the cloud tier feature as described in this paper. The two systems are representative of midrange (DD6800) and high-end (DD9300) products. We provide the size of the active tier and local storage for the cloud tier configuration.

8.2.1 Load Generator

To measure performance of our algorithms, we used an in-house synthetic load generator described previously [1, 11, 7]. A first generation backup is randomly generated, and the following generations have deletions, shuffles, and additions. We typically write many streams in parallel, each stream consisting of generations of backups beginning from a unique seed. The change rate between two consecutive generations is 5%. Gen0 is the first generation of backups where we only get local compression (an average of 2×) and no deduplication. GenX is aged data where generations Gen0-Gen(X-1) are already written to the active or cloud tiers. Due to deduplication, only the new content in GenX is stored while the rest deduplicates. In the experiments below, we vary the initial backup size, number of generations, and number of parallel streams. Beyond 42 generations, the physical locality of data is degraded at a similar level as what many of our customers experience. In one experiment (Section 8.2.4), we generated 100 generations to explore the impact of extremely poor locality.

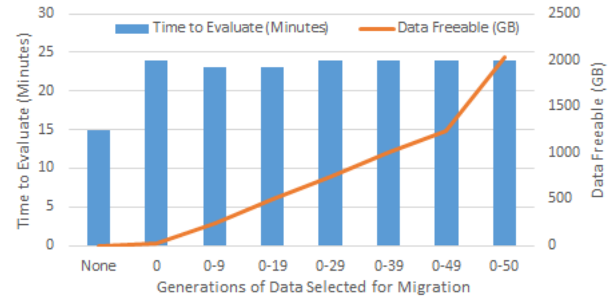

Figure 8: Space estimation performance

8.2.2 Freeable Space Estimation

To evaluate space estimation, we used the synthetic generator to create a data set, selected portions of the data set to potentially migrate, and ran the space estimation algorithm. We created a dataset using 96 parallel streams, each writing generations 0-50 of backups that average 24GB each for a total logical size of 120TB. Figure 8 shows the evaluation time and amount of space that can be freed as we vary the number of generations selected to potentially migrate. With no generations selected (`None`), the evaluation time is 15 minutes, and no space can be freed. As the number of generations selected increases up to including every generation (the rightmost bar), the evaluation time is consistently about 24 minutes while the amount of freeable space increases with the number of generations selected. When all generations are selected, the amount of freeable space jumps since chunks common to the highest generation can finally be freed. These results show that our space estimation algorithm has a run time based on the allocated space of the system. This is because space estimation does physical scans of metadata chunks followed by a container walk to calculate the estimated space that will be freed. The time for both physical scans and a container walk are a function of the physical space on the system.

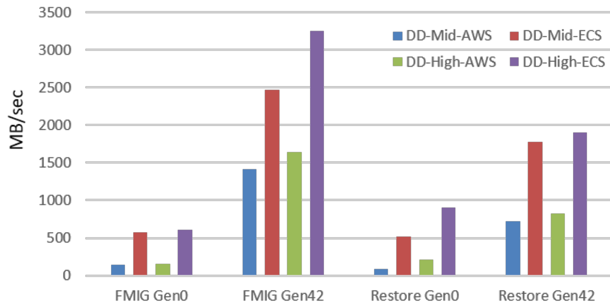

Figure 9: File Migration and Restore performance

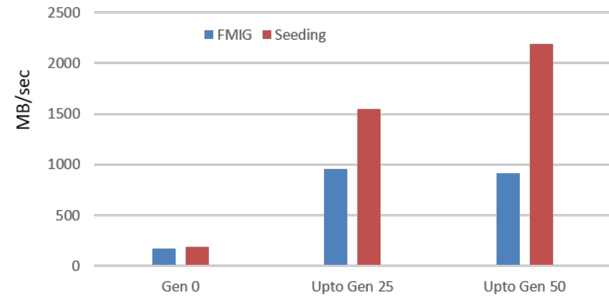

Figure 10: File Migration vs. Seeding performance

The duration of each run is only a few minutes because we wrote a small dataset instead of filling up a 1 PB system, which can take weeks. From experiences with active GC runs on a 1PB system (with the same underlying perfect hashing and physical scans), space estimation on a system of such capacity should finish within a couple of days.

8.2.3 File Migration and Restore from Cloud

Figure 9 shows the logical performance of file migration and restore on DD-Mid and DD-High using both AWS and ECS for object storage. We connected to AWS across the public Internet, while ECS was within our lab. We used Gen42 data to model aged data with high deduplication ratio. Gen42 file migration performance is higher than Gen0 file migration performance because of deduplication, as we only need to transfer the changed data to the cloud tier. In the case of Gen0 file migration, the performance for both hardware configurations is the same. This is because for Gen0, we are reading non-deduplicated data from the active tier and writing to the cloud tier, which is mainly gated by object storage latency and the hardware configuration does not have much impact. But in the case of Gen42, DD-High performs 16% better than DD-Mid on Amazon S3 and 31% better on ECS. This happens because Gen42 has highly deduplicated data compared to Gen0, and DD-High is able to sustain a higher throughput because it has higher parallelism. High object storage latencies continue to be a bottleneck, otherwise the performance difference between the systems would be higher. Gen42 restore from object storage is better than Gen0 restore because in case of Gen42 we are deduplicating against the previous generations of active tier. Also, the latest generation has better locality and hence better performance as GC tries to keep the latest copy of the chunk and hence over time the old generations get fragmented.

Restoring from object storage is typically slower than writing, because it involves reading data from different objects in object storage and writing to the active tier. For comparison, Gen42 write performance on the active tier with the same hardware is 3x better than writing to ECS and 2x better than restore performance from ECS. The major difference in performance is due to object storage latencies. On the active tier latencies of 10-50ms latencies are common, while on the cloud tier these latencies vary from 100 ms to 1 second for both public and private cloud vendors.

8.2.4 File Migration vs. Seeding Performance

Seeding does a bulk transfer of data in a breadth-first manner as opposed to the depth-first manner of file migration. To fairly compare the two algorithms, we did a transfer using both techniques. We ran three sets of tests, where we wrote Gen0, Gen0-50, and Gen0-100 to the active tier and then moved Gen0, Gen0-25, and Gen0-50 to the cloud tier, respectively, using both seeding and file migration. After every 5th generation written, we ran active tier GC and forced it to copy forward 30% of the containers to remove duplicates and degrade the physical locality of the data on the active tier. This simulates the scenario where customers have old, highly deduplicated data on the active tier and would like to move 50% of their oldest data to the cloud tier.

Figure 10 shows that seeding and file migration have similar performance for Gen0 because locality is high and seeding has the overhead of generating the perfect hash functions. As we transfer Gen0-25 and Gen0-50, seeding is faster than file migration by a 2x factor. This is because Gen0-50 have highly deduplicated data with degraded locality and the depth-first approach of file migration has to traverse the same containers repeatedly and incur random I/Os. In the case of seeding, the sequential scans during the breadth-first traversal compensates for the overhead of perfect hashing hence making the movement more efficient. This experiment was only performed on a DD-Mid system with Amazon S3 as the cloud storage. Similar to the Gen0 file migration performance discussed in Section 8.2.3, the hardware configuration does not have much impact because we are bottlenecked by the network throughput.

8.2.5 Garbage Collection Performance

Our analysis focuses on the copy forward process of cloud tier GC, as shown in Figure 11, since it is the only phase that differs from active tier GC. As described in Section 7.2, we developed a new API to perform copy forward for pri-

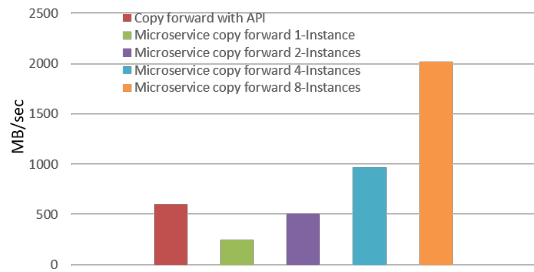

Figure 11: GC copy forward with different algorithms

vate cloud providers. Using this API, the system performs a copy forward of live compression regions (64-128KB) from existing container objects into new container objects without reading the data back to the Data Domain system to avoid transfer costs. Using the API, we are able to achieve a copy forward performance of 600MB/s.

For public cloud providers that do not provide a copy forward API, we developed an experimental microservice algorithm for garbage collection. The Data Domain system makes compression region cleaning decisions and passes a recipe to one or more GC microservice instances running in the cloud that perform the copy forward operations, similar to the functionality of the API. We increased the number of AWS t3.xlarge instances [4] to evaluate how well it scales. Aggregate performance scaled close to linearly, starting at 256 MB/s with one instance and increasing to 2,040 MB/s with eight instances. Even though microservice performance is better than API performance, we can use a microservice only in the case of a public provider where we can spin up compute to run the microservice. This might not be possible in private cloud environments.

9 Related Work

Deduplication is a well-studied field with multiple survey articles [21, 23, 31]. Deduplication is a key aspect of the Data Domain product to enable space savings and high performance for backups [32], and Data Domain has evolved with media and use case changes [1, 2].

There have been multiple papers characterizing backup data [15, 17, 19, 26, 30], and the terms backup and archive are often used interchangeable, so the previous analysis may have applications to archival system design. In our data analysis, customers have specifically decided to archive a subset of their backup data for longer term retention in the cloud.

Reading from deduplicated cloud storage can be slow, and several papers suggest ways to improve read performance, usually involving writing duplicates, caching, and prefetching techniques [18, 27]. Security implications of cloud storage have also been considered [16, 22, 24]. In contrast to these papers, we show how to evolve an existing deduplicated backup product to support a cloud tier.

The issue of deciding where to place large directories to maximize content overlap has been considered [10, 12]. Nagesh et al. [20] presented a technique to partition a collection of files by related content using an in-memory graph relationship on fingerprints. A current publication represents the content of storage volumes with sketches of sampled fingerprints to determine unique content for volumes [14]. In contrast, our technique can estimate the amount of space referenced from an arbitrary set of files selected by the user and scales to PB capacity.

Cumulus [28] provides backups to cloud storage by transferring file differences and storing files in large objects. BlueSky [29] presents a file system backed by cloud storage that uses a local cache for performance. Though neither incorporates deduplication, both projects describe garbage collection for large objects in the cloud as regions become unreferenced. Fu et al. [13] improve GC and restore performance in deduplicated storage by analyzing the history of container references during a backup. They rewrite duplicate chunks from sparse containers from a previous backup and record emerging sparse containers. They also manage container manifests that record which backups reference each container, and when a manifest becomes empty, a container can be safely removed. Such techniques could be used within our cloud GC algorithm, though copy-forward bandwidth is unlikely to be improved.

10 Conclusion

Data protection continues to be a key priority as customers transition their archival data to cloud storage. Data Domain is a mature data protection product, and adding a cloud tier involved trade-offs within the current architecture. We had to make decisions about object sizes and data structure relationships to balance performance and cost not only of migrating data to the cloud tier but also running GC. To address these concerns, we developed several techniques: mirroring metadata locally supports efficient deduplication and GC, and using perfect hashes to track billions of references in memory enables space estimation, seeding, and cloud GC. Experiences with initial customers shows a strong interest in deduplicated archival storage. Large amounts of data are transferred each month, which benefit from deduplication both in terms of faster transfer speeds but also lower storage costs.

GAIA: An OS Page Cache for Heterogeneous Systems

Tanya Brokhman, Pavel Lifshits and Mark Silberstein
Technion – Israel Institute of Technology

Abstract

We propose a principled approach to integrating GPU memory with an OS page cache. We design *GAIA*, a weakly-consistent page cache that spans CPU and GPU memories. GAIA enables the standard `mmap` system call to map files into the GPU address space, thereby enabling data-dependent GPU accesses to large files and efficient write-sharing between the CPU and GPUs. Under the hood, GAIA (1) integrates lazy release consistency protocol into the OS page cache while maintaining backward compatibility with CPU processes and *unmodified* GPU kernels; (2) improves CPU I/O performance by using data cached in GPU memory, and (3) optimizes the readahead prefetcher to support accesses to files cached in GPUs.

We prototype GAIA in Linux and evaluate it on NVIDIA Pascal GPUs. We show up to 3× speedup in *CPU* file I/O and up to 8× in *unmodified* realistic workloads such as Gunrock GPU-accelerated graph processing, image collage, and microscopy image stitching.

Introduction

GPUs have come a long way from fixed-function accelerators to fully-programmable, high-performance processors. Yet their integration with the host Operating System (OS) is still quite limited. In particular, GPU physical memory, which today may be as large as 32GB [9], has been traditionally managed entirely by the GPU driver, without the host OS control. One crucial implication of this design is that the OS cannot provide core system services to GPU kernels, such as efficient access to memory mapped files, nor can it optimize I/O performance for CPU applications sharing files with GPUs. To mitigate these limitations, tighter *integration of GPU memory into the OS page cache and file I/O mechanisms* is required. Achieving such integration is one of the goals of this paper.

Prior works demonstrate that mapping files into GPU memory provides a number of benefits [34, 36, 35]. Files can be accessed from the GPU using an intuitive pointer-based programming model, enabling GPU applications with data-dependent access patterns. Transparent system-level performance optimizations such as prefetching and double buffering can be implemented to achieve high performance for I/O intensive GPU kernels. Finally, file contents can be easily shared between legacy CPU and GPU-accelerated processes.

Extending the OS page cache into GPU memory is advantageous even for CPU I/O performance. With modern servers commonly hosting 8 and more GPUs, the total GPU memory available (100-200GB) is large enough to be used for caching file contents. As we show empirically, doing so may boost the I/O performance by up to 3× compared to accesses to a high-performance SSD (§6). Finally, the OS management of the page cache in GPU memory may allow caching GPU file accesses directly in the GPU page cache, bypassing CPU-side page cache and avoiding its pollution [15].

Unfortunately, today's commodity systems fall short of providing full integration of GPU memory with the OS page cache. ActivePointers [34] enable a memory-mapped files abstraction for GPUs, but their use of special pointers requires intrusive modifications to GPU kernels, making them incompatible with closed-source libraries such as cuBLAS [7]. NVIDIA's Unified Virtual Memory (UVM) [8] and the Heterogeneous Memory Management (HMM) [4] module in Linux allow GPUs and CPUs to access shared virtual memory space. However, neither UVM nor HMM allow mapping files into GPU memory, which makes them inefficient when processing large files (§6.3.2). More fundamentally, both UVM and HMM force the physical page to be present in the memory of only one processor. This results in a performance penalty in case of false sharing in data-parallel write-sharing workloads. Moreover, false sharing has a significant impact on the system as a whole, as we show in (§3).

Several hardware architectures introduce cache coherence between CPUs and GPUs. In particular, CPUs with integrated GPUs support coherent shared *virtual* memory in hardware. In contrast to discrete GPUs, however, integrated GPUs lack large separate physical memory. Therefore, today's OSes do not provide any memory management services for them.

Recent high-end IBM Power-9 systems feature hardware cache-coherent shared virtual memory between CPUs and discrete GPUs [31]. GPU memory is managed as another NUMA node. Thus, the OS is able to provide memory management services to GPUs, including memory-mapped files. Unfortunately, cache coherence between the CPU and discrete GPUs is not available in x86-based commodity systems, and it is unclear when it will be introduced (see §4.3). Clearly, using the NUMA mechanisms for non-coherent GPU memory

management would not work. For example, migrating a CPU-accessible page into GPU memory will break the expected memory behavior for CPU processes, e.g., due to the lack of atomic operations across the PCIe bus, among other issues.

To resolve these limitations, we propose **GAIA**[1], a distributed, weakly-consistent page cache architecture for heterogeneous multi-GPU systems that extends the OS page cache into GPU memories and integrates with the OS file I/O layer. With GAIA, CPU programs use regular file I/O to share files with GPUs. Calling `mmap` with a new `MMAP_ONGPU` flag makes the mapping accessible to the GPU kernels, thus providing support for GPU accesses to shared files. This approach allows access to memory-mapped files from *unmodified* GPU kernels.

This paper makes the following contributions:

- We characterize the overheads of CPU-GPU false sharing in existing systems (§3.1). We propose a unified page cache which eliminates false sharing by using a lazy release consistency model [22, 10].
- We extend the OS page cache to control the *unified* (CPU and GPU) page cache and its consistency (§4.1), without requiring CPU-GPU hardware cache coherence. We introduce a *peer-caching* mechanism and integrate it with the OS readahead prefetcher, enabling any processor accessing files to retrieve them from the best location, and in particular, from GPU memory (§6.2).
- We present a fully functional generic implementation in Linux, *not tailored* to any particular GPU.
- We prototype GAIA on NVIDIA Pascal GPU, leveraging its page fault support. We modify public parts of the GPU driver and reliably emulate the functionality which cannot be implemented due to the closed-source driver.
- We evaluate GAIA using real workloads, including (1) an *unmodified* graph processing framework - Gunrock [38], (2) a Mosaic application that creates an image collage from a large image database [34], and (3) a multi-GPU image stitching application [16, 18] that determines the optimal way to combine multiple image tiles, demonstrating the advantages and the ease-of-use of GAIA for real-life scenarios.

Background

We briefly explain the main principles of several existing memory consistency models relevant to our work.

Release consistency. Release consistency (RC) [22] is a form of relaxed memory consistency that permits delaying the effects of writes to distributed shared memory. The programmer controls the visibility of the writes from each processor by means of the *acquire* and *release* synchronization operations. Informally, the writes are guaranteed to be visible to the readers of a shared memory region after the writer *release*-s the region and the reader *acquire*-s it.

RC permits concurrent updates to different versions of the page in multiple processors, which get *merged* upon later accesses. A common way to resolve merge conflicts is by using the version vectors mechanism, explained below.

Lazy release consistency. In Lazy Release Consistency (LRC) [22, 10] the propagation of updates to a page is delayed until *acquire*. At synchronization time, the acquiring processor receives the updates from the other processors. Usually, the underlying implementation leverages page faults to trigger the updates [22]. Specifically, a stale local copy of the page is marked inaccessible, causing the processor to fault on the first access. The faulting processor then retrieves the up-to-date copy of the page from one or more processors. In the home-based version of the protocol, a home node is assigned to a page to maintain the most up-to-date version of the page. The requesting processor contacts the home node to retrieve the latest version of the page.

Version vectors. Version vectors (VVs) [32] are used in distributed systems to keep track of replica versions of an object. The description below is transcribed from Parker et al. [32].

A version vector of an object O is a sequence of n pairs, where n is the number of sites at which O is stored. The pair $\{S_i : v_i\}$ is the latest version of O made at site S_i. That is, the vector entry v_i counts the number of updates to O made at site S_i. Each time O is copied from site S_i to S_j at which it was not present, the version vector of site S_i is adopted by site S_j. If the sites have a conflicting version of the replica, the new vector is created by taking the largest version among the two for each entry in the vector.

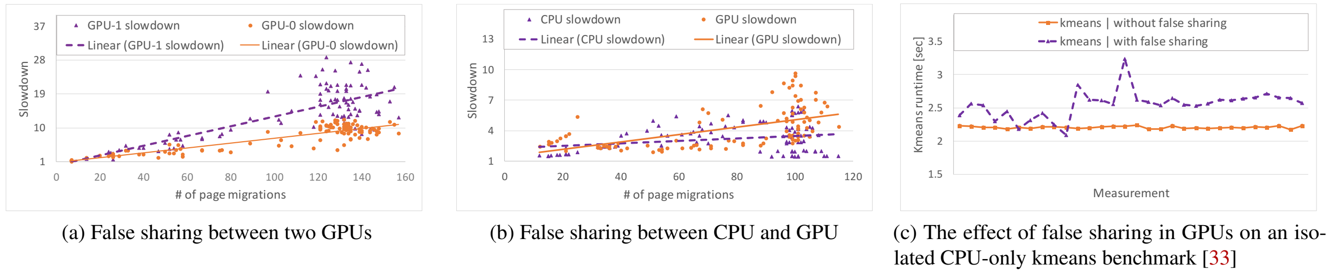
Consistency model considerations

The choice of the consistency model for the unified page cache is an important design question. We describe the options we considered and justify our choice of LRC.

POSIX: strong consistency. In POSIX writes are immediately visible to all the processes using the same file [5]. In x86 systems without coherent shared memory and with GPUs connected via a high latency (relative to local memory) PCIe bus, such a strong consistency model in a unified page cache would be inefficient [36].

GPUfs: session semantics. GPUfs [36] introduces a GPU-side library for file I/O from GPU kernels. GPUfs implements a distributed page cache with session semantics. Session semantics, however, couple between the file open/close operations and data synchronization. As a result, they cannot be used with `mmap`, as sometimes the file contents need to be synchronized across processors without having to unmap and close the file and then reopen and map it again. Therefore, we find session semantics unsuitable for GAIA.

[1] **G**lob**A**l un**I**fied p**A**ge cache, or simply the daughter's name of one of the authors, born during this project.



(a) False sharing between two GPUs

(b) False sharing between CPU and GPU

(c) The effect of false sharing in GPUs on an isolated CPU-only kmeans benchmark [33]

Figure 1: Impact of false sharing on the performance of GPU kernels and the system as a whole.

UVM: page-level strict coherence. NVIDIA UVM [8] and Linux (HMM) [4] implement strict coherence [24] at the GPU page granularity (e.g., 64KB in NVIDIA GPUs). In this model, a page can be mapped only by one processor at a time. Thus, two processors cannot observe different replicas of the page (multiple read-only replicas are allowed). If a processor accesses a non-resident page, the page fault causes the page to migrate, i.e., the data is transferred, and the page is remapped at the requestor and unmapped at the source.

Although this model might seem appealing for page cache management, it suffers from sporadic performance degradation due to *false sharing*. False sharing of a page occurs when two processors inadvertently share the same page, at least one of them for write, while performing non-overlapping data accesses [17]. False sharing is known to dramatically degrade the performance of distributed shared memory systems with strict coherence because it causes repetitive and costly page migration among different physical locations [17]. False sharing has been also reported in multi-GPU applications that use NVIDIA's UVM [8]. The official recommended solution is to allocate private replicas of the shared buffer in each processor and manually merge them after use.

False sharing in a page cache. If strict coherence is used for managing a unified page cache, false sharing of the page cache pages might occur quite often. Consider an image processing task that stitches multiple image tiles into a large output image stored in a file, e.g., when processing samples from a microscope [16]. False sharing will likely occur when multiple GPUs process the images in a data-parallel way, each writing its results to a shared output file. Consider two GPUs, one processing the left and another the right half of the image. In this case, false sharing might occur at every *row* of the output. This is because for large images (thousands of pixels in each dimension) stored in row-major format, each row will occupy at least one memory page in the page cache. Since each half of the row is processed on a different GPU, the same page will be updated by both GPUs. We observe this effect in real applications (§ 6.3.3).

False sharing with UVM

Impact of false sharing on application performance. To experimentally quantify the cost of false sharing in multi-GPU systems, we allocate a 64KB-buffer (one GPU page) and divide it between two NVIDIA GTX1080 GPUs. Each GPU executes read-modify-write operations (so they are not optimized out) on its half in a loop. We run a total of 64 threadblocks per GPU, each accessing its own part of the array, all active during the run. To control the degree of contention, we vary the number of loop iterations per GPU.

We compare the execution time when both GPUs use a shared UVM buffer (with false sharing) with the case when both use private buffers and merge them at the end of the run (no false sharing). Figure 1a shows the scatter graph of the measurements. False sharing causes slowdown that grows with the number of page migrations, reaching 28×, and results in large runtime variance [2]. Figure 1b shows similar results when one of the GPUs is replaced with a single CPU thread. This also indicates that adding more GPUs is likely to cause even larger degradation due to higher contention and increased data transfer costs.

System impact of false sharing. False sharing among GPUs affects the performance of the system as a whole. We run the CPU-only kmeans benchmark from Phoenix [33] *in parallel* with the multi-GPU false sharing benchmark above. We allocate two CPU cores for GPU management, and the remaining four cores to running kmeans (modified to spawn four threads). The GPU activity *should not* interfere with kmeans because kmeans does not use the GPU.

However, *we observe significant interference when GPUs experience false sharing*. Figure 1c depicts the runtime of kmeans when run together with the multi-GPU run, with and without false sharing. Not only does kmeans become up to 47% slower, but the execution times vary substantially. Thus, false sharing affects an *unrelated* CPU application, breaking the fundamental OS performance isolation properties.

Preventing page bouncing via pinning. In theory, the false sharing overheads could be reduced by pinning the page in

[2]The difference in the slowdown between the two GPUs stems from the imperfect synchronization between them. Thus, the one invoked first (GPU0) can run briefly without contention.

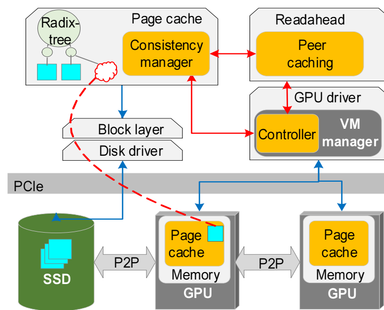


Figure 2: GAIA high-level design in the OS kernel. The modified parts are highlighted.

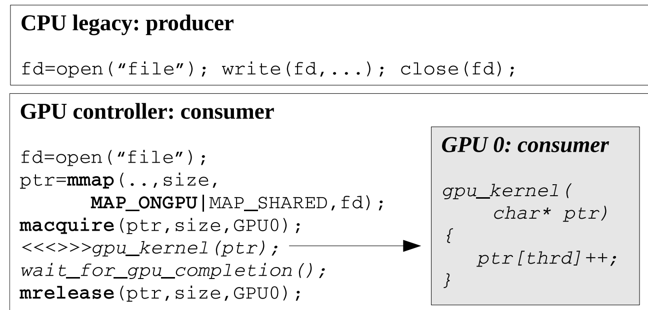

Figure 3: Code sketch of `mmap` for GPU. The CPU writes data into the file and then invokes the GPU controller, which maps the file and runs the GPU kernel.

memory of one of the processors, and mapping it into the address space of the other processors for remote access over PCIe. Unfortunately, pinning page cache pages is quite problematic. It would require substantial modifications to the existing page cache management mechanisms. For example, to be evicted, the pinned page would need to be unmapped from the virtual address space of all the mapping processors.

Moreover, even though pinning is likely to yield better system performance for pages experiencing false sharing, in the common case remote accesses from other processors would be slower than accessing the pages locally. Thus, robust false sharing detection heuristics should be designed, such that only the actual page bouncing triggers the pinning mechanism. On the other hand, enabling the programmer to pin pages manually at the `mmap` time is not efficient either, because then the pages must be initialized with the contents of the file. Mapping large files would thus require reading them in full from the disk, which not only nullifies the on-demand file loading benefits of `mmap`, but might not even be possible for the large files exceeding physical memory.

Implications for Unified Page Cache design. We conclude that *the UVM strict coherence model is unsuitable for implementing a unified page cache*. It may suffer from spurious and hard-to-debug performance degradation that affects the whole system, and only worsens as the number of GPUs increases. A system-level service with such inherent limitations would be a poor design choice. Thus, we chose to build a unified cache that follows the lazy-release consistency model and sidesteps the false sharing issues entirely.

Design

Overview. Figure 2 shows the main GAIA components in the OS kernel. A distributed page cache spans across the CPU and GPU memories. The OS page cache is extended to include a *consistency manager* that implements home-based lazy release consistency (LRC). It keeps track of the versions of all the file-backed memory pages and their locations. When a page is requested by the GPU or the CPU (due to a page fault), the consistency manager determines the locations of the most recent versions, and retrieves and merges them if necessary. We introduce new `macquire` and `mrelease` system calls which follow standard Release Consistency semantics and have to be used when accessing shared files. We explain the page cache design in (§4.1).

If an up-to-date page replica is available in multiple locations, the *peer-caching* mechanism retrieves the page via the most efficient path, e.g., from GPU memory for the CPU I/O request, or directly from storage for the GPU access as in SPIN [15]. This mechanism is integrated with the OS readahead prefetcher to achieve high performance (§6.2). To enable proper handling of memory-mapped files on GPUs, the GAIA controller in the GPU driver keeps track of all the GPU virtual ranges in the system that are backed by files.

File-sharing example. Figure 3 shows a code sketch of sharing a file between a legacy CPU application (producer) and a GPU-accelerated one (consumer). This example illustrates two important aspects of the design. First, *no GPU kernel changes* are necessary to access files, and no new system code runs on the GPU. The consistency management is performed by the CPU consumer process that uses the GPU, which we call the *GPU controller*. Second, *no modifications to legacy CPU programs* are required to share files with GPUs or among themselves, despite the weak page cache consistency model. The consistency control logic is confined to the GPU controller process. Besides being backward compatible, this design simplifies integration with the CPU file I/O stack.

Consistency manager

Version vectors. GAIA maintains the version of each file-backed 4K page for every entity that might hold the copy of the page. We call such an entity a *page owner*. We use the well-known version vector mechanism (§2) to allow scalable version tracking for each page [32].

A page owner might be a CPU, each one of the GPUs, or the storage device. Keeping track of the storage copy is important because GAIA supports direct transfer from the disk to GPU memory. Consider the example in Figure 4, where a page is first concurrently modified by the CPU and the GPU, and then flushed to storage by the CPU. Flushing it from the CPU

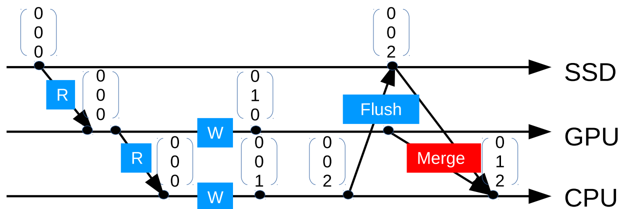

Figure 4: Version vectors in GAIA. The CPU flushes its replica to disk, the GPU keeps its version. The following CPU read must merge two replicas.

removes both the data and its version information from CPU memory. The next reader must be able to retrieve the most recent version of the page, which in our example requires *merging* the page versions on the disk and on the GPU. The storage entry in the version vector is always zero.

A new *Time Stamp Version Table (TSVT)* stores all the version vectors for a page. This table is located in the respective node of the page cache radix tree. The GPU entries are updated by the CPU-side GPU controller on behalf of the GPU. We choose the CPU-centric design to avoid intrusive modifications to GPU software and hardware.

Synchronizing system calls for consistency control. We introduce two new system calls to implement LRC.

`macquire(void *addr, size len, void* device)` must be called to ensure that the `device` accesses the latest version of the data in the specified address range. `macquire` scans through the address range on the `device` and invalidates (unmaps and drops) all the outdated local pages. When called for the CPU, it unmaps such pages from all the CPU processes. Thus, the following access to the page will cause a page fault trap to retrieve the most recent version of the page, as we describe later in (§4.1.1).

`mrelease(void *addr, size_t len, void* device)` must be called by the `device` that writes to the respective range to propagate the updates to the rest of the system. Similarly to `macquire`, this operation does not involve data movements. It only increases the versions of all the modified (since the last `macquire`) pages in the owner's entry of its version vector.

Tracking the status of CPU pages requires a separate `LRC_modified` flag in the page cache node, in addition to the original modified flag used by the OS page cache. This is because the latter can be reset by other OS mechanisms, e.g, flush, resulting in a missed update. The new flag is set together with the original one, but is reset by `mrelease` call as part of the version vector update.

Transparent consistency support for the CPU. GAIA does not change the original POSIX semantics when sharing files among CPU processes, because all the CPUs share the same replica of the cached page. However, `macquire` and `mrelease` calls must be invoked by *all* the CPU processes that might inadvertently share files with GPUs. In GAIA we seek to eliminate this requirement.

Our solution is to perform the CPU synchronization calls eagerly, combining them with `macquire` and `mrelease` calls issued on behalf of GPUs. The `macquire` call for the GPU is invoked after internally calling `mrelease` for the CPU, and `mrelease` of the GPU is always followed by `macquire` for the CPU. This change does not affect the correctness of the original LRC protocol, because it maintains the relative ordering of the acquire and release calls on different processors, simply moving them closer to each other.

Consistency and GPU kernel execution. GAIA's design does not preclude invocation of `macquire` and `mrelease` during the kernel execution on the target GPU. However, the current prototype does not support such functionality, because we cannot retrieve the list of dirty pages from the GPU while it is running, which is necessary for implementing `mrelease`. Therefore, we support the most natural scenario (also in Figure 3), which is to invoke `macquire` and `mrelease` at the kernel execution boundaries. Integrating these calls with the CUDA streaming API might be possible by using CUDA CPU callbacks [2]. We leave this for future work.

Page faults and merge

Page faults from any processor are handled by the CPU (hence, home-based LRC). CPU and GPU-originated page faults are handled similarly. For the latter, the data is moved to the GPU. The handler locates the latest versions of the page according to its TSVT in the page cache. If the faulting processor holds the latest version in its own memory (minor page fault), the page is remapped. If, however, the present page is outdated or not available, the page is retrieved from the memory of other processors or from storage.

This process involves handling the merge of multiple replicas of the same page. The overlapping writes to the same memory locations (i.e., the actual data races) are resolved via an "any write wins" policy, in a deterministic order (i.e., based on the device hardware ID). However, non-overlapping writes to the same page must be explicitly merged via 3-way merge, as in other LRC implementations [22].

3-way merge. The CPU creates a *pristine* base copy of the page when a GPU maps the page as writable. Conflicting pages are compared with their base copies first to detect the changes.

The storage overheads due to pristine copies might compromise scalability, as we discuss in (§6.1). The naive solution is to store a per-GPU copy of each page. A more space-efficient design might use a single page base copy for all the processors, employing copy-on-write and eagerly propagating the updates after the processor `mrelease`-s the page, instead of waiting for the next page fault (lazy update). Our current implementation uses the simple variant.

The overheads of maintaining the base copy are not large in practice. First, the base copy can be discarded after the page is evicted from GPU memory. Further, it is not required for

read-only accesses, or when there is only one-page owner (excluding the storage) in the system. Most importantly, creating the base copy is not necessary for writes from CPU processes. This is because the CPU is either the sole owner, or the base copy has already been created for the modifying GPU.

Interaction with file I/O

Peer-caching. GAIA architecture allows a page replica to be cached in multiple locations, so that the best possible I/O path (or possibly multiple I/O paths in parallel) can be chosen, to serve page access requests. In particular, the CPU I/O request can be served from GPU memory. Note that access to the GPU-cached page does not invalidate it for the GPU.

A naive approach to peer-caching is to determine the best location individually for each page. However, this approach *degrades* the performance for sequential accesses by an order of magnitude, due to the overheads of small data transfers over the PCIe bus. Instead, GAIA leverages the OS prefetcher to optimize PCIe transfers. We modify the prefetcher to determine the data location in conjunction with deciding how much data to read at once. This modification results in a substantial performance boost, as we show in (§6.2).

Readahead for GPU streaming access. GPUs may concurrently run hundreds of thousands of threads that access large amounts of memory at once. GPU hardware coalesces multiple page faults together (up to 256, one for 64KB page). If the page faults are triggered by accesses to the memory-mapped file on the GPU, GAIA reads the file according to the GPU-requested locations and copies the data to GPU pages. We call such accesses *GPU I/O*.

We observe that the existing OS readahead prefetcher does not work well for GPU I/O. It is often unable to optimize streaming access patterns where a GPU kernel reads the whole file in data-parallel strides, one stride per group of GPU threads. The file accesses from the GPU in such a case appear random when delivered to the CPU due to the non-deterministic hardware schedule of GPU threads, thereby confusing the CPU read-ahead heuristics.

We modify the existing OS prefetcher by adjusting the upper bound on the read-ahead window to 16MB (64× of the CPU), but only for GPU I/O accesses. We also add `madvise` hints that increase the minimum read size from a disk to 512KB for sequential accesses. These changes allow the prefetcher to retrieve more data faster when the sequential pattern is recognized, but it does not fully recover the performance. Investigating a better prefetcher heuristic that can cope with massive multi-threading is left for future work.

Discussion

GAIA and cache-coherent accelerator architectures. Cache-coherent systems with global virtual address space may allow a simpler solution to the page cache management. However, we believe that cache coherence between the CPU and discrete accelerators is unlikely to fully replace existing systems soon. Despite the cache coherent technologies (CAPI [37]) having been available, the high cost and the need for industry-wide coordination on open interfaces have hindered their adoption thus far. Nor is it apparent how and to what extent these technologies will improve commodity applications (i.e., graphics, deep learning). Many additional open issues (for example, scalability) also must be addressed. Therefore, in GAIA we choose not to rely on cache-coherence among CPUs and accelerators.

No snapshot isolation. GAIA does not provide snapshot isolation. This is consistent with prior work on GPU file system support [36]. While adding such guarantee is possible, we did not find applications that require it.

Prefetching hints. Our current prototype could be extended to support more advanced prefetching hints similar to UVM [1]. For example, it could employ eager data copy into the page cache of a specific GPU that is known to exclusively access the data. We leave this for future work.

Using huge CPU pages. GAIA design and implementation is tailored for 4KB pages managed by the OS. However, GAIA can be adapted to support different page sizes as well, i.e. 2MB huge pages. Huge pages require only minor modifications to the TSVT management logic and tables, and might improve performance for applications with sequential file access. This is because transferring 2MB pages over PCIe is about 5× more efficient than 4KB pages. On the other hand, increasing the page sizes would affect the workloads with poor spatial locality, such as Mosaic (§6.3.1).

GAIA compatibility with other accelerators. GAIA's design can be extended to other GPUs and accelerators with paging capabilities. In fact, support for paging was introduced recently in AMD GPUs [4, 6]. However, implementation in GAIA would require an accelerator to expose minimal page management APIs, as we explain in the next section.

Implementation

GAIA implementation requires changing 3300 LOC and 1200 LOC in Linux kernel and the NVIDIA UVM driver respectively.

OS changes

Page cache with GPU pointers. In Linux, the page cache is represented as a per-file radix tree with each leaf node corresponding to a continuous 256KB file segment. Each leaf holds an array of addresses (or NULLs) of 64 physical pages caching the file content.

GAIA extends the tree leaf node data structure to store the addresses of GPU pages. We add 4 pointers per leaf node per GPU, to cover a continuous 256KB file segment (GPU page is

	Function	Purpose	UVM implementation\ GAIA emulation	Used by
Available in UVM	allocVirtual/allocPhysical mapP2V	allocate virtual/physical range map physical-to-virtual	cudaMallocManaged()	mmap
	freeVirtual/freePhysical	free virtual/physical range unmap virtual	cudaFree()	munmap
Emulated by GAIA	unmapV	Invalidate mapping in GPU	Migrate page to CPU	maquire
	fetchPageModifiedBit	Retrieve dirty bit in GPU	Copy page to CPU and compute diff	mrelease

Table 1: Main GPU Virtual Memory management functions and their implementation with UVM

64KB). The CPU only keeps track of file-backed GPU pages rather than the entire GPU physical memory. The leaf node stores all the versions (TSVT) for the 64 4KB pages.

Linking the page cache with the GPU page ranges. GAIA keeps track of all the GPU virtual ranges in the system that are backed by files to properly handle the GPU faults for file-backed pages. When `mmap` allocates a virtual address range in the GPU via the driver, it registers the range with GAIA and associates it with the file radix tree.

Data persistence. GAIA inherits the persistence semantics of the Linux file I/O. It updates both `msync` and `fsync` to fetch the fresh versions of the cache pages (similarly to the logic in the page fault handler) and write their contents to storage.

GPU cache size limit. GAIA enforces an upper bound on the GPU cache size by evicting pages. The evicted pages can be discarded from the system memory entirely (after syncing with the disk if necessary) or cached by moving them to available memory of other processors. In our current implementation, we cache the evicted GPU pages in CPU memory. We implement the Least Recently Allocated eviction policy [36], due to the lack of the access statistics for GPU pages.

Integration with GPU driver

The NVIDIA GPU driver provides no public interface for low-level virtual memory management. Indeed, giving the OS the full control over GPU memory management might seem undesirable. For example, only the vendors might have the intimate knowledge of the device/vendor-specific properties that require special handling, such as different page sizes, texture memory, alignment requirements, and physical memory constraints. However, we believe that a minimal subset of APIs is enough to allow generic advanced OS services for GPUs, such as unified page cache management, without forcing the vendors to give up on the GPU memory control.

We define such APIs in Table 1. The driver is in full control of the GPU memory, i.e., it performs allocations and implements the page eviction policy, only notifying the OS about the changes (callbacks are not shown in the table). We demonstrate the utility of such APIs for GAIA, encouraging GPU vendors to add them in the future.

Using the GPU VM management API

Implementing GAIA functionality is fairly straightforward, and closely follows the implementation of the similar functionality in the CPU OS. We provide a brief sketch below just to illustrate the use of the API.

mmap/munmap. When `mmap` with `MAP_ONGPU` is called, the system allocates a new virtual memory range in GPU memory via `allocVirtual` and registers it with the GAIA controller in the driver to associate it with the respective file radix tree, similar to the CPU `mmap` implementation. The `munmap` function performs the reverse operation using `unmapV` call.

Page fault handling. To serve the GPU page fault, GAIA determines the file offset and searches for the pages that cache the content in the associated page cache radix tree. If the most recent version of the page is found, and it is already located on the requesting GPU (minor page fault), GAIA maps the page at the appropriate virtual address using `mapP2V` call.

Otherwise (major page fault), GAIA allocates a new GPU physical page via `allocPhysical` call, populates it with the appropriate data (merging replicas if needed), updates the page's TSVT structure in the page cache to reflect the version, and maps the page to the GPU virtual memory. If necessary, GAIA creates a pristine copy of the page.

If a page has to be evicted to free space in GPU memory, GAIA chooses the victim page, unmaps it via `unmapV`, retrieves its dirty status via `fetchPageModifiedBit`, stores the page content on the disk or CPU memory if marked as dirty, removes the page reference from the page cache, and finally frees it via `freePhysical`.

Consistency system calls. GPU `macquire` scans through the GPU-resident pages of the page cache to identify outdated GPU page replicas and unmaps the respective pages via `unmapV`. GPU `mrelease` retrieves the modified status via `fetchPageModifiedBit` for all the GPU-resident pages in the page cache, and updates their versions in TSVT.

Functional emulation of the API

Implementing the proposed GPU memory management API without vendor support requires access to low-level internals of the closed-source GPU driver. Therefore, we choose to implement it in a limited form.

First, we use the user-level NVIDIA's UVM memory management APIs to implement a limited version of the API for allocation and mapping physical and virtual pages in GPU (refer to Table 1). Specifically, `cudaMallocManaged` is used to allocate the GPU virtual address range, and `cudaFree` to tear down the mapping and de-allocate memory.

Second, we modify the open-source part of the NVIDIA UVM driver. The GPU physical page allocation and mapping of the virtual to physical addresses are all part of the GPU page fault handling mechanism, yet they are implemented in the closed-source part of the UVM driver. To use them, GAIA modifies the open-source UVM page fault handler to perform the file I/O and page cache-related operations, effectively implementing the scheme described above (§5.2.1).

Finally, whenever the public APIs and open-source part of the driver are insufficient, we resort to emulation. To implement `unmapV`, we use a public driver function to *migrate the page* to the CPU, which also unmaps the GPU page. The `fetchPageModifiedBit` call is emulated by copying the respective page to the CPU *without unmapping it on the GPU* and computing *diff* with the base copy.

In Table 1 we highlight the emulated functions (in red) and specify where they are used.

Ultimately, this pragmatic approach allows us to build a functional prototype to evaluate the concepts presented in the paper. We hope that tese APIs will be implemented properly by GPU vendors in the future.

Limitations due to UVM

Our forced reliance on NVIDIA UVM leads to several limitations. The page cache lifetime and scope are limited to those of the process where the mapping is created, as UVM does not allow allocating physical pages that do not belong to a GPU context. Therefore, the page cache cannot be shared among GPU kernels belonging to different CPU processes. Further, the maximum mapped file size is limited by the size of the maximum UVM buffer allocation, which must fit in the CPU physical memory. Finally, UVM controls memories of all the system GPUs, *preventing us from implementing a distributed page cache between multiple NVIDIA GPUs*.

These limitations are rooted in our use of UVM, and *are not pertinent to GAIA design*. They limit the scope of our evaluation to a single CPU process and a single GPU, but allow us to implement a substantial prototype to perform thorough and reliable performance analysis of the heterogeneous page cache architecture.

Evaluation

We evaluate the following aspects of our system [3]:

- Benefits of peer-caching and prefetching optimizations;
- Memory and compute overheads;
- End-to-end performance in real-life applications with read and write-sharing.

Platform. We use an Intel Xeon CPU E5-2620 v2 at 2.10GHz with 78GB RAM, GeForce GTX 1080 (with 8GB GDDR) GPU and 800GB Intel NVMe SSD DC P3700 with 2.8GB/s sequential read throughput. We use Ubuntu 16.04.3 with kernel 4.4.15 that includes GAIA modifications, CUDA SDK 8.0.34, and NVIDIA-UVM driver 384.59.

Performance cost of functional emulation. The emulation introduces performance penalties that do not exist in the CPU analogues of the emulated functions. In particular, `unmapV` constitutes more than 99% of `macquire` latency, and `fetchPageModifiedBit` occupies nearly 100% of `mrelease`.

These functions are expensive only because of the lack of the appropriate GPU driver and hardware support. We expect them to be as fast as their CPU analogues if implemented by GPU vendors. For example, `mmap` or `mprotect` calls for a 1GB region take less than 10 μseconds on the CPU. If implemented for the GPU, they might last slightly longer due to over-PCIe access to update the page tables.

To be safe, we conservatively assume that `unmapV` and `fetchPageModifiedBit` are as slow as *10 msec* in all the reported results. These are the worst-case estimates, yet they allow us to provide a *reliable estimate* of GAIA performance in future systems.

Evaluation methodology. We run each experiment 11 times, omit the first result as a warmup, and report the average. We flush the system page cache before each run (unless stated otherwise). We do not report standard deviations below 5%.

Overhead analysis

Impact on CPU I/O. GAIA introduces additional version checks into the CPU I/O path. To measure the overheads, we run the standard TIO benchmark suite [23] for evaluating CPU I/O performance. We run random/sequential reads/writes using the default configuration with 256KB I/O requests, accessing a 1GB file. As a baseline, we run the benchmark on the unmodified Linux kernel 4.4.15.

We vary the number of supported GPUs in the system as it affects the number of version checks. We observe less than 1% and up to 5% overhead for 32GPUs and 160GPUs respectively for random reads, and no measurable overheads for sequential accesses. We conclude that *GAIA introduces negligible performance overheads for legacy CPU file I/O*.

Memory overheads. The main dynamic cost stems from pristine page copies for 3-way merge. However, common read-only workloads require no such copies, therefore incurring no extra memory cost. Otherwise, the memory overheads depend on the write intensity of the workload. GAIA creates one copy for every writable GPU page in the system.

The static cost is due to the addition of version vectors to the page cache. This cost scales linearly with the utilized

[3] GAIA source code is publicly available at https://github.com/acsl-technion/GAIA.

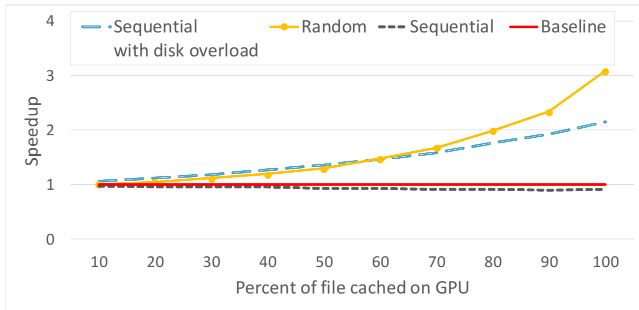

Figure 5: CPU I/O speedup of GAIA over unmodified Linux. Higher is better.

GPU memory size as GPU versions are stored only for GPU-resident pages, but grows quadratically with the number of GPUs. With 512 bytes per version vector entry, the worst-case memory overhead (all GPUs fill their memories with files) and 100 GPUs each with 8GB memory, the overhead reaches about 5GB, which is less than 1% of the total utilized GPU memory (800GB).

Microbenchmarks

Benefits of peer caching. We measure the performance of *CPU* POSIX `read` accesses to a 1GB file which is partially cached in GPU memory. Thus, these accesses result in reading the GPU-resident pages from the GPU instead of the SSD. We vary the cached portion of the file, reading the rest from the SSD. We run three experiments: (1) random reads (2) sequential reads, and (3) sequential reads while the SSD is busy serving other I/O requests. We compare to unmodified Linux, where all the data is fetched from the SSD.

Figure 5 shows that peer-caching can boost the CPU performance by up to 3× for random reads, and up to 2× when the SSD is under load. GAIA is no faster than SSD for sequential reads, however. This is due to the GPU DMA controller bottleneck, stemming from the lack of public interfaces to program its scatter-gather lists. Therefore, GAIA is forced to perform the I/O one GPU page at a time.

False sharing. We run the same CPU-GPU false-sharing microbenchmark as in §3.1. We map the shared buffer from a file, and let the CPU and the GPU update it concurrently with non-overlapping writes. GAIA merges the page when the GPU kernel terminates. We compare with the execution where each of the processors writes into a private buffer, without false sharing. We observe that GAIA with shared buffer is *the same* as the baseline. The cost of merging the page in the end is constant per 4KB page: 1.4 μsecond.

This experiment highlights the fact that *GAIA eliminates the overheads of false sharing entirely*.

Streaming read performance. We evaluate the case where the GPU reads and processes the whole file. We use three kernels: (1) a zero-compute kernel that copies the data from the input pointer into an internal buffer, one stride at a time per threadblock; (2) an unmodified LUD kernel, representative of compute-intensive kernels in Rodinia benchmark suite [19]; (3) a *closed-source* cuBLAS SGEMM library kernel [7]. We modify their CPU code such that the GPU input is read from a file rather than from memory, as in prior work [40].

We evaluate several techniques to read files into the GPU:

1. **CUDA-[must fit in GPU memory]**: read from the host, copy to GPU;
2. **GPUfs-[requires GPU code changes]**: read from the GPU kernel via GPUfs API. GPUfs uses 64KB pages as in GPU hardware;
3. **UVM**: read from the host into UVM memory (physically residing in CPU), read from the GPU kernel;
4. **GAIA**: map the file into GPU, read from the GPU kernel.

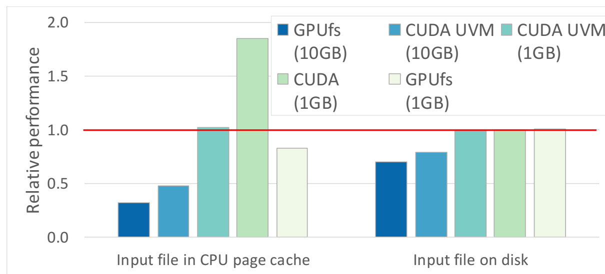
We implement all four variants for the zero-compute kernel. LUD and cuBLAS cannot run with GPUfs because that requires changing their code. We run the experiments with two input files, one smaller and one larger than GPU memory.

Figure 6a shows the results of reading a 1GB and 10GB file for the zero-compute kernel. GAIA is competitive with UVM and GPUfs for all of the evaluated use cases, but slower than CUDA when working with a small file in the CPU page cache, due to inefficiency of the GPU data transfers in GAIA. In CUDA, the data is copied in a single transfer over PCIe, whereas in GAIA the I/O is broken into multiple non-consecutive 64KB blocks, which is much slower.

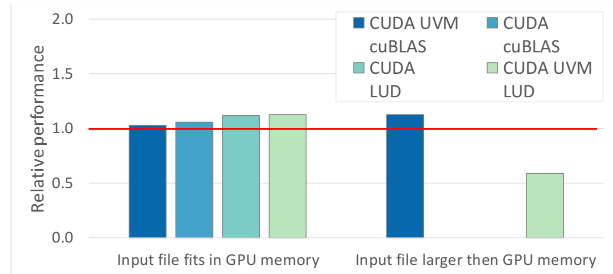
GAIA is faster than UVM when reading cached files due to the UVM's extra data copy, and faster than GPUfs with 1GB because of GPUfs trashing. The thrashing occurs because the GPUfs buffer cache in GPU memory is not large enough to store the whole file. Pages are constantly evicted as a result, introducing high runtime overheads.

Figure 6b shows the results of processing a 1GB and a 10GB file for the compute-intensive LUD and cuBLAS kernels for techniques (1), (3) and (4). Large files cannot be evaluated with CUDA as they do not fit in GPU memory. GAIA is faster than LUD on UVM, yet slightly slower than the other methods. With cuBLAS, the specific access pattern results in a large working set, causing trashing with GAIA.

The insufficient coordination with the OS I/O prefetcher in the current implementation makes it slower when the file fits GPU memory. The performance can be improved via a more sophisticated prefetcher design and transfer batching in future GPU drivers. With large files, however, *GAIA is on par with and faster than UVM, while offering the convenience of using a GPU-agnostic OS API and supporting unmodified GPU kernels.*



(a) Zero-compute kernel, normalized to GAIA. Higher is better.



(b) LUD and cuBLAS small and large files (from disk). Higher is better.

Figure 6: Streaming read I/O performance analysis

	Prefetched	On disk
GAIA (sec)	1.2	2.9
UVM (sec)	11.4 (↑ 9×)	17.8 (↑ 6×)
ActivePointers(4 CPU threads) (sec)	0.5 (↓ 2×)	1.7 (↓ 2×)
ActivePointers(1 CPU thread) (sec)	0.6 (↓ 2×)	5.5 (↑ 2×)

Table 2: Image collage: GAIA vs. UVM vs. ActivePointers

Applications

Performance of on-demand data I/O

We use an open-source image collage benchmark [34]. It processes an input image by replacing its blocks with "similar" tiny images from a large indexed dataset stored in a file. The access pattern depends on the input: each block of the input image is processed separately to generate the index into the dataset, fetching the respective tiny image afterward. The dataset is 19GB, thus it does not fit in memory of our GPU. While only about 25% of the dataset is required to completely process one input, the accesses are input-dependent.

We compare three implementations: (1) original ActivePointers, (2) UVM and (3) GAIA. For the last two we modify the original code by replacing ActivePointers [34] with regular pointers. In UVM the dataset is first read into a shared UVM buffer. In GAIA the file is `mmap`-ed into GPU memory.

Both ActivePointers and GAIA allow random file access from the GPU, but they differ in that they rely on software-emulated and hardware page faults respectively.

Table 2 shows the end-to-end performance comparison. GAIA is 9× and 6× faster than UVM, because it accesses the data in the file on-demand, whereas in UVM the file must be read in full prior to kernel invocation.

We investigate the performance difference between ActivePointers and GAIA. We observe that ActivePointers use four I/O threads on the CPU to serve GPU I/O requests. Reducing the number of I/O threads to only one as in GAIA provides a more fair comparison. In this case, GAIA is 2× faster when reading data from disk, but still 2× slower when the file is prefetched. The reasons are not yet clear, however.

We conclude that GAIA's on-demand data access is competitive with highly optimized ActivePointers, and *significantly faster* than UVM.

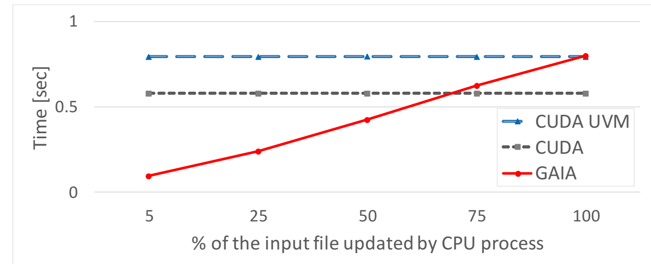


Figure 7: Graph processing with dynamic graph updates, while varying the number of updates. Lower is better.

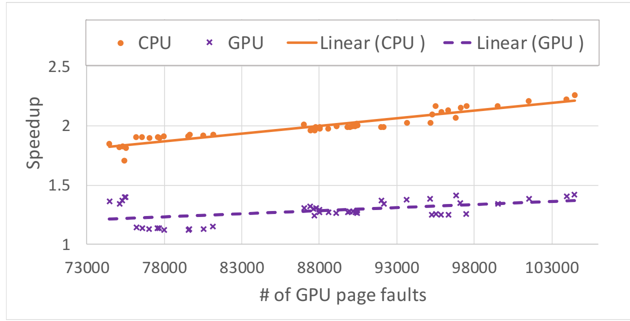
Dynamic graph processing with Gunrock

We focus on a scenario where graph computations are invoked multiple times, but the input graph periodically changes. This is the case, for example, for a road navigation service such as Google Maps, which needs to accommodate the traffic changes or road conditions while responding to user queries.

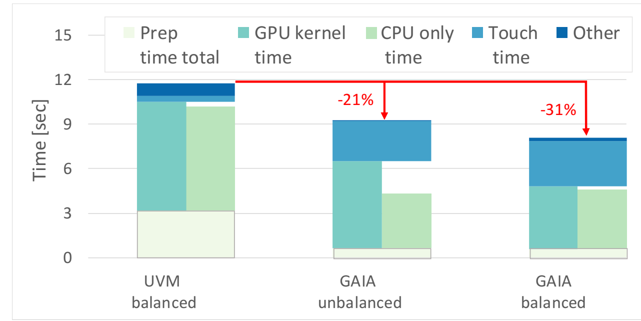
We assume the following service design. There are two processes: an updater daemon (producer) and a GPU-accelerated compute server (consumer), which share the graph database. The daemon running on the CPU (1) retrieves the graph updates (traffic status) from an external server; (2) updates the graph database file; and (3) signals to the compute service to recalculate the routes. The latter reads these updates from the file each time it recomputes in response to a user query. The producer updates only part of the graph (i.e., edge weights representing traffic conditions). This design is modular, easy to implement, and supports very large datasets. Similar producer-consumer scenarios have also been used in prior work [15].

We use an *unmodified* Gunrock library [38] for fast graph processing. We run the Single Source Shortest Path algorithm provided with Gunrock, modifying it to read input from a file, which is updated in a separate (legacy) CPU process that uses standard I/O (no consistency-synchronizing system calls). The file updates and graph computations are interleaved: the compute server invokes the updater, which in turn invokes the computations, and so on. We run a loop of 100 iterations and measure the total running time.

We implement the benchmark using UVM and GAIA, and also compare it with the original CUDA implementation. For



(a) CPU and GPU speedups over UVM while varying the number of computations. Higher is better.



(b) End-to-end runtime comparison. Other: memory (de)/allocation. Touch time = time of first access from CPU, includes merge for GAIA. Prep time = time of reading input. Lower is better.

Figure 8: Performance impact of false sharing in image stitching.

both UVM and CUDA, the *whole file* must be copied into a GPU-accessible buffer on every update because the locations of the modified data in the file are unknown. No such copy is required for GAIA, where each GPU kernel invocation is surrounded by `macquire` and `mrelease` calls.

We run the experiment on the uk_2002 input graph provided with Gunrock examples, extended to include edge weights. The file size is 5.2GB.

Figure 7 shows the performance as a function of the portion of the graph being updated. GAIA is faster than the alternatives with fewer changes to the file, automatically detecting the changes in the pages that were indeed modified. For the worst case of full file update (above 75%) GAIA becomes slower than the original CUDA implementation. This is due to the inefficiency of the GPU data transfers, as we also observed in Fig. 6a. This experiments shows *the utility of GAIA's fine-grain consistency control, which enables efficient computations in a read-write sharing case.*

Effects of false sharing in image stitching

We consider an image processing application used in optical microscopy to acquire large images. Microscopes acquire these images as grids of overlapping patches that are then stitched together. Recent works accelerate this process on multiple GPUs [18, 16]. The output image is split into non-overlapping sub-images, where each GPU produces its output independently, and the final result is merged into a single output image.

This application benefits from using GAIA to write into the shared output file directly from GPUs, eliminating the need to store large intermediate buffers in CPU memory. We seek to show the effects of false sharing in this workload if it were implemented with GAIA. Unfortunately, we cannot fully evaluate GAIA on multiple GPUs, as we explained earlier (§5.2.3). Instead, we implement only its I/O-intensive component in the CPU and the GPU.

Both the CPU and GPU load their patches, with already pre-computed output coordinates. Each patch is sharpened via a convolution filter, and then is written to the output file. The convolution filter is invoked several times per output to explore a range of different compute loads. In GAIA, we map both the input patches and the output file into the CPU and the GPU. For the UVM baseline, the inputs are read into UVM memory before kernel invocation.

We run the experiment on a public Day2 Plate [3] stitching dataset with 5.3GB of input tiles and 1.3GB of output. We use the patch locations included in the dataset to write the patches, which ensures realistic access to the output file.

We split the output image over the vertical dimension and load-balance the input such that both the CPU and the GPU run about the same time in the baseline implementation which writes into a UVM shared output buffer. The patch coordinates determine the amount of false sharing in this application.

Figure 8a shows the speedup of GAIA over UVM while varying the amount of computations per patch. We observe up to 45% speedup for the CPU, and over 2.3× speedup for the GPU. This experiment corroborates the conclusions of the microbenchmark in (§3.1), now in a realistic write-sharing workload. GAIA enables *significant performance gain by eliminating false sharing in the unified page cache*.

To evaluate the complete system rather than the performance of each processor separately, we pick one of the runtime parameters in the middle of Figure 8a, and measure the end-to-end runtime, including file read, memory allocation, and page merging. We prefetch the input into the page cache on the CPU to highlight the performance impact.

Figure 8b shows the results. For exactly the same runtime configuration GAIA *outperforms UVM by 21%*. Moreover, GAIA allows further improvements by rebalancing the load between the processors (GPU runs faster without false sharing), achieving overall 31% performance improvement.

Related work

To the best of our knowledge, GAIA is the first system to offer a distributed page cache abstraction for GPUs that is integrated into the OS. Our work builds on prior research in

the following areas.

Memory coherence for distributed systems. Lazy Release Consistency [22, 10] serves as the basis for GAIA. GAIA implements the home-based version of LRC [41]. Munin [14] implements eager RC by batching the updates. GAIA adopts this idea by using LRC-dirty bit to batch multiple updates. Version Vectors is an idea presented in [32] for detecting mutual inconsistency in multiple-writers systems. We believe that GAIA is the first to apply these ideas to building a heterogeneous OS page cache.

Heterogeneous, multi-core, and distributed OS design for systems without cache coherence. Several proposed OSes support heterogeneous and non-cache coherent systems by applying distributed system principles to their design [29, 13, 12]. None of these systems implements shared page cache support, which is the main tenet of our work.

K2 [25] is a shared-most OS for mobile devices running over several coherence domains. It implements a sequentially consistent software DSM for the OS structures shared among the domains. K2 DSM implements sequential consistency, which is a strict coherence model. Similarly to GAIA, K2 relies on page faults as the trigger for consistency operations. K2 DSM implementation of the coherence model relies heavily on the underlying hardware. Thus, even read-only sharing is not possible as it requires a different MMU for handling reads and writes. GAIA does not have this limitation. Solros [27] proposes a data-centric operating system to enable efficient I/O access for XeonPhi accelerators. Solros includes a buffer cache for faster I/O, but unlike GAIA, it is limited to host memory, and does not explicitly discuss inter-accelerator sharing.

The file system in the FOS multikernel [39] shares data between cores but is limited to read-only workloads. Hare [21] is a file system for non-cache-coherent multicores in which each node may cache file data in the private memory and a shared global page cache. Hare uses close-to-open semantics, which GAIA refines. Distributed OSes such as Sprite [30], Amoeba [28], and MOSIX [11] aim to provide a single system image abstraction and in particular, coherent and transparent access to files from different nodes, but they achieve this via process migration/use home nodes to forward their I/O.

GPU file I/O. GPUfs [36] allows file access from GPU programs and implements a distributed weakly consistent page cache with session semantics. ActivePointers [34] extend GPUfs with a software-managed address translation and page faults, enabling GPU memory mapped files. However, unlike GAIA, ActivePointers require intrusive changes to GPU kernels, its session semantics is too coarse-grain for our needs, and its page cache is not integrated with the CPU page cache, thus lacks peer-caching support. SPIN [15] integrates direct GPU-SSD communications into the OS. As in GAIA peer-caching, SPIN adds a mechanism for choosing the best path for file I/O to the GPU. However, it does not extend the page cache into the GPU.

Memory management in GPUs. NVIDIA Unified Virtual Memory (UVM) and Heterogeneous Memory Management (HMM) [4] allow both the CPU and GPU to share virtual memory, migrating the pages to/from GPU/CPU upon page fault. Neither currently supports memory mapped files on x86 processors. Both introduce a strict coherence model that suffers from false sharing overheads. Asymmetric Distributed Shared Memory [20] is a precursor of UVM that emulates a unified address space between CPUs and GPUs in software.

IBM Power9 CPU with NVIDIA V100 GPUs provides hardware support for coherent memory between the CPU and the GPU. Since GPU memory is managed as another NUMA node, memory-mapped files are naturally accessible from the GPUs. This approach would not work for commodity x86 architectures which lack CPU-GPU hardware coherence.

Dragon [26] extends NVIDIA UVM to enable GPU access to large data sets residing in NVM storage, by mapping them into the GPU address space. Dragon focuses exclusively on accessing the NVM from the GPU, does not integrate GPU memory into a unified page cache, has no peer-caching support, and does not consider CPU-GPU file sharing, all of which are the main contributions of our work.

Conclusions

GAIA enables GPUs to map files into their address space via a weakly consistent page cache abstraction over GPU memories that is fully integrated with the OS page cache. This design optimizes both CPU and GPU I/O performance while being backward compatible with legacy CPU and unmodified GPU kernels. GAIA's implementation in Linux for NVIDIA GPUs shows promising results for a range of realistic application scenarios, including image and graph processing. It demonstrates the benefits of lazy release consistency for write-shared workloads.

GAIA demonstrates the importance of integrating GPU memory in the OS page cache, and proposes the minimum set of memory management extensions required for future OSes to provide the unified page cache services introduced by GAIA.

Transkernel: Bridging Monolithic Kernels to Peripheral Cores

Liwei Guo, Shuang Zhai, Yi Qiao, and Felix Xiaozhu Lin

Purdue ECE

Abstract

Smart devices see a large number of ephemeral tasks driven by background activities. In order to execute such a task, the OS kernel wakes up the platform beforehand and puts it back to sleep afterwards. In doing so, the kernel operates various IO devices and orchestrates their power state transitions. Such kernel executions are inefficient as they mismatch typical CPU hardware. They are better off running on a low-power, microcontroller-like core, i.e., peripheral core, relieving CPU from the inefficiency.

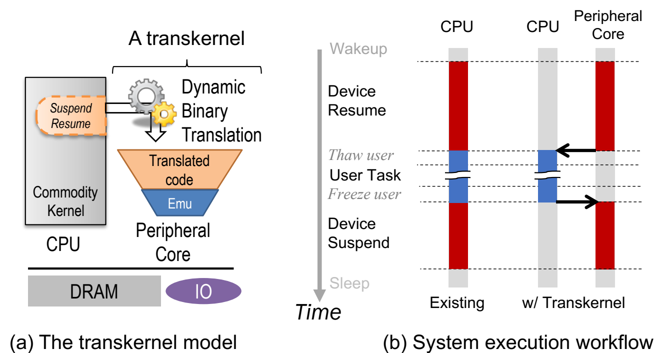
We therefore present a new OS structure, in which a lightweight virtual executor called *transkernel* offloads specific phases from a monolithic kernel. The transkernel translates stateful kernel execution through cross-ISA, dynamic binary translation (DBT); it emulates a small set of stateless kernel services behind a narrow, stable binary interface; it specializes for hot paths; it exploits ISA similarities for lowering DBT cost.

Through an ARM-based prototype, we demonstrate transkernel's feasibility and benefit. We show that while cross-ISA DBT is typically used under the assumption of efficiency *loss*, it can enable efficiency *gain*, even on off-the-shelf hardware.

1 Introduction

Driven by periodic or background activities, modern embedded platforms[1] often run a large number of ephemeral tasks. Example tasks include acquiring sensor readings, refreshing smart watch display [44], push notifications [38], and periodic data sync [91]. They drain a substantial fraction of battery, e.g., 30% for smartphones [13, 12] and smart watches [45], and almost the entire battery of smart things for surveillance [84]. To execute an ephemeral task, a commodity OS kernel, typically implemented in a monolithic fashion,

[1] This paper focuses on battery-powered computers such as smart wearables and smart things. They run commodity OSes such as Linux and Windows. We refer to them as embedded platforms for brevity.



(a) The transkernel model (b) System execution workflow

Figure 1: An overview of this work

drives the whole hardware platform out of deep sleep beforehand (i.e., "resume") and puts it back to deep sleep afterwards (i.e., "suspend"). During this process, the kernel consumes much more energy than the user code [44], up to 10× shown in recent work [38].

Why is the kernel so inefficient? Recent studies [26, 92, 44] show the bottlenecks as two kernel phases called *device suspend/resume* as illustrated in Figure 1. In the phases, the kernel operates a variety of IO devices (or *devices* for brevity). It invokes device drivers, cleans up pending IO tasks, and ensures devices to reach expected power states. The phases encompass concurrent execution of drivers, deferred functions, and hardware interrupts; they entail numerous CPU idle epochs; their optimization is proven difficult (§2) [92, 50, 46].

We deem that device suspend/resume mismatches CPU. It instead would be much more efficient on low-power, microcontroller-like cores, as exemplified by ARM Cortex-M. These cores are already incorporated as *peripheral cores* on a wide range of modern system-on-chips (SoCs) used in production such as Apple Watch [59] and Microsoft Azure Sphere [52]. On IO-intensive workloads, a peripheral core delivers is much more efficient than the CPU due to lower idle power and higher execution efficiency [42, 43, 54, 1]. Note that running *user code* (which often builds atop POSIX) on peripheral cores is a non-goal: on one hand, doing so would gain much less efficiency due to fewer idle epochs in user

execution; on the other hand, doing so requires to support a much more complex POSIX environment on peripheral cores.

Offloading the execution of a commodity, monolithic kernel raises practical challenges, not only i) that the peripheral core has a different ISA and wimpy hardware but also ii) that the kernel is complex and rapidly evolving [68]. Many OS proposals address the former while being inadequate in addressing the latter [5, 61, 6, 48, 75]. For instance, one may refactor a monolithic kernel to span it over CPU and a peripheral core; the resultant kernel, however, depends on a wide binary interface (ABI) for synchronizing state between the two ISAs. This interface is brittle. As the upstream kernel evolves, maintaining *binary compatibility* across different ISAs inside the kernel itself soon becomes unsustainable. Instead, we argue for the code running on peripheral cores to enjoy firmware-level compatibility: developed and compiled *once*, it should work with *many* builds of the monolithic kernel – generated from different configurations and source versions.

Our response is a radical design called *transkernel*, a lightweight virtual executor empowering a peripheral core to run specific kernel phases – device suspend/resume. Figure 1 overviews the system architecture. A transkernel executes unmodified kernel binary through cross-ISA, dynamic binary translation (DBT), a technique previously regarded as expensive [5] and never tested on microcontroller-like cores to our knowledge. Underneath the translated code, a small set of emulated services act as lightweight, drop-in replacements for their counterparts in the monolithic kernel. Four principles make transkernel practical: i) translating stateful code while emulating stateless kernel services; ii) identifying a narrow, stable translation/emulation interface; iii) specializing for hot paths; iv) exploiting ISA similarities for DBT.

We demonstrate a transkernel prototype called ARK (**A**n a**R**m trans**K**ernel). Atop an ARM SoC, ARK runs on a Cortex-M3 peripheral core (with only 200 MHz clock and 32KB cache) alongside Linux running on a Cortex-A9 CPU. ARK transparently translates unmodified Linux kernel drivers and libraries. It depends on a binary interface consisting of only 12 Linux kernel functions and one kernel variable, which are stable for years. ARK offers complete support for device suspend/resume in Linux, capable of executing diverse drivers that implement rich functionalities (e.g., DMA and firmware loading) and invoke sophisticated kernel services (e.g., scheduling and IRQ handling). As compared to native kernel execution, ARK only incurs 2.7× overhead, 5.2× lower than a baseline of off-the-shelf DBT. ARK reduces system energy by 34%, resulting in tangible battery life extension under real-world usage.

We make the following contributions on OS and DBT:

- We present the transkernel model. In the design space of OSes for heterogeneous multi-processors, the transkernel represents a novel point: it combines DBT and emulation for bridging ISA gaps and for catering to core asymmetry, respectively.
- We present a transkernel implementation, ARK. Targeting Linux, ARK presents specific tradeoffs between kernel translation versus emulation; it identifies a narrow interface between the two; it contributes concrete realization for them.
- Crucial to the practicality of ARK, we present an inverse paradigm of cross-ISA DBT, in which a microcontroller-like core translates binary built for a full-fledged CPU. We contribute optimizations that systematically exploit ISA similarities. Our result demonstrates that while cross-ISA DBT is typically used under the assumption of efficiency *loss*, it can enable efficiency *gain*, even on off-the-shelf hardware.

The source code of ARK can be found at http://xsel.rocks/p/transkernel.

2 Motivations

We next discuss device suspend/resume, the major kernel bottleneck in ephemeral tasks, and that it can be mitigated by running on a peripheral core. We show difficulties in known approaches and accordingly motivate our design objectives.

2.1 Kernel in device suspend/resume

Expecting a long period of system inactivity, an OS kernel puts the whole platform into deep sleep: in brief, the kernel synchronizes file systems with storage, freezes all user tasks, turns off IO devices (i.e., device suspend), and finally powers off the CPU. To wake up from deep sleep, the kernel performs a mirrored procedure [11]. In a typical ephemeral task, the above kernel execution takes hundreds of milliseconds [31] while the user execution often takes tens of milliseconds [44]; the kernel execution often consumes several times more energy than the user execution [38].

Problem: device suspend/resume By profiling recent Linux on multiple embedded platforms, our pilot study [92] shows the aforementioned kernel execution is bottlenecked by device suspend/resume, in which the kernel cleans up pending IO tasks and manipulates device power states. The findings are as follows. i) ***Device suspend/resume is inefficient.*** It contributes 54% on average and up to 66% to the total kernel energy consumption. CPU idles frequently in numerous short epochs, typically in milliseconds. ii) ***Devices are diverse.*** On a platform, the kernel often suspends and resumes tens of different devices. Across platforms, the bottleneck devices are different. iii) ***Optimization is difficult.*** Device power state transitions are bound by slow hardware and low-speed buses, as well as physical factors (e.g., voltage ramp-up). While Linux already parallelizes power transitions with great efforts [50, 46], many power transitions must happen sequentially per *implicit* dependencies of power, voltage, and clock. As a result, CPU idle constitutes up to 68% of the device suspend/resume duration.

SoC	Cores	ISAs	Shared DRAM?	Mapping kern mem?	Shared IRQ
OMAP4460 [83] (2010)	A9+M3	v7a+v7m	Full	Yes. MPU	39/102

Table 1: Our hardware model fits many popular SoCs which are used in popular products such as Apple Watch and Azure Sphere. Section 7.5 discusses caveats. *: lack public technical details.

Challenge: Widespread, complex kernel code Device suspend/resume invokes multiple kernel layers [68, 32]. Specifically, it invokes functions in individual drivers (e.g., MMC controllers), driver libraries (e.g., the generic clock framework), kernel libraries (e.g., for radix trees), and kernel services (e.g., scheduler). In a recent Linux source tree (4.4), we find that over 1000 device drivers, which represent almost all driver classes, implement suspend/resume callbacks in 154K SLoC. These callbacks in turn invoke over 43K SLoC in driver libraries, 8K SLoC in kernel libraries, and 43K SLoC in kernel services. The execution is control-heavy, with dense branches and callbacks.

Opportunities We observe the following kernel behaviors in device suspend/resume. i) ***Low sensitivity to execution delay*** On embedded platforms, most ephemeral tasks are driven by background activities [38, 53, 13]. This contrasts to many servers for interactive user requests [93, 53]. ii) ***Hot kernel paths*** In successful suspend/resume, the kernel acquires all needed resources and encounters no failures [41]. Off the hot paths, the kernel handles rare events such as races between IO events, resource shortage, and hardware failures. These branches typically cancel the current suspend/resume attempt, perform diagnostics, and retry later. Unlike hot paths, they invoke very different kernel services, e.g., syslog. iii) ***Simple concurrency*** exists among the syscall path (which initiates suspend/resume), interrupt handlers, and deferred kernel work. The concurrency is for hardware asynchrony and kernel modularity rather than exploiting multicore parallelism.

Summary: design implications Device suspend/resume shall be treated systematically. We face challenges that the invoked kernel code is diverse, complex, and cross-layer; we see opportunities that allow focusing on hot kernel paths, specializing for simple concurrency, and gaining efficiency at the cost of increased execution time.

2.2 A peripheral core in a heterogeneous SoC

Hardware model We set to exploit peripheral cores already on modern SoCs. Hence, our software design only assumes the following hardware model which fits a number of popular SoCs as listed in Table 1.

1. ***Asymmetric processors***: In different coherence domains, the CPU and the peripheral core offer disparate performance/-efficiency tradeoffs. The peripheral core has memory protection unit (MPU) but no MMU, incapable of running commodity OSes as-is.

2. ***Heterogeneous, yet similar ISAs***: The two processors have different ISAs, in which many instructions have similar *semantics*, as will be discussed below.

3. ***Loose coupling***: The two processors are located in separate power domains and can be turned on/off independently.

4. ***Shared platform resources***: Both processors share access to platform DRAM and IO devices. Specifically, the peripheral core, through its MPU, should map all the kernel code/-data at identical virtual addresses as the CPU does. Both processors must be able to receive interrupts from the devices of interest, e.g., MMC; they may, however, see different interrupt line numbers of the same device.

How can peripheral cores save energy? They are known to deliver high efficiency for IO-heavy workloads [42, 54, 78, 1, 76]. Specifically, they benefit the kernel's device suspend/resume in the following ways. i) A peripheral core can operate while leaving the CPU offline. ii) The idle power of a peripheral core is often one order of magnitude lower [43, 64], minimizing system power during core idle periods. iii) Its simple microarchitecture suits kernel execution, whose irregular behaviors often see marginal benefits from powerful microarchitectures [58]. Note that a peripheral core offers much higher efficiency than a LITTLE core as in ARM big.LITTLE [24], which mandates a homogeneous ISA and tight core coupling. We will examine big.LITTLE in Section 7.

ISA similarity On an SoC we target, the CPU and the peripheral core have ISAs from the same family, e.g., ARM. The two ISAs often implement similar instruction *semantics* despite in different *encoding*. The common examples are SoCs integrating ARMv7a ISA and ARMv7m ISA [62, 65, 81, 52, 83]. Other families also provide ISAs amenable to same-SoC integration, e.g., NanoMIPS and MIPS32. We deem that the ISA similarities are *by choice*. i) For ISA designers, it is feasible to explore performance-efficiency tradeoffs within one ISA family, since the family choice is merely about instruction *syntax* rather than *semantics* [8]. ii) For SoC vendors, incorporating same-family ISAs on one chip simplifies software efforts [40], silicon design, and ISA licensing.

2.3 OS design space exploration

We set to realize heterogeneous execution for an *existing* monolithic kernel.

How about refactoring the kernel and cross-compiling statically? One may be tempted to modify a monolithic kernel (we use Linux as the example below) [43, 5] to be one unified source tree; the tree shall be cross-compiled into a kernel binary for CPU and a "peripheral kernel" for the peripheral core. This approach results in an OS structure shown in Figure 2(a). Its key drawback is the two interfaces that are difficult to implement and maintain, shown as ∿∿∿ in the figure.

① The interface between two heterogeneous ISAs, as needed for resolving inter-kernel data dependency. Through the interface, both kernels synchronize their kernel state, e.g., devices configurations, pending IO tasks, and locks, before and after the offloading. Built atop shared memory [43, 5, 23], the interface is essentially an agreement on thousands of shared Linux kernel data types, including their semantics and/or memory layout. The agreement is brittle, as it is affected by ISA choices, kernel configurations, and kernel versions. Hence, keeping data types consistent across ISAs entails tedious tweak of kernel source and configurations [22, 23]. As Greg Kroah-Hartman puts, "you will go insane over time if you try to support this kind of release, I learned this the hard way a long time ago." [36]

② The interface between the transplant code and the peripheral kernel, as needed for resolving functional dependency. In principle, this interface is determined by the choice of transplant boundary. In prior work, the example choices include the interface of device-specific code [22, 23, 80], that of driver classes [10, 79], or that of driver libraries [43]. All these choices expose at least hundreds of Linux kernel functions on this interface, as summarized in Figure 3(a). This is due to Linux's diverse, sophisticated drivers. Implementing such an interface is daunting; maintaining it is even more difficult due to significant ABI changes [37] as shown in Figure 3(b).

In summary, all these difficulties root in the peripheral kernel's *deep dependency* on the Linux kernel. This is opposite to the common practice: heterogeneous cores to run their own "firmware" that has little dependency on the Linux kernel. This is sustainable because the firmware stays compatible with many builds of Linux.

How about virtual execution? Can we minimize the dependency? One radical idea would be for a peripheral core to run the Linux kernel through virtual execution, as shown in Figure 2(b). Powered by DBT, virtual execution allows a *host* processor (e.g., the peripheral core) to execute instructions in a foreign *guest* ISA (e.g., the CPU). Virtual execution is free of the above interface difficulties: the translated code precisely reproduces the kernel behaviors and directly operates the kernel state (③). The peripheral core interacts with Linux through a low-level, stable interface: the CPU's ISA (④).

The problem, however, is the high overhead of existing cross-ISA DBT [4]. It is further exacerbated by our *inverse* DBT paradigm: whereas existing cross-ISA DBT is engineered for a brawny host emulating a weaker guest (e.g., an x86 desktop emulating an ARM smartphone) [17, 87], our DBT host, a peripheral core, shall serve a full-fledged CPU. A port of popular DBT exhibits up to 25× slowdown as will be shown in §7. Such overhead would negate any efficiency promised by the hardware and result in overall efficiency *loss*. Furthermore, cross-ISA DBT for the *whole* Linux kernel is complex [7]. A peripheral core lacks necessary environment, e.g., multiple address spaces and POSIX, for developing and debugging such complex software.

2.4 Design objective

We therefore target threefold objective.

G1. Tractable engineering. We set to reuse much of the kernel source, in particular the drivers that are impractical to build anew. We target simple software for peripheral cores.

G2. Build once, work with many. One build of the peripheral core's software should work with a commodity kernel's binaries built from a wide range of configurations and source

versions. This requires the former to interact with the latter through a stable, narrow ABI.

G3. Low overhead. The offloaded kernel phases should yield a tangible efficiency gain.

3 The Transkernel Model

Running on a peripheral core, a transkernel consists of two components: a DBT engine for translating and executing the unmodified kernel binary; a set of emulated, minimalistic kernel services that underpin the translated kernel code, as will be described in detail in Section 4. A concrete transkernel implementation targets a specific commodity kernel, e.g., Linux. A transkernel does not execute user code in ephemeral tasks as stated in Section 1.

The transkernel follows four principles:

1. Translating stateful code; emulating stateless services By *stateful code*, we refer to the offloaded code that must share states with the kernel execution on CPU. The stateful code includes device drivers, driver libraries, and a small set of kernel services. They cover the most diverse and widespread code in device suspend/resume (§2). By translating their binaries, the transkernel reuses the commodity kernel without maintaining wide, brittle ABIs. (objective G1, G2)

The transkernel emulates a tiny set of kernel services. We relax their semantics to be stateless, so that their states only live within one device suspend/resume phase. Being stateless, the emulated services do not need to synchronize states with the kernel on CPU over ABIs. (G2)

2. Identifying a narrow, stable translation/emulation ABI The ABI must be unaffected by kernel configurations and unchanged since long in the kernel evolution history. (G2)

3. Specializing for hot paths In the spirit of OS specialization [20, 71, 51], the transkernel only executes the hot path of device suspend/resume; in the rare events of executing off the hot path, it transparently falls back on CPU. The transkernel's emulated services seek *functional equivalence* and only implement features needed by the hot path; they do not precisely reproduce the kernel's behaviors. (G1)

4. Exploiting ISA similarities for DBT The transkernel departs from generic cross-DBT that bridges arbitrary guest/host pairs; it instead systematically exploits similarities in instructions semantics, register usage, and control flow transfer. This makes cross-ISA DBT affordable. (G3)

Limitations First, across ISAs of which instruction semantics are substantially different, e.g., ARM and x86, the transkernel may see diminishing or even no benefit. Second, the transkernel's longer delays (albeit lower energy) may misfit latency-sensitive contexts, e.g., for waking up platforms in response to user input. Our current prototype relies on heuristics to recognize such contexts and falls back on the CPU accordingly (Section 4).

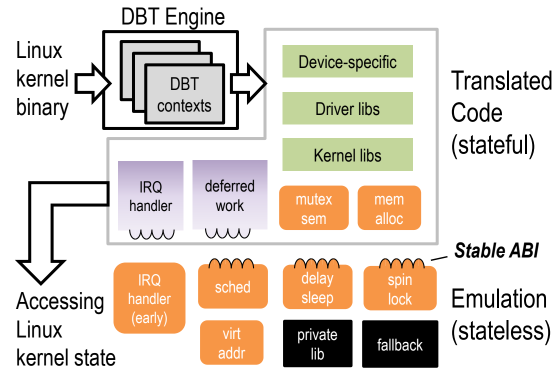

Figure 4: The ARK structure on a peripheral core

In Section 4 below we describe how to apply the model to a concrete transkernel, in particular our translation/emulation decisions for major kernel services, and our choices of the emulation interface. We will describe DBT in Section 5.

4 ARK: An ARM Transkernel

Targeting an ARM SoC, we implement a transkernel called ARK. The SoC encompasses a popular combination of ISAs: ARMv7A for its CPU and ARMv7m for its peripheral core. The CPU runs Linux v4.4.

Offloading workflow ARK is shipped as a standalone binary for the peripheral core, accompanied by a small Linux kernel module for control transfer between CPU and the peripheral core. We refer to such control transfer as *handoff*. Prior to a device suspend phase, the kernel shuts down all but one CPU cores, passes control to the peripheral core, and shuts down the last CPU core. Then, ARK completes the device phase in order to suspend the entire platform. Device resume is normally executed by ARK on the peripheral core; in case of urgent wakeup events (e.g., a user unlocking a smart watch screen), the kernel resumes on CPU with native execution.

System structure As shown in Figure 4, ARK runs a DBT engine, its emulated kernel services, and a small library for managing the peripheral core's private hardware, e.g., interrupt controllers. The emulated services serves downcalls (⌒⌒⌒) from the translated code and makes upcalls (~⌣⌣⌣) into the translated code. Table 2 summarizes the interfaces. Upon booting, ARK replicates Linux kernel's linear memory mappings for addressing kernel objects in shared memory [43, 23]. ARK maps I/O regions with MPU and time-multiplexes the regions on the MPU entries.

To support concurrency in the offloaded kernel phases, ARK runs multiple DBT contexts. Each context has its own DBT state (e.g., virtual CPU registers and a stack), executing DBT and emulated services independently. Context switch is as cheap as updating the pointer to the DBT state.

ARK executes the hot paths. Upon entering cold branches pre-defined by us, e.g., kernel `WARN()`, ARK migrates all the

Kernel services	Implementations & reasons
Scheduler (§4.1)	Emulated. Reason: simple concurrency.
IRQ handler (§4.2)	Early stage emulated; then translated
HW IRQ controller (§4.2)	Emulated. Reason: core-specific
Deferred work (§4.3)	Translated. Reason: stateful
Spinlocks (§4.4)	Emulated. Reason: core-specific
Sleepable locks (§4.4)	Fast path translated. Reason: stateful
Slab/Buddy allocator (§4.5)	Fast path translated. Reason: stateful
Delay/wait/jiffies (§4.6)	Emulated. Reason: core-specific

jiffies	udelay()	msleep()	tasklet_schedule()	irq_thread()
ktime_get()	queue_work_on()	worker_thread()	run_local_timers()	
generic_handle_irq()	schedule()	async_schedule()*	do_softirq()*	

*=ABI unchanged since 2014 (v3.16); others unchanged since 2011 (v2.6).

Table 2: Top: Kernel services supported by ARK. Bottom: Linux kernel ABI (12 funcs+1 var) ARK depends on. ARK offers complete support for device suspend/resume in Linux.

DBT contexts of *translated* code back to the CPU and continues as *native* execution there (§6).

4.1 A Scheduler of DBT Contexts

ARK emulates a scheduler which shares no state, e.g., scheduling priorities or statistics, with the Linux scheduler on the CPU. Corresponding to the simple concurrency model of suspend/resume (§2), ARK eschews reproducing Linux's preemptive multithreading but instead maintains and switches among cooperative DBT contexts: one primary context for executing the syscall path of suspend/resume, one for executing IRQ handlers (§4.2), and multiple for deferred work (§4.3). Managing no more than tens of contexts, ARK uses simple, round-robin scheduling. It begins the execution in the syscall context; when the syscall context blocks (e.g., by calling `msleep()`), ARK switches to the next ready context to execute deferred functions until they finish or block. When an interrupt occurs, ARK switches to the IRQ context to execute the kernel interrupt handler (§4.2).

4.2 Interrupt and Exception Handling

During the offloaded device phase, all interrupts are routed to the peripheral core and handled by ARK.

Kernel interrupt handlers ARK emulates a short, early stage of interrupt handling while translating the kernel code for the remainder. This is because this early stage is ISA-specific (e.g., for manipulating the interrupt stack), on which the CPU (v7a) and the peripheral core (v7m) differ. Hence, the emulated services implement a v7m-specific routine and install it as the hardware interrupt handler. Once an interrupt happens, the routine is invoked to finish the v7m-specific task and make an upcall to the kernel's ISA-neutral interrupt handling routine (listed in Table 2), from where the ARK translates the kernel to finish handling the interrupt.

Hardware interrupt controller ARK emulates the CPU's hardware interrupt controller. This is needed as the two cores have separate, heterogeneous interrupt controllers. The CPU controller's registers are unmapped in the peripheral core; upon accessing them (e.g., for masking interrupt sources) the translated code triggers faults. ARK handles the faults and operates the peripheral core's controller accordingly.

Exception: unsupported We don't expect any exception in the offloaded kernel phases. In case exception happens, ARK uses its fallback mechanism (§6) to migrate back to CPU.

4.3 Deferred Work

Device drivers frequently schedule functions to be executed in the future. ARK translates the Linux services that schedule the deferred work as well as the actual execution of the deferred work. ARK chooses to translate such services because they must be *stateful*: the peripheral core may need to execute deferred work created on the CPU prior to the offloading, e.g., freeing pending WiFi packets; it may defer new work until after the completion of resume.

ARK maintains dedicated DBT contexts for executing the deferred work (Section 4.1). While the Linux kernel often executes deferred work in kernel threads (daemons), our insight is that deferred work is oblivious to its execution context (e.g., a real Linux thread or a DBT context in ARK). Beyond this, ARK only has to run the deferred work that may *sleep* with separate DBT contexts so that they do not block other deferred work. From these DBT contexts, ARK translates the main functions of the aforementioned kernel daemons, which retrieve and invoke the deferred work.

Threaded IRQ defers heavy-lifting IRQ work (i.e., deferred work) to a kernel thread which executes the work after the hardware IRQ is handled. A threaded IRQ handler may sleep. Therefore, ARK maintains per-IRQ DBT contexts for executing these handlers. Each context makes upcalls into `irq_thread()` (the main function of threaded irq daemon, listed in Table 2).

Tasklets, workitems, and timer callbacks The kernel code may dynamically submit short, non-sleepable functions (tasklets) or long, sleepable functions (workitems) for deferred execution. Kernel daemons (softirq and kworker) execute tasklets and workitems, respectively.

ARK creates one dedicated context for executing all non-sleepable tasklets and per-workqeueue contexts for executing workitems so that one workqueue will not block others. These contexts make upcalls to the main functions of the kernel daemons (`do_softirq()`, `worker_thread()`, and `run_local_timers()`), translating them for retrieving and executing deferred work.

4.4 Locking

Spinlocks ARK emulates spinlocks, because their implementation is core-specific and that ARK can safely assume all spinlocks are free at handoff points: as described in early

Section 4, handoff happens between one CPU core and one peripheral core, which do not hold any spinlock; all other CPU cores are offline and cannot hold spinlocks. Hence, ARK emulates spinlock acquire/release by pausing/resuming interrupt handling. This is because ARK runs on one peripheral core and the only hardware concurrency comes from interrupts.

Sleepable locks ARK translates sleepable locks (e.g., mutex, semaphore) because these locks are stateful: for example, the kernel's clock framework may hold a mutex preventing suspend/resume from concurrently changing clock configuration [56]. Furthermore, mutex's seemingly simple interface (i.e., compare & exchange in fast path) has *unstable* ABI and therefore unsuitable for emulation: a mutex's reference count type changes from `int` to `long` (v4.10), breaking the ABI compatibility. The translated operations on sleepable locks may invoke spinlocks or the scheduler, e.g., when updating reference counts or putting the caller to sleep, for which the translated execution makes downcalls to the emulated services.In practice, no sleepable lock is held prior to system suspend.

4.5 Memory Allocation

The device phase frequently requests dynamic memory, often at granularities of tens to hundreds of bytes. By Linux design, such requests are served by the kernel slab allocator backed by a buddy system for page allocation (fast path); when the physical pages runs low, the kernel may trigger swapping or kill user processes (slow path).

ARK provides memory allocation as a stateful service. It translates the kernel code for the fast path, including the slab allocator and the buddy system. In the case that the allocation enters the slow path (e.g., due to low physical memory), ARK aborts offloading; fortunately, our stress test suggests such cases to be extremely rare, as will be reported in Section 7. With a stateful allocator, the offloaded execution can free dynamic memory allocated during the kernel execution on CPU, and vice versa. Compare to prior work that instantiates per-kernel allocators with split physical memory [43], ARK reduces memory fragmentation and avoids tracking *which* processor should free *what* dynamic memory pieces. Our experience in Section 7 show that ARK is able to handle intensive memory allocation/free requests such as in loading firmware to a WiFi NIC.

4.6 Delays & Timekeeping

Delays ARK emulates `udelay()` and `msleep()` for busy waiting and sleeping. ARK converts the expected wait time to the hardware timer cycles on the peripheral core. ARK implements `msleep()` by pausing scheduling the caller context.

jiffies The Linux kernel periodically updates jiffies, a global integer, as a low-overhead measure of elapsed time. By consulting the peripheral core's hardware timer, ARK directly updates the jiffies. It is thus the only shared variable on the kernel ABI that ARK depends (all others are functions).

5 The Cross-ISA DBT Engine

A Cross-ISA DBT Primer DBT, among its other uses [60, 49, 27], is a known technique allowing a *host* processor to execute instructions in a foreign *guest* ISA. In such cross-ISA DBT, the host processor runs a program called DBT engine. At run time, the engine reads in guest instructions, translates them to host instructions based on the engine's built-in *translation rules*, and executes these host instructions. The engine translates guest instructions in the unit of translation block – a sequence (typically tens) of guest instructions that has one entry and one or more exits. After translating a block, the engine saves the resultant host instructions to its *code cache* in the host memory, so that future execution of this translated block can be directed to the code cache.

Design overview We build ARK atop QEMU [7], a popular, opensource cross-ISA DBT engine. ARK inherits QEMU's infrastructure but departs from its generic design which translates between arbitrary ISAs. ARK targets two well-known DBT optimizations: i) to emit as few host instructions as possible; ii) to exit from the code cache to the DBT engine as rarely as possible. We exploit the following similarities between the CPU's and the peripheral core's ISAs (ARMv7a & ARMv7m):

1. Most v7a instructions have v7m counterparts with identical or similar semantics, albeit in different encoding. (§5.1)
2. Both ISAs have the same general purpose registers. The condition flags in both ISAs have same semantics. (§5.2)
3. Both ISAs use program counter (PC), link register (LR), and stack pointer (SP) in the same way. (§5.3)

Beyond the similarities, the two ISAs have important discrepancies. Below, we describe our exploitation of the ISA similarities and our treatment for *caveats*.

5.1 Exploiting Similar Instruction Semantics

	Category	Cnt	v7m
w/ CNTPRT	Identity	447	1
	Side effect	52	3-5
	Const constraints	22	2-5
	Shift modes	10	2
w/o counterparts		27	2-5
Total (v7a)		558	

Table 3: Translation rules for v7a instructions. Column 3: the number of v7m instructions emitted for one v7a instruction

We devise translation rules with a principled approach by parsing a machine-readable, formal ISA specification recently published by ARM [72]. Our overall guideline is to map each v7a instruction to one v7m instruction that has identical or similar semantics. We call them *counterpart* instructions. For a counterpart instruction with similar (yet

ARMv7a	ARMv7m (by ARK)
G1: `ldr r0, [r1], r2, lsr #4`	**H1:** `ldr.w r0, [r1]` **H2:** `lsr.w t0, r2, 0x4` **H3:** `add.w r1, r1, t0`
G2: `adds r0, r1, 0x80000001`	**H4:** `mov.w t0, 0xc0` **H5:** `ror.w t0, t0, 0x7` **H6:** `adds.w r0, r1, t0`
G3: `sub r0, r1, r2`	**H7:** `sub.w r0, r1, r2`

Table 4: Sample translation by ARK. By contrast, our baseline QEMU port translates G1–G3 to **27** v7m instructions

non-identical) semantics, ARK emits a few "amendment" v7m instructions to make up for the semantic gap. The resultant translation rules are based on individual guest instructions, different from translation rules based on one or more translation blocks commonly seen in cross-ISA DBT [86]. This is because semantics similarities allows identity translation for most guest instructions. Amendment instructions are oblivious to interrupts/exceptions: as stated in §4.2, ARK defers IRQ handling to translation block boundary and expects no exceptions.

Table 3 summarizes ARK's translation rules for all 558 v7a instructions. Among them, 80% can be translated with identity rules, for which ARK only needs to convert instruction encoding at run time. 15% of v7a instructions have v7m counterparts but may require amendment instructions, which fortunately fall into a few categories: i) ***Side effects.*** After load/store, v7a instructions may additionally update memory content or register values (shown in Table 4, G1). ARK emits amendment instructions to emulate the extra side effect (H3). ii) ***Constraints on constants.*** The range of constants that can be encoded in a v7m instruction is often narrower (Table 4, G2). In such cases, the amendment instructions load the constant to a scratch register, operate it, and emulate any side effects (e.g., index update) the guest instruction may have. iii) ***Richer shift modes.*** v7a instructions support richer shift modes and larger shift ranges than their v7m counterparts. This is exemplified by Table 4 G1, where a v7m instruction cannot perform LSR (logic shift right) inline as its v7a counterpart. Similar to above, the amendment instructions perform shift on the operand in a scratch register.

Beyond the above, only 27 v7a instructions have no v7m counterparts, for which we manually devise translation rules.

In summary, through systematic exploitation of similar instruction semantics, ARK emits compact host code at run time. In the example shown in Table 4, three v7a instructions are translated into seven v7m instructions by ARK, while to 27 instructions by our QEMU baseline.

5.2 Passthrough of CPU registers

General purpose registers Both the guest (v7a) and the host (v7m) have the same set (13) of general-purpose registers. In allocating registers of a host instruction, ARK follows guest register allocation with best efforts (e.g., one-to-one mapping in best case, as in Table 4, G1). ARK emits much fewer host instructions than QEMU, which emulates all guest registers in host memory with load /store.

Caveats fixed The amendment host instructions operate scratch registers as exemplified by `t0` in Table 4, H2-H6. However, the wimpy host faces higher register pressure, as it (v7m) has no more registers than the brawny guest (v7a). To spill some registers to memory while still reusing the guest's register allocation, we make the following tradeoff: we designate one host register as the *dedicated* scratch register, and emulates its guest counterpart register in memory. We pick the *least* used one in the guest binary as the dedicated scratch register, which is experimentally determined as R10 by analyzing kernel binary. We find most amendment instructions are satisfied by *one* scratch register; in rare cases when extra scratch registers are needed, ARK follows a common design to allocate dead registers and spill unused ones to memory.

Condition flags Both the guest and the host ISAs involve five hardware condition flags (e.g., zero and carry) with identical semantics; fortunately, most guest (v7a) instructions and their host (v7m) counterparts have identical behaviors in testing/setting flags per the ISA specifications [72]. ARK hence directly emits instructions to manipulate the host's corresponding flags. Such flag passthrough especially benefits control-heavy suspend/resume, which contains extensive conditional branches (§2); we study its benefits quantitatively in §7.3.

Caveats fixed Amendment host instructions may affect the hardware condition flags unexpectedly. For amendment instructions (notably comparison and testing) that *must* update the flags as mandated by ISA, ARK emits two host instructions to save/restore the flags in a scratch register around the execution of these amendment instructions.

5.3 Control Transfer and Stack Manipulation

Function call/return Both guest (v7a) and host (v7m) use PC (program counter) and LR (link register) to maintain the control flow. QEMU emulates guest PC and LR in host memory. As a result, the return address, loaded from stack or the emulated LR, points to a guest address (i.e., kernel address). Each function return hence causes the DBT to step in and look up the corresponding code cache address. This overhead is magnified in the control-heavy device phase.

By contrast, ARK never emits host code to emulate the guest (i.e., kernel) PC or LR. For each kernel function call, ARK saves the return addresses within *code cache* on stack or in LR; for each kernel function return, ARK loads the return address (which points to code cache) to hardware PC from the stack or the hardware LR. By doing so, ARK no longer participates in all function returns. Our optimization is inspired by same-ISA DBT [34].

Stack and SP QEMU emulates the guest (i.e., kernel) stack and SP with a host array and a variable. Each guest push/pop translates to multiple host instructions updating the stack array and the emulated SP. This is costly, as suspend/resume frequently makes function calls and operates stack heavily.

ARK avoids such expensive stack emulation by emitting host push/pop instructions to directly operate the guest stack *in place*. This is possible because ARK emulates the Linux kernel's virtual address space (§4). ARK also ensures the host code generate the same stack frames as the guest would do by making amendment instructions avoid using stack, which would introduce extra stack contents. In addition, this further facilitates the migration in abort (§6).

Caveats fixed i) As the host saves on the guest stack the code cache addresses, which are meaningless to the guest CPU, upon migrating from the peripheral core (host) to the CPU (guest), the DBT rewrites all code cache addresses on stack with their corresponding guest addresses. ii) guest push/pop instruction may involve emulated registers (i.e., scratch register). ARK must emit multiple host instructions to correctly synchronize the emulated registers in memory.

6 Translated ⟶ Native Fallback

As described in Section 3, when going off the hot paths, ARK migrates the kernel phase back to the CPU and continues as native execution, analogous to virtual-to-physical migration of VMs [85]. Migrating one DBT context is natural, as ARK passes through most CPU registers and uses the kernel stack in place (§5.3). Yet, to migrate *all* active DBT contexts, ARK address the following unique challenges.

Migrate DBT contexts for deferred work After fallback, all blocked workitems should continue their execution on the CPU. Unfortunately, their enclosing DBT contexts do not have counterparts in the Linux kernel. To solve this issue, we again exploit the insight that the workitems are oblivious to their execution contexts. Upon migration, the Linux kernel creates temporary kernel threads as "receivers" for blocked workitems to execute in. Once the migrated workitems complete, the receiver threads terminate.

Migrate DBT context for interrupt If fallback happens inside an ISA-neutral interrupt handler (translated), the remainder of the handler should migrate to the CPU. This challenge, again, is that ARK's interrupt context has no counterpart on the CPU: the interrupt never occurs to the CPU. ARK addresses this by *rethrowing* the interrupt as an IPI (interprocessor interrupt) from the peripheral core to the CPU; the Linux kernel uses the IPI context as the receiver for the migrated interrupt handler to finish execution.

Section 7 will evaluate the fallback frequency and cost.

7 Evaluation

We seek to answer the following questions:

1. Does ARK incur tractable engineering efforts? (§7.2)
2. Is ARK correct and low-overhead? (§7.3)
3. Does ARK yield energy efficiency benefit? What are the major factors impacting the benefit? (§7.4)

7.1 Methodology

Test Platform We evaluate ARK on OMAP4460, an ARM-based SoC [83] as summarized in Table 6. We chose this SoC mainly for its good documentation and longtime kernel support (since 2.6.11), which allows our study of kernel ABI over a long timespan in Section 2. As Cortex-M3 on the platform is incapable of DVFS, for fair comparison, we run both cores at their highest clock rates. Note that OMAP4460 is not completely aligned with our hardware model, for which we apply workarounds as will be discussed in Section 7.5.

Benchmark setup We benchmark ARK on the whole suspend/resume kernel phases. We run a user program as the test harness that periodically kicks ARK for suspend/resume; the generated kernel workloads are the same as in all ephemeral tasks. Our benchmark is macro: it exercise extensive drivers and services, during which ARK translates and executes over 200 million instructions.

The benchmark operates nine devices for suspend/resume. 1. **SD card**: SanDisk Ultra 16GB SDHC1 Class 10 card; 2. **Flash drive**: a generic drive connected via USB; 3. **MMC controller**: on-chip OMAP HSMMC host controller; 4. **USB controller**: on-chip OMAP HS multiport USB host controller; 5. **Regulator**: TWL6030 power management IC connected via I2C; 6. **Keyboard**: Dell KB212-B keyboard connected via USB; 7. **Camera**: Logitech c270 connected via USB; 8. **Bluetooth NIC**: an adapter with Broadcom BCM20702 chipset connected via USB; 9. **WiFi NIC**: TI WL1251 module. The kernel invokes sophisticated drivers, thoroughly exercising various services including deferred work (2–4,6–8), slab/buddy allocator (1–4,6–9), softirq (9), DMA (2,6–9), threaded IRQ (1,5,9), and firmware upload (9).

We measure device suspend/resume executed by ARK on Cortex-M3 and report the measured results. We compare ARK to native Linux execution on Cortex-A9. We further compare to a baseline ARK version: its DBT is a straightforward v7m port of QEMU that misses optimizations described in Section 5. We report measurements taken with warm DBT code cache, as this reflects the real-world scenario where device suspend/resume is frequently exercised.

7.2 Analysis of engineering efforts

ARK eliminates source refactoring of the Linux kernel (§2.3). As shown in Table 5, ARK transparently reuses substantial kernel code (15K SLoC in our test), most of which are drivers

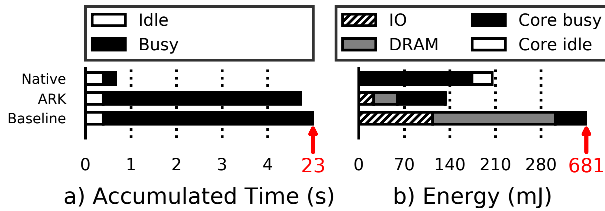

Figure 5: Execution time and energy in device suspend/resume. ARK substantially reduces the energy.

and their libraries. We stress that ARK, as a driver-agnostic effort, not only enables reuse of the drivers under test but also other drivers in the ARMv7 Linux kernel.

Table 5 also shows that ARK requires modest efforts in developing new software for the peripheral core. The 9K new SLoC for DBT is low as compared to commodity DBT (e.g., QEMU has 2M SLoC). ARK implements emulation in as low as 1K SLoC and in return avoids translating generic, sophisticated Linux kernel services [34, 21]. The result validates our principle of specializing these emulated services.

Existing code (unchanged)	
Translated	15K SLoC
Substituted w/ emu	25K SLoC
New implementation	
DBT	9K SLoC
Emulation	1K SLoC

Table 5: Source code

ARK meets our goal of "build once, run with many". We verify that the ARK binary works with a variety of kernel configuration variants (including `defconfig-omap4` and `yes-to-all`) of Linux 4.4. We also verify that ARK works with a wide range of Linux versions, from version 3.16 (2014) to 4.20 (most recent at the time of writing). This is because ARK only depends on a narrow ABI shown in Table 2, which has not changed since Linux 3.16.

7.3 Measured execution characteristics

ARK's correctness Formally, we derive translation rules from the specification of ARM ISA [72]; experimentally, we validate ARK by comparing its execution results side-by-side with native execution and examining the translated code with the native kernel binary. Over 200 million executed instructions, we verify that ARK's translation preserves kernel's semantics and presents consistent execution results.

Core activity We trace core states during ARK execution. Figure 5 (a) shows the breakdown of execution time. Compared to the native execution on CPU, ARK shows the same amount of accumulated idle time but much longer (16×) busy time. The reasons are Cortex-M3's much lower clock rate (1/6 of the A9's clock rate) and ARK's execution overhead. Despite the extended busy time, ARK still yields energy benefit, as we will show below.

Memory activity We collect DRAM activities by sampling

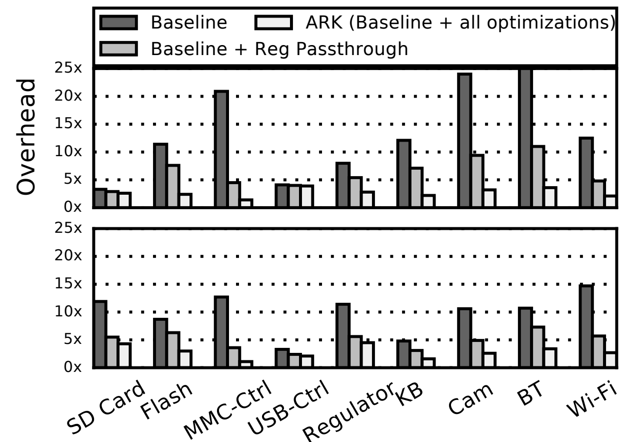

Figure 6: Busy execution overhead for devices under test (top: suspend; bottom: resume). Our DBT optimizations reduce the overhead by up to one order of magnitude

the hardware counters of the SoC's DDR controller. We observed that ARK on Cortex-M3 generates much higher average DRAM utilization (32 MB/s read and 2MB/s write) than the native execution on A9 (only 8MB/s read and 4MB/s write). We attribute such thrashing to M3's small (32KB) last-level cache (LLC). Throughout the test, the ARK emitted and executed around 230KB host instructions, which far exceeds the LLC capacity and likely causes thrashing. By contrast, Cortex-A9 has a much larger LLC (1MB), which absorbs most of the kernel memory access. The memory activity has a strong energy impact, as will be shown below.

Busy execution overhead Our measurement shows that ARK incurs low overhead in busy kernel execution, which includes both DBT and emulation. We report the overhead as the ratio between ARK's cycle count on Cortex-M3 to the Linux's cycle count on A9. Note that an M3 cycle is 6× longer than A9 due to different clock rates.

Overall, the execution overhead is 2.7× on average (suspend: 2.9×; resume: 2.6×). Of individual drivers, the execution overhead ranges from 1.1× to 4.5× as shown in Figure 6. Our DBT optimizations (§5) have strong impact on lowering the overhead. Lacking them, our baseline design incurs a 13.9× overhead on average, 5.2× higher than ARK. We examined how our optimizations contribute to the gap: register passthrough (§5.2) reduces the baseline's overhead by 2.5× to 5.5×. Remaining optimizations (e.g., control transfer) collectively reduce the overhead by additional 2×. Our optimizations are less effective on drivers with very dense control transfer (e.g., USB) due to high DBT cost.

Emulated services Our profiling shows that ARK's emulated services incur low overhead. Overall, the emulated services only contribute 1% of total busy execution. i) The early, core-specific interrupt handling (§4.2) takes 3.9K Cortex-M3 cycles, only 1.5–2× more cycles than the native execution on

	CPU	Peripheral core
Core	Cortex A9@1.2GHz	Cortex M3@200MHz
Cache	L1:64KB + L2:1MB	L1:32KB
Typical busy/idle power	630mW/80mW	17mW/1mW

Table 6: The test platform - OMAP4460 on a Pandaboard

A9. ii) Emulated workqueues (§4.3) incurs a typical queueing delay of tens of thousands M3 cycles. The delay is longer than the native execution but does not break the deferred execution semantics.

Fallback frequency & cost We stress test ARK by repeating the benchmark for 1000 runs. Throughout the 1000 runs, ARK encounters only four cases when the execution goes off the hot path, all of which caused by the WiFi hardware failing to respond to resume commands; it is likely due to an existing glitch in WiFi firmware. In such a case, ARK migrates execution by spending around 20 us on rewriting code cache addresses on stack (§5.3), 17 us to flush Cortex-M3's cache, and 2 us to wake up the CPU through an IPI.

7.4 Energy benefits

Methodology We study system-level energy and in particular how it is affected by ARK's its extended execution time. We include energy of both cores, DRAM, and IO.

We measure power of cores by sampling the inductors on the power rails for the CPU and the peripheral core. As the board lacks measurement points for DRAM power [19], we model DRAM power as a function of DRAM power state and read/write activities, with Micron's official power model for LPDDR2 [55]. The system energy of ARK is given by:

$$E_{ARK} = \underbrace{E_{core}}_{\text{Measured}} + T_{idle} \cdot \underbrace{(P_{mem_sr} + P_{io})}_{\textit{Modeled}} + T_{busy} \cdot \underbrace{(P_{mem} + P_{io})}_{\textit{Modeled}}$$

Here, E_{core} is the measured core energy. All Ts are measured execution time. Ps are power consumptions for DRAM and IO: P_{mem} is DRAM's active power derived from measured DRAM activities as described in Section 7.3; P_{mem_sr} is DRAM's self-refresh power, 1.3mW according to the Micron model; P_{io} is the average IO power which we estimate as 5mW based on prior work [90]. Note that during suspend/resume, IO devices no longer actively perform work, thus consuming much less power.

Energy saving ARK consumes 66% energy (a reduction of 34%) of the native execution, despite its longer execution time. The energy breakdown in Figure 5(b) shows the benefit comes from two portions: i) in busy execution, ARK's energy efficiency is 23% higher than the native execution due to low overhead (on average 2.7×); ii) during system idle, ARK reduces system energy to a negligible portion, as the peripheral core's idle power is only 1.25% of the CPU's. Figure 5(b) highlights the significance of our DBT optimizations: the baseline, like ARK, benefits from lower idle power as well; however its high execution overhead ultimately leads to 5.1× energy compared to the native execution. Interestingly, ARK

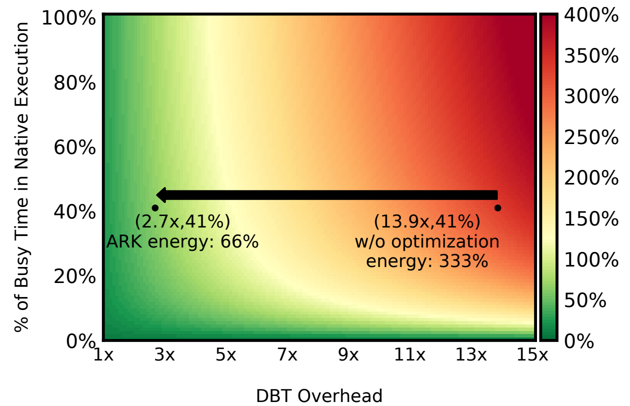

Figure 7: System energy consumption (inc. cores, DRAM, and IO) of ARK relative to native execution (100%), under different DBT overheads (x-axis) and processor core usage (y-axis). ARK's low energy hinges on low DBT overhead.

consumes *more* DRAM energy than the native execution. We deem the cause as Cortex-M3's tiny LLC (32KB) as describe earlier. Our result suggests that the current size is suboptimal for the offloaded kernel execution.

What-if analysis How sensitive is ARK's energy saving to two major factors: the DBT overhead (ARK's behavior) and the processor core usage (Linux's behavior)? To answer the question, we estimate the *what-if* energy consumption by using the power model as described above. The analysis results in Figure 7 show two findings. i) ARK's energy benefit will be more pronounced with lower core usage (i.e., longer core idle), because ARK's efficiency advantage over native execution is higher during core idle. ii) ARK's energy benefit critically depends on DBT. When the DBT overhead (on x-axis) drops to below 3.5×, ARK saves energy even for 100% busy execution; when the overhead exceeds 5.2×, ARK wastes energy even for 20% busy execution, the lowest core usage observed on embedded platforms in prior work [92].

Qualitative comparison with big.LITTLE We estimate ARK saves tangible energy compared to a LITTLE core. We use parameters based on recent big.LITTLE characterizations [66, 25]: compared to the big (i.e., CPU on our platform), a LITTLE core has 40 mW idle power [69] and offers 1.3× energy efficiency at 70% clock rate [47]. We favorably assume LITTLE's DRAM utilization is as low as the big, while in reality the utilization should be higher due to LITTLE's smaller LLC. Even with this favorable assumption for LITTLE and unfavorable, tiny LLC for ARK, LITTLE consumes 77% energy of native execution, more than ARK (51%–66%), mainly because LITTLE's idle power is 40× of Cortex-M3. Furthermore, ARK's advantage will be even more pronounced with a proper LLC as discussed earlier.

Battery life extension Based on ARK's energy reduction in device suspend/resume, we project the battery life extension for ephemeral tasks reported in prior work [38]. When the ephemeral tasks are executed at 5-second intervals and the

native device suspend/resume consumes 90% system energy in a wakeup cycle, ARK extends the battery life by 18% (4.3 hours per day); with 30-second task intervals and a 50% energy consumption percentage, ARK extends the battery life by 7% (1.6 hours per day). This extension is tangible compared to complementary approaches in prior work [38, 90].

7.5 Discussions

Workarounds for OMAP4460 While OMAP4460 mostly matches our hardware model as summarized in Table 1, for minor mismatch we apply the following workarounds. ***Memory mapping*** Our hardware model (§2.2) mandates that the peripheral core should address the entire kernel memory. Yet, Cortex-M3, according to ARM's hardware specification [82], is only able to address memory in certain range (up to `0xE0000000`), which unfortunately does not encompass the Linux kernel's default address range. As a workaround, we configure the Linux kernel source, shifting its address range to be addressable by Cortex-M3. ***Interrupt handling*** While our hardware model mandates that both processors should receive all interrupts, OMAP4460 only routes a subset of them (39/102) to Cortex-M3, leaving out IO devices such as certain GPIO pins. These IO devices hence are unsupported by the ARK prototype and are not tested in our evaluation.

Recommendation to SoC architects To make SoCs friendly to a transkernel, architects may consider: i) routing all interrupts to CPU and the peripheral core, ideally with the identical interrupt line numbers; ii) making the peripheral core capable of addressing the whole memory address space; iii) enlarging the peripheral core's LLC size modestly. We expect a careful increase (e.g., to 64 KB or 128 KB) will significantly reduce DRAM power at a moderate overhead in the core power.

Applicability to a pair of 64-bit/32-bit ISAs While today's smart devices often use ARMv7 CPUs, emerging ARM SoCs start to combine 64-bit CPUs (ARMv8) with 32-bit peripheral core (ARMv7m), as listed in Table 1. On one hand, transkernel's idea of exploiting ISA similarity still applies, as exemplified by G2→H2 in Table 7; on the other hand, its DBT overhead may increase significantly for the following reasons. Compared to the 32-bit ISA, the 64-bit ISA has richer instruction semantics, more general purpose registers, and a much larger address space. As a result, ARK cannot pass through 64-bit CPU registers but instead have to emulate them in memory; ARK must translate the guest's 64-bit memory addresses to 32-bit addresses supported by the host (Table 7 G1→H1), e.g., by keeping consistent two sets of page tables, for 64-bit and 32-bit virtual address spaces, respectively; with large physical memory (>4GB), even this technique will not work because the peripheral core's page tables are incapable of mapping the extra physical memory.

ARMv8	ARMv7m (by ARK, ideally)

G1:
 	
`ldrb w2, [x22, #1059]`
 	
`ldrb w1, [x0, #160]`
	H1:
	`(emulate x22+#1059 in addr1)`
	`ldrb r2, [addr1]`
	`(emulate x0+#160 in addr2)`
	`ldrb r1, [addr2]`

G2: `cmp w2, w1`	H2: `cmp r2, r1`

Table 7: Ideal AARCH64 translation by ARK for `mmc_compare_ext_csds()` in Linux v4.4. While identity mapping still exists (G2→H2), software emulation can diminish ARK's benefits (G1→H1).

8 Related Work

OS for heterogeneous cores A multikernel OS runs its kernels on individual processors. A number of such OSes are designed anew with a strong distributed system flavor. They define explicit message interfaces among kernels [6, 88, 2]; some additionally exploit managed languages/compilers to generate such interfaces [61]. Unlike them, transkernel targets spanning an *existing* monolithic kernel and therefore adopts DBT to address the resultant interface challenge.

OSes like Popcorn [5] and K2 [43] seek to present a single Linux image over heterogeneous processors. For sharing kernel state across ISAs, they rely on manual source tweaks or hand-crafted communication. They face the interface difficulty as described in §2.3.

Prior systems distribute OS functions over CPU and accelerators [57, 77]. The accelerators cannot operate autonomously, which is however required by device suspend/resume. Prior systems offload apps from a smartphone (weak) to cloud servers (strong) for efficiency [15, 14]. Unlike them, transkernel offloads kernel workloads from a strong processor to a weak peripheral core on the same chip.

DBT DBT has been used for system emulation [7] and binary instrumentation [34, 27, 49, 21]; DeVuyst et al. [18] uses DBT to speed up process migration. Related to transkernel, prior systems run translated user programs atop an emulated syscall interface [7, 29, 87]. Unlike them, transkernel translates kernel code and emulates a narrow interface *inside* the kernel. Prior systems use DBT to run binaries in commodity ISAs (e.g., x86) on specialized VLIW cores and hence gain efficiency [9, 35, 73, 74]. None runs on microcontrollers to our knowledge. transkernel demonstrates that DBT can gain efficiency even on off-the-shelf cores. Existing DBT engines leverage ISA similarities, e.g., between aarch32 and aarch64 [17, 16]. They still fall into the classic DBT paradigm, where the host ISA is brawny and the guest ISA is wimpy (i.e., lower register pressure). With an inverse DBT paradigm, ARK addresses very different challenges. Much work is done on optimizing DBT translation rules, using optimizers [28, 3] or machine learning[86]. Compared to them, ARK leverages ISA similarities and hence reuses code optimization already

in guest code by guest compilers.

Kernels and drivers The transkernel is inspired by the POSIX emulator [30] however is different as it emulates kernel ABIs. Prior kernel studies show rapid evolution of the Linux kernel and the interfaces between kernel layers are unstable [68, 67]. This observation motivates transkernel. Extensive work transplants device drivers to a separate core [23], user space [22], or a separate VM [39]. However, the transplant code cannot operate independent of the kernel, whereas transkernel must execute autonomously.

Encapsulating the NetBSD kernel subsystems (e.g., drivers) behind stable interfaces respected by developers, rump kernel [33] seeks to enable their reuse in foreign environments, e.g., hypervisors. The transkernel targets a different goal: spanning a live Linux kernel instance over heterogeneous processors. Applying Rump kernel's approach to Linux is difficult, as Linux intentionally rejects interface stability for drivers [36].

Suspend/resume's inefficiency raises attention for cloud servers [53, 89] and mobile [38]. Drowsy [38] mitigates inefficiency by reducing the devices involved in suspend/resume through user/kernel co-design; Xi *et al.* propose to reorder devices to resume [89]. While acknowledging the value of such kernel optimizations, we believe ARK is a key complement that works on unmodified binaries. ARK can co-exist with the mentioned optimizations in the same kernel. PowerNap [53] takes a hardware approach to speed up suspend/resume for servers. It does not treat kernel execution for operating diverse IO on embedded platforms. Kernels may put idle devices to low power at runtime [90], complementary to suspend/resume that ensures all devices are off.

9 Conclusions

We present transkernel, a new executor model for a peripheral core to execute a commodity kernel's phases, notably device suspend/resume. The transkernel executes the kernel binary through cross-ISA DBT. It translates stateful code while emulating stateless services; it picks a stable ABI for emulation; it specializes for hot paths; it exploits ISA similarities for DBT. We experimentally demonstrate that the approach is feasible and beneficial. The transkernel represents a new OS design point for harnessing heterogeneous SoCs.

Detecting Asymmetric Application-layer Denial-of-Service Attacks In-Flight with FINELAME

Henri Maxime Demoulin Isaac Pedisich Nikos Vasilakis
Vincent Liu Boon Thau Loo Linh Thi Xuan Phan
University of Pennsylvania

Abstract

Denial of service (DoS) attacks increasingly exploit algorithmic, semantic, or implementation characteristics dormant in victim applications, often with minimal attacker resources. Practical and efficient detection of these asymmetric DoS attacks requires us to (i) catch offending requests in-flight, before they consume a critical amount of resources, (ii) remain agnostic to the application internals, such as the programming language or runtime system, and (iii) introduce low overhead in terms of both performance and programmer effort.

This paper introduces FINELAME, a language-independent framework for detecting asymmetric DoS attacks. FINELAME leverages operating system visibility across the entire software stack to instrument key resource allocation and negotiation points. It leverages recent advances in the Linux extended Berkeley Packet Filter virtual machine to attach application-level interposition probes to key request processing functions, and lightweight resource monitors—user/kernel-level probes—to key resource allocation functions. The data collected is used to train a model of resource utilization that occurs throughout the lifetime of individual requests. The model parameters are then shared with the resource monitors, which use them to catch offending requests in-flight, inline with resource allocation. We demonstrate that FINELAME can be integrated with legacy applications with minimal effort, and that it is able to detect resource abuse attacks much earlier than their intended completion time while posing low performance overheads.

1 Introduction

Denial-of-Service (DoS) attacks aim to hinder the availability of a service from its legitimate users. They work by overwhelming one or more of the resources of the service (*e.g.*, , CPU, network, memory, or disk), causing the service to become slow or, in the limit, entirely unavailable.

Classic DoS attacks are simple in structure: attackers, in large-scale, brute-force volumetric attacks, send many requests that far exceed the service's available resources. Although potentially crippling—sometimes reaching aggregate volumes of terabits per second [24, 43]—many effective mitigation techniques have been developed over the years, including commercial services like CloudFlare, Akamai, or the intrusion detection systems of Arbor Networks.

In response to these defenses, recent attacks have become much more sophisticated in nature: rather than relying on the sheer volume, they take the form of highly specialized, application-specific *asymmetric* DoS (ADoS) attacks [11, 12, 36, 48]. These attacks contain carefully-crafted, pathological payloads that target algorithmic, semantic, or implementation characteristics of the application's internals. They require significantly lower volumes of traffic and attacker resources to compromise resource availability. With the prevalence of third-part libraries, broad swaths of applications can be vulnerable to a given attack. For instance, the Regular-Expression DoS (ReDoS) attack [12, 13, 51] affects many programs that use regular expressions by leveraging algorithmic complexity to craft a single payload of a few characters that can occupy a service for several hours.

Due to this increase in sophistication, existing defenses are becoming inadequate [10, 26–28, 31, 40, 54, 60–62]. Network-based defenses are generally ineffective against ADoS attacks because these attacks lack identifiable problematic patterns at the network level. To be successful, network tools would not only need to perform deep packet inspection, but would also need to be able to predict which requests will hog resources a priori—a challenge analogous to solving the halting problem. Similarly, existing application-level defenses are limited in their efficacy: since these attacks can target arbitrary resources and arbitrary components of the service, which may be written in different programming languages and contain multiple binary third-party packages whose source code is not available or with complex dependencies, manual instrumentation of the application is prohibitively difficult, expensive, and time-consuming.

This paper presents the design and implementation of FINELAME (Fin-Lahm), a practical framework for detect-

ing ADoS attacks. In FINELAME, users only need to annotate their own code to mark the start and end of request processing; in many cases, annotations are not even required as applications lend themselves naturally to this demarcation. Our interaction with the most recent Apache Web Server[1] and Node.js[2] versions, for example, involves tracing three and seven functions, respectively, and not a single modification in their source code. Based on the annotations, FINELAME automatically tracks CPU, memory, storage, and networking usage across the entire application (even during execution of third-party compiled binaries). It does so with low overhead and at an ultra-fine granularity, which allows us to detect divergent requests before they leave the system and while they are attempting to exhaust resources.

Enabling our approach is a recent Linux feature called extended Berkeley Packet Filter (eBPF). eBPF enables the injection of verified pieces of code at designated points in the operating system (OS) and/or application, regardless of the specific programming language used. The OS is a natural, *de facto* layer of resource arbitration, with extensive infrastructure and pluggable tooling for fine-grained resource monitoring and distribution. By interposing on key OS services, such as the network stack, the scheduler, and user-level memory management facilities, FINELAME can detect abnormal behavior in a unified fashion across the entire software stack at run time.

FINELAME consists of three synergistic components that operate at the user/kernel interface. The first component allows attaching application-level interposition probes to key functions responsible for processing requests. These probes are based on inputs from the application developers, and they are responsible for bridging the gap between application-layer semantics (*e.g.*, HTTP requests) to its underlying operating system carrier (*e.g.*, process IDs). Examples of locations where those probes are attached include event handlers in a thread pool. The second component attaches resource monitors to user or kernel-space data sources. Examples of such sources include the scheduler, TCP functions responsible for sending and receiving packets on a connection, and the memory manager used by the application. To perform anomaly detection, a third component deploys a semi-supervised learning model to construct a pattern of legitimate requests from the gathered data. The model is trained in the user space, and its parameters are shared with the resource monitors throughout the system, so that anomaly detection can be performed in-line with resource allocation.

In summary, we make the following contributions:

- A novel, backward-compatible architecture at the user/kernel interface for transparently implanting resource monitors, exposed to applications via a probe API.

[1] 2.4.38 at the time of this writing

[2] v12.0.0-pre, 4a6ec3bd05e2e2d3f121e0d3dea281a6ef7fa32a on the Master branch at the time of this writing

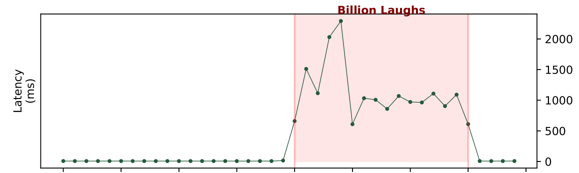

Fig. 1: Billion Laughs (XML Bomb) Attack. Under a normal load of about 500 requests per second, legitimate users experience a median of 6.75ms latency. After a short period of time, we start a malicious load of 10 requests per second (shaded area). XML bombs can take up to 200ms to compute (*vs.* a median of about 60*ns* for normal input). As a results, legitimate requests get serviced much slower, experiencing up to 2s latency. Setup details covered in (§6).

- A library of resource monitors and associated probes that can be used to detect asymmetric DoS attacks.
- An eBPF-based implementation and evaluation of FINELAME on Linux.

Our evaluation shows that FINELAME requires low additional instrumentation overhead, requiring between 4-11% additional overhead for instrumenting web applications ranging from Apache, Node.js, and DeDOS [15]. Moreover, when evaluated against real application-layer attacks such as ReDOS [5], Billion Laughs [3], and SlowLoris [46], FINELAME is able to detect the presence of these attacks in near real-time with high accuracy, based on the attack deviation from normal behavior.

The rest of the paper is structured as follows: it first motivates FINELAME's goals by providing a brief overview of asymmetric DoS attacks (§2); it then lays out our threat model and assumptions (§3); it describes the FINELAME's design and its three component parts, (i) request mapping (§4.1), (ii) resource monitoring (§4.2), and (iii) anomaly detection (§4.3); it next details several prototype implementations (§5) and evaluates the FINELAME prototypes' intrusiveness, overheads and accuracy, using a combination of micro-benchmarks and real applications (§6); finally, it compares with prior work (§7) and concludes with a discussion of limitations and possible directions for future research (§8).

2 Motivation

We begin by showing via an example server-side application the operation of an ADoS attack, the limitations of current detection mechanisms, and design goals for our system.

2.1 Background on ADoS Attacks

Fundamentally, asymmetric DoS attacks are attacks that leverage application-specific behaviors to cause disproportionate harm to the system using comparatively low amount of attacker resources. They can target any layer of the stack and

any resource within the system. ADoS vulnerabilities are widespread and often affect entire software ecosystems [41]. We detail a few of them below.

Regular-expression DoS (ReDoS) [12, 13, 51]. ReDoS attacks target programs that use regular expressions. Attackers craft patterns that result in worst-case asymptotic behavior of a matching algorithm. An example pattern is `(a+)+`, which does not match any string of the form `a*X`, but requires the system to check 2^N decomposition of the pattern to reach that conclusion, where N is the length of the target string.

XML Bomb [3]. An XML bomb (or Billion-Laughs attack) is a malicious XML document that contains layers of recursive data definitions[3], resulting in quadratic resource consumption: a 10-line XML document can easily expand to a multi-gigabyte memory representation and consume an inordinate amount of CPU time and memory on the server. Fig. 1 illustrates the impact of XML bombs on the latency of requests on a susceptible server. Under normal operation, a load of 500 legitimate requests per second are served in less than 10 milliseconds each; under a low-volume attack of 10 XML bombs per second, the latency jumps up to more than two seconds. An XML bomb affects any serialization format that can encode references (*e.g.*, YAML, but not JSON).

Improper (de-)serialization [47, 52, 53]. This class of attacks encompasses those where malicious code can be injected into running services. These vulnerabilities are, unfortunately, common in practice, and they allow malicious users to, for instance, inject a `for (;;) {}` loop to stall a process indefinitely.

Event-handler Poisoning (EHP) [14]. Attacks like the preceding can be additionally amplified in an event-driven framework. In event-handler poisoning, attackers exploit the blocking properties of event-driven frameworks so that, when a request unfairly dominates the time spent by an event handler, other clients are further blocked from proceeding. Any slowdown, whether it is in the service itself or in its recursive layers of third-party libraries can contribute to this head-of-line blocking.

2.2 Design Goals

The attacks in the previous section highlight several goals that drive FINELAME's design (§4) and implementation (§5).

In-flight Detection. Actions often need to be taken while the offending requests are "in the work"—for example, when a single request can bring the system down (*e.g.*, cooperative scheduling) or when subsequent defenses cannot be deployed (*e.g.*, IP spoofing). DoS detection needs to catch such requests *before* they leave the system, by monitoring resource consumption at a very fine temporal and spatial granularity.

[3] For example, the first layer consists of 10 elements of the second layer, each of which consists of 10 elements of the third layer, and so on.

Resource Independence. ADoS attacks may target arbitrary system-level resources (CPU, memory, storage, or networking), and may even target multiple resources (*i.e.*, multi-vector attacks). A desirable solution needs to be agnostic to the resource and able to handle any instance of inordinate consumption.

Cross-component Tracking. Given the complex structure of modern applications, ADoS attacks can also cross the boundaries of the application's internal components or processing phases. For instance, if a request causes the triggering of a timeout to an event queue, resources consumed by the initial request parsing and the timeout should both be attributed to the same request.

Language Independence. Applications today combine several ready-made libraries, which are written in multiple programming languages and often available only as compiled binaries. Thus, DoS detection should remain agnostic to the application details such as the programming language, language runtime, and broader ecosystem (*e.g.*, packages, modules).

Minimal Developer Effort. Detection needs to impose minimal burden to developers and devops, who should benefit from DoS mitigation without having to study the application internals. Rather than presenting developers with an overabundance of configuration knobs, a DoS detection system should direct precious human labor at sprinkling applications with key semantic information utilized at runtime.

3 Threat Model

To be more concrete, FINELAME assumes the following about the attacker and the broader environment.

Threats. We consider a powerful remote attacker that (i) can send arbitrary requests to a service hosting a vulnerable application, (ii) has control over potentially all of the application's legitimate clients, and (iii) is aware of the application's structure and vulnerabilities, including exploits in its dependency tree. We do not distinguish between legitimate and malicious clients who intersperse harmful requests that attack resources with one or more benign requests. Specifically, any subset of hosts can send any number of requests that may or may not attack any subset of resources. We do not limit resources of interest to CPU; attackers can target memory, file descriptors, or any other limited resource in the host system. That means that attacks can take the form of a single client attempting to consume 100% of the CPU indefinitely, or of multiple attacks from multiple clients over many of the system's resources.

Assumptions. We assume (i) vulnerable but not actively malicious code, and (ii) that FINELAME sees at least some benign traffic. If all traffic is malicious from the beginning, in-flight detection and mitigation become less urgent, as anomalies become the norm, and the application owners should first

revise their deployment pipeline. We also assume that the resource utilization of request processing can be attributed to a single request by the end of each processing phase, even if the processing phases is split into multiple phases across different application components. As keeping a reference to the originating request is a natural design pattern, in all of the services we tested, a unique identifier was already available; in cases where there is no such identifier, one must be added, and we detail how to do so in section 4.

4 FINELAME Design

Figure 2 depicts the overall design of FINELAME. Conceptually, FINELAME consists of three main components:

- *Programmer annotations* that mark when a request is being processed. FINELAME requires only a few annotations, even for complex applications, to properly attribute resource utilization to requests.
- *Fine-grained resource monitors* that track the resource utilization of in-flight requests at the granularity of context switches, mallocs, page faults.
- A *cross-layer anomaly detection* model that learns the legitimate behavior and detects attacks as soon as they deviate from such behavior.

Programmers can use FINELAME by annotating their application with what we call *request-mappers*. These annotations delineate, for each component and processing phase, the start and end of processing, as well as the request to which resource utilization should be attributed. For example, in an event-driven framework, the beginning and the end of each iteration of the event handler loop should be marked as the start and the end of a request's processing, respectively.

At runtime, when FINELAME is installed on the host environment, FINELAME attaches small, low-overhead *resource monitors* to particular points in the application or operating system. The aforementioned request-mappers enable FINELAME to determine the request to which the resource consumed by a thread or process should be credited. In section 5, we detail our out-of-the-box FINELAME library of request-mappers and resource monitors for several popular cloud frameworks. Our library tracks the utilization of a range of key OS-level resources; however, programmers can further extend it with user-level resource monitors to track application-specific resources (*e.g.*, the occupancy of a hash table).

Finally, FINELAME's monitoring data is used to perform lightweight, inline anomaly detection. Resource monitors first feed data to a machine learning model training framework that computes a fingerprint of legitimate behavior. Parameters of the trained model are installed directly into the resource monitors, which evaluate an approximation of the model to automatically detect anomalous behavior on-the-fly. The end result of FINELAME is a system for high-accuracy, fine-grained, and general ADoS attack detection.

4.1 Request-mapping in FINELAME

Conceptually, there are three operations in request mapping:

- `startProcessing()`: This annotation denotes the start of a processing phase. Any resource utilization or allocations after this point are attributed to a new unique request.
- `attributeRequest(reqId)`: As soon as we can determine a unique and consistent request identifier, we map the current processing phase to that request. For instance, when reading packets from a queue, if the best consistent identifier for a packet is its 5-tuple, resource tracking would start as soon as the packet is dequeued, but would only be attributed to a consistent request ID after Layer-3 and Layer-4 processing are completed. In general, `attributeRequest(reqId)` is called directly after `startProcessing()`, and depending on the specific of the application, the two can sometimes be merged (§ 5).
- `endProcessing()`: Finally, this operation denotes the completion of processing, indicating that subsequent utilization should not be attributed to the current request.

In order for the resource monitors to properly attribute utilization to a request, FINELAME requires programmers to annotate their applications using the above three *request mapping* operations. Ideally, the annotations should cover as much of the code base as possible; however, not all resource utilization can be attributed to a single request. In such cases, programmers have flexibility in how they perform mapping: for true application overhead—rather than request processing overhead—utilization can remain unattributed, and for shared overhead (*e.g.*, garbage collection), utilization can be partitioned or otherwise assigned stochastically.

Every request is given an identifier that must be both unique and consistent across application components and processing phases. This identifier is used to maintain an internal mapping between OS entity (process or thread) and the request. Example identifiers include the address of the object representing the request in the application, a request ID generated by some application-level tracing solution [7, 20, 29, 34, 45, 49, 55], or a location in memory if the request is only processed once. From the moment a `startProcessing` annotation is called to the moment the `endProcessing` annotation is called, FINELAME will associate all the resources consumed by the OS entity to the request.

An optimization of this technique can be implemented when the application lends itself naturally to such mapping

Fig. 2: FINELAME overview. Key elements: (1, right) user and kernel data-collection probes at points where an HTTP request interacts with resource allocation; (2, mid-left) a data structure shared between user and kernel space, that aggregates and arranges collected data; (3, left) a userspace training component that instantiates model parameters, fed back to the probes. Information flow between 1–3 is bidirectional.

between OS entity and request. For instance, event-driven frameworks or thread-pool based services usually have a single or small number of entry points for the request, to which FINELAME can readily attach request-mappers via eBPF without source code modification. We found this optimization to be the common case, and FINELAME does not require any modification to the application we explore in section 6.

4.2 Resource Monitoring in FINELAME

Resource tracking between `startProcessing` and `endProcessing` annotations are done via a recent Linux kernel feature called eBPF. We first provide some background on the operation of eBPF, and then discuss how we utilize it to perform extremely fine-grained resource monitoring of in-flight requests.

4.2.1 Background on eBPF

The original Berkeley Packet Filter (BPF) [35] has been a long-time component of the Linux kernel networking subsystem. It is a virtual machine interpreting a simple language traditionally used for filtering data generated by kernel events. Notable use cases are network packets parsing with Tcpdump [56] and filtering access to system calls in the seccomp facility. In version 3.0 a just-in-time compiler was implemented, allowing for a considerable speedup of the processing of BPF programs by optimizing them on the fly.

In version 3.15, Alexei Starovoivtov significantly extended BPF (dubbing the new system “eBPF”). The new version has access to more registers and an instruction set mimicking a native RISC ISA, can call a restricted subset of kernel functions, and can share data from kernel-space to user-space through hash-like data structures. While eBPF is a low-level language, users can write programs in higher languages such as C (and even Python with the BCC project [2]) and generate eBPF code with compilers such as GCC and LLVM.

Generated programs are verified before being accepted in the kernel. The verifier imposes a set of strict constraints to eBPF programs to guarantee the safety of the kernel. Common constraints include the absence of floating point instructions, a limit of 4096 instructions per program, a stack size capped at 512 Bytes, no signed division, and the interdiction of back-edges in the program’s control flow graph (*i.e.*, no loops).

The ability of eBPF programs to be attached to both kernel and user-space functions and events, their extremely low overhead, and their ability to share data with user space without the need for any IPC or queuing mechanism make eBPF a prime candidate for implementing resource monitors in FINELAME.

4.2.2 Resource Monitor Architecture

FINELAME’s resource monitors are attached to various user- and kernel-space data sources (*e.g.*, the scheduler or TCP stack) and use the mapping described in section 4.1 to associate resource consumption to application-level workflow (*e.g.*, HTTP requests). A resource monitor requires the following information: the type and name of the data source, and potentially the path of its binary.

Our current prototype of FINELAME uses the features listed in Table 1. When executed, most resource monitors operate under the following sequence of actions: i) verify whether a request mapping is active for the current PID and exit if not; ii) collect the metric of interest (usually through the arguments of the function triggering it) and store it, time-stamped, in a shared data structure; and iii) perform anomaly detection on the request if the model’s parameters are available (see section 4.3).

The time a request spends executing instructions on a processor is represented by *cputime*. We instrument both the *scheduler_tick()* and the *finish_task_switch()* kernel functions, which are called at every timer interrupt and context switch, respectively, to either start a timer when a thread executing a registered request is scheduled for execution or collect the amount of CPU time consumed by the task swapped out. We instrument the *tcp_sendmsg()* and *tcp_rcleanbuf()* to collect *tcp_sent* and *tcp_rcvd*, the amounts of bytes sent and read from a TCP connection, respectively. To compute *tcp_idle_time*, which represents the period of inactivity from the sender on a TCP connection, we measure the time elapsed between two occurrences of *tcp_cleanup_rbuf()*. To monitor the heap memory consumption occasioned by the processing

Name	Description	Event	Type
tcp_idle_time	Inactivity time on a TCP connection	tcp_cleanup_rbuf	kernel probe
tcp_sent	Bytes sent through TCP connections	tcp_sendmsg	kernel probe
tcp_rcvd	Bytes received through TCP connections	tcp_cleanup_rbuf	kernel probe
cputime	Amount of CPU time consumed	scheduler_tick, finish_task_switch	kernel probe
malloc_memory	Bytes allocated through the *malloc* function	glibc_malloc	user probe
page_faults	Number of page faults events	exceptions:page_fault_user	kernel tracepoint

Tab. 1: Default resource monitors in FineLame.

of a request, we monitor the glibc *malloc* function. Applications where memory management is partly handled by the runtime (such as in Python) can be monitored in a similar fashion. Likewise, the model can be generalized to garbage collected languages. Finally, we monitor the page fault events in the application by attaching a resource monitor to the *exception: page_fault_user* kernel tracepoint. We observed in our evaluation that CPU time was the best discriminant for CPU based attacks, while connection idle time the best for slow attacks (such as Slowloris and RUDY).

The above default, general-purpose resource monitors in FineLame are sufficient for a large set of existing applications; however, it can be extended to all the kernel events available for tracing and probing, as well as user-level functions (to monitor application-level metrics). If any application-level metrics are required (such as data structure occupancy, counters, and so on), programmers can augment our resource monitors with custom eBPF programs attached to arbitrary probe points in either kernel- or user-space.

4.3 Attack Detection in FineLame

Detection algorithm. For fast detection, FineLame is designed to enable anomaly detection as close as possible to the resource allocation mechanism. Without a method for in-flight anomaly detection *in addition to* mechanisms for in-flight resource tracing, detection and mitigation of in-flight requests would not be possible.

This detection problem can be reduced to quantizing the abnormality of a vector in *n*-dimensional space. Once a sufficient amount of data has been gathered to compute a fingerprint of the legitimate requests' behavior, we can train an anomaly detection model. The model can span all the metrics collected by the resource monitors, allowing us to detect abuse on any of the resources of the system as well as cross-resource (multi-vector) attacks.

For the unsupervised version of this problem, the most popular methods take one of two approaches: distance-based or prediction-based. The former family of models aims to cluster known, legitimate data points and compute the distance of new data points to those clusters—distance that is used to quantify the anomaly. The latter family assumes the existence of a set of input data points that are correct, and learns a function representing those points. When a new point enters the system, the model computes the value of the learned function; the prediction error is then used to quantify the degree of

Fig. 3: FineLame anomaly detection. Pseudocode for FineLame's inline anomaly detection.

anomaly.

Because of the training complexity, prediction complexity, and required training data, many existing solutions in both distance-based and prediction-based categories are impractical to execute at fine granularity. For instance, the popular algorithm DBSCAN [18] is not suitable for FINELAME, as it requires us to evaluate the distance of new data points to all the possible "core" data points in the model. The amount of data points considered (and therefore the size of the model) is usually linearly proportional to the size of the training set. Some accurate approximations of DBSCAN have been proposed [22], but even with a small number of clusters, almost all of the training dataset still needs to be part of the model. Likewise, the performance of prediction-based models made on neural networks, such as Kitsune [38], is highly dependent on the depth and width of the model. The amount of parameters of such networks grows exponentially with the number and size of the hidden layers.

Given the above concerns, we chose to implement anomaly detection in FINELAME with K-means, a technique that allows us to summarize the fingerprint of legitimate requests with a small amount of data. In K-means, the objective function seeks to minimize the distance between points in each cluster. The model parameters are then the centroids and distribution of the trained clusters. In a typical use-case scenario, FINELAME is configured to perform only request monitoring for a certain amount of time, after which it trains k-means on the monitoring data gathered in user-space from the resource monitors shared maps. In practice, we found that a K value equal to the number of request types in the application yields a reasonable estimation of the different behaviors adopted by legitimate requests, while being a number low enough such as to contain FINELAME's overhead.

Model training and deployment. Gathering the training data is done by a simple look-up from the user-space agent to the shared eBPF maps holding the requests resource consumption data. Using those profiles, the user-space agent standardizes the data (center to 0 and cast to unit standard deviation). Subsequently, the agent trains K-means to generate a set of centroids representing the fingerprint of the good traffic. The parameters of the model, to be shared with the performance monitors, are then the cluster centroids, as well as the mean μ and standard deviation σ of each feature in the dataset, and a threshold value τ statistically determined for each cluster.

As described above, the performance monitors have limited computing abilities and do not have access to floating point instructions. Thus, they are designed to perform fixed point arithmetic in a configurable shifted space, and require FINELAME's to shift the model parameters in this space before sharing them. Using two precision parameters a and b, each datapoint is transposed in a higher space 10^a, and normalized such that the resulting value lies in an intermediate space 10^{a-b}, retaining a precision of $a-b$ digits. This means that during the normalization operation each parameter value x undergoes the following transformation: $x = \frac{(x*10^a)-(\mu*10^a)}{\sigma*10^b}$.

Node.js	9	64
DeDoS	2	21

Tab. 2: Intrusiveness of FINELAME, quantified.

Once standardized, the clusters' centroids as well as each feature's mean and standard deviation are shared with the resource monitors through eBPF maps. Upon availability of those parameters, the resource monitors update not only the resource consumption of existing requests, but also their *outlier scores*, a measure we use to quantify the degree of anomaly of a request. Due to the constraints imposed on eBPF programs—specifically, taking a square root is complex as we do not have access to loops—we choose the normalized L1 distance to the closest cluster as the outlier score. While being a crude measure, the L1 is equivalent to more complex norms as resource vectors are of finite dimension. It preserves information about which resource is abused, and it lets us set statistical thresholds to determine cut-off points used for flagging abnormal requests. The algorithm for this entire process is shown in Figure 3.

Finally, we note that because FINELAME is primarily designed toward the detection of resource exhaustion attacks, we allow the anomaly detection engine to maintain signed values for outlier scores. This means that requests that have not reached their expected legitimate amounts of resource consumption, and that would look abnormal in an absolute value setting, are not flagged as such. This is important because it highlights the fact that FINELAME is not geared toward volumetric attacks that aim to bring the system down with a vast amount of low consumption requests.

5 Use Cases and Implementation

To demonstrate the generality of FINELAME and the minimal developer effort required to use it, we apply FINELAME to three web platforms: Apache [1], which is estimated to serve ~40% of all active webpages; Node.js [4] a popular server-side JavaScript-based web server; and DeDoS [15] an open source component-based framework for building web services. Our prototype of FINELAME is available on https://github.com/maxdml/Finelame. Table 2 quantifies the programming effort required to write request-mappers for those three applications to use FINELAME.

Apache web server. Primarily written in C, Apache's request processing is implemented by Multi-Processing Modules (MPM). In the latest versions of Apache (2.x), requests are served by multiple processes which can have multiple

worker threads themselves; each thread handles one connection at a time.

When a request enters the system, an application-level (`conn`) object is created by the `core_create_conn` function to contain it before the request is dispatched to a worker thread. Subsequently, the request is processed by either the `ap_process_http_sync_connection` or the `ap_process_http_async_connection` functions, which take the `conn` object as argument. From FINELAME, we attach one request-mapper to `core_create_conn`, and two requests-mappers to the http processing functions, one over a *uprobe* called upon entering the function, the other over a *uretprobe* called when returning from it. We exploit the `conn` object to generate a unique identifier for each request and map it to the underlying thread worker, so that resource monitors can later gather resource consumption data on the request's behalf. The mapping is undone when the function returns and the request exits the system. When a worker thread executes a new request, the request-mapper updates the mapping with the new request's ID. This solution requires no modification to the Apache source code, and 41 lines of eBPF code over 5 probes.

Node.js required more slightly more instrumentation due to its asynchronous model, which offloads work to a worker pool (implemented with *libuv* [30]). The instrumentation required eBPF probes to be attached to seven user-space functions within the libuv library. As in Apache, we found a data structure—`struct uv_stream_t`—that could (i) be used to generate a unique identifier, and (ii) was carried consistently across the disparate components of the framework.

Request-mappers were applied to the seven libuv functions as follows:

- `uv_accept`: a new request is initialized, and is associated with the `uv_stream_t` structure that handled communication with the client.
- `uv__read` and `uv__write`: the request associated with the client's stream is assigned to the current thread for the duration of the function.
- `uv__work_submit`: the request assigned to the current thread is associated with a work-request submitted to the worker pool.
- `uv__fs_work`, and `uv__fs_done`: the request associated with the work-request is assigned to the current (worker) thread.
- `uv_async_send`: the request is unassigned from the current thread.

Again, this solution requires no changes in Node.js source code, only knowledge of which functions are processing requests. The request-mappers totalized 64 lines of eBPF code.

DeDoS is an event-driven framework where programmers write and deploy their application as software components that are automatically allocated and deallocated based on demand. Each of those components monitor a local event-queue from which new requests are consumed. Unifying the disparate components is a generic event-handling function (`receive()`). Programmers implement their component's functionality inside this event-handling function.

DeDOS provides request tracing and explicitly tracks the passing of requests between components. We chose DeDoS as a proof-of-concept proxy for micro-service, event-driven applications providing request tracing capability. In these types of applications, annotation is simple as FINELAME can maintain a direct mapping between the application-level unique request identifier and the event handler's thread PID in order to track resource consumption across component boundaries. FINELAME traces only the `receive()` function class with request mappers, and does not require modifications to the framework. The request-mappers require 21 lines of eBPF code.

6 Evaluation

In this section, we present our evaluation results of FINELAME. Our evaluation is centered around the following aspects of the system:

- **Overhead.** The overhead of FINELAME compared to no monitoring, or in-application instrumentation
- **Accuracy.** The ability of FINELAME to accurately detect real attacks never seen yet by the application

6.1 Experimental setup

We present the setup on which we evaluate both the overhead and accuracy aspects of FINELAME. In all cases, the server applications are running on a 12 cores Xeon Silver 4114 at 2.20GHz , while our legitimate and attack clients are running on an Intel Xeon E5-2630L v3 at 1.80GHz. Both server and client machines have a total of 62G of RAM, and have hyper-threading and DVFS disabled.

We use version 2.4.38 of Apache, and configure it to use 50 worker threads. We use version $12.0.0 - pre$ of Node.js with the default configuration of 4 worker threads for libuv. Both Apache and Node.js are configured to serve a set of Wikipedia [59] pages. Node.js parses a regular expression provided in the request's URI to find the path of the file to serve. It's parser, *liburi*, is vulnerable to the ReDoS attack. All the applications impose a timeout of 20 seconds on connections. We deploy a simple webserver in DeDoS which can process three types of requests: serve a Wikipedia article, process a randomly generated XML file uploaded in a POST request, and parse a regular expression. The server is decomposed into

several software components: socket reading, HTTP parsing, file serving, XML parsing, regular expression parsing, and response writing. The XML parser is implemented with *libxml2*, which is vulnerable to the Billion Laughs attack.

Our good traffic is generated by Tsung [6] and explores evenly all the servers' exposed endpoints; bad traffic is generated by an in-house **C** client for the ReDoS and Billion Laughs attacks, and pylorys [23] for the Slowloris attack. Tsung generates load under an exponential distribution centered on a configurable mean, while our attack client is configured to send a fixed load.

6.2 Overhead of FINELAME

Figures 4 presents the overheads incurred by FINELAME's instrumentation on Apache, Node.js and DeDoS. In all of our experimental setups, we evaluate the legitimate client latency experienced when the server is not instrumented, when it is instrumented by FINELAME, and when FINELAME's resource monitors are also performing anomaly detection (FINELAME +). The load is as described earlier in sec 6.1, and explore all the instrumented paths in the applications. We also evaluate the cost of instrumenting the DeDoS framework itself to evaluate FINELAME overheads compared to a traditional user-space solution. The bars plot the median of the clients latency, and all our experiments are run thrice for a period of 100 seconds. In the case of Node.js the instrumentation cost adds 8.55% overheads and adding anomaly detection 9.21%. In the case of Apache, FINELAME adds 11.38% and 11.72% overheads respectively. In the case of DeDoS, the baseline latency is higher than with the two previous services, due to the fact that the application is not only serving files but also parsing POST requests, and also the framework is less optimized than the two battle-tested Apache and Node.js. Instrumenting directly the framework comes with an overhead of 2.9%, while FINELAME comes with 4.23% overheads, 6.3% if also performing anomaly detection.

In general we observe that the overheads incurred by FINELAME are higher when the baseline processing time of the service is low, and does not grow linearly with the complexity of the application. In addition, we found that performing anomaly detection in addition to monitoring resource consumption almost comes for free.

6.3 Performance of FINELAME

https://www.overleaf.com/project/5c22751775031d099f528e64 Our performance evaluation of FINELAME is centered around its ability to detect attacks requests before they exit the system, while providing accuracy competitive with non-approximated user-level algorithms.

6.3.1 Attacks

Our experiments aim to quantify the impact of attacks on quality of service. Consequently, we tune attacks strength such that they will not bring down the server but rather degrade the quality of service provided to legitimate users.

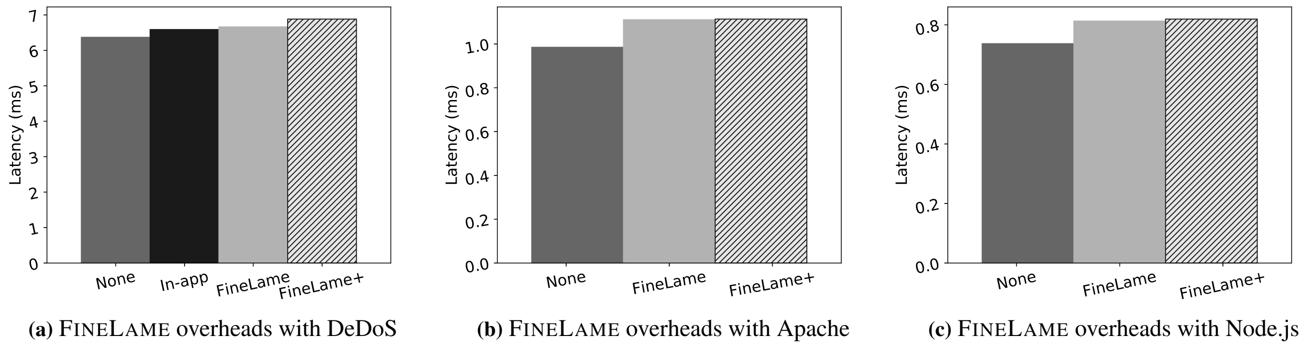
ReDoS: This attack consist of specially crafted regular expressions which are sent to the server for processing. The strength of the attack grows exponentially with the number of malicious characters present in the expression. Because the application processing units are busy handling those requests, legitimate requests get queued for a longer period of time, and ends-up being responded to more slowly.

Billion Laughs: The attack consists of XML files filled with several levels of nested entities. The parsing cost is exponentially proportional to the depth of the document. The impact is similar to the ReDoS attack.

SlowLoris: The attack consists in maintaining open connections to the server, keeping them alive by sending individual HTTP headers at a regular interval smaller than the server's timeout, but never completing the request—we assume that the attacker is able to probe the service and discover this timeout. As a result, the server's connection pool gets exhausted, and it can't answer new requests. This technique can also implement a dormant attack which cripples the ability of the server to handle surges of legitimate traffic, by denying a fraction of the total connection pool.

6.3.2 Anomaly Detection Performance

Evaluation metrics As is common with anomaly detectors, the output of FINELAME is a score which quantifies the abnormality of a request. This score is then either used as a raw metric for mitigation algorithms, or compared against a threshold τ to be transformed into a binary variable where 0 means negative (no anomaly), and 1 means positive (attack). With τ set, and using our knowledge of the ground truth, we can determine the accuracy of each of the detector's outputs as true/false positive/negative. The choice of τ is crucial, as too low a value can result in a large amount of false positive, while too high a value can induce a large amount of false negative. For our experiments, we set τ to be the outermost point for each cluster in the training set, *i.e.*, the most consuming legitimate request we've seen so far for the cluster. The challenge associated with deriving a large τ from the training traffic is that attacks can now take longer to detect—and might not be detected at all if they are too weak. This latter case does not concern us, because to bring down the system with weaker attacks, an attacker would be forced to change its method from asymmetric to volumetric. The benefit of a higher τ is that it helps decreasing the False Positive Rate (FPR, $\frac{FP}{FP+TN}$), a desirable behavior for operators using the system. For our experiments, we present the True Positive



(a) FINELAME overheads with DeDoS **(b)** FINELAME overheads with Apache **(c)** FINELAME overheads with Node.js

Fig. 4: Overhead of FINELAME with various applications

Rate (TPR, $\frac{TP}{TP+FN}$), True Negative Rate (TNR, $\frac{TN}{TN+FP}$) and F1 ($\frac{2TP}{2TP+FP+FN}$). TPR evaluates the system's ability to detect all the attack requests. TNR evaluates its ability to evaluate legitimate requests as such. The F1 score is the harmonic mean of the TPR and the recall. It evaluates both the TPR and the precision of the system.

In addition to its post-hoc instrumentation abilities and low programmer burden, the main contribution of FINELAME is it's detection pace. We evaluate the *Detection Speedup* (DS) of the system, which we define as being the delta between the time of last detection and the time to first detection, over the lifetime of the request. We expect DS to increase as users set more strict thresholds (lower values of τ), but found that even with τ set to the outermost point in each training cluster, FINELAME is able to detect attacks up to more than 97% faster.

Experiments All our experiments are run for a duration of 400 seconds, split into 3 phases. The first phase sees only legitimate traffic flowing through our target applications, and last 200 seconds. FINELAME is configured to only have the performance monitors gather data for the first 180 seconds, after which point it triggers the training of the anomaly detection model and share its parameters. Attacks start at time 200, and last for 150 seconds. A final period of 50 seconds sees the attack stop, and only good traffic is sent to the application. We perform two CPU exhaustion attacks, Billion Laughs and ReDoS, as well as a connection pool exhaustion attack, SlowLoris. For all experiments, we compare the TPR and TNR of FINELAME to a non approximated user-space implementation of K-means (that is, with floating point arithmetic) to confirm that the system is competitive with more complex user space solutions. We set $K = 3$, the maximum number of request types that the application we setup can accept, and use $a = 10$ and $b = 6$ factor to retain 4 digits in fixed point arithmetic.

Table 3 presents the detection speed and performance of FINELAME.

ReDoS: In our first experiment, we attack Node.js with three strengths of ReDoS requests. In the two first experiments, the workload is made of 98% of benign requests and 2% of malicious regular expressions blocking the event loop of the server (about 500 and 10 r/s, respectively). In the third experiment, with the strongest attack, we reduce the attack rate to 1 r/s, such that the attack does not bring down the server. Legitimate requests are served in about 0.8ms on average under normal conditions, but get delayed in proportion of the intensity of the ReDoS requests when the attack starts. During the first attack, bad requests are served in 23ms on average, a 28.75× increase compared to normal requests. Good requests are also penalized and are served in about 4ms. During the second attack, bad requests are served in 45.6ms on average, a 57× increase compared to normal requests. Legitimate requests are affected and incur an average latency of 13.5ms. During the third attack, bad requests are served in 90.9ms on average, a 113.6× increase. Legitimate requests incur an average latency of 6ms. Due to its ability to credit requests' resource consumption at the granularity of context switches, in both experiments, FINELAME is able to detect attack requests before they exist the system, at least 80.9% earlier for 50% of the bad traffic, and up to 95.3% earlier. The user-space, non-approximated evaluation of k-means using the L2 norm for measuring distances, perform only marginally better.

Billion Laughs: In this experiment, we attack DeDoS with two different strengths of Billion Laughs (XML bomb) requests. The good traffic follows a diurnal pattern, oscillating between 250 and 750 requests per second. Under normal conditions, legitimate requests are served in 6.87ms on average. In the first experiment, we send 15 malicious requests per seconds (about 2% of the peak legitimate traffic, and 6% of the lower phase), which are served in 29.28ms on average, a 4.26× increase in response time. In the second experiment, we decrease the number of bad requests to one per second (about 0.1% and 0.4% of the peak and low traffic, respectively), and increase their intensity such that they are served in 203ms in average (an order of magnitude increase compared to the first case), which represents a 29.55× increase

Attack	Strength	TPR		TNR		F1		DS		
		FL	K-means L2	FL	K-means L2	FL	K-means L2	median	75th	max
ReDoS	28.7×	100%	100%	99.995%	99.999%	99.88%	99.98%	80.9%	81.2%	83.2%
	57×	100%	100%	99.993%	99.994%	99.81%	99.83%	90.4%	90.5%	91.0%
	113.7×	100%	100%	99.997%	99.999%	99.29%	99.76%	90.9%	95.1%	95.3%
Billion Laughs	4.7×	100%	100%	100%	100%	100%	100%	83.1%	85.5%	87.7%
	34.8×	100%	100%	99.998%	99.998%	99.53%	99.76%	97.0%	97.1%	98.2%
SlowLoris	5 sockets	100%	100%	100%	100%	100%	100%	75%	n/a	n/a

Tab. 3: FINELAME TPR, and detection Speedup for Apache, Node.js and DeDoS.

in load compared to legitimate requests in normal conditions. For the weaker attack, FINELAME is able to detect malicious requests 78.83% faster than the user-space solution, at least 50% of the time, and up to and 97% faster for the strongest attack.

SlowLoris: In this experiment, we configure Apache to handle requests with 25 worker threads, and timeout on reading HTTP headers after 20 seconds. We configure the attack client to maintain 5 connections to the server opened at all times, refreshing it every 5 seconds. Effectively, this drives the *tcp_idle_time* of the malicious request high and makes them standout from the legitimate ones. This attack is "all or nothing", in the sense that it will not impact the legitimate requests until the connection pool gets exhausted. FINELAME's is able to detect the abnormal idle time about 75% faster than the application ($1 - \frac{5}{20} * 100$), which would have otherwise to experience the timeout before reporting the request.

7 Related Work

Volumetric Attack Detection There is a large body of work addressing volumetric DoS attacks [10, 26, 31, 40, 60–62], including attacks that target the network [27, 28, 54]. As described earlier (§1), these systems do not protect against *asymmetric* DoS attacks, a concern shared by both industry [32, 50] and academia [13, 14, 51].

Application-based Detection Prior works on application-layer DoS detection either depend heavily on repeated outliers, or are often deeply tied to a specific application. Techniques include comparing the entropy of offending and legitimate traffic [39, 63], sampling traffic flows [25], and sketch-based feature-dimensionality reduction [58]. While these techniques work well for volumetric attacks, they have self-assumed limitations when the attack traffic is low—the primary focus of this paper.

DSHIELD [44] is a system that assigns "suspicion scores" to user sessions based on their distance from legitimate session. While similar in nature to FINELAME's anomaly detection technique, it relies on the operator knowing all the possible classes of requests that the server can process. FINELAME anomaly detection engine learns on legitimate requests so that it does not depend on *a priori* knowledge of execution paths or vulnerabilities.

BreakApp [57] is a module-level compartmentalization system that attempts to defend against DoS attacks, among other threats stemming from third-party modules. While BreakApp's capabilities increase with more and smaller modules, FINELAME works even with monolithic applications entirely developed as a single module. BreakApp's mitigation uses simple queue metrics (*i.e.*, queue length at the module boundary *vs.* replica budget), whose cut-off parameters are statically provided by the programmer; FINELAME uses a more advanced learning model, which parameters are adjusted at runtime.

Rampart [36] focuses on asymmetric application-level CPU attacks in the context of PHP. It estimates the distribution of a PHP application function's CPU consumption, and periodically evaluates running requests to assess the likelihood they are malicious. It then builds filters to probabilistically drop offenders—repeated offenders increase their probability of being filtered out. While FINELAME profiles legitimate requests resource consumption, it is not limited to CPU-based attacks. It also works with applications with components built with many different languages.

In-kernel Detection Recent work has shown good results for mitigating ADoS attacks by exploiting low level system metrics. Radmin [16] and its successor Cogo [17] train Probabilistic Finite Automatas (PFAs) offline for each resource of a process they want to monitor, then perform anomaly detection by evaluating how likely the process' transition in the resource space is. Training the PFAs requires days in Radmin, and minutes in Cogo, while FINELAME can train accurate models in seconds or hundreds of microseconds. We expect this capability to be helpful in production systems where the model has to be updated, *e.g.*, to account for changes in an application's component. In addition, Cogo reports detection time in the order of seconds, while FINELAME's inline detection operates at the scale of the request's complexity—milliseconds in our experiments. Lastly, Radmin/Cogo operate at the granularity of processes/connections. FINELAME assumes a worst-case threat model where malicious requests are sent sporadically

by compromised clients, and thus operate at this granularity. Per-request detection has the added benefit to enable precise root cause analysis, further enhancing the practicality of FINELAME.

Programmer Annotations Prior work proposes an annotation toolkit that programmers can use in their code to specify resource consumption requirements [42]. The framework detects connections that violate the provided specification (and then attempts to mitigate by rate limiting or dropping them). Unfortunately, it requires knowledge of the application internals. Worse even, it expects developers to understand the program's expected resource consumption quite accurately. Moreover, such a hard cut does not distinguish between occasional consumption that is slightly above limits and true attackers.

Prevention-as-a-Service A recent vein of work proposed "Attack prevention as a Service", where security appliances are automatically provisioned at strategic locations in the network [19, 37]. Those techniques are largely dependent on attack detection (to which they do not provide a solution), and thus are orthogonal to our platform, which operates directly at the victim's endpoint.

Performance anomaly detection ADoS attacks are a subset of the broader topic of performance degradation, a topic that has been extensively studied. Magpie [9] instruments an application to collect events from the entire stack and obtain request profiles *post-mortem*. X-trace [21] is a tracing framework that preserves causal relationship between events, and allow the offline reconstruction of request trees. X-ray [8] builds on taint-tracking to provide record and replay system to summarize the performance of application events offline. One of FINELAME's key difference with those systems is its lightweight in-flight profiling technique, which allows us to perform anomaly detection while the request is still in the system. Retro [33] provides a tracing architecture for multi-tenant systems that enables the implementation of resource management policies. While its architecture is similar to FINELAME's, its focus is on performance degradation caused by competing workloads, rather than the detection of degradation within a single application.

While the impact can be similar, we note that for ADoS attacks, in-flight request tracking is critical to timely detection and mitigation.

8 Conclusion

In this paper, we describe and evaluate FINELAME, a novel fine-grained application-level DoS detection framework. FINELAME is designed for interaction with modern distributed applications, operates orders of magnitude faster than previous techniques, and is able to detect yet-unseen attacks on an application. FINELAME is enabled by recent advances in the Linux kernel, and bridges the gap between application-layer semantic and low-level resource allocation sub-systems. It is a first step toward deploying complex machine learning applications for fine grained services, in an era where the size of services is shrinking (micro/pico-services).

SemperOS: A Distributed Capability System

Matthias Hille[†] Nils Asmussen[† *] Pramod Bhatotia[‡] Hermann Härtig[† *]
[†]*Technische Universität Dresden* [‡]*The University of Edinburgh* [*] *Barkhausen Institut*

Abstract

Capabilities provide an efficient and secure mechanism for fine-grained resource management and protection. However, as the modern hardware architectures continue to evolve with large numbers of non-coherent and heterogeneous cores, we focus on the following research question: *can capability systems scale to modern hardware architectures?*

In this work, we present a scalable capability system to drive future systems with many non-coherent heterogeneous cores. More specifically, we have designed a distributed capability system based on a HW/SW co-designed capability system. We analyzed the pitfalls of distributed capability operations running concurrently and built the protocols in accordance with the insights. We have incorporated these distributed capability management protocols in a new microkernel-based OS called SEMPEROS. Our OS operates the system by means of multiple microkernels, which employ distributed capabilities to provide an efficient and secure mechanism for fine-grained access to system resources. In the evaluation we investigated the scalability of our algorithms and run applications (Nginx, LevelDB, SQLite, PostMark, etc.), which are heavily dependent on the OS services of SEMPEROS. The results indicate that there is no inherent scalability limitation for capability systems. Our evaluation shows that we achieve a parallel efficiency of 70% to 78% when examining a system with 576 cores executing 512 application instances while using 11% of the system's cores for OS services.

1 Introduction

Capabilities are unforgeable tokens of authority granting rights to resources in the system. They can be selectively delegated between constrained programs for implementing the principle of least authority [48]. Due to their ability of fine-grained resource management and protection, capabilities appear to be a particularly good fit for future hardware architectures, which envision byte granular memory access to large memories (NVRAM) from a large numbers of cores (e.g. The Machine [31], Enzian [18]). Thereby, capability-based systems have received renewed attention recently to provide an efficient and secure mechanism for resource management in modern hardware architectures [5, 24, 30, 36, 44, 64, 67].

Today the main improvements in compute capacity are achieved by either adding more cores or integrating accelerators into the system. However, the increasing core counts exacerbate the hardware complexity required for global cache coherence. While on-chip cache coherence is likely to remain a feature of future hardware architectures [45], we see characteristics of distributed systems added to the hardware by giving up on global cache coherence across a whole machine [6, 28]. Additionally, various kinds of accelerators are added like the Xeon Phi Processor, the Matrix-2000 accelerator, GPUs, FPGAs, or ASICs, which are used in numerous application fields [4, 21, 32, 34, 43, 60]. These components also contribute to the number of resources an OS has to manage.

In this work, we focus on capability-based systems and how their ability to implement fine-grained access control combines with large systems. In particular, we consider three types of capability systems: L4 [30], CHERI [67] (considered for The Machine [31]), and M^3 [5] (see Section 2.1). For all these capability types it is not clear whether they will scale to modern hardware architectures since the scalability of capability systems has never been studied before. Also existing capability schemes cannot be turned into distributed schemes easily since they either rely on centralized knowledge, cache-coherent architectures, or are missing important features like revocation.

Independent of the choice which capability system to use, scaling these systems calls for two basic mechanisms to be fast. First, it implies a way of concurrently updating access rights to enable fast decentralized resource sharing. This means fast *obtaining* or *delegating* of capabilities, which acquires or hands out access rights to the resources behind the capabilities. The other performance-critical mechanism is the revocation of capabilities. *Revoking* the access rights should be possible within a reasonable amount of time and with minimal overhead. The scalability of this operation is tightly coupled to the enforcement mechanism, e.g. when using L4 capabilities the TLB shootdown can be a scalability bottleneck.

We base our system on a hardware/software co-designed capability system (M^3). More specifically, we propose a scalable distributed capability mechanism by building a multikernel OS based on the M^3 capability system. We present a detailed analysis of possible complications in distributed capability systems caused by concurrent updates. Based on this investigation we describe the algorithms, which we implemented in our prototype OS—the SEMPEROS multikernel.

Our OS divides the system into groups, with each of them being managed by an independent kernel. These independently managed groups resemble islands with locally managed resources and capabilities. Kernels communicate via messages to enable interaction across groups. To quickly find objects across the whole system—a crucial prerequisite for our capability scheme—we introduce an efficient addressing scheme.

Our system design aims at future hardware, which might connect hundreds of processing elements to form a powerful rack-scale system [28]. To be able to experiment with such systems, we use the gem5 simulator [14] Our evaluation focuses on the performance of the kernel, where we showcase the scalability of our algorithms by using microbenchmarks as well as OS-intensive real-world applications. We describe trade-offs in resource distribution between applications and the OS to determine a suitable configuration for a specific application. We found that our OS can operate a system which hosts 512 parallel running application instances with a parallel efficiency of 70% to 78% while dedicating 11% of the system to the OS and its services.

To summarize, our contributions are as follows.

- We propose a HW/SW co-designed distributed capability system to drive future systems. Our capability system extends M^3 capabilities to support a large number of non-cache-coherent heterogeneous cores.
- We implemented a new microkernel-based OS called SEMPEROS that operates the system by employing multiple microkernels and incorporates distributed capability management protocols.
- We evaluated the distributed capability management protocols by implementing the HW/SW co-design for SEMPEROS in the gem5 simulator [14] to run real applications: Nginx, SQLite, PostMark, and LevelDB.

2 Background

We first assess existing capability systems and explain the basic principles of M^3, which is the foundation of our work.

2.1 Capability Systems

The term capability was first used by Dennis and van Horn [20] to describe a pointer to a resource, which provides the owner access to the resource. There are three basic types of capabilities: (1) partitioned capabilities, which have been employed in multiple OSes such as KeyKOS [27], EROS [56] and various L4 microkernels [30,36,40,62], (2) instruction set architecture (ISA) capabilities, as implemented by the CAP computer [49] and recently revived by CHERI [67] and (3) sparse capabilities which are deployed in the password-capability system of the Monash University [2] and in Amoeba [63].

	L4	M^3	CHERI
Scope	Coherence Dom.	Machine	Address space
Enforcement	MMU / Kernel	DTU / Kernel	CHERI co-proc.
Limitation	Coherence Dom.	Core count	no revoke

Table 1: Classification of capability types.

Capabilities can be shared to exchange access rights. ISA capabilities and sparse capabilities can be shared without involving the kernel since their validity is either ensured by hardware or checked by the kernel using a cryptographic one-way function in the moment they are used. In contrast, sharing of partitioned capabilities is observed by the kernel.

To analyze capability systems regarding their scalability, we inspect their enforcement mechanism, their scope, and their limitation in Table 1. The three categories of capability systems in Table 1 represent a relevant subset of capability systems for the scope of this work: (1) L4 capabilities which are partitioned capabilities employed in L4 μ-kernels [30,36,40,62], (2) M^3 capabilities which are a special form of partitioned capabilities involving a different enforcement mechanism explained in the following, and lastly (3) CHERI capabilities which are ISA capabilities implemented by the CHERI processor [64,67].

L4 capabilities utilize the memory management unit (MMU) of the processor to restrict a program's memory access. Access to other resources like communication channels or process control are enforced by the kernel. Since L4 is built for cache coherent machines both the scope of a capability and the current limitation is a coherence domain.

In contrast, M^3 introduces a hardware component called data transfer unit (DTU) which provides message passing between processing elements and a form of remote direct memory access. Consequently, memory access and communication channels are enforced by the DTU and access to other system resources by the kernel. The DTU is the only possibility for a core to interact with other components. Hence it can be used to control a core's accesses to system resources via NoC-level isolation. (We will give a more detailed explanation of M^{3}capabilities in the following section.) Importantly, M^3 capabilities are valid within a whole machine spanning multiple coherence domains. However, M^3 is currently limited by using a single kernel core to control multiple application cores.

Lastly, the ISA capabilities of the CHERI system are enforced by a co-processor. CHERI capabilities contain a description of the resource, i.e., memory they point to. This information is used by the co-processor to determine the validity of accesses. The scope of a CHERI capability is an address space. Thus, such a system typically uses one address space for multiple applications. However, CHERI does not support revocation and therefore does not have the problem we are solving.

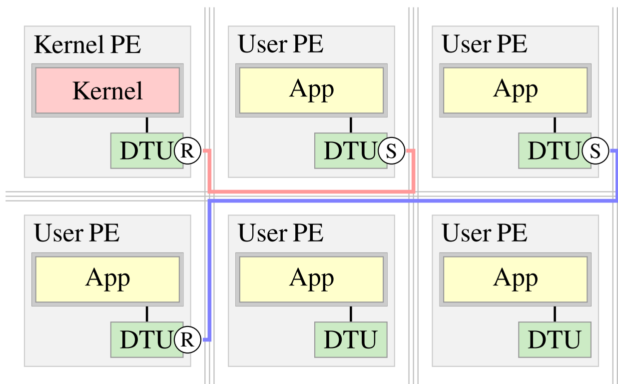

Figure 1: System architecture of M^3. Each processing element (PE) has a data transfer unit (DTU) connecting them to the network-on-chip. DTUs are configured by the kernel PE.

For both L4-style and M^3-style capabilities, scaling to larger systems and maintaining consistency demands the extension to multiple kernels and their coordination. For L4-style systems, multiple kernels are required to scale beyond coherence domains. For M^3-style systems, multiple kernels are required to scale to large core counts.

2.2 M^3: HW/SW Co-designed Capabilities

To accommodate for the hardware trends of growing systems without global cache coherence and an increasingly diverse set of processing elements, we chose M^3 as the foundation of our work. Additionally, M^3 already supports byte-granular memory capabilities including their (selective) revocation (in contrast to CHERI).

The hardware architecture of M^3 is depicted in Figure 1. The key idea of M^3 is to introduce a new hardware component next to each processing element (PE), which is used as an abstraction for the heterogeneity of the PEs, ranging from general purpose cores to accelerators. This hardware component is called data transfer unit (DTU). All PEs are integrated into a network-on-chip (NoC) as prevalent in current multi- and manycore architectures [15, 39, 60]. The DTU represents the gateway for the PE to access remote memory (memories in other PEs or off-chip memory such as DRAM) and to exchange messages with other PEs. As such, the DTU enables a different isolation mechanism, called *NoC-level isolation*, that does not require the PEs to possess hardware features like MMUs and privileged mode execution to ensure isolation. Instead, since all communication between the PEs and all memory accesses are performed via the NoC, controlling the access to the NoC suffices to control and isolate the PEs.

The M^3 kernel runs on a dedicated PE, called *kernel PE*. The M^3 kernel is different from traditional kernels because it does not run user applications on the same PE based on user/kernel mode and entering the kernel via system call, interrupt, or exception. Instead, the kernel runs the applications on other PEs, called *user PEs*, and waits for system calls in the form of messages, sent by the applications via the DTU (red communication channel in Figure 1). Because there is only a single privileged kernel PE in M^3 this kernel PE quickly becomes the limiting factor when scaling to large systems.

Data Transfer Unit (DTU). The DTU provides a number of *endpoints* to connect with other DTUs or memory controllers. Endpoints can represent send, receive or memory endpoints. Establishing communication channels requires to configure endpoints to these representations. This can only be done by a privileged DTU. Initially all DTUs in the system are privileged and get downgraded by the kernel during boot up. Only the DTU of the kernel PE remains privileged. The kernel is required to establish the communication channels between applications (blue in Figure 1) which can be used by applications later on without involving the kernel.

Operating system. The M^3 OS follows a microkernel-based approach, harnessing the features of the DTU to enforce isolation at NoC-level. So far, it employs a single kernel PE to manage the system. M^3 implements drivers and OS services such as filesystems as applications, like other microkernel-based OSes. The execution container in M^3 is called *virtual PE* (VPE), which represents a single activity and is comparable to a single-threaded process. Each VPE has its own capability space and the M^3 kernel offers system calls to create, revoke, and exchange capabilities between the VPEs.

Services on M^3. Services are registered at the M^3 kernel and offer an IPC interface for clients. Additionally, clients can exchange capabilities with services. For example, M^3's in-memory file system, *m3fs*, offers an IPC interface to open files and perform meta operations such as `mkdir` and `unlink`. To access the files' data, the client requests memory capabilities from m3fs for specific parts of the file. The client can instruct the kernel to configure a memory endpoint for the memory capability to perform the actual data access via the DTU, without involving m3fs or the kernel again. This works much like memory mapped I/O, but with byte granular access. Reading the files' data via memory capabilities without involving the OS lends itself well for upcoming non-volatile memory (NVM) architectures.

3 Design

Our design strives to build a scalable distributed capability management for an operating system that uses multiple kernels. An application's scalability depends on two OS components: the kernel itself, especially the capability subsystem, and the OS services, e.g. a filesystem service. To investigate distributed capability management we concentrate on the kernel. The kernel sets up communication channels and memory mappings. How a service implementation uses the kernel mechanisms depends on the type of service. A copy-on-write filesystem for example can be implemented efficiently on top of a capability system with a sufficiently fast revoke operation.

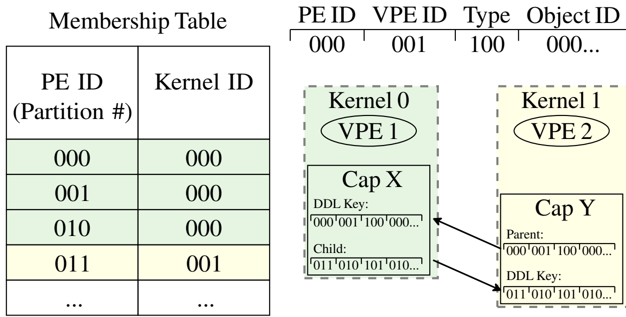

Figure 2: DDL addressing with globally valid DDL keys.

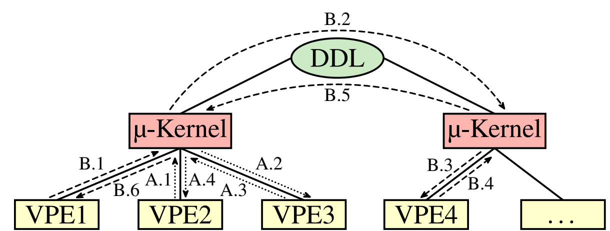

Figure 3: Two VPEs establish a communication channel. Sequence A shows the group-internal communication, whereas sequence B is group-spanning involving two kernels.

When an application performs a write it receives a mapping to its own copy of data and access to the original data has to be revoked. In a capability system with slow revocation it is questionable whether an efficient implementation of a copy-on-write filesystem is possible. The distributed capability system presented in this work shall lay a foundation for various service implementations, however, a discussion on the scaling of OS services is out of scope for this work.

3.1 System Overview

SEMPEROS employs multiple μ-kernels, each kernel running on a dedicated PE. This way we can distribute the handling of system calls to improve the scalability of the capability system. We use message passing as communication means between the kernels since we are not assuming a cache coherent system.

PE groups. To maintain a large number of PEs, we divide them into groups. Each group is managed by a single kernel; that means, every group has to contain at least one PE capable of executing a kernel. A simple general-purpose core is sufficient for this purpose. The group's kernel has exclusive control over all PEs of its group and manages the corresponding capabilities. The mapping of a PE's capabilities to a kernel is static in the current implementation of SEMPEROS because we do not yet support the migration of PEs. The unit of execution being scheduled on a PE is a virtual PE (VPE). A VPE is in general comparable to a process. All system calls of a VPE are handled by the kernel responsible for the PE, which the VPE is running on. If a system call does not affect any VPEs outside the group, only the group's kernel is involved in handling the request. Operations covering the VPEs of other groups involve their kernels as well. A more detailed view on the communication to handle system calls is given in Section 3.3.

Distributed state. The system state consists of the hardware components (available PEs), the PE groups, and the resource allocations and permissions, represented as capabilities. The capabilities represent VPEs, byte-granular memory mappings, or communication channels. Our high-level approach to manage the aforementioned kernel data is to store it where the data emerges and avoid replication as far as possible. Thereby, we minimize the shared state, which reduces the communication required to maintain the coherence.

3.2 Distributed Data Lookup (DDL)

The distributed data lookup is our capability addressing scheme and the mechanism to determine the location of kernel data. Each kernel object or capability which needs to be referable by other kernels is given a *DDL key* which acts as its global ID. In the top right corner of Figure 2 we illustrate how we split the key's value into several regions representing the following: the *PE ID* and *VPE ID*, denoting the creator of the object, and the *Type* and *Object ID*, describing the object itself. To clarify the concept the amount of digits is deliberately kept smaller than our system requires in practice. We use the PE ID to split the key space into multiple partitions. Each PE in the system is allocated to one such partition, which in turn are assigned to kernels individually. The mapping of partitions to the kernels designates the PE groups and is stored in a membership table which is present at each kernel and depicted on the left of Figure 2. To support the migration of PEs, in SEMPEROS, the mappings in the membership table would have to be updated at all kernels of the system However, our current implementation does not support migration yet.

With this addressing scheme we are able to reference objects, for example capabilities, across the whole system which is a key enabler for our capability scheme. The lower right part of Figure 2 illustrates how the relations between the capabilities are tracked by this means. It depicts a situation in which two applications, VPE 1 and VPE 2, are residing in different PE groups, thus managed by different kernels. The (simplified) excerpt of the kernels' internal capability mappings shows that VPE 1 has a capability Cap X and delegated it to VPE 2, which in turn created Cap Y. This group-spanning relation is tracked using the DDL keys.

3.3 System Call Handling

System calls are implemented by messages sent to the kernel PE. Some of the actions taken by the kernel receiving a system call involve agreement between the kernels depending on the involved VPEs. Hence, we divide the handling of system calls into group-internal and group-spanning operations. The different message sequences are outlined in Figure 3.

Group-internal operations. Sequence A in Figure 3 depicts the establishing of a communication channel between two

VPEs (2 & 3) in the same group. Such an operation only involves resources managed by a single kernel, thus it is called a group-internal operation. The sequence starts with a message to the kernel (A.1), which is the counterpart to the traditional mode switch. The connection request is forwarded to VPE3 (A.2) which then responds to the kernel. Depending on the response, the kernel hands out the appropriate capabilities and informs VPE2 (A.4). Once the endpoint for the exchanged communication capability is configured, the kernel is not involved in further communication.

Group-spanning operations. Sequence B in Figure 3 shows the message flow when VPEs of different PE groups establish a communication channel. The second kernel is involved in the operation because it is in charge of VPE4's capabilities. This is where our distributed capability protocol will be used. After receiving the system call in step B.1, the first kernel uses the DDL to determine which kernel is responsible for VPE4 in step B.2 and forwards the request. Steps B.3 and B.4 are identical to A.2 and A.3 of the group-internal operation. After these steps, the channel at VPE4's side is prepared which the first kernel indicates to VPE 1. As for the group-internal operations, the communication via the created channel does not involve the kernel anymore after the endpoint has been configured.

3.4 Capabilities

SemperOS employs capabilities for managing permissions. Each VPE has its own set of capabilities, describing the resources it can access. To share resources with other VPEs, capabilities can be exchanged. In SemperOS delegating a capability starts with a system call by the supplying VPE indicating to the kernel which capability should be delegated. The kernel makes a copy of the selected capability and adds that copy to the capability's children. The copied capability (the child) is handed over to the VPE which shall receive the new access rights. If the sharing is no longer desired, the access rights to the resource can be withdrawn recursively by revoking the capability. These operations require action of the kernel.

From the kernel's perspective, a capability references a kernel object, a VPE, and other capabilities. The kernel object is the resource this capability permits access to and the reference to the VPE (which is a kernel object of its own) tells the kernel who holds these access rights. Individual references to other capabilities are maintained to track sharing as is done by the mapping database in other microkernel-based systems [30, 36, 40, 62]. SemperOS keeps sharing information in a tree structure which is used to enable recursive revocation. In the capability tree, capabilities of different VPEs are interlinked, as indicated in Figure 2.

Challenges in a distributed setting. Capabilities are modified by multiple operations, requested via system calls from applications. For example, when creating a VPE, a capability to control the new VPE is delegated to the parent VPE. We call such actions *capability modifying operations* (CMO). Running a system with multiple independent kernel instances introduces new properties of capability handling:

1. Multiple CMOs can be in flight at the same time.
2. CMOs can involve the modification of capabilities owned by other kernel instances.
3. A capability managed by one kernel can reference a kernel object owned by another kernel.

The first property requires to assure that the modifications of one kernel do not overlap with changes of another kernel. The second and third property are results of our system's distributed nature. Resources such as a service, which is resembled by a service capability, could be used by VPEs of different PE groups. Consider the connection establishment to a service. Assuming that the service is controlled by kernel 1 and the connecting VPE by kernel 2, kernel 2 would create a session capability. A session can only be created between a client and a service; hence, the client's session capability is listed as a child of the service capability. This modification of the service capability's list of children involves the other kernel, because the service capability is owned by kernel 1.

Since capabilities are used to control access to resources, we host a capability at the kernel which owns the resource. Yet, this attribution is not always obvious. The example of a session capability illustrates the third property. One could argue, that the session is a resource which is used by both, the service and the client; thus, any of the two corresponding kernels could actually be responsible for the session. To avoid the overhead of coordination between multiple resource owners, we allow only one kernel to be the owner of a resource.

4 Implementation

SemperOS implements a distributed capability scheme with multiple kernels in order to scale to large numbers of PEs. We based SemperOS on M^3 [5]. SemperOS adds PE groups to the base system, requiring coordination of the kernels which we implement by so called inter-kernel calls explained in the following Section 4.1. Furthermore, SemperOS is implemented as a multithreaded kernel for reasons explained in Section 4.2. The transparent integration of the PE groups into a single system presented to the applications requires the kernels to implement a distributed capability system described in Section 4.3.

4.1 Inter-Kernel Calls

The system call interface of SemperOS did not change compared to M^3 though the action to be taken by the kernel changed to incorporate the coordination with other kernels. The kernels in SemperOS communicate via messages adhering to a messaging protocol. We call this type of remote procedure calls *inter-kernel calls*. These calls can be split into three functional groups: (1) messages to start up and shutdown kernels and OS services, (2) messages to create connections to the services in other PE groups, and lastly, (3) messages

used to exchange and revoke capabilities across PE-group boundaries. Messages of the last two groups are part of the distributed capability protocol.

The DTU, which is used to send and receive messages, provides only a limited number of message slots. If this limit is exceeded then the messages will be lost. To prevent this, we limit the number of in-flight messages between two kernels. We dedicate a certain number of DTU endpoints for the kernel-to-kernel communication, which also determines the maximum number of kernels supported by the system. We keep track of free message slots at each kernel to avoid the message loss.

4.2 Multithreaded Kernel

The kernel needs to split some operations, e.g. revocation or service requests across the PE groups, into multiple parts to prevent deadlocks. For instance, a revocation might run into a deadlock in the following situation: three capabilities are involved forming the capability tree: $A_1 \rightarrow B_2 \rightarrow C_1$. The index indicates the kernel which owns the capability. If A_1 is revoked, kernel 1 contacts kernel 2 which in turn contacts kernel 1 again to revoke capability C_1. If kernel 1 would block on the inter-kernel call to kernel 2, the system would end up in a deadlock because kernel 2 is waiting for kernel 1 to respond. While this can be implemented as an event-driven system, this involves the danger to loose the overview of the logical flow of complicated operations like the revocation.

Therefore, we decided to use cooperative multithreading within the kernel. This approach allowed us to implement such capability operations sequentially with dedicated preemption points in between, which made it comparatively easy to reason about the code. Note that, in contrast to simultaneous multithreading, SEMPEROS only executes one thread per kernel at a time because it executes on one single-threaded core. The preemption points do not only prevent deadlocks, but also allow to process other system calls or requests from other kernels until the suspended operation can be continued.

To prevent the denial-of-service attacks on the kernel, the kernel cannot spawn new threads on behalf of system calls. Instead, a fixed number of threads needs to suffice. We create a kernel's thread pool at start up. The size of the pool is determined by the number of system calls and kernel requests which can arrive at the same time. It is calculated as:

$$V_{group} + K_{max} * M_{inflight} \quad (1)$$

Since each VPE can issue only one system call at a time, the kernel needs one thread per VPE in its PE group, denoted as V_{group}. The number of kernel requests is limited by the maximum amount of kernels in the system, denoted as K_{max}, multiplied by the maximum number of in-flight messages between two kernels, denoted as $M_{inflight}$.

4.3 Distributed Capability Management

SEMPEROS uses capabilities to control the access to resources such as VPEs, service connections, send/receive endpoints and memory. Applications can *create*, *use*, *exchange*, and *revoke* capabilities. Creation means to create a new capability for a given resource (e.g., memory) and usage means to use a previously created capability without changing it (e.g., configure a DTU endpoint for a send capability). Exchanges and revokes are *capability modifying operations* (CMO), requiring the most attention. Exchanging capabilities allows two VPEs to share resources and it comes in two flavors: a capability can be *delegated* to another VPE, and *obtained* from another VPE. Capability exchanges can be undone with the revoke operation. Revocation is performed recursively, that is, if VPE V_1 has delegated a capability to VPE V_2, which in turn has delegated it to V_3 and V_4, and V_1 revokes its capability, it is revoked from all four VPEs.

As in other capability systems [30, 36, 40, 62], the recursive revoke requires a way to track former exchanges. The kernel uses a so-called *mapping database* for this purpose. In SEMPEROS each capability has a parent and a list of children to explicitly track all such links. These tree relations can span multiple kernels; hence, we use DDL keys to identify and locate the capabilities across all kernels. The mapping database is updated on every CMO. In a multikernel setting multiple CMOs can be started concurrently potentially involving the same capability. We next describe how inconsistent updates on the mapping database are prevented if multiple CMOs run in parallel.

4.3.1 Interference between CMOs

Exchanging a capability consists of two actions: (1) creating a new capability based on the donor's capability and (2) inserting the new capability into the capability tree. The latter requires to store a reference to the parent capability and to update the parent's list of children. Revoking a capability requires to revoke all of its children and to remove it from the parent's list of children. Both need to perform inter-kernel calls in case capabilities reside at other kernels, possibly leading to interference.

An important precondition for all operations is that messages between two kernels need to sustain ordering. More specifically, if kernel K_1 first sends a message M_1 to kernel K_2, followed by a message M_2 to kernel K_2, then K_2 has to receive M_1 before M_2.

Table 2 shows an overview of all combinations and their effects. The operation in the leftmost column is started first and overlaps with the operation in the topmost row. The following walks through the combinations and describes the effects.

Serialized. Overlapping exchange operations do not present a problem for our scheme because they serialize at one kernel. For example, if two VPEs obtain a capability from VPE V_1, these operations serialize at the kernel that manages V_1. In general, each VPE can only perform one system call at a time preventing two parallel delegates initiated by the same VPE.

1st \ 2nd	Obtain	Delegate	Revoke/Crash
Obtain	✓Serialized	✓Serialized	! Orphaned
Delegate	✓Serialized	✓Serialized	ϟ Invalid
Revoke	! Pointless	! Pointless	ϟ Incomplete

Table 2: Types of interference with overlapping CMOs.

However, during an exchange operation initiated by a VPE V_1 other VPEs could exchange capabilities with V_1, which again serializes at the kernel that manages V_1.

Orphaned. The obtain operation needs to ask the capability owner for permission before being able to obtain the capability. If the owner resides at a different kernel this requires an inter-kernel call. Before its completion nothing is changed in the obtainer's capability tree. However, the obtainer could be killed while waiting for the inter-kernel call. This leaves an orphaned child capability in the owner's capability tree, in case the owner agreed to the exchange. The orphaned capability cannot be accessed by anyone, but it wastes a bit of memory, which will be freed the latest when its parent capability is revoked.

Invalid. The delegate operation is similar to obtain regarding leaving the delegator's capability tree untouched until the inter-kernel call returns successfully. However, if the delegator is killed while waiting for the inter-kernel call, the receiving VPE might have already received the capability. This constitutes a problem, because the child of the capability in delegation does not yet exist in the delegator's capability tree. That is, although all capabilities of the delegator are revoked, the delegated capability stays valid at the receiving VPE.

Incomplete. The naive implementation of the revoke operation would simply perform a depth-first walk through the capability tree, remove local capabilities on its own and perform the inter-kernel calls to remove remote capabilities. However, if two revoke operations run in parallel on overlapping capability subtrees, this approach results in early replies to revoke system calls, that is, acknowledgements of incomplete revokes.

For instance, let us consider the following capability tree with the owning kernel as the index: $A_1 \rightarrow B_2 \rightarrow C_3$. If a VPE requests the revoke of A_1, kernel K_1 performs a call to K_2 to revoke the remaining part of the tree. If another VPE requested the revoke of B_2 in the meantime, K_2 does not know B_2 anymore, potentially leading to an early response to K_1. The reason is that K_2 might still be waiting for K_3 to revoke C_3. Since applications have to rely on the semantic that completed revokes are indeed completed, we consider this behavior unacceptable.

Pointless. The revoke operation requires inter-kernel calls if the capability tree spans multiple kernels. Hence, VPEs might request capability exchanges of not yet revoked capabilities within this tree. This does not lead to inconsistencies because these capabilities would be revoked as soon as the running revoke operation continues. However, the exchange is pointless because it is already known that the capabilities will be revoked afterwards.

4.3.2 Capability Exchange

This section details the capability exchange operations to address the problems described in the previous section. As already mentioned, the beginning of obtain and delegate is similar. If a VPE (V_1) requests an exchange, the corresponding kernel (K_1) checks whether the other party (V_2) is in the same PE group. If so, the operation is handled by K_1. If V_1 and V_2 are in different PE groups, K_1 forwards the exchange request to the second kernel (K_2). K_2 asks V_2 whether it accepts the capability exchange. If V_2 denies the exchange, the operation is aborted and a corresponding reply is sent to K_1. Otherwise, we distinguish between obtain and delegate:

(1) Obtain:. V_2's capability (C_2) will become the parent of V_1's new capability (C_1). Hence, C_1 will be added to C_2's list of child capabilities. Afterwards, K_2 sends a reply to K_1. As outlined previously, if V_1 was killed in the meantime, C_2 stays in the child capability list as an orphaned capability. To prevent a permanent memory waste, we let K_1 send a notification to K_2 on behalf of K_2's reply for the obtain operation in case V_1 was killed.

(2) Delegate: . K_2 creates a new capability (C_2) for V_2 with C_1 as its parent. If C_1 was revoked in the meantime, V_2's resource access through C_2 would be unjustified. To avoid this, we implement delegation with a two-way handshake. Instead of inserting C_2 into V_2's capability tree, K_2 only sends a reply to K_1. After that K_1 adds C_2 to C_1's list of children and sends an acknowledgement back to K_2 to actually insert C_2 into V_2's capability tree.

Note that the two-way handshake creates an orphaned capability if V_2 is killed while waiting for the acknowledgement of K_1. As for obtain, we handle this case by sending an error back to K_1 to allow a quick removal of the orphaned capability.

4.3.3 Capability Revocation

Like the capability exchange, the revocation requires inter-kernel calls in case the capability tree spans multiple kernels. To keep the kernel responsive it should not wait synchronously for the reply of another kernel. Instead, the revoke should be paused using the threading infrastructure introduced in Section 4.2. However, in contrast to the exchange operation, the number of inter-kernel calls for a revoke can be influenced by applications. For example, two malicious applications residing in different PE groups could exchange a capability back and forth, building a deep hierarchy of capabilities at alternating kernels. Revoking this capability hierarchy would lead to inter-kernel calls sent back and forth between the two kernels. Thus, the naive approach of spawning a new thread for every incoming revoke inter-kernel call cannot be used, because this would enable denial-of-service attacks. Our solution uses a maximum of two threads per kernel to avoid this attack.

To avoid acknowledgements of incomplete revokes, our algorithm uses two phases, similar to mark-and-sweep [46]. Algorithm 1 presents a high-level overview of the approach. The function `revoke_syscall_hdlr` is executed by the

kernel that receives the revoke system call. First, it calls `revoke_children`, which recursively marks all local capabilities and sends inter-kernel calls for remote capabilities. Each capability maintains a counter for outstanding kernel replies. If it encountered any remote capabilities, the function `wait_for_remote_children` waits for the kernel replies by pausing the thread.

The inter-kernel call is handled by `receive_revoke_request`, which will also call `revoke_children`. In this case, the thread will not be paused to stay at a fixed number of threads. Instead, the thread calls `receive_revoke_reply` in case there are no outstanding kernel replies and returns. The function `receive_revoke_reply` is also called whenever a reply to an inter-kernel call is received, which first updates the counter of the capability accordingly. If there are no further outstanding kernel replies, it deletes the capability tree starting at the given capability. Afterwards, it wakes up the syscall thread or sends a reply, depending on whether this kernel started the revoke operation or participated due to an inter-kernel call.

To keep the pseudo code brief it does not show how already running revocations for a capability are handled. In this case, `revoke_syscall_hdlr` will also wait for the already outstanding kernel replies to prevent acknowledgement of an incomplete revoke. Furthermore, the two phases allow us to immediately deny exchanges of capabilities that are in revocation, which prevents pointless capability exchanges.

Algorithm 1: Capability revocation

```
1  Function revoke_syscall_hdlr(capability)
2  |   revoke_children(capability)
3  |   wait_for_remote_children()
4  Function revoke_children(capability)
5  |   mark_for_revocation(capability)
6  |   foreach child of capability do
7  |   |   if child is local then
8  |   |   |   revoke_children(child)
9  |   |   else
10 |   |   |   send_revoke_request(child)
11 |   |   end
12 |   end
13 Function receive_revoke_request(capability)
14 |   revoke_children(capability)
15 |   receive_revoke_reply(capability) // see line 10
16 Function receive_revoke_reply(capability)
17 |   if all revoke requests are serviced then
18 |   |   delete_tree(capability)
19 |   |   if initiator then
20 |   |   |   notify_syscall_hdlr_thread()
21 |   |   else
22 |   |   |   send_revoke_reply()
23 |   |   end
24 |   end
```

Operation	Scope	SemperOS (cycles)	M^3 (cycles)	Increase
Exchange	Local	3597	3250	10.7%
Exchange	Spanning	6484	—	—
Revoke	Local	1997	1423	40.3%
Revoke	Spanning	3876	—	—

Table 3: Runtimes of capability operations.

5 Evaluation

5.1 Experimental Testbed

We evaluate SemperOS using the gem5 system simulator [14], which enables us to evaluate the hardware/software co-designed capability system and perform experiments on systems larger than currently available. The system is composed of 640 out-of-order x86_64 cores, which are clocked at 2 GHz. However, the cores used for applications could also be exchanged with any other architecture or accelerator. Each core is equipped with a DTU similar to the one used in Asmussen et al.'s work [5]. We modified the mechanism to store incoming messages to support delayed replying which enables us to interrupt kernel threads. Messages are kept in a fixed number of slots. Each DTU provides 16 endpoints with 32 message slots each. Kernel PEs use one endpoint to send messages to other kernels, one endpoint to send messages to services, and 14 endpoints to receive messages. Six of the receiving endpoints are used for the system calls. Each kernel can handle up to 192 PEs in the current implementation since each VPE can only issue one (blocking) system call at a time. Eight endpoints are used to receive messages from other kernels. In contrast to system calls, the inter-kernel calls are non-blocking and we limit the number of in-flight messages to four messages per kernel. Thus, at most 64 kernel PEs are supported.

5.2 Microbenchmarks

Capability exchange and revocation. To examine the exchange and revocation of capabilities we start two applications where the second application obtains a capability from the first, followed by a revoke by the first application. We distinguish two scopes for these operations: group-local and group-spanning. In the group-local case one kernel manages both applications and their capabilities. The group-spanning case involves two kernels, each handling one application.

Table 3 lists the execution times in cycles for exchanging and revoking capabilities in the group-local and group-spanning case. We can only compare the group-local case to M^3, because in M^3 there is only one kernel. To support multiple kernels, SemperOS references parent and child capabilities via DDL keys instead of plain pointers. Analyzing the DDL key to determine the capability's owning kernel and VPE introduces overhead in the local case. Group-spanning operations involve another kernel, which almost doubles the time of exchanges and revokes. This suggests, that applications should be assigned to PE groups such that the group-spanning operations are minimized.

Chain revocation. In the chain revocation benchmark we measure the time to revoke a number of capabilities forming a chain. Such a chain emerges when a capability is exchanged with an application which in turn exchanges this capability

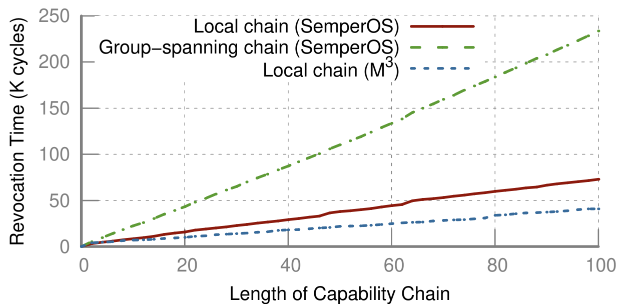

Figure 4: Revoking capability chains of varying sizes.

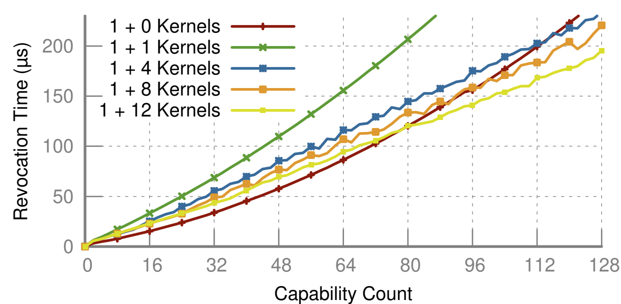

Figure 5: Parallel revocation of capability trees with different breadths utilizing multiple kernels.

again with another application and so on. Figure 4 depicts the time to revoke such capability chains depending on their length. A local chain comprises only applications managed by one kernel and can again be compared to M^3. As the previous microbenchmarks showed, revocation in SEMPEROS needs about twice the time compared to M^3 due to the added indirections.

The group-spanning chain depicts a scenario in which an ill-behaving application repeatedly exchanges a capability between two VPEs, which are managed by different kernels. This creates a circular dependency between the two involved kernels during revocation. However, as described in Section 4.3.3, this is not a problem for our revocation algorithm. In particular, only the kernel thread for the revoke system call is blocked during the operation. Still, the revocation of a group-spanning chain takes about three times longer than revoking a group-local chain, because messages are sent back and forth between the two kernels.

Tree revocation. This microbenchmark resembles a situation, in which an application exchanges a capability with many other applications, for example, to establish shared memory. This results in a capability tree of one root capability with several children. Figure 5 shows the performance of the revocation depending on the capability count and their distribution among kernels. The line labeled with 1 + 0 Kernels represents the local scenario in which the whole capability tree is managed by one kernel. For all other lines, the second number indicates the number of kernels the child capabilities have been distributed to. After exchanging the capabilities, the application owning the root capability revokes the capability tree. Figure 5 illustrates that the revocation scales to many capabilities and kernels. It also shows that our current implementation can take advantage of multiple kernels by performing the revoke in parallel, but the effect is rather small. It currently leads to a break-even at 80 child capabilities, when comparing the local revocation time with a parallel revocation with 12 kernels. However, we believe that this can be further improved by the use of message batching. So far, the kernel managing the root capability sends out one message for each child capability.

5.3 Application-level Benchmarks

We next perform application-level benchmarks to examine the scalability of SEMPEROS in more realistic settings.

5.3.1 Experimental Setup

Applications. We use seven different applications to analyze the scalability: *tar* and *untar* pack or unpack an archive of 4 MiB containing five files of sizes between 128 and 2048 KiB. The *find* benchmark scans a directory tree with 80 entries for a non-existent file. The *SQLite* database and the *LevelDB* key-value store both create a table to insert 8 entries into it and select them afterwards. The PostMark mailserver application resembles a heavily loaded mail server, thus does a lot of operations on the mail files. (In addition, we evaluated *Nginx* Webserver in Section 5.3.3.) Note that we were forced to use rather short running applications to keep the simulation times of gem5 acceptable (e.g. SQLite required five days on a 48-core machine). The selected applications are well suited for this evaluation since they make heavy use of the OS in various ways. In particular they use the in-memory filesystem service which implements file access by handing out the memory capabilities to the clients so they can access the memory region in which the requested file is stored. More specifically, the filesystem service hands out a memory capability to a range of the file's contents. If the application exceeds this range, for example by appending to the file, it is provided with an additional memory capability to the next range. When the file is closed again, the memory capabilities are revoked.

Table 4 lists the number of capability operations for the individual benchmark applications. We show the numbers for a single benchmark instance and 512 parallel instances. The capability operations per second for 512 benchmark instances are retrieved when employing 64 kernels and 64 filesystem services; we will explain what this means in the following paragraph on our methodology. The tar and untar benchmarks are memory-bound applications exposing a regular read and write pattern which requires the filesystem service to hand out several memory capabilities throughout the benchmark execution. The find benchmark mainly stresses the filesystem service by doing many stat calls to examine the directory's metadata. The small database engine of SQLite exhibits a more compute intensive behavior with several bursts of capability operations when opening and closing the database and the database journal whereas the LevelDB key-value store accesses its data files with a higher frequency resulting

Benchmark	Cap. ops	Cap. ops/s	Cap. ops	Cap. ops/s
# of instances	1		512	
tar	21	7,295	10,752	191,703
untar	11	4,012	5,632	100,772
find	3	1,310	1,536	27,096
SQLite	24	5,987	12,288	207,072
LevelDB	22	8,749	11,264	201,204
PostMark	38	21,166	19,456	348,285

Table 4: Number of capability operations for the selected applications. Values shown for 1 and 512 parallel benchmark instances. The capability operations per second are the average rate of capability operations over the runtime.

in more capability operations per second. PostMark does little computation and operates on many files resulting in the highest load for the capability system.

Performance metric. We use the system call tracing infrastructure introduced by Asmussen et al. [5] to run the benchmarks. We run an application on Linux, trace the system calls including timing information, and replay the trace on SEMPEROS while checking for correct execution. We account for the system calls which are not supported by our system yet by waiting for the time it took to execute them on Linux. However, all relevant system calls (especially those to interact with the file system) are executed. We replay the same trace multiple times in parallel, which is denoted as number of benchmark or application instances in the graphs. We assess scalability using the parallel efficiency of these benchmark instances. In a perfectly scaling system, a benchmark instance will have the same execution time when running alone as when running with other instances in parallel. However, due to resource contention for the kernel and for hardware resources like the interconnect and the memory controller, each instance will need more time if multiple of them are executed in parallel. The discrepancy in runtime is shown by *parallel efficiency*.

Methodology. There are two main factors influencing the scalability of applications running in a μ-kernel-based system: the OS services and the kernel. The OS service used by the examined applications is the m3fs filesystem. To concentrate our analysis on the scalability of the kernel, especially the distributed capability management, we simplify scaling of the m3fs service by adding more service instances, each having its own copy of the filesystem image in memory. We exclude accessing the actual memory locations of the files because our current simulator does not include a scalable memory architecture yet. Instead we let the application compute for the amount of time the access would have taken, assuming a non-contended memory controller. We argue that this still produces useful results since we do not want to show the scalability of the memory architecture but of the distributed capability scheme. Furthermore, a non-contended memory puts even more burden on the OS because capability operations might occur with higher frequency.

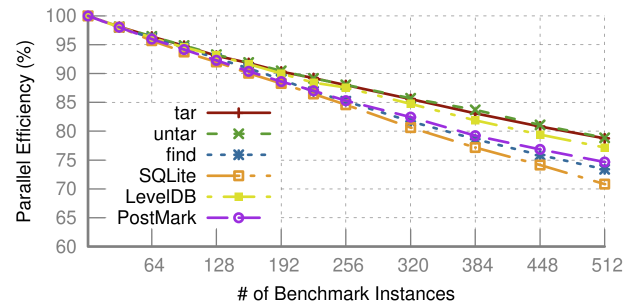

Figure 6: Parallel efficiency of all six applications using 32 kernels and 32 file service instances.

5.3.2 Results

Scalability. Figure 6 depicts the parallel efficiency of the six applications when distributing them equally between 32 kernels and 32 filesystem services. With this configuration the tar benchmark already reaches an efficiency of 78% when running 512 instances in parallel. However, SQLite achieves only 70%, which is not the optimal configuration for this type of application as we will show in the next measurement (see Figure 7). We next discuss how to determine a fitting configuration for an application.

Service dependence. To determine the number of services required to scale an application we set the number of kernels to a high number and then gradually increase the number of services. As long as there are less services than kernels, services are shared between PE groups. Kernels which host a service in their PE group prefer to connect their applications to the service in their PE group over a service in another PE group. Figure 7 shows the parallel efficiency for tar and SQLite depending on the number of services.

The tar benchmark is not very dependent on the filesystem service, which can be inferred from the fact that using 48 services does not pose any improvement over 32 services. In fact, it seems already fair enough to use only 16 service instances. SQLite shows a higher dependence on the number of services. For example, increasing the number of service instances from 16 to 32 leads to further improvement of 9 percent points.

Kernel dependence. Similarly to the dependence on the number of services, we now show the influence of the number of kernels. Figure 8 depicts the parallel efficiency of PostMark and LevelDB using a fixed number of services. LevelDB exhibits smaller improvements when employing more than 16 kernels compared to PostMark, indicating that PostMark is even more susceptible to the number of kernels. However, all applications show a relatively high sensitivity to the number of kernels, which in fact are mostly handling capability operations. This confirms our expectation that a scalable distributed capability system is a vital part of a fast μ-kernel-based OS for the future hardware architectures. The analysis so far only involved tuning for parallel efficiency, which is analogous to optimize for execution time. We next discuss the efficient usage of PEs.

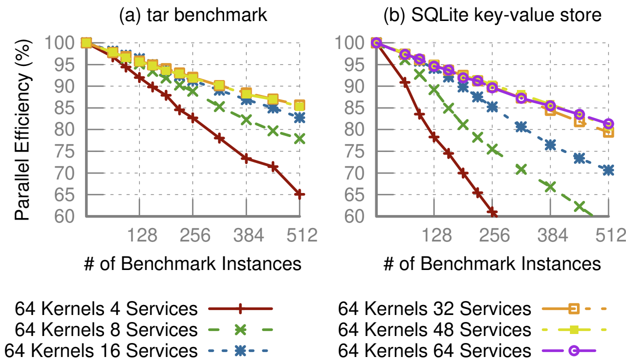

Figure 7: Service dependence: Parallel efficiency of tar and SQLite with fixed number of kernels.

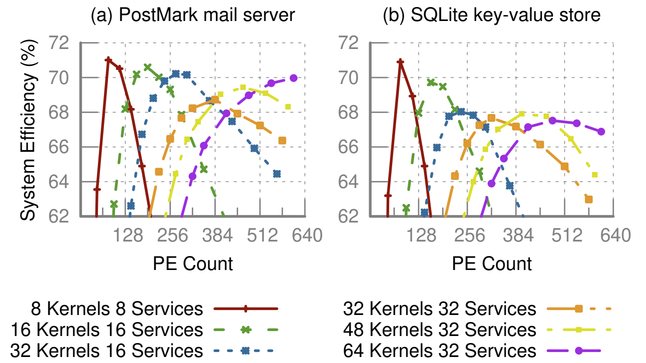

Figure 9: System efficiency of PostMark and SQLite with different configurations.

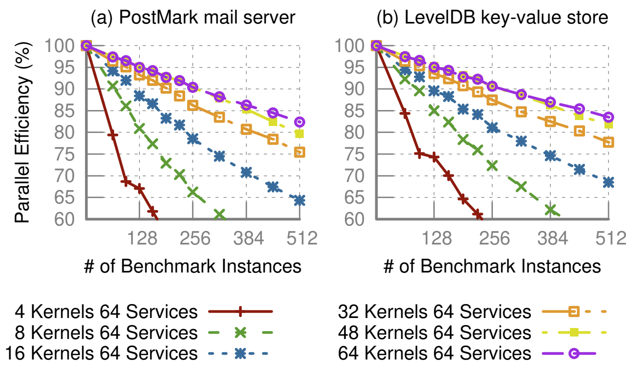

Figure 8: Kernel dependence: Parallel efficiency of PostMark and LevelDB with fixed number of services.

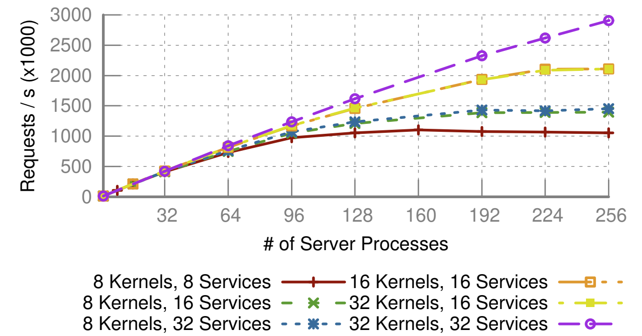

Figure 10: Scalability of the Nginx webserver.

System efficiency. If we consider the whole system and account for the PEs used by the OS with an efficiency of zero, the optimal configurations change. We call this measure the *system efficiency*, which is depicted in Figure 9. Instead of showing the efficiency only in relation to the benchmark instances executed we relate them to the total number of PEs. By means of this metric we can tune a system for throughput and determine the optimal number of kernels and services for an application depending on the number of PEs available. For SQLite this implies to choose 16 kernels and 16 service instances if the system had 192 PEs, but if the system would consist of 256 PEs we would run it with 32 kernels and 16 services.

5.3.3 Server Benchmark

We next detail the results for the Nginx webserver [53]. We used our system call tracing infrastructure to record the behavior of Nginx on Linux when handling requests. We stressed Nginx similar to the Apache ab benchmark [1] by introducing PEs that resemble a network interface. These PEs constantly send out requests to our webserver processes running on separate PEs. These PEs replay the trace upon receiving a request and send the response back. Figure 10 depicts the number of requests per second of all webserver PEs. Despite this OS-intensive benchmark, the number of requests scales almost linearly when employing 32 kernels and 32 services. Using less resources for the OS flattens the graph.

6 Related Work

Capability systems. The evaluation of previous capability systems typically resorted to performance measurements of single core or small systems. Since many capability systems, such as Mach, Fluke or EROS [19,23,56] are based on μ-kernels which had to prove their enhanced efficiency over previous μ-kernel generations [29,41], their kernel mechanisms like inter-process communication, system-call performance, context-switch overhead or process-creation time have been measured to demonstrate their in fact competitive performance. With these measurements it is only partly possible to derive the performance of the capability subsystem. So far the only work which included capabilities in a distributed setting is Barrelfish [11] but only parts of the capability subsystem's scalability can be concluded from the reported results. Barrelfish's two-phase commit approach to reach agreement (determining the relations between capabilities) requires broadcasting to every other kernel in the system, which is different from our approach. The revocation in Barrelfish uses a mark-sweep algorithm and

so called *delete cascades* which also require to broadcast to every kernel if capabilities have cross-kernel relations because these are not stored explicitly in Barrelfish [25]. Even though this broadcast operation can be tuned to fit the interconnect of the machine it is running on [33], it is unknown how well it performs in conjunction with their capability scheme.

Other capability systems like Capsicum [65] and CHERI [67] emphasize their sandboxing features and compatibility to existing software by executing application benchmarks. However, these do not include any assessment of large scalable systems. Further, CHERI does not support revocation, thus eliminating the overhead of tracking capability relations.

Operating systems. Apart from a scalable capability subsystem the OS also has to entail mechanisms to drive large possibly heterogeneous systems. The monolithic architecture of Linux, which runs a shared-memory kernel on homogeneous cores, has many scalability bottlenecks [16, 17, 26]. Developers try to counteract that by utilizing scalable data structures like RCU [47] within the kernel. To investigate more profound changes researchers built frameworks like K42 [37] to enable development and testing of new approaches like clustered objects [3]. Song et al. proposed Cerberus [61] which runs multiple Linux instances on top of a virtualization layer.

Systems like Popcorn Linux [8–10], and K2 [42] adapt Linux for heterogeneous ISAs. These systems also run multiple Linux instances closely resembling a distributed system. Rack-scale operating systems like LegoOS employ multiple distributed components to manage disaggregated resources [55]. They can benefit from our approach when combined with capabilities.

Barrelfish proposed the multikernel approach which aims to improve the scalability and support for many heterogeneous cores by constructing the OS as a distributed system. Cosh [12], a derivative of Barrelfish, demonstrated how to share and provide the OS services across different domains. While Cosh defines an interface how to communicate between different coherence islands and adds guarantees regarding memory accesses after sharing, it is not discussing the underlying capability system. Barrelfish/DC [68] examined the separation of kernel state from a kernel instantiation to provide an elastic system. Fos [66] targets manycore systems by proposing the concept of service fleets to provide OS services via spatially distributed servers. Importantly, these OSes are based on communication over message passing and do not assume cache coherent shared memory. Our system SEMPEROS shares the same two design principles: (1) the multikernel approach, and (2) communication via message passing. However, the design of Barrelfish and fos require executing a kernel on every core. Whereas, we based our work on M^3 [5] which runs the kernel only on a single dedicated core. This allows us to explore another design point in the multikernel design space in which the capabilities of several processing units are managed by one kernel which has to coordinate with other kernels to scale to large systems.

The philosophy of providing OS services without executing a kernel on every core has also been explored in NIX [7], which is based on Plan 9 [52]. NIX proposes an OS with a concept of application cores which do not execute a kernel to prevent OS noise. However, the communication in NIX is based on shared memory. Similarly, Helios [50], an extension of Singularity [22], minimizes the kernel requirement for some cores to a smaller satellite kernel.

Motivated by the recent trends in hardware, in a similar spirit but with a different focus, new OSes such as Arrakis [51], IX [13], and Omnix [57] have been proposed. These OSes share a similar design philosophy to SEMPEROS where we aim to provide applications direct control of the underlying hardware to improve the performance.

Alternatively, there are several proposals to support OS services for one specific type of accelerator. For instance, GPUfs [58], GPUNet [35], and PTask [54] are designed for GPUs. Likewise, BORPH [59], FPGAFS [38], etc. are designed to support FPGAs. In contrast, using M^3 as our foundation allows us to support different types of accelerators and general purpose heterogeneous cores as first-class citizens.

7 Conclusion

In this paper, we presented a HW/SW co-designed distributed capability system based on M^3. More specifically, we presented a detailed analysis of distributed capability management, covering the inconsistencies which can arise in a distributed multikernel setting where concurrent updates to capabilities are possible. Leveraging the results of this investigation we devised efficient algorithms to modify capabilities in a scalable and parallel manner.

We implemented these algorithms in our microkernel-based OS, SEMPEROS, which employs multiple kernels to distribute the workload of managing the system. We evaluated the distributed capability management protocols by co-designing the HW/SW capability system in the gem5 simulator [14]. Our evaluation shows that there is no inherent scalability limitation for capability systems for running real applications: Nginx, SQLite, PostMark, and LevelDB. In particular, we showed that SEMPEROS achieves a parallel efficiency of 70% to 78% when running 512 applications and dedicating 11% of the system's cores to the OS.

Software availability. SEMPEROS will be open-sourced at https://github.com/TUD-OS/SemperOS.

Pragh: Locality-preserving Graph Traversal with Split Live Migration

Xiating Xie, Xingda Wei, Rong Chen, Haibo Chen
Shanghai Key Laboratory of Scalable Computing and Systems
Institute of Parallel and Distributed Systems, Shanghai Jiao Tong University
Contacts: rongchen@sjtu.edu.cn

Abstract

Many real-world data like social, transportation, biology, and communication data can be efficiently modeled as a graph. Hence, graph traversal such as multi-hop or graph-walking queries has been key operations atop graph stores. However, since different graph traversals may touch different sets of data, it is hard or even impossible to have a one-size-fits-all graph partitioning algorithm that preserves access locality for various graph traversal workloads. Meanwhile, prior shard-based migration faces a dilemma such that coarse-grained migration may incur more migration overhead over increased locality benefits, while fine-grained migration usually requires excessive metadata and incurs non-trivial maintenance cost.

This paper proposes Pragh, an efficient locality-preserving live graph migration scheme for graph store in the form of key-value pairs. The key idea of Pragh is a split migration model which only migrates values physically while retains keys in the initial location. This allows fine-grained migration while avoiding the need to maintain excessive metadata. Pragh integrates an RDMA-friendly location cache from DrTM-KV to provide fully-localized accesses to migrated data and further makes a novel reuse of the cache replacement policy for lightweight monitoring. Pragh further supports evolving graphs through a check-and-forward mechanism to resolve the conflict between updates and migration of graph data. Evaluations on an 8-node RDMA-capable cluster using a representative graph traversal benchmark show that Pragh can increase the throughput by up to 19× and decrease the median latency by up to 94%, thanks to split live migration that eliminates 97% remote accesses. A port of split live migration to Wukong with up to 2.53× throughput improvement further confirms the effectiveness and generality of Pragh.

1 Introduction

Graph data ubiquitously exist in a wide range of application domains, including social networks, road maps, biological networks, communication networks, electronic payment, semantic webs, just to name a few examples [47]. Graph traversal (aka multi-hop or graph-walking) queries have been prevalent and important operations atop graph store to support emerging applications like fraud detection in e-commerce transaction [45], user profiling in social networking [11, 18, 6], query answering in knowledge base [52, 63], and urban monitoring in smart city [64].

With the increasing scale of data volume and the growing number of concurrent operations, running graph traversal workloads over distributed graph store becomes essential. Graph traversal workloads are severely sensitive to the access locality, while it is notoriously difficult to partition graph with good locality. For example, the difference of median latency for two-hop query (like friends-of-friends (FoF) [18]) over a Graph500 dataset (RMAT26) [12] is about 30× (0.75ms vs. 22.5ms) between a single machine and an 8-node cluster. Further, preserving locality is even more challenging where workloads and datasets may evolve, while it is common for many production applications [7, 16, 42, 33].

We argue that live migration of graph data is a necessary mechanism for preserving access locality in graph traversals, because existing alternatives have several limitations in many scenarios. First, locality-aware graph partitioning algorithms may improve the performance of a specific dataset and workload [27, 13]. However, *one partition scheme cannot fit all* [62]. Further, a proper graph partitioning scheme for a certain workload may be ineffective and even harmful to another graph traversal workload. Second, replicating data to multiple or all machines allows more (fast) localized read accesses, but also leads to excessive memory overhead as the increase of machines and heavy synchronization cost among replicas for write operations.

Hence, live migration becomes a compelling approach to preserve locality, which has been widely investigated in the database and distributed systems community over the last decade. Unfortunately, the unique characteristics of graph data and traversal operations significantly weaken the benefits of live migration using a shard-based approach, even which is adopted by almost all existing systems. For example,

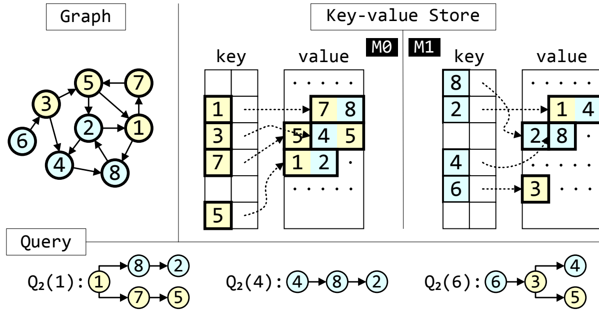

Fig. 1. A sample graph (G), key-value store over 2 machines, and three two-hop queries (Q_2).

using a typical shard-based live migration [25, 60] with an optimal migration plan on above two-hop query experiment will just decrease 29% (22.5ms vs. 15.9ms) median latency, still far from the performance of ideal setting (pure localized access). This is because the majority of the migrated data in a shard would likely have different location preferences. On the other hand, decreasing the size of the shard (fine-grained) would incur high memory and CPU overhead due to storing and maintaining excessive metadata (a location mapping for every shard).

In this paper, we present Pragh, an efficient locality-preserving live migration scheme for distributed in-memory graph store. The key idea of Pragh is a new migration scheme called *split live migration*, which separates the migration of keys and values. Only the value would be migrated physically, while the key would always be stationary at its initial location. This allows fine-grained migration (vertex granularity) while avoiding the need to maintain excessive metadata.

Pragh is made efficient and cost-effective with several key design choices. First, to migrate well-selected vertices (scattered over the entire store) efficiently, Pragh proposes a *unilateral migration protocol* such that the target machine can migrate vertices alone by carefully leveraging one-sided RDMA primitives, while the traversal workloads can concurrently execute on the store. Second, Pragh integrates split live migration with location-based caching [61] to provide *fully-localized* accesses to migrated data. This eliminates the restriction from the stationary key and unleashes the full power of split migration. Third, to support the evolving graph with live migration, Pragh designs a *check-and-forward mechanism* to resolve the conflict between updating and migrating data. Finally, fine-grained monitoring both local and remote accesses to every vertex may incur non-trivial memory and CPU overhead to traversal workloads. Pragh makes a novel reuse of the cache replacement policy to concentrate on tracking remote data accessed frequently. Pragh further provides two optional mechanisms (eager and deferred) for local access tracking to balance the accuracy and the timeliness of migration.

We have implemented Pragh by extending DrTM-KV [61], a state-of-the-art RDMA-enable key-value store, to store graph data and support split live migration. To demonstrate

Table 1: A detail analysis of shard-based live migration.

	Ideal	Shard-based	
		Before	After
Throughput (K ops/sec)	3,248	123	171
Median/50th Latency (msec)	0.75	22.5	15.9
Tail/99th Latency (msec)	4.2	76.6	59.2
Remote Access Rate (%)	0	86.2	64.4
Data Migration Rate (%)	-	-	85.6

the effectiveness and efficiency of Pragh, we have conducted a set of experiments using a state-of-the-art graph traversal benchmark on an 8-node RDMA-capable cluster. The experimental results show that Pragh can increase the throughput by up to 19× and decrease the median latency by up to 94% through live migration, as the rate of remote accessing reduces from 86.2% to 2.0%. We have also integrated split live migration to Wukong [52], a state-of-the-art distributed graph store that leverages RDMA-based graph exploration (graph traversals in parallel) to provide highly concurrent and low-latency queries. An evaluation using original concurrent workload benchmark [52] shows that the throughput increases by up to 2.53× due to using split live migration.

2 Background and Motivation

2.1 Graph Store and Traversal Workload

The graph-structured store (aka graph store) becomes more and more prevalent in an increasing number of applications [47] for modeling the relationships among connected data. Due to fast lookup and good scalability, distributed key-value stores are widely used by existing graph systems [52, 64, 57, 22, 31, 24, 51, 63, 54] as the underlying storage layer to support graph traversal operations efficiently, which play a vital role for many emerging and crucial applications [45, 11, 18, 63, 52].

A natural way to build a graph model on top of the key-value store is to simply use the vertex as the key and the adjacency list as the value [51]. Further, separate key and value memory regions are used to support variable-sized key-value pairs [39, 61, 52]. Specifically, the key region is a fix-sized hash table, where each entry stores a key and an address (i.e., offset and size) of the value region. The value region stores variable-sized values consecutively. As shown in Fig. 1, a sample graph (G) is stored into a key-value store over two machines. Various graph traversal operations (like FoF, multi-hop query, and random walking) can be implemented by iteratively accessing key and value pairs. For example, the two-hop query on vertex 1 ($Q_2(1)$) will first retrieve neighbors of the start point (vertex 1) by hashing it as the key and accessing its value (vertex 7 and 8). The next hop will use the value in this hop as the keys (hash(7) and hash(8)) to retrieve their neighbors (vertex 2 and 5) recursively. The accesses over key and value may be either local or remote according to the partitioning scheme.

2.2 Poor Locality and Partitioning

For distributed in-memory stores, the locality of data accessing is quite important because accessing local memory is still more than 20× faster than accessing remote memory across networks, even using high-speed networks [22]. Unfortunately, the traversal on distributed graph data is notoriously slow due to poor data locality. Prior work shows that assigning vertices to N machines randomly will lead to the expected fraction of remote accesses reaching $1 - \frac{1}{N}$ [27].

To illustrate the performance impact of locality for graph store, we conducted a motivating experiment using two-hop queries (like FoF [18]) over Graph500 dataset [12] (RMAT26) on an 8-node RDMA-capable cluster. The graph is partitioned into 8 machines randomly (hash-based), and a set of vertices randomly sampled with a Zipf distribution (θ=0.99) is used to run two-hop queries which access fixed 100 friends of 100 friends. As shown in Tab. 1, the distributed setting using 8 machines only achieves less than 4% throughput (123K vs. 3,248K) and about 30× median (50th percentile) latency (22.5ms vs. 0.75ms) of the ideal setting since the rate of remote accessing reaches up to 86.2%.[1]

Therefore, designing locality-aware graph partitioning algorithms has been an active area of research for a decade [27, 13], especially for graph analytics systems. However, *one partition scheme cannot fit all* [62]. It is hard or even impossible to handle dynamic workloads or evolving graphs only relying on static partition-based approaches. One example is shown in Fig. 1 such that $Q_2(1)$ and $Q_2(4)$ contends for the same vertices (8 and 2). The queries may arrive at different times, which causes *false contention*. Actually, prior work on production applications has shown that workloads change rapidly over time [7, 16, 42, 33].

2.3 Live Migration

Live migration (aka dynamic migration) is a compelling approach for handling dynamic workloads and has been widely investigated in the database and distributed systems communities [20, 21, 26, 25, 35, 60, 5]. Generally, a centralized coordinator will make the migration plan according to the statistics (e.g., access frequency) collected by the monitor on each machine. The migration threads on the source and/or target machines will implement the plan by migrating key-value pairs in a synchronous way (see Fig. 2(b)). Since the position of vertices may change after migration, additional metadata (POS) will be accessed to look up the latest positions of the key-value pairs before accessing them (see Fig. 2(a)). The metadata should be updated by the coordinator during live migration and usually is consistently cached at each machine to avoid remote lookup for every accesses.

[1]The ideal result is gained by running the benchmark on a single machine (fully local accessing). The throughput is further magnified 8× (the number of machines).

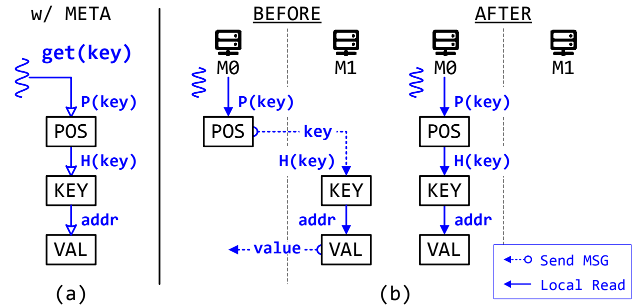

Fig. 2. (a) The sequence of an access on (kv-based) graph store and (b) a comparison of accesses before and after live migration.

Shard-based migration. A ubiquitous approach in live migration is to group the data into *shards* (*partitions*) by key ranges or key hashing [49, 53, 4, 35, 5]. Shards serve as the unit of migration for load balancing and locality-aware optimization. Prior work mainly focuses on relational workloads (e.g., TPC-C) or simple CRUD (Create, Read, Update, and Delete) workloads (e.g., YCSB [15]). Compared to traversing graph data, such workloads with datasets usually have high access locality (e.g., accessing 1% remote key in TPC-C). Consequently, leveraging shard-based migration on the graph store is ineffective and may be harmful, due to the following reasons:

First, migrating data at shard granularity will significantly weaken the benefits of data migration. Due to lacks of data locality, after migrating a shard, the majority of the migrated data in the shard would likely not be accessed by the workload at the target machine. Meanwhile, it will also increase the number of remote accesses at the source machine. Based on the above motivating experiment, we partition graph data into one hundred shards per machine (about 70K keys per shard), similar to prior work [11, 5]. All of the local and remote accesses to every shard are monitored and aggregated to make an optimal migration plan. As shown in Tab. 1, the rate of remote accessing only decrease from 86.2% to 64.4% even after migrating more than 85.6% of graph data (about 20GB). As a result, the throughput only increases 39% (123K vs. 171K) and the median latency also just decreases 29% (22.5ms vs. 15.9ms), still far from the performance of an ideal setting.

Second, though decreasing the size of shard could enhance the effectiveness of migration, it still faces the same drawbacks of static graph partitioning approaches when handling dynamic workloads, unless vertices (key-value pairs) serve as the unit of migration. For example, two irrelevant queries may contend the same shard even assigning two vertices to one shard by key ranges, like vertex 2 and 4 for $Q_2(1)$ and $Q_2(6)$ in Fig. 1. More importantly, the amount of metadata (POS) needed to manage the shards would incur extremely high memory pressure. For example, the metadata for the motivating experiment will consume about 3GB memory on each machine to support vertex granularity migration. Each machine has to cache the entire metadata since the workload

may access any vertex of the graph. Consequently, the size of metadata may exceed the size of graph data when the graph scales.

3 Approach and Overview

Our approach: split live migration. We propose a new migration approach, named *split live migration*, that enables live migration at the minimum level of granularity (i.e., key-value pair). A landmark difference compared to prior approaches is that *split live migration has no need of metadata at all*. This is the greatest advantage but also the biggest challenges for live migration.

The key principle of split migration is to separate the migration of keys and values. The key will always be *stationary* at its initial location, which can be found without metadata (e.g., key hashing). The value will be *migratory* on demand to improve locality or rebalance the load. Our design naturally tackles the issue of memory pressure by avoiding metadata due to the stationary key. Further, allowing fine-grained migration (even a single value) would maximize the effectiveness of data migration for graph store. However, there are still many challenges before making split live migration come true.

Opportunity: RDMA. Remote Direct Memory Access (RDMA) is a networking feature to provide cross-machine accesses with high speed, low latency, and kernel bypassing. The one-sided RDMA primitive (e.g., `READ`, `WRITE`, and `CAS`) allows one machine to directly access the memory of another machine without involving the host CPU. Much prior work has demonstrated the benefit of using RDMA for in-memory key-value stores [39, 22, 32, 61]. Generally, the GET/PUT (read/write) operation first uses `RDMA READ`s to look up the location (address) of the value by hashing the given key, and then use `RDMA READ/WRITE` to retrieve/update the value (see the left part of Fig. 4(b)). We observe that *one-sided RDMA primitives decouple the accesses of keys and values, which make it easy and efficient to separate keys and values in physical.* It opens a new opportunity to *split* live migration.

Challenges and solutions. First, split live migration uses the key-value pair as the unit of migration, such that the key-value pairs which will be migrated are scattered over the entire graph store. Therefore, directly using existing protocols designed for shard-based migration may be inefficient. We propose a unilateral (target-only) migration protocol that the target machine can do it alone and efficiently by carefully leveraging one-sided RDMA primitives (§4.1).

Second, the basic split migration only migrates the values of key-value pairs, which can at most eliminate about half of the remote accesses. This is because the read access to the key of key-value pair (look up the location of the value) will still be remote. We address this challenge by integrating split migration with RDMA-friendly location-based caching [61] to provide *fully-localized* access to migrated data (§4.2).

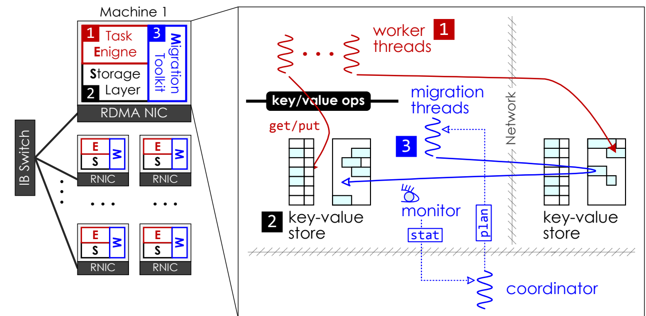

Fig. 3. The architecture of Pragh.

Third, the split of key and value after performing migration presents a new challenge to the support of evolving graphs, especially for the target-only protocol. We use a check-and-forward mechanism to resolve the conflict between data updating and data migrating tasks (§4.3).

Finally, to maximize the effectiveness of data migration, both local and remote accesses to every key-value pair should be tracked to generate an optimal migration plan. It may incur non-trivial memory and CPU overhead to traversal workloads. We design a lightweight, memory-saving monitor, which reuses the location cache to track frequent remote accesses and provides two optional mechanisms for local access tracking to balance the accuracy and the timeliness of live migration (§4.4).

Architecture. As shown in Fig. 3, Pragh is a distributed in-memory graph store with split live migration. It follows a decentralized architecture to deploy servers on a cluster of machines connected with a high-speed, low-latency RDMA network. Each server is composed of three components: task engines, a storage layer, and a migration toolkit. The task engine binds a worker thread on each core with a task queue to continuously execute operations (e.g., GET and PUT) from clients or other servers. The storage layer adopts an RDMA-enabled key-value store over distributed hashtable to support a partitioned global address space. The migration toolkit enables a monitor to collect statistics of graph store and runs migration threads to perform live migration. Pragh scales by partitioning graph data randomly (hash-based) into multiple servers. Each server stores a partition of the graph, which is shared by all of the workers and migration threads on the same machine.

Execution flow. Pragh is designed to handle concurrent operations on graph data with low-latency and high-throughput. The key advantage of Pragh over previous systems is capable of physically migrating data to improve locality in a split way, which can promptly and significantly enhance performance for dynamic workloads.

Similar to prior work [53, 60, 35], a *centralized coordinator* will make migration plan according to the statistics (e.g., access frequency) collected by the monitor on each server and migration policies. The details – how to make a proper policy and how to find an optimal plan – are beyond the

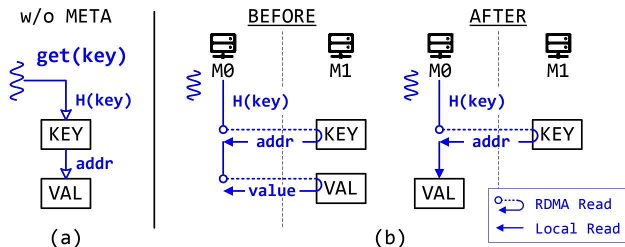

Fig. 4. (a) The sequence of an access on (kv-based) graph store without meta-data and (b) a comparison of accesses before and after split live migration.

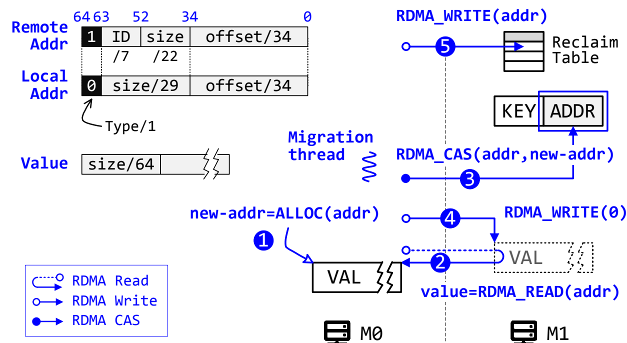

Fig. 5. The execution flow of basic split migration.

scope of this paper and are part of our future work. Currently, Pragh uses a simple threshold-based policy to generate migration plans. On each server, the monitor will track the accesses of worker threads to the key-value store in the background and report to the coordinator periodically (e.g., 10s) or instantly (e.g., when exceeding 100 times per second). The coordinator will compare the statistics from the applicant and the machine hosting the vertex at present, and approve the migration if the profit is more than a threshold (e.g., 50% more accesses per second). After that, the migration threads will migrate the key-value pairs according to the plan from the coordinator, while the worker threads will continue to execute queries by accessing the same key-value store concurrently. Note that the centralized coordinator is just used to collect a few statistics from servers and approve migrations by simply comparing the statistics. Further, the fine-grained approach commonly only needs to migrate much fewer vertices (e.g., 0.13% in §6.1). Hence, the coordinator may hardly become a bottleneck in a medium-sized cluster.

4 Split Live Migration

Pragh uses an RDMA-enabled key-value store over distributed hashtable to store graph data physically. For brevity, Pragh supposes that each vertex has a unique ID (vid) and use it as the key. The hash value of the key (`H(key)`) can be used to identify the host machine (`mid`) and the location in the key region (`off`). As shown in Fig. 4(a), to get neighbors of a given vertex, the worker thread first uses `H(key)` to look up the address of its value and then retrieves the value (a list of IDs of neighbors). For remote key-value pairs, `RDMA READ`s are used to access keys and values (see the left part of Fig. 4(b)), which are at least 20× slower than local reads. Hence, Pragh uses split live migration to eliminate such remote accesses.

4.1 Basic Split Migration

We start from the basic migration protocol, assuming that there only exist traversal workloads (i.e., GET operations) in the graph store. Since the key is always stationary in the split migration, Pragh will only move the value to the target machine. This could improve locality by avoiding remote accesses to the values (see the right part of Fig. 4(b)).

Address layout. To avoid the influence between accessing and migrating key-value pairs, the address (within the key) should be changed from local to remote in a lock-free way (e.g., compare-and-swap (CAS)). Therefore, both the local and remote location of value should use a 64-bit address uniformly, which can be modified atomically using both local and RDMA atomic instructions.[2]

Considering the machine ID should be added into the address, a simple layout may severely restrict the scope of address space. Pragh adopts a differentiated layout for local and remote addresses. As shown in the top left corner of Fig. 5, The most significant bit is used to present the type of address, local (0) or remote (1). For local addresses, the rest of the bits are used to store 29-bit value size and 34-bit offset within the value region. Thus, the size of a single value and value region on a single machine can reach 4GB and 128GB respectively (assuming 8-byte granularity and alignment). For remote addresses, the value offset still occupy 34 bits to present the entire remote value region, while the value size reduces to 22 bits for hosting 7-bit machine ID. Thus, the graph store can scale up to 128 machines, while the size of the maximum value that can be migrated is limited to 32MB. The observation is that the system will prefer to migrate the workloads rather than very large key-value pairs [52, 57]. Further, a large key-value pair can be split into multiple ones (vertex decomposition [52, 57]), and each one can be migrated separately.

Unilateral migration protocol. Similar to traditional shard-based migration systems, the split live migration also could be implemented by the collaboration of migration threads on source and target machines. However, the key-value pairs which will be migrated, are scattered over the entire graph store due to lacks of locality. It means that migrating multiple key-value pairs may incur a prolonged interruption to the concurrent graph accessing and/or lengthy migration delay since multiple addresses (within separated keys) should be modified by atomic operations (e.g., CAS).

Pragh proposes a unilateral (target-only) migration protocol based on one-sided RDMA primitives. It only uses the

[2] Note that RDMA primitives guarantee atomic 64-bit transfer [9], and `RDMA READ/WRITE` operations are also cache coherent with local accesses [22, 61].

```
   MIGRATE(key)
   1 retry:
   2   kmid = H(key).mid          ▸ e.g., key % machines
   3   addr = LOOKUP(kmid, key)
❶  4   buf = ALLOC(addr.sz)
   5   new_addr = { 1, local_mid, addr.sz, buf }
❷  6   RDMA_READ(addr.mid, buf, addr.off, addr.sz)
❸  7   if !RDMA_CAS(kmid, H(key).off, addr, new_addr)
   8   | goto retry                 ▸ conflict w/ PUT
   9   zero = 0                     ▸ invalidate value
❹ 10   RDMA_WRITE(addr.mid, addr.off, zero, 8)
❺ 11   RDMA_WRITE(addr.mid, reclaim, addr, 8)  ▸ reclaim
```

Fig. 6. Pseudo-code of MIGRATE operation.[3]

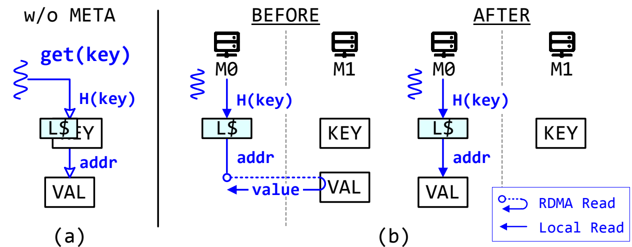

Fig. 7. (a) The sequence of an access on (kv-based) graph store with location cache and (b) a comparison of accesses before and after split live migration with location cache (for remote kv pair).

migration thread on the target machine to migrate the key-value pair instantly, while the worker threads on every machine can still access the key-value pair concurrently. Fig. 5 illustrates three steps of the migration protocol (a detail pseudo-code is shown in Fig. 6). First, the migration thread on the target machine will allocate memory space in local value region (`new_addr`) to host migrated value (❶), according to the size in the original address. Second, the migration thread will retrieve the value using one RDMA READ from the original address to the new address (❷). Finally, one RDMA CAS is used to replace the original (local) address with the new (remote) address (❸).

Invalidation and reclaim. Unilateral migration protocol will incur two new problems. First, the memory of migrated value in the source machine should be invalidated. However, some worker threads may still have the original address of the migrated value and will access it in the future. To solve it, Pragh proposes a passive invalidation mechanism. The migration thread will invalidate the original memory of migrated value by zeroing (RDMA WRITE) the size within the value (❹). Before using the retrieved value, the worker thread should check whether the size within the value and address are equal. If not, the address should be regained. Note that the worker thread can safely read the value from the original memory before invalidation even it has just been migrated (❸).

Second, the memory of migrated value on the source machine should be reclaimed. However, it is hard or even impossible for the migration thread on the target machine to solely free the memory. Therefore, Pragh uses a lease-based mechanism to reclaim the memory of migrated values in the background by a garbage collection (GC) thread on the source machine.[4] The migration thread will actively write (RDMA WRITE) the original address to the reclaim table[5] of the source machine, at the end of live migration (❺). The GC thread on each machine will periodically check the reclaim table to free the expired memory, which has been migrated before a pre-agreed lease (e.g., 60s). All the worker threads comply with the convention that the value address obtained before a lease duration should not be used, since it may have been freed and reused. The performance impact could be trivial by using a long-term lease.

4.2 Fully-localized Split Migration

The basic split migration only avoids remote accesses to the values, which limits the effects of migration since only at most half of remote accesses can be eliminated.

Observation: location cache. Prior work [61, 23, 59] proposes location-based caching for RDMA-friendly key-value stores, which aims at avoiding remote accesses to the keys. Different to caching the content (value) of key-value pairs, the location cache (L$) only stores the location (address) of key-value pairs, which is very space-efficient and effective (see the left part of Fig. 7). We observe that *location cache is a perfect counterpart to split migration*. They focus on two different halves of the access to the remote key-value pair, and the candidates of them are also well matched, namely remote key-value pairs frequently accessed. Finally, a small cache has negligible memory overhead (e.g., 128MB) and lookup cost, yet it is sufficient to achieve fully-localized accesses for most workloads [46, 61].

Integration with location cache. Pragh extends the graph store with location cache (L$) and integrates it with split live migration to enable fully localized accesses after migration. Fig. 8 illustrates the pseudo-code of GET operation with the integration of location cache and split live migration. When accessing a remote key-value pair (Line 9), the worker thread will first check location cache (Line 21) and fill the cache (if missed) with the address of the value (Line 25) obtained by the remote access to the key (Line 24). Given the address, the worker thread will retrieve the value using one RDMA READ (Line 14).

If the worker threads access the key-value pair frequently enough, the value will be migrated to the local using the basic migration protocol. After that, the address stored in location cache will be updated by the new address, which points to the local value region. Therefore, the accesses to the key-value pair will be fully localized (Line 10-12), as shown in the right part of Fig. 7. In contrast, the local key-value pair could also

[3]RDMA provides fences between different requests [38], and Pragh uses them before invalidating and reclaiming the memory (Line 10 and 11).
[4]Pragh uses the precision time protocol (PTP) [1] to implement lease.
[5]We implement the reclaim table like the circular buffer [22].

```
 GET(key, buf)
+1 retry:
 2   kmid = H(key).mid           ▸ e.g., key % machines
 3   addr = LOOKUP(kmid, key)
 4   if kmid == local_mid                    ▸ local key
+5   | if addr.type == 0                   ▸ local value
 6   | | MEMCPY(buf, vals[addr.off], addr.sz)
+7   | else                ▸ remote value (migrated)
+8   | | RDMA_READ(addr.mid, buf, addr.off, addr.sz)
 9   else                                   ▸ remote key
+10  | if addr.type == 1                      ▸ migrated
+11  | | && addr.mid == local_mid         ▸ local value
+12  | MEMCPY(buf, vals[addr.off], addr.sz)
+13  | else                                ▸ remote value
 14  | | RDMA_READ(addr.mid, buf, addr.off, addr.sz)
+15  if CHECK(addr, buf)
+16  | if kmid != local_mid
+17  | | cache.DELETE(key)                   ▸ invalidate
+18  | goto retry

 LOOKUP(kmid, key)
 19  if (kmid == local_mid)                  ▸ local key
 20  |  return keys[H(key).off]
x21  if cache.FIND(key)
+22  |  && !EXPIRED(cache.GET(key).lease)
x23  |  return cache.GET(key).addr            ▸ cache hit
 24  RDMA_READ(kmid, addr, H(key).off, 8)
x25  cache.INSERT(key, addr)                 ▸ fill cache
+26  cache.GET(key).lease = NOW()
 27  return addr
```

Fig. 8. Pseudo-code of GET operation with location cache. The code lines with "x" and "+" stand for additional instructions to integrate with location cache and split live migration, respectively.

be migrated to other machines, thus the type of address will be used to decide how to retrieve the value (Line 5-8).

Finally, the address stored in the location cache should also follow the convention of the invalidation and the reclaim mechanisms. First, if the retrieved value is invalid (Line 15), the worker thread has to delete the address in location cache for the remote key-value pair (Line 16-17), and needs to retry (Line 18). Second, the cached address must expire after a lease duration (e.g., 60s) from the last cache time (Line 22 and 26). Note that the duration of the (cache) lease should be equal or smaller than that of the (reclaim) lease (§4.1).

4.3 Full-fledged Split Migration

The basic migration protocol only considers traversal workloads (i.e., GET operations) concurrently execute in the graph store. Pragh extends it with a check-and-forward mechanism to support the evolving graph (i.e., PUT operations). For brevity, suppose that graph store has provided some mechanisms (e.g., snapshot read [52, 64]) to run traversal workloads over evolving graphs correctly.[6] Therefore, Pragh only tackles the conflict between split live migration and the change of graph. More specifically, Pragh only needs to consider the concurrent update to edges (i.e., change the value of a key-value pair).

[6]Pragh assumes the PUT operation will use atomic in-place updates on the key to ensure consistency, which is common in prior work [52, 64].

```
 PUT(key, val)
+1 retry:
 2   kmid = H(key).mid
 3   addr = LOOKUP(kmid, key)
+4   if addr.mid != local_mid               ▸ migrated
+5   | SEND(addr.mid, key, val)       ▸ forward PUT op
+6   | return false
 7   new_addr = WRITE_VALUE(addr, val)
 8   if !RDMA_CAS(kmid, H(key).off, addr, new_addr)
 9   | goto retry         ▸ conflict w/ put or migrate
 10  zero = 0                         ▸ invalidate value
 11  MEMCPY(vals[addr.off], zero, 8)
 12  MEMCPY(reclaim, addr, 8)                ▸ reclaim
 13  return true
```

Fig. 9. Pseudo-code of PUT operation. The code lines with "+" stand for additional instructions to support split live migration.

We observe that both MIGRATE and PUT operations will change the address within the key atomically to mark the success of processing (Line 7 in Fig. 6 and Line 8 in Fig. 9).[7] Moreover, PUT operation will always be assigned to the machine hosting the key at first. So for key-value pairs migrated, a better choice is to forward the PUT operation to the machine hosting the value upon conflicts, which also ensures consistency and reclaims the memory. Consequently, Pragh adopts different strategies for MIGRATE and PUT operations when detecting the conflict over the address; MIGRATE operation will be retried (Line 8 in Fig. 6), while PUT operation will forward itself (Line 5 in Fig. 9), if it conflicts with some MIGRATE operation and then is retried (Line 9 in Fig. 9). Note that PUT operation will always update the address in the machine hosting the key using RDMA CAS, even though PUT operation is forwarded.

4.4 Lightweight Monitoring

To generate a proper migration plan, the coordinator should collect the statistics of both local and remote accesses to every key-value pair. A (much) higher remote access number from a certain machine to a key-value pair in the most recent interval (e.g., 10s) indicates that migrating the key-value pair to that machine may improve locality (fewer remote accesses). It has been a great challenge to track the accesses at the granularity of key-value pairs.[8] Even worse, the remote accesses using RDMA READ contributes much more extra burdens (both memory and CPU overhead) to the monitor, since each machine has to track the accesses to remote key-value pairs (except local key-value pairs).

Pragh designs a lightweight, memory-saving monitor for split live migration by tracking local and remote accesses separately. For remote accesses, worker threads may access

[7]Suppose that PUT operation will change the size or the offset of the address (or both), namely addr is not equal to new_addr.

[8]Relational database can leverage table schema to reduce the number of tuples should be tracked, by grouping co-accessed tuples into blocks [53, 25, 50, 60]. Unfortunately, graph store is generally schema-less.

any key-value pairs, while the monitor may (very likely) only care about remote key-value pairs *accessed frequently*. This observation also matches the intention of the location cache. Hence, Pragh reuses the cache to track (partial) remote accesses(remote key). The monitor relies on the replacement policy of cache to recognize the key-value pairs (worth tracking) freely. Note that the accesses for the values migrated to local will still be tracked through the cache.

For local accesses, reserving space for every key and tracking every access might be not worth, especially for a very large store. This is because only a small fraction of key-value pairs should be migrated for a while. For example, migrating less than 0.2% of key-value pairs is sufficient for the motivating experiment (§6.1). Therefore, Pragh allows to skip tracking local accesses to the key-value pairs and provides two optional mechanisms to balance the timeliness and the accuracy of split live migration. Note that the monitor on each machine will report to the coordinator when remote accesses to a key-value pair exceed a threshold.

Eager migration: The coordinator will eagerly approve the migration of the key-value pair. After migration, the machine hosting the key will track the (remote) accesses to the key-value pair using a separate table, and then may migrate it back in future if it accesses the key-value pair more frequently.[9]

Deferred migration: The coordinator will notify the machine hosting the key to track the (local) accesses to the key-value pair using a separate table. After a migration interval, the coordinator will decide whether to migrate the key-value pair according to the statistics from all of the machines.

4.5 Discussion

Even though the current design of split live migration highly relies on RDMA, we believe that it can still benefit graph traversal workloads without RDMA, including no need for metadata and vertex granularity migration. However, after migrating the value to local, the cost to retrieve the address would be almost the same as the cost to retrieve the value directly. Hence, location cache must be deployed even without RDMA. On the other hand, the lack of RDMA would also need to rethink the implementation of migration protocol. Our future work may extend Pragh to support commodity networks without RDMA.

5 Implementation

Fault tolerance. Pragh supposes distributed in-memory graph store has provided durability and/or availability by using specific mechanisms like checkpointing or replication. Pragh only needs to consider the interrupted migration tasks and the recovery of crashed machines, because split live migration only changes the location of key-value pairs rather than the content of key-value pairs.

Interrupted migration tasks: If the crashed machine is the source of migration, there is nothing to do since the key-value pair will be recovered on the crashed machine later. If the crashed machine is the target of migration, a corner case that the interruption occurs after replacing address (❸ in Fig. 5) but before reclaiming memory (❺ in Fig. 5) will cause a little memory leakage, which can be detected and reclaimed by scanning the entire value memory region in background.

System recovery: Pragh relies on the mechanism provided by graph store to detect machine failures, like Zookeeper [30]. It will notify surviving machines to assist the recovery of crashed machines, which needs to handle two kinds of key-value pairs. First, the key-value pairs hosted by a crashed machine will be reloaded by the substitute of the crashed machine. Before that, all surviving machines will flush addresses in location cache which point to the key-value pairs hosted by crashed machines (i.e., `H(key).mid`) whether they have been migrated or not, and reclaim the memory of values migrated from crashed machines. Second, the key-value pairs, hosted by a surviving machine but migrated to a crashed machine, will be reloaded by the surviving machine. Before that, all surviving machines will also flush addresses in location cache which point to the key-value pairs migrated to the crashed machines (i.e., `addr.mid`). The coordinator will record the latest target machines of values migrated persistently before approving the migration, which could help surviving machines reload vertices precisely. Moreover, all workloads running on surviving machines involving crash machines will be aborted and suspended until recovery is complete. Finally, the coordinator in Pragh is stateless and easy to recover. The coordinator failure will not influence the execution of worker threads and only pause launching new migration tasks and recovering crashed machines. The migration thread can continue to complete the outstanding migrations.

Optimizations. Pragh adopts a unilateral migration protocol (see §4.1) to migrate one key-value pair (vertex) at a time, which requires *at most* five one-sided RDMA operations: two `READ`s to lookup and retrieve the value, one `CAS` to change the address atomically, and two `WRITE`s to invalidate and reclaim the original memory. Though this approach can provide instant response to migration demands and fully bypass the CPU and kernel of source machine, the throughput of migration may be bottlenecked by the network due to too many RDMA operations with small payloads.

To remedy it, Pragh enables three optimizations to further accelerate split migration. First, in most cases, the migrated key-value pair is frequently accessed by the target machine; thus, its address (very likely) has been already cached in the location cache. It means that the migration thread can skip the first `RDMA READ` to look up the address. Second, Pragh will

[9] Pragh relies on the coordinator to prevent the “ping-pong” of migrations, which prefers not to migrate the vertex competed by multiple machines.

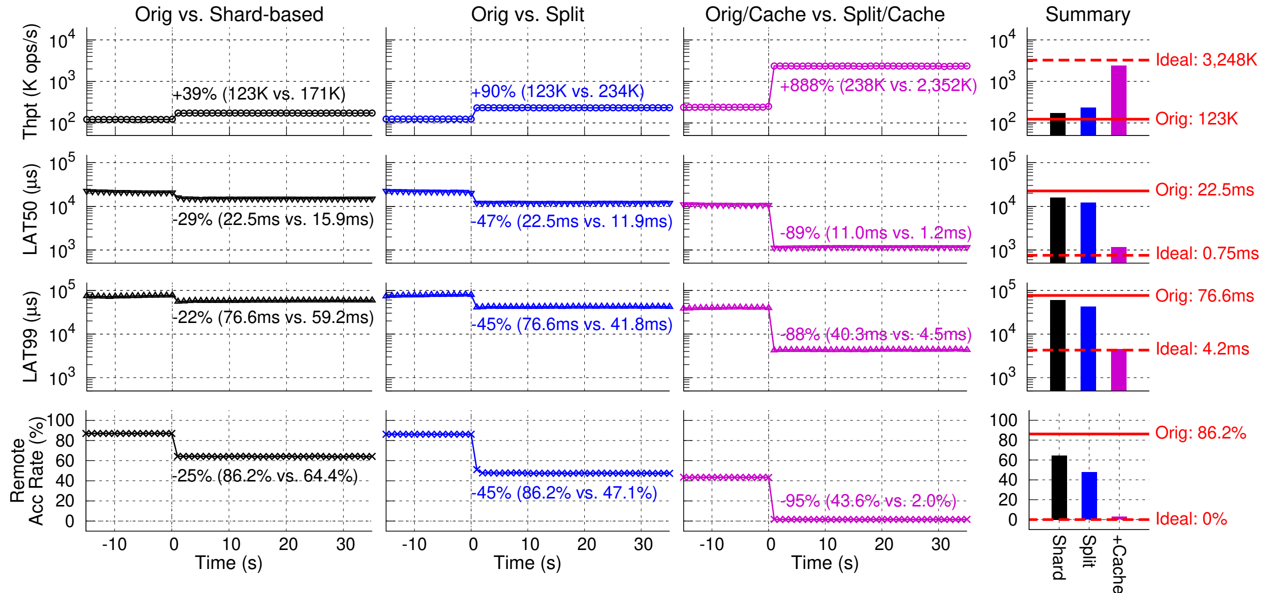

Fig. 10. *A comparison of migration schemes on the traversal benchmark with a skewed workload (a Zipf distribution with $\theta = 0.99$).*

migrate multiple key-value pairs concurrently in a pipelined fashion to better utilize network bandwidth. Each RDMA operation to migrate one key-value pair is implemented as one stage, and Pragh schedules these stages without waiting for the request completion. Finally, since the memory invalidation and reclaim are not on the critical path to migrate one key-value pair[10], Pragh enables passive ACK [59] to acknowledge the completion of such two `RDMA WRITE`s passively, which further reduces the network bandwidth. As a result, a single migration thread is sufficient to migrate more than one million vertices per second (§6).

Load balance. Though Pragh mainly focuses on using live migration to improve the locality of graph traversal workloads, it also can be used to rebalance load across machines, similar to prior work [53, 60, 35]. Basically, it all depends on the migration plan generated by the coordinator. Generally, the traversal workload will be sent to the machine hosting the initial vertex and run to completion. The remote key-value pairs will be retrieved by RDMA operations. Therefore, the coordinator should recognize such hotspots and generate proper plans to scatter them over all of the machines using live migration, like Pragh. Meanwhile, different goals also need different migration policies and statistics. It is orthogonal to the design of Pragh and beyond the scope of this paper.

6 Evaluations

Hardware configuration. All evaluations were conducted on a rack-scale cluster with 8 nodes. Each node has two 12-core Intel Xeon E5-2650 v4 processors and 128GB DRAM. Each node is equipped with two ConnectX-4 MCX455A 100Gbps InfiniBand NIC via PCIe 3.0 x16 connected to a Mellanox SB7890 100Gbps IB Switch, and an Intel X540 10GbE NIC connected to a Force10 S4810P 10GbE Switch. In all experiments, we reserve four cores on each CPU to generate requests to avoid the impact of networking between clients and servers as done in prior work [56, 58, 61, 14, 60, 52]. All experimental results are the average of five runs.

Traversal benchmark. Inspired by YCSB [15], we build a simple benchmark to evaluate the effectiveness of different migration approaches for graph traversal workloads. The traversal benchmark uses a synthetic graph provided by Graph500 [12]. In this paper, the graph with 2^{26} vertices and 2^{30} edges (RMAT26) is used as default dataset since we need to run the benchmark on a single machine to gain the performance of ideal setting (pure localized access). Note that the experimental results on larger graphs (e.g., RMAT29) are similar. The traversal benchmark consists of 95% two-hop queries (Get) and 5% edge updates/inserts (Put), similar to YCSB-B (read-heavy) [15]. Note that the majority of many traversal workloads [11] are two-hop queries, and it is easy to compose other complicated queries like SPARQL query [52]. The starting vertices of two-hop queries are chosen according to a Zipf distribution with $\theta = 0.99$. The scope of starting vertices and the number of neighboring vertices retrieved could be configured. The default values are 2^{10} and 100, respectively. We will compare the performance impact with different settings in separate experiments.

Comparing targets. The following five results are provided in the evaluation of the traversal benchmark. ***Orig*** indicates the performance of running the benchmark over the graph data partitioned randomly and without data migration. ***Ideal*** is the result gained by running the benchmark on a single machine. Specifically, throughput is simply magnified by

[10] To ensure consistency, the (original) memory invalidation must be completed before the next Put operation on (new) memory starts, which is easy to implement with the check-and-forward mechanism (§4.3).

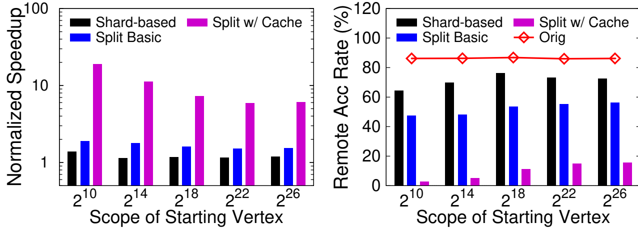

Fig. 11. *A comparison of migration benefits for different approaches with the increase of scopes of starting vertices.*

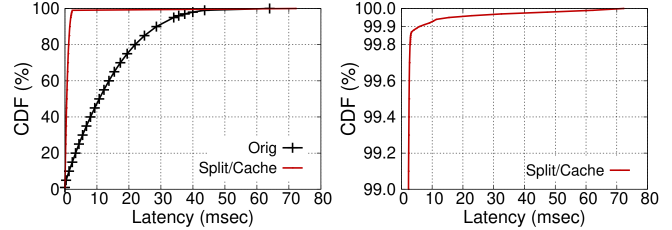

Fig. 12. *The CDF graph of latency for* Put *operations.*

the number of machines (i.e., 8×). ***Shard-based*** represents the performance of a shard-based migration approach, which deploys one hundred shards at each machine, similar to prior work [11, 5]. Note that we always generate optimal migration plans for shard-based migration by tracking every access but do not consider the tracking cost. ***Split/Cache*** and ***Split*** are the performance of Pragh using split live migration with and without location cache. The size of the location cache is 128MB. The migration plan is built by the statistics collected by our lightweight monitor. The default interval is set to 10 seconds.

6.1 Migration Benefits

To study the benefits of migration approaches, we run the traversal benchmark using different migration schemes and compare to the result of the original and ideal settings. As shown in Fig. 10, the original throughput and latency are about 26× slower than the ideal results (123K vs. 3,248K) since about 86.2% accesses to the key-value store are remote. Shard-based approach can only increase the throughput by 39% (123K vs. 171K) and decrease the median (50th percentile) latency by 29% (22.5ms vs. 15.9ms) as it just removes about 25% remote accesses. Pragh can almost double the throughput and reduce the latency by half, thanks to the basic split migration, which removes nearly all remote accesses to the values. Using location cache can remove almost all of the remote accesses to the keys, as the cache hit rate is about 99%. Note that the performance of enabling basic split migration or location cache alone are similar, because both of them still need one `RDMA READ` to retrieve the remote key or value separately.

When combining two techniques, the throughput of Split/Cache can reach 2,352K queries per second (19× compare to Orig). It has achieved close to 72% of ideal performance. The remaining 2.0% of remote accesses is due to the competition on vertices shared by multiple queries running on different machines. Note that traditional migration scheme is hard to integrate with location cache, since they will migrate both keys and values physically and make location cache useless.

Migration time and network traffic. Both split migration and shard-based migration can complete migration in seconds since we optimize the data transmissions in both methods. For shard-based migration, we migrate the shards in block granularity to fully utilize network bandwidth. However, split migration is still faster even using more network round-trips for one key. This is because fine-grained migration migrates much less data than coarse-grained, shard-based migration. For this experiment, only 78,242 keys (0.13% of the total vertices) are migrated in split migration, where 782MB data is migrated in total. For comparison, 85.6% of shards (685 out of 800) are migrated in shard-based migration with a total size of 20GB key-value to transfer.

Scope of starting vertices. Generally, the query will start from a certain type of vertices (e.g., users or tweets in social networks), and the size of the subset of vertices may be various. Fig. 11 further presents the impact of using different scopes of starting vertices in the traversal benchmark from 2^{10} to 2^{26}. The speedup after migration decreases with the increase of scope steadily due to the increase of contention on key-value pairs accessed by multiple queries. It will also result in the rise of remote accesses (see Fig. 11(b)).

Impact on Put operations. To reveal the impact of check-and-forward mechanism in Pragh on the latency of Put operations, we use an update-heavy traversal benchmark, which consists of 50% two-hop queries (Get) and 50% edge updates/inserts (Put), similar to YCSB-A [15]. Fig. 12(a) shows the CDF graph of latency for Put operations with and without split live migration. After migration, the latency of 99.9% Put operations decreases significantly, thanks to the decline of waiting time in the queue. Moreover, as shown in Fig. 12(b), the check-and-forward mechanism will just impact the 99.9^{th} percentile latency, since about 0.11% Put operations updates migrated key-value pairs and is forwarded to another machine. Note that Pragh only migrates 0.13% of total key-value pairs. The increase of latency is mainly contributed by the extra cost for forwarding the operation, waiting in the queue, and re-executing the operation.

Uniform workload. We also evaluate the traversal benchmark with a uniform workload. Shard-based approach can hardly gain benefits and only increases the throughput by 8% (126K vs. 136K) after migration, as the remote access rate just drops from 85% to 82%. In contrast, the basic split migration eliminates over 43% of remote accesses and increases the throughput by 84% (126K vs. 232K). By using location cache, the throughput of Split/Cache can reach 1,521K queries per second (12× compared to Orig). The remote access rate reduces to 5%.

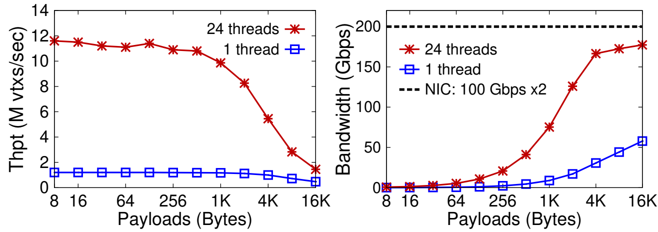

Fig. 13. *The throughput and bandwidth of unilateral migration using 1 and 24 threads.*

6.2 Migration Speed

To evaluate the capability of unilateral migration protocol, we conduct an experiment to migrate values from a remote machine to local with full speed. Fig. 13 shows the throughput of migration and network bandwidth consumed with the increase of payload (i.e., value) size. A single thread is enough to migrate values for millions of vertices per second with less than 4KB payloads. Using parallel migration with 24 threads can further increase the throughput of moving values to more than 10 million per second. Further, using multiple RDMA primitives to migrate a single value will not be limited by network. It should be noted that split live migration will only use the CPU of the target machine.

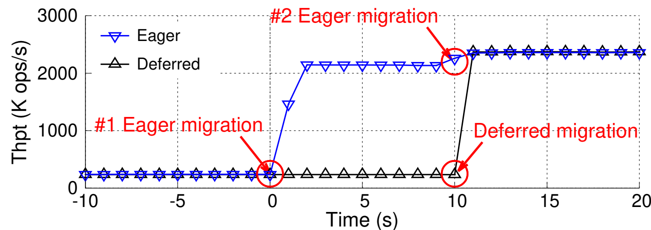

Fig. 14. *The throughput timeline for split live migration (w/ Cache) using eager or deferred mechanism.*

6.3 Eager Migration vs. Deferred Migration

Pragh provides two optional migration mechanisms, eager and deferred, to balance the accuracy and the timeliness of live migration. Fig. 14 compares these two mechanisms using the traversal benchmark. The monitor on each machine tracks remote accesses and reports the statistics to the coordinator periodically. After receiving statistics at 0 second, the coordinator adopts different mechanisms to notify migration threads. For eager migration, all of the migration threads will start migration directly, and the throughout reflects the benefits immediately, increasing from 239K to 2,142K. However, since the migration plan may not be optimal, the second migration happens at the next interval (after about 10s). The throughput further increases to 2,362K. For deferred migration, the coordinator will only ask monitors to track the local accesses on the potential key-value pairs for migration at 0 second, and do the migration with an optimal plan at the next interval. The throughput will directly increase from 239K to about 2,362K.

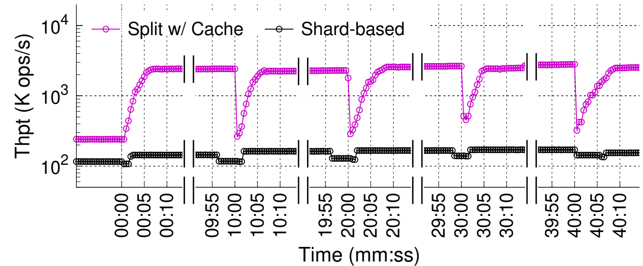

Fig. 15. *The throughput timeline for dynamic workloads using shard-based or split live migration.*

6.4 Dynamic Workloads

To study the effectiveness of split live migration in the face of dynamic workloads, we change workloads every 10 minutes by using non-overlapping scopes of starting vertices. As shown in Fig. 15, the performance notably drops every time the workloads change, because the location of vertex migrated for the current workload is very likely not suitable for the next workload. Shard-based migration can only provide very limited performance improvement as expected. Split migration with location cache can recover the performance after migration. Note that Pragh uses instant migration in this case, which is hard to implement in traditional migration approaches. When the monitor detects the frequency of accesses to some remote key-value pair exceeding a threshold (100 times per second), it will instantly report to the coordinator. Further, the migration on every machine can move values at any time, and there is no need to synchronize with other machines. Therefore, the performance is recovered gradually in about 5 seconds. Note that using a more aggressive policy could further reduce the time spent in recovery.

6.5 Application: RDF Graph and SPARQL Query

Wukong+M. To demonstrate the generality of Pragh, we have integrated *split live migration* with Wukong [52], called Wukong+M. Wukong is a state-of-the-art distributed graph store that leverages RDMA-based graph exploration to provide highly concurrent and low-latency SPARQL queries over large RDF graph datasets. RDF (Resource Description Framework) is a standard data model for the Semantic Web, recommended by W3C [2], which presents linked data as a set of $\langle subject, predicate, object\rangle$ triples forming a directed and labeled graph. SPARQL is the standard query language for RDF datasets, which can be supported by using graph exploration (i.e., graph traversals in parallel). We also implement an RDMA-friendly location cache on Wukong+M, similar to DrTM-KV [61].

Benchmark and workload. We use the Lehigh University Benchmark (LUBM) [3] which is widely used to evaluate the performance of RDF query systems [63, 36, 28, 52, 64, 37]. More specifically, we use LUBM-10240 dataset where each machine deploys about 32GB memory. We use the query set published in Atre et al. [8] and a mixed workload consist-

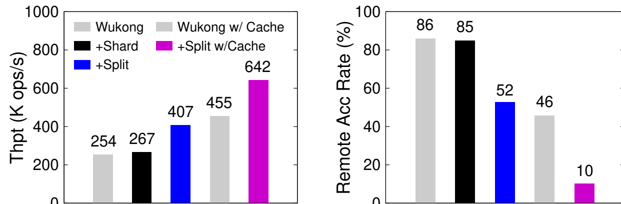

Fig. 16. *The comparison of (a) throughput and (b) remote access rate using a mixed workload for Wukong with various settings.*

ing of 6 classes as the same in the original paper [52]. The workload is skewed such that the starting vertices are chosen following a Zipf distribution ($\theta = 0.99$) over all vertices.

Performance. As shown in Fig. 16, Wukong+M (+Split) with location cache (w/ Cache) can outperform all other counterparts by up to 2.53×, thanks to split live migration that eliminates about 88% remote accesses (from 86% to 10%). Shard-based live migration (+Shard) only improves the mixed query throughput by about 5%, since it is hard to balance requirements for keys in each shard. The basic split migration (+Split) outperforms shard-based migration by 1.52× (407K ops/s vs. 267K ops/s) due to allowing fine-grained migration. After enabling location cache (+Split w/ Cache), the throughput further increases by 1.58× (642K ops/s vs. 407K ops/s).

7 Related Work

Live migration on relational stores. There have been many efforts to provide live migration features for distributed relational databases, considering different low-level architectures, such as shared-storage [20, 21, 26, 48, 19, 10] or partitioned database [53, 25, 60, 35]. They mainly focus on migrating shards efficiently across machines for balancing load and reducing latency. There are two main types of approaches: pre-copy based [20, 21, 60] and post-copy based [26, 25, 35].

To the best of our knowledge, almost all such systems adopt shard-based mechanisms (e.g., range or hash partitioning [17, 43]) and the changes of the ownership of shard are necessary when migration. Hence, they must maintain the state of shards explicitly by using internal global data structures or external location services [55, 4, 5]. Differently, split live migration fixes the (logical) location of data to avoid the maintenance overhead, which makes it different from all of the previous approaches.

The inherent drawback of one-off sharding has driven a few recent efforts to support dynamic sharding [25], auto sharding [4] and application-specific sharding [5] techniques. However, when shards still serve as the unit of migration, it is hard to balance the effectiveness (granularity) and efficiency (CPU and memory) for large-scale graph data with dynamic workloads due to lacks of locality.

Live migration on graph stores. The increasing importance of graph data models has stimulated a few recent designs of vertex migration or graph re-partitioning techniques targeting graph systems [44, 62, 34, 41, 65], since it is hard or even impossible to handle dynamic workloads or evolving graphs only relying on static partition-based approaches [27, 13]. The most related work is Mizan [34], a distributed graph processing system that leverages fine-grained vertex migration to improve *load balance* for iterative analytics workloads (e.g., PageRank and DMST [34]) over a *static* graph. Further, vertex migration can only happen when all worker threads reach a synchronization barrier (*stop-the-world*), and all selected vertices in one machine can only be migrated to a pairwise machine (*non-flexible*). By contrast, Pragh uses live migration to preserve *locality* for *concurrent* and *dynamic* traversal operations over *evolving* graphs. Thus, it makes many fine-grained migrations *on demand*, and vertices can be migrated to any machines *flexibly*.

Most graph re-partitioning approaches [44, 62, 65] need to maintain global metadata to map vertices to partitions, and use multiple phases to iteratively migrate vertices for reducing the communication cost. Therefore, these design choices make them slow to react to changes of workloads and other real-time events. Pragh can provide instant response to migration demands using lightweight monitoring and unilateral migration protocol.

Further, data replication has been used to improve the locality of traversal workloads over graph stores [29, 62, 40] by duplicating vertices on multiple machines. However, it will consume more memory and complicate the design of graph store in the face of evolving graphs. It should be noted that data replication is orthogonal to live migration, and integrating split live migration with fine-grained vertex replication [27, 13] is part of our future work.

8 Conclusion

This paper presents Pragh, an efficient locality-preserving live migration scheme for graph store. The key idea of Pragh is *split live migration*, which allows fine-grained migration while avoiding the need to maintain excessive metadata. Several key designs like the unilateral migration protocol, the integration of location-based caching, and the check-and-forward mechanism for evolving graphs made Pragh fast and full-fledged. Evaluations using both a graph traversal benchmark and SPARQL workloads confirmed the effectiveness and generality of Pragh.

ElasticBF: Elastic Bloom Filter with Hotness Awareness for Boosting Read Performance in Large Key-Value Stores

Yongkun Li, Chengjin Tian, Fan Guo, Cheng Li, Yinlong Xu
University of Science and Technology of China

Abstract

LSM-tree based key-value (KV) stores suffer from severe read amplification because searching a key requires to check multiple SSTables. To reduce extra I/Os, Bloom filters are usually deployed in KV stores to improve read performance. However, Bloom filters suffer from false positive, and simply enlarging the size of Bloom filters introduces large memory overhead, so it still causes extra I/Os in memory-constrained systems. In this paper, we observe that access skewness is very common among SSTables or even small-sized segments within each SSTable. To leverage this skewness feature, we develop ElasticBF, a fine-grained heterogeneous Bloom filter management scheme with dynamic adjustment according to data hotness. ElasticBF is orthogonal to the works optimizing the architecture of LSM-tree based KV stores, so it can be integrated to further speed up their read performance. We build ElasticBF atop of LevelDB, RocksDB, and PebblesDB, and our experimental results show that ElasticBF increases the read throughput of the above KV stores to 2.34×, 2.35×, and 2.58×, respectively, while keeps almost the same write and range query performance.

1 Introduction

With the exponential growth of data volume, traditional relational database meets challenges in scalability in dealing with extremely large-scale data. As an alternative, key-value (KV) store is widely used as the fundamental storage infrastructure in many applications, such as cloud systems [25], advertising [8, 16], social networks [3, 37], search indexing [8, 21], online gaming [13], etc. According to the used index structures, KV stores can be categorized into hash index based design [12,13,26], B-tree based design [20,31] and LSM-tree based design [27, 30, 32, 36]. Because hash index based design requires large memory and can not well support range query, and B-tree based design involves an abundance of random writes, so most modern KV stores use LSM-tree, e.g., LevelDB [21] at Google, RocksDB [16] at Facebook, Dynamo [14] at Amazon, and Cassandra [1] at Apache.

An LSM-tree based KV store is typically composed of two components, and we take LevelDB as an example to illustrate. One resides in memory to cache KV pairs, and it includes a MemTable and an Immutable MemTable. The other is stored in secondary storage, which is divided into multiple levels consisting of multiple SSTables. Each SSTable contains a set of sorted KV pairs and necessary metadata. When a level reaches its size limit, its SSTables will be compacted into the next level via compaction, which first reads out the SSTables in the two levels, then performs a merge sort, and finally writes back the new SSTables into the next level. As a result, compaction induces severe write amplification [27, 32].

Various designs are recently proposed to mitigate the compaction overhead [5, 27, 32, 42]. The most recent work PebblesDB [32] proposes a novel data structure called Fragmented Log-Structured Merge-Trees (FLSM), which follows the LSM-tree structure, but relaxes the fully sorted constraint in each level. Thus, compaction just needs to append data to multiple fragments in the next level, and there is no need to merge with the SSTables in the next level. Therefore, PebblesDB can greatly reduce the write amplification. However, sacrificing the sorted nature of KV pairs in each level, PebblesDB inevitably degrades the read performance.

On the other hand, LSM-tree based KV stores also suffer from severe read amplification [27, 31, 39]. This is because when lookup a KV pair, KV store needs to check multiple SSTables from the lowest level to the highest level until the key is found or all levels have been checked. Furthermore, it is required to read multiple metadata blocks to really check whether a KV pair exists in one SSTable. Thus, read amplification can reach a factor of over 300× [27]. To reduce extra I/Os induced by checking multiple SSTables, modern designs use Bloom filters in KV stores [35] to quickly check the existence of a KV pair in an individual SSTable. However, Bloom filters suffer from false positive, so they may return a positive result even when a KV pair does not exist in the SSTable, and this incurs unnecessary I/Os. We also conduct experiments to measure the impact of false positive by using Bloom filters with four `bits-per-key` in a 100GB KV store. Other parameter settings and system configurations are presented in §4.1. Results show that a key lookup incurs 7.6 inspections to SSTables on average, but 1.3 disk accesses are needless and induced by false positive.

Allocating more bits for each key can reduce the false positive rate, but the volume of all Bloom filters also increases, e.g., a 10TB KV store with 100B KV pairs requires 128GB Bloom filters under 10 `bits-per-key` setting. If the volume of Bloom filters exceeds the memory capacity, some filters will be swapped out to secondary storage, which induces extra I/Os and increases the read amplification.

It is a consensus that data access is usually skewed in real

applications [4, 9]. Some KV pairs are hot and frequently accessed, while most KV pairs are seldom accessed. Thus, if we allocate more bits to the Bloom filters for hot KV pairs, then we can reduce the overall false positive rate in the whole process of running an application, while still limit the volume of all Bloom filters. However, it is not an easy task to dynamically adjust the setting of Bloom filters in KV stores due to the following reasons, which are revealed by our experiments. First, different levels exhibit significantly different access unevenness. Even though KV pairs in a lower level are usually more frequently accessed, there are still a considerable proportion of SSTables in a higher level that are evidently hotter than SSTables in a lower level. Second, even for KV pairs within the same SSTable, the access unevenness is also serious. Last but not least, the hotness of KV pairs dynamically changes during the running time of applications. Monkey [10] proposes a heterogeneous scheme which allocates more bits to Bloom filters in lower levels, but it uses the same setting for all filters in the same level and fails to dynamically adjust the setting according to data hotness.

In this paper, we propose ElasticBF, a fine-grained and elastic Bloom filter management scheme. Its basic idea is assigning multiple small-sized Bloom filters to each small group of KV pairs when building SSTables, and these Bloom filters reside in secondary storage and are dynamically loaded into memory to activate according to the hotness of KV pairs. However, to realize dynamical allocation of Bloom filters, the following key issues must be addressed: (1) How to accurately measure and record the hotness of KV pairs with low storage and CPU overheads? (2) How to dynamically change the ability of Bloom filters based on hotness with low memory and computation overheads? (3) How to efficiently inherit the hotness of SSTables with low metadata overhead when SSTables are reorganized during compaction? ElasticBF carefully addresses the above issues by developing multiple techniques to limit its overhead, including *fine-grained allocation*, *hotness inheritance* and *in-memory management optimization*.

We emphasize that ElasticBF is orthogonal to existing works focusing on the optimization of KV store structures, so it can be combined with these designs to further accelerate the lookup of KV pairs. To demonstrate its efficiency, we carefully build ElasticBF atop three commonly used or state-of-the-art KV stores, LevelDB, RocksDB and PebblesDB. Experiments show that for all of the above KV stores, ElasticBF increases the read throughput to 2.34×, 2.35×, and 2.58×, respectively, while keeps almost the same write performance. Also, for workloads with mixed reads and writes, ElasticBF reduces read latency by 38.9% - 51.8% without affecting writes. Compared with Monkey, which is the state-of-the-art heterogeneous Bloom filter management scheme, ElasticBF achieves up to 2.20× throughput. In summary, our contributions are as follows.

- **Fine-grained allocation.** We find that the hotness of KV pairs varies significantly in different ranges within the same SSTable. So we divide each SSTable into different segments, measure and record their hotness with acceptable storage and CPU overheads, so as to receive relatively accurate hotness estimation and enable fine-grained Bloom filter allocation.

- **Hotness inheritance.** We design an effective scheme to estimate the access frequencies of new SSTables during compaction by inheriting from the outdated SSTables. So ElasticBF can preserve the hotness during the whole execution process of applications, and avoids frequent cold start of hotness due to compaction and consistently improves read performance.

- **In-memory management optimization.** We propose a Multi-Queue to manage the in-memory Bloom filters, and use parallel I/Os to accelerate the adjustment. Thus, we can dynamically adjust the Bloom filters in memory according to the hotness of KV pairs with negligible CPU overhead.

The rest of this paper is as follows. §2 introduces LSM-tree based KV stores and shows our observations on access skewness to motivate this work. §3 presents the design details of ElasticBF and §4 evaluates its performance. Finally, §5 reviews related work and §6 concludes this paper.

2 Background & Motivation

In this section, we first briefly introduce LSM-tree, then analyze the read amplification in LSM-tree based KV stores, and finally present our observations about data access locality in KV stores to motivate this work.

2.1 Log-Structured Merge Trees

Figure 1 illustrates the structure of an LSM-tree based KV store, which mainly consists of two components. One is in memory, which includes a *MemTable* and an *Immutable MemTable*. The other is in secondary storage, which is divided into multiple levels, say L_0, L_1, $\cdots$, L_k, where k depends on the KV store size. Besides, the size limit of level L_i is usually m times of that of level L_{i-1} for $1 \leq i \leq k$, e.g., $m = 10$ in LevelDB by default.

Now we illustrate how data is stored. Specifically, KV pairs are first written to the *MemTable* which works as a cache. When *MemTable* is filled up, it will be converted to an *Immutable Memtable*, which can not be written any more.

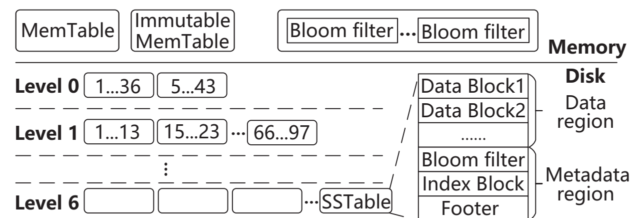

Figure 1: Structure of LSM-tree based KV store.

Later, *Immutable Memtable* will be packed into an SSTable and appended into L_0 in the secondary storage. Note that keys in each SSTable are sorted, but they are not sorted between SSTables in L_0 so as to make the writes to disk fast. Thus, this write policy degrades read performance, so the size of L_0 is usually limited, e.g., it is limited as 12 SSTables in LevelDB. To balance read and write performance, SSTables are organized into a multi-level tree, and if one level (say L_{i-1}) is filled up, its SSTables will be merged into its higher level (say L_i) by compaction, which merges all KV pairs in L_{i-1} into L_i, so data are sorted in every level except for L_0.

To find a key in the secondary storage, we need to search it level by level from L_0 to L_k. Note that we should check all SSTables in L_0 because they are not sorted, while we only need to check one SSTable in each of the other levels until we find the key or all levels are checked. Thus, we usually need to read multiple SSTables to find a key, which induces read amplification, and Bloom filters are commonly used to reduce the read amplification. As a result, besides KV pairs, each SSTable also includes Bloom filters and other metadata (see Figure 1). For performance consideration, the Bloom filters are usually required to be also buffered in memory.

However, Bloom filters suffer from false positive because of hash collision, and thus incur extra I/Os to read out data from SSTables for key comparison. The false positive rate of a Bloom filter is $(1-e^{-k/b})^k$, where b is the number of bits allocated to each key, i.e., `bits-per-key`, and k means the number of hash functions [24]. Since $(1-e^{-k/b})^k$ is minimized when $k = ln2 \cdot b$, false positive rate can be simply represented as 0.6185^b. Thus, the value of b directly determines the memory usage of a Bloom filter. We can reduce the false positive rate by allocating more `bits-per-key` for Bloom filters, but allocating more bits to each keys will increase the volume of all Bloom filters and thus consumes more memory. Even worse, if the volume of all Bloom filters exceeds the memory capacity, some Bloom filters will be swapped out to secondary storage, and this will induce extra I/Os and further aggravate read amplification.

2.2 Motivation

Uneven accesses are still very common in KV stores [9, 22], where only a small proportion of the KV pairs are frequently accessed, while the majority of the KV pairs are seldom accessed. Therefore, if we allocate more bits to the Bloom filters for hot KV pairs and fewer bits for cold ones, then the overall positive false rate during the whole execution process of applications will be reduced. Clearly, we will face to a series of challenges to realize such heterogeneous Bloom filters and enable dynamic adjustment. In this subsection, we present our observations on the access skewness of KV stores to motivate this work. The detailed design of ElasticBF will be presented in §3.

We run experiments with RocksDB to validate the access unevenness in KV stores. We use YCSB [9] to load a 256GB

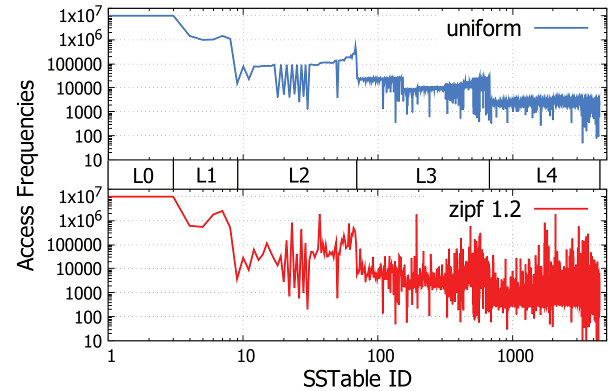

Figure 2: File access frequencies under different workloads.

database in the experiments, where the size of each SSTable is set as 64MB, which is the default configuration, and the size of each key value pair is 1KB. Note that the maximum size of L_1 is configured as 256MB in RocksDB, and the size of L_i is 10 times of that in L_{i-1} ($i \geq 2$), therefore 5 levels are enough to keep 256GB data. We then generate two representative workloads with uniform and Zipfian distributions, and each workload contains ten million Get requests. Note that there are about 4400 SSTables in the tested KV store, so issuing ten million Get requests is enough to study the access pattern. To make the evaluation of the hotness of SSTables and the hotness of different regions in the same SSTable accurate, we disable the Bloom filters in these experiments. That is, we search the keys level by level, and at each level, we compare the target key with the key ranges of SSTables. If the key falls into the range of an SSTable, we will read the data out and check whether the key exists or not until the key is found or all levels are checked.

We first show the file-level access characteristics, and Figure 2 shows the access frequency of each SSTable. The x-axis represents the identities of SSTables which are numbered sequentially from the lowest level to the highest level, and the y-axis shows the number of accesses to each SSTable. From the results, we can have two observations. First, on average, the access frequencies of SSTables in lower levels are higher than those in higher levels. This is because lookup always flows from lower levels to higher levels. Second, if we zoom in one particular level, we can find that the access frequencies vary very significantly from SSTables, i.e., some SSTables are much hotter than others within each level. Besides, when we compare the access frequencies of SSTables in adjacent two levels, we can find that it is very common to have some SSTables in level L_{i+1} which are even hotter than some SSTables in level L_i, especially for the skewed workload with Zipf distribution. That is, SSTables in higher levels may also be hotter than those in lower levels. For example, 21% of SSTables in L_4 is even hotter than 11% of SSTables in L_3. More importantly, since more than 98% SSTables are stored in the highest two levels, i.e., L_3 and L_4 in this example, we can conclude that the hotness of most SSTables can not be

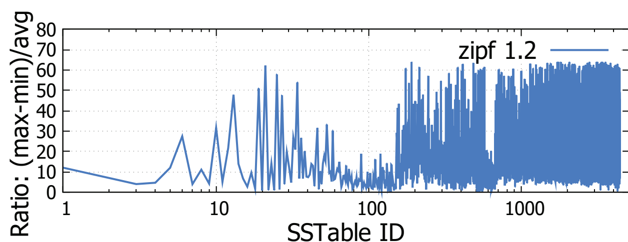

Figure 3: The ratio of the difference between the maximum and the minimum access frequencies of different regions to their average access frequency within each file.

accurately characterized according to which level they are placed. This observation implies that Monkey's level-based coarse-grained heterogeneous Bloom filters can not take full advantage of the access skewness, and finer-grained Bloom filter design is necessary.

Since the size of an SSTable may still be configured to be large to leverage sequential I/O bandwidth, e.g., RocksDB uses 64MB or even larger SSTables, the access skewness may still be serious within each SSTable. Note that it will bring very large memory and CPU overheads to record the hotness of each KV pair, so we divide each 64MB SSTable into 64 regions, each of which has 1MB, and record the access frequencies of different regions in each SSTable. Figure 3 shows the ratio of the difference between the maximum and the minimum access frequencies of all regions in the same SSTable to their average access frequency. We can see the ratio value is very large for many SSTabes, e.g., greater than 10 for 73% SSTables. So the access unevenness is very serious even within the same SSTable.

In summary, access skewness is very serious among different SSTables, and even among different regions within the same SSTable. This offers an opportunity to develop finer-grained heterogeneous Bloom filters by allocating more `bits-per-key` for hot SSTables or regions so as to reduce the overall false positive rate without increasing the volume and memory overhead of Bloom filters.

3 Design

The main idea of ElasticBF is to construct multiple Bloom filters for each SSTable, but allocate less `bits-per-key` to each filter. Note that the Bloom filters in SSTables are stored in secondary storage, and they are just reserved for future use. That is, Bloom filters become active only after being loaded into memory, which is a dynamical process according to the hotness of SSTables. If an SSTable becomes hot, we will load more of its Bloom filters into memory, and we may also disable some of its Bloom filters in memory when it becomes cold. Thus, we can dynamically adjust Bloom filters while avoiding heavy I/O and CPU overheads for computing the hash functions when we change Bloom filters according to the hotness of SSTables. Thanks to the dynamic allocation and adjustment of Bloom filters, we can reduce the overall false positive rate, while keeping the same memory usage.

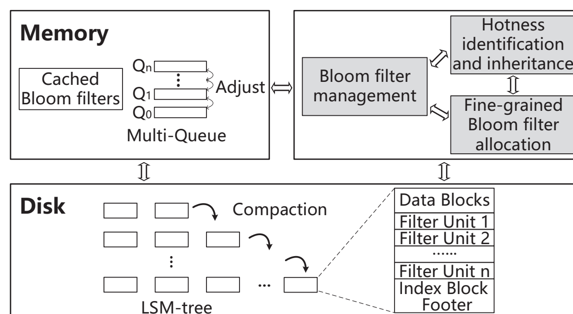

Figure 4: The architecture of ElasticBF.

3.1 Overview

Figure 4 depicts the architecture of ElasticBF, which mainly contains three components, *fine-grained Bloom filter allocation*, *hotness identification and inheritance*, and *Bloom filter management in memory*. For the design of fine-grained Bloom filter allocation, we mainly face to the problems of how many Bloom filters should be allocated to each SSTable and how many bits should be assigned to each filter so as to achieve low false positive rate and low memory usage. We also need to carefully design the data structure and management scheme with low I/O overhead. For hotness identification, our goal is to achieve relatively accurate estimation of hotness with low overhead. Finally, hotness inheritance is designed to avoid cold start of hotness identification after compaction, and Bloom filter management in memory is to efficiently adjust Bloom filters according to hotness.

Remarks: ElasticBF realizes an elastic Bloom filter management scheme with little extra memory usage and small CPU and I/O overheads. It is orthogonal to existing works focusing on optimizing the structure of KV stores and can be integrated to accelerate their read performance. Besides, ElasticBF may also be applied in other scenarios to improve object lookups, and the management technique for hot/cold adaption is applicable to other summary data structures.

3.2 Fine-grained Bloom Filter Allocation

The read performance of KV stores can be improved by reducing the I/Os caused due to false positive of Bloom filters. In the following, we first analyze the expected false positive rate by dynamically activating Bloom filters according to hotness, then we describe how to construct multiple Bloom filters for SSTables to realize fine-grained allocation.

Construction of multiple Bloom filters. ElasticBF generates multiple Bloom filters for each SSTable by using different and independent hash functions. Each filter is allocated with less `bits-per-key`, and we call it a *filter unit*. All filter units assigned to an SSTable are named as a *filter group*, as shown in Figure 5. Since the multiple filters within a filter group are independent, a key is certainly not in an SSTable as long as one filter unit returns a negative answer. That is, if multiple filter units are enabled, then only when all enabled

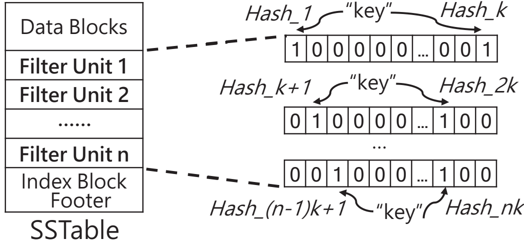

Figure 5: Construction of multiple Bloom filters.

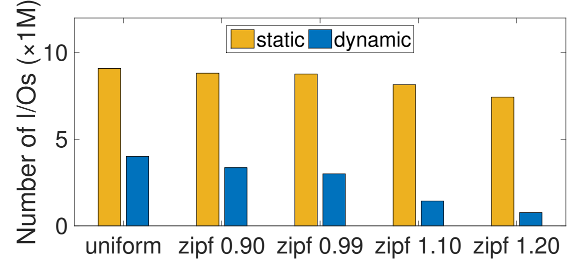

Figure 6: Number of I/Os caused due to false positive.

filter units indicate the existence of a key, we need to read out the SSTable to search the key.

As pointed out in [24], the false positive rate of a filter group is equivalent to a single Bloom filter which has the same `bits-per-key` to all filter units within the filter group. We call this feature *separability*, which can be further justified as follows. Assume that a filter group consists of *n* filter units, each of which is a b/n `bits-per-key` filter, then the false positive rate of each filter unit is $0.6185^{b/n}$. Since the filter units in a group are generated by different independent hash functions, the false positive rate of n filter units in a group is $(0.6185^{b/n})^n = 0.6185^b$, which is exactly the same with that of a single Bloom filter with b `bits-per-key`.

Based on the separability feature, we should determine b and n to optimize the setting of multiple Bloom filters. As we should enable all the filter units in a group for the hottest SSTables such that the false positive rate 0.6185^b closes to zero, in our configuration, we set $b = 24$ with a false positive rate of about 0.001%. On the other hand, n indicates the maximum number of hotness categories to distinguish different SSTables. Increasing n will more accurately differentiate the hotness of SSTables, but it needs more I/Os to load filter units to achieve low false positive rate. Thus, we set $n = 6$, i.e., a filter group has 6 filter units, each is allocated with 4 `bits-per-key`. We will analyze the impact of `bits-per-key` of each filter unit on the read performance in §4. Notice that ElasticBF allocates multiple filter units to SSTables, which induces extra storage usage. Assuming that the size of KV pairs is 1KB, thus one group of filter units cost about 192KB storage, which is only 0.3% of a 64MB SSTable, and the filters are stored in secondary storage, so the storage overhead of ElasticBF is negligible.

Benefit analysis. Now we analyze the benefit of using multiple Bloom filters. Suppose that there are N SSTables, $s_1, s_2, ..., s_N$, in a KV store, and we use static setting to set b `bits-per-key` for all SSTables, i.e., the memory usage to reside Bloom filters is b bits for each key. Suppose that a workload needs to access SSTable s_i with p_i times, then the expected number of times to really read out data from all SSTables due to false positive with static setting is

$$R_{static} = \sum_{i=1}^{N} p_i \cdot 0.6185^b. \quad (1)$$

In a contrary, if we dynamically set multiple Bloom filters with the same memory usage as the static setting, and suppose we load n'_i filter units for SSTable s_i according to its hotness, each allocates b' `bits-per-key`, then under the assumption of the same memory usage with static setting, the expected number of times to read out data from SSTables is

$$R_{dynamic} = \sum_{i=1}^{N} p_i \cdot \left(0.6185^{b'}\right)^{n'_i}, \quad (2)$$
$$\text{subject to} \quad \sum_{i=1}^{N} n'_i \times b' \le Nb,$$

where the inequality $\sum_{i=1}^{N} n'_i \times b' \le Nb$ represents the same memory usage constraint.

To better understand why dynamical allocation can reduce I/Os, i.e., $R_{dynamic} < R_{static}$, we count the number of I/Os due to false positive by conducting experiments on RocksDB. We set the average `bits-per-key` as 4 for both Bloom filter allocation schemes. For the dynamical allocation scheme, we generate 6 filter units for each SSTable and still use 4 `bits-per-key` for each filter unit. We first issue ten million Get requests on a 100GB database using static setting of Bloom filters, half of the Get operations request non-existent items, and we count the real number of I/Os issued due to false positive as R_{static}. Then we classify SSTables into 7 categories (C_0, C_1, ..., C_6) according to their access frequencies, and initially load i filter units for SSTables in C_i in the dynamical allocation. We use this configuration to replay the ten million Get requests and count $R_{dynamic}$. Figure 6 shows the results under different workloads, we find that with the same memory usage, dynamic setting of Bloom filters reduces the number of I/Os caused due to false positive under different workloads by 55.9% - 89.7% compared to static setting, and the reduction becomes larger for more skewed workloads. Note that in practical systems, Bloom filters may be configured with larger `bits-per-key` so as to achieve very low false positive rate, dynamical allocation still has its benefit, e.g., it can use much less memory to achieve similar false positive rate.

Finer-grained design with chunking. As mentioned in Section 2.2, access unevenness is still serious within an SSTable. So we may further reduce the false positive rate by differentiating the hotness of keys within the same SSTable. However, this will bring too large extra overheads of memory usage and CPU for recording the hotness of individual keys. To balance the accuracy of measuring hotness and the extra

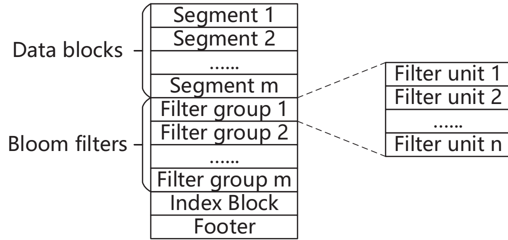

Figure 7: Segments in one SSTable.

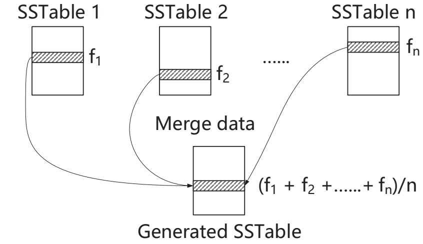

Figure 8: Hotness inheritance after compaction.

overheads to KV stores, we further divide each SSTable into multiple regions called *segments* and record the hotness at the granularity of the segment. Each segment is then allocated a group of filter units, as shown in Figure 7. From §2.2, we know the hotness of different segments still significantly varies, so we are still expected to reduce the false positive rate by differentiating the hotness of segments.

The challenging issue is to optimize the size of segments, as large segment can not accurately reflect the hotness of different KV pairs in an SSTable and small segment will bring large overhead to KV stores. Our rule to configure the size of segment is to make the size of each Bloom filter be close to the device block size, e.g., 4KB, so as to reduce the I/O overhead when loading Bloom filters. We will analyze the impact of segment size on the read performance in §4.

Finally, since we only need several bytes to record the hotness for each segment, the memory overhead is smaller than 1% of the Bloom filter size. For storage overhead, if the KV pair size is 1KB and ElasticBF uses 4 `bits-per-key` for each filter unit, then one filter unit only costs around 2KB storage space, which is only 0.05% of a 4MB segment.

Remarks: All Bloom filters allocated to an SSTable are stored in its metadata area and kept in secondary storage. Upon reading an SSTable, the default number of Bloom filters are also loaded into memory, so loading Bloom filters at initialization does not induce extra I/Os.

3.3 Hotness Identification and Inheritance

Hotness identification. The hotness of a segment is determined by its access frequency and the time duration since its last access. Specifically, we propose an *expiring policy* to differentiate hot/cold segments. We maintain a global variable named `currentTime`, which is defined as the total number of Get requests issued to the whole KV store so far, and we also associate a variable named `expiredTime` with each segment to denote the time point at which the segment will be "expired". Precisely, `expiredTime` is defined as `lastAccessedTime + lifeTime`, where `lastAccessedTime` denotes the time of the most recent access to the segment and `lifeTime` is a fixed constant. Note that the "time" concept here means logical time which is actually represented by the number of accesses. Each time when a segment is accessed, we increase the `currentTime` by one and update the `expiredTime` of this segment by setting `lastAccessedTime` as the updated value of the `currentTime`. We define a segment as "expired" if `currentTime` already becomes larger than `expiredTime`. The physical meaning of the above policy is that if a segment is not accessed during a fixed number of Get requests which is defined by `lifeTime`, then it is expired and considered as cold. Note that the time complexity to update the hotness metadata of a segment is only $O(1)$. Besides, the memory overhead is also small, e.g., for a 100GB KV store, there are around 25K segments whose size is 4MB, assume that 4 bytes are used to record the `expireTime` of each segment, then the total memory overhead is only around 100KB.

Hotness inheritance after compaction. Compaction will trigger merge sort between SSTables to generate new SSTables. So the segments in new SSTables are also newly generated and their hotness should be changed. If we set the hotness of new segments as 0, then ElasticBF will face to cold start of hotness and this may degrade the performance of future read from the new segments. To inherit the hotness, ideally, we can accurately estimate the hotness of new segments based on the hotness of all keys within it, but this will bring into KV stores too large overhead.

Instead, ElasticBF uses the hotness of old segments to estimate the hotness of new segments. Specifically, as illustrated in Figure 8, when a new segment is generated, we first find out the old segments which are involved in the procedure of generating the new segment and also have overlapped key ranges, then we estimate the hotness value of the new segment by simply using the mean of the hotness of all old segments. At last, we enable some filter units for the new segment accordingly. Experiments in §4 show that this simple scheme is efficient to improve the read performance for workloads with mixed reads and writes in KV stores.

3.4 Bloom Filter Management in Memory

Now the final issue is to determine how many filter units should be enabled for each segment. Although we can address this issue by formulating an optimization problem to minimize the overall false positive rate, but this will consume lots of CPU resources. Besides, every access changes the access frequency of some segment, so it needs to recompute the optimal solution and incurs lots of I/Os to adjust the optimal configuration. To address this issue, ElasticBF develops a lightweight and efficient adjustment scheme.

Bloom filter adjusting rule. We use a metric which is defined as the expected number of I/Os caused by false positive to guide the adjustment, and we denote this amount of extra I/Os as $E[\text{Extra_IO}]$, which can be expressed as

$$E[\text{Extra_IO}] = \sum_{i=1}^{M} f_i \times r_i, \quad (3)$$

where M means the total number of segments in the KV store, f_i denotes the access frequency of segment i, r_i denotes the false positive rate and it is determined by the number of filter units loaded in memory for segment i. Here, the rule of thumb is to adjust the number of filter units, and thus changes r_i, so as to make $E[\text{Extra_IO}]$ be decreased.

The procedure of adjusting Bloom filters is as follows. Each time when a segment is accessed, we update its access frequency and the $E[\text{Extra_IO}]$, then we check whether $E[\text{Extra_IO}]$ could be decreased if we enable one more filter unit for this segment and disable one unit for other segment to guarantee the same memory usage. If the $E[\text{Extra_IO}]$ could be decreased, then we apply the adjustment, otherwise, we do nothing. Note that in this adjusting procedure, one key issue is to find out which filter unit should be disabled, and we address this problem by maintaining an in-memory index based on Multi-Queue, which will be described later.

Realizing dynamic adjustment with Multi-Queue. Recall that the challenging issue in the adjust procedure is to decide which filter unit should be disabled. We extend Multi-Queue (MQ) [33,46] to address this problem. Specifically, ElasticBF maintains multiple in-memory Least-Recently-Used (LRU) queues to manage the metadata of each segment as shown in Figure 9. We denote these queues as Q_0,...,Q_n, where n is equal to the maximum number of filter units allocated to each segment. Each element of a queue corresponds to one segment, and it manages the filter units enabled for the segment. Precisely, each element in queue Q_i indicates that i filter units are enabled for the corresponding segment, i.e., only these i filter units are used to check the existence of keys. To keep the LRU feature of each queue, each time when a segment is accessed, we move the corresponding element to the MRU side within the same queue.

To find out which filter unit should be disabled and then removed from memory, we use the hotness information defined by the *expiring policy* described in §3.3. Specifically, we search "expired" segments from Q_n to Q_1, and for each queue, we search from the LRU side to the MRU side, since an "expired" segment must be the least recently used one. When we find an "expired" segment, and if the $E[\text{Extra_IO}]$ can be decreased when we disable one filter unit of this segment, we then downgrade it to the next lower-level queue to release one filter unit. Note that the access frequency of the "expired" segment does not change, while the $E[\text{Extra_IO}]$ could be decreased because of the change of false positive rates by adjusting the Bloom filters in corresponding segments. If there is no "expired" segment,

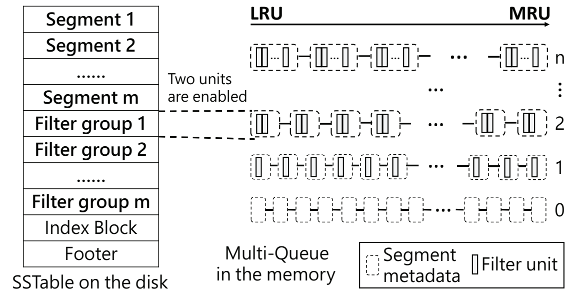

Figure 9: The in-memory Multi-Queue in ElasticBF.

we skip the Bloom filter adjustment this time, this is a conservative strategy to prevent us from degrading the lookup efficiency of possible hot segments (which are not "expired"), and combined with checking if $E[\text{Extra_IO}]$ (which is related to the access frequency) can be decreased, the adjustment overhead is limited as the adjustment frequency is limited, we also analyze the adjusting overhead in §4. On the other hand, we set `lifeTime` as the same order of magnitude as the total number of segments. The rationale is that if there is no "expired" segment, it means almost all the segments have been accessed recently, so they may have similar hotness during that time and we do not need to do the adjustment.

3.5 Implementation Issues

We implement ElasticBF on top of various commonly used KV stores, including LevelDB, RocksDB and PebblesDB. Here, we briefly describe the issues in the implementation.

ElasticBF keeps multiple filter units for each segment in each SSTable, to make minimum changes to SSTables, each filter unit is treated as a *meta block* in original SSTable organization, and the offset information in the file are recorded in *meta index block*. Besides, as generating multiple Bloom filters may add latency to writes, ElasticBF leverages multi-threading via *threadpool* to generate multiple filter units simultaneously so as to further reduce the computation time. On the other hand, ElasticBF maintains a background thread to manage Multi-Queue, so loading filter units and fetching data from secondary storage can be done in parallel, therefore the device bandwidth can be efficiently exploited.

4 Evaluation

In this section, we evaluate ElasticBF to validate its efficiency. We build ElasticBF atop LevelDB [21], RocksDB [16], and PebblesDB [32], and compare the performance of these systems with and without ElasticBF so as to study how much improvement ElasticBF can achieve. We point out that LevelDB is the classical LSM-tree based design, and RocksDB further improves the performance of LevelDB with multiple optimizations. Both of them are widely used as baselines for performance comparison [27, 32]. Besides, PebblesDB is developed based on the new and state-of-the-art index called fragmented LSM-tree, so we also take it as a baseline to demonstrate the effectiveness of ElasticBF. We

emphasize that since ElasticBF is orthogonal to the works optimizing architecture of KV stores, it can also be integrated to other KV stores to further speedup their read performance. In the evaluation, we try to address the following questions.

- How much improvement does ElasticBF achieve to speedup the read performance of KV stores? (§4.2)
- How is the performance of ElasticBF under the workloads of YCSB benchmark? (§4.3)
- What is the performance impact of dynamically allocating bits to Bloom filters in ElasticBF, as compared to the static heterogeneous scheme in Monkey? (§4.4)
- What is the performance impact of different configurations on ElasticBF? (§4.5)

4.1 Experiment Setup

We run experiments on a Dell PowerEdge R730 with an 12-cores Intel Xeon CPU E5-2650 v4 with 2.20GHz processor, 64GB RAM, and Ubuntu 16.04 OS with Linux 4.15 kernel. The testbed is equipped with one 500GB SSD and one 1TB 7200RPM HDD. By default, we run experiments on the SSD. We build ElasticBF on top of LevelDB (v1.20), RocksDB (v5.14) and PebblesDB. As RocksDB and PebblesDB use 64MB or larger SSTables as their default configuration, we also set the SSTable size by modifying *max_file_size* to 64MB in LevelDB. To make a fair comparison, only the management strategy of Bloom filters was changed accordingly, while the memory usage is limited as the same and other parameters are also set as the same with the default values.

In the experiment, we use the benchmark YCSB-C [31,34], which is the C++ version of YCSB [9] with low overhead. Unless specifically mentioned, we use the following default configuration. We set the size of each KV pair as 1KB, and load a 100GB database with randomly generated distinct keys. For the benchmarked workload, we generate 10M Get operations by following the Zipf distribution with a Zipfian constant 0.99 by default. Note that there is no warm up phase, i.e., we immediately issue the benchmarked workload to the randomly loaded database. We also point out that the performance is already stable after issuing 10M operations. By default, we assume that half of the Get operations request non-existent items (i.e., zero lookup), mainly because lookups of non-existent KV pairs are very common in practical systems [6, 23, 35, 38]. As many KV stores provide their own cache mechanisms, thus we enable *direct I/O* [19] to better manage memory. For the default setting, we disable the *block cache* [17] to minimize the influence of cache. This represents the scenario in which a KV store runs within a memory-constrained environment [11,25], we also show the performance impact of block cache size in §4.5. For ElasticBF, the segment size of each SSTable is set as 4MB, and the `lifeTime` is set as 10K as there are around 30K segments in total. The average Bloom filter space for each key (i.e., `bits-per-key`) is set as four bits, this is because allocating a large number of bits for each key is not cost-efficient and it may be impractical in very large KV stores. Cassandra [2] also uses a similar setting of about 5 `bits-per-key` by configuring the Bloom filter to have the false positive rate of 0.1 in its *LeveledCompactionStrategy*. We also study the impact of different system configurations on the performance of ElasticBF in §4.5.

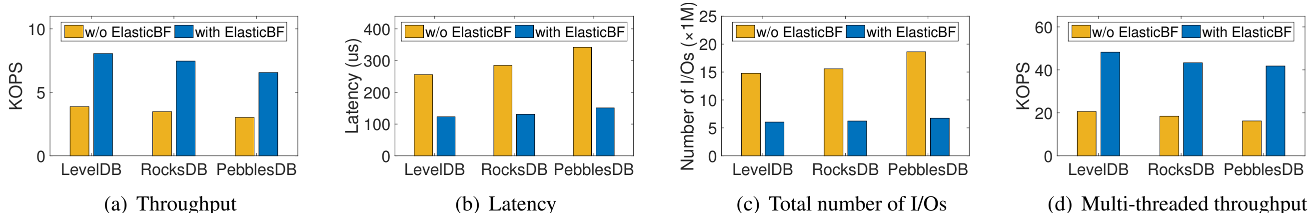
4.2 Micro-benchmarks

We first evaluate the performance of ElasticBF with micro-benchmarks. To evaluate the read performance, we consider both read-only workload and mixed workloads with different read/write ratios so as to validate the effectiveness of the hotness inheritance technique in ElasticBF. Finally, we also show the performance impact on writes and range queries.

Read-only workload. We use one thread to run the YCSB benchmark to perform 10M Get requests. Figure 10(a)-(c) show the results of read throughput, average read latency, and total number of I/Os. We can see that ElasticBF improves the read performance of different KV stores. Specifically, the read throughput with ElasticBF is increased to 2.08×, 2.15× and 2.17× compared to the results without ElasticBF under LevelDB, RocksDB and PebblesDB, respectively. For average read latency, ElasticBF can reduce the latency of LevelDB, RocksDB and PebblesDB by 51.9%, 54.0% and 55.8%, respectively. The improvement of ElasticBF is mainly because the reduction of extra I/Os caused by false positive of Bloom filters. To validate this, we also count the total number of I/Os generated to serve the Get requests, and the results are shown in Figure 10(c). We can see ElasticBF reduces the number of I/Os issued under different KV stores by 59.1% - 63.8%. As a result, ElasticBF can further improve the read performance of KV stores. To validate the effectiveness of the *expiring policy* and the adjusting rule, we count the total number of I/Os issued by loading filter units, it is only about 1% of the total number of I/Os generated to serve the Get requests, thus the adjusting overhead is small.

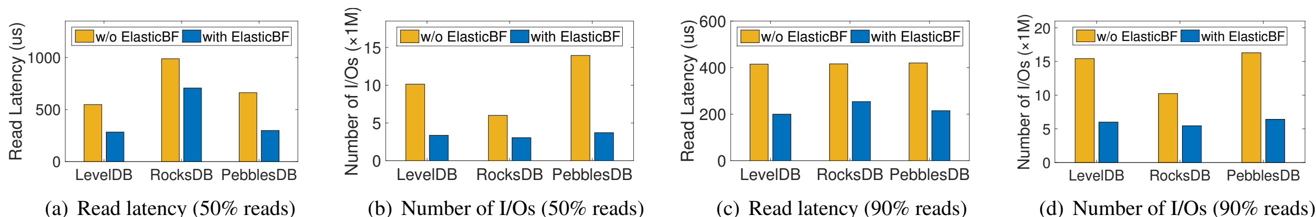
We further study the concurrent read performance of ElasticBF by using 16 threads to run the YCSB benchmark, and each thread performs 1M Get requests. Since we observe similar results for throughput, latency and total number of I/Os, we only show the throughput results in Figure 10(d) for the interest of space. In particular, ElasticBF increases the read throughput to 2.34× - 2.58× in these KV stores. Note that the improvement is slightly larger than that in single-threaded scenario, this is because multi-threaded reads can better utilize the I/O bandwidth.

Mixed workloads. Now we show the performance of ElasticBF under mixed workloads with different read/write ratios. The goal of this experiment is to validate that ElasticBF can still achieve a consistent improvement for reads due to the hotness inheritance design, even though compaction continuously generates new SSTables.



(a) Throughput (b) Latency (c) Total number of I/Os (d) Multi-threaded throughput

Figure 10: Read performance of KV stores with and without ElasticBF under read-only workload.

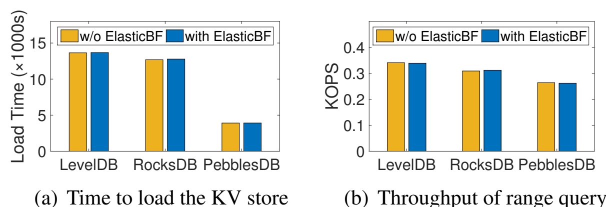


(a) Read latency (50% reads) (b) Number of I/Os (50% reads) (c) Read latency (90% reads) (d) Number of I/Os (90% reads)

Figure 11: Read performance of KV stores with and without ElasticBF under mixed workloads.

Figure 11 (a)-(b) show the results under the workload with 50% reads and 50% writes, and Figure 11 (c)-(d) show the results under the workload with 90% reads and 10% writes. Note that the total number of requests in the workload is 10M. We can see that ElasticBF can help reduce the read latency by 48.2%, 28.4%, and 54.8% for LevelDB, RocksDB and PebblesDB, respectively, under the workload with 50% reads, and the corresponding reduction ratios are 51.8%, 38.9% and 48.8% under the workload with 90% reads. We also count the total number of I/Os issued by Get operations. Specifically, ElasticBF reduces 66.8% (61.1%), 49.1% (46.7%), and 73.3% (60.7%), for LevelDB, RocksDB and PebblesDB, respectively, for workloads with 50% (90%) reads. Note that the reduction of read latency is smaller than that under read-only workload, the reason is that different KV stores use different compaction strategies, e.g., RocksDB enables multiple threads to do compaction and PebblesDB reduces compaction I/Os by avoiding rewriting SSTables to the same level, so the background compaction I/Os that are competed with the foreground Get I/Os are varied from KV stores. Note that the write performance does not decrease, and we will evaluate the write performance later.

Write and range query performance. Now we study the impact on write and range query performance. For different KV stores, we first randomly load a 100GB database and then issue 10M scan requests. We compare the time of loading the database and performing scan requests to evaluate the write and range query performance, and the results are shown in Figure 12. We can see that both the write and range query performance keep almost the same (the difference is less than 1%) even when ElasticBF is integrated in KV stores. The main reason is that Bloom filters are organized into blocks in SSTables, and ElasticBF also uses multi-threading to speedup the generation of Bloom filters. For range query, since it needs to fetch all blocks overlapped with the given range, Bloom filters are not involved in this procedure. Thus, ElasticBF has negligible impact on write and range query performance.



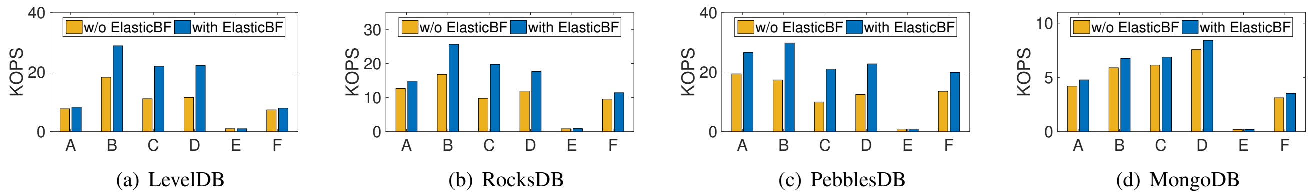
(a) Time to load the KV store (b) Throughput of range query

Figure 12: Put and Scan performance.

4.3 YCSB Benchmarks

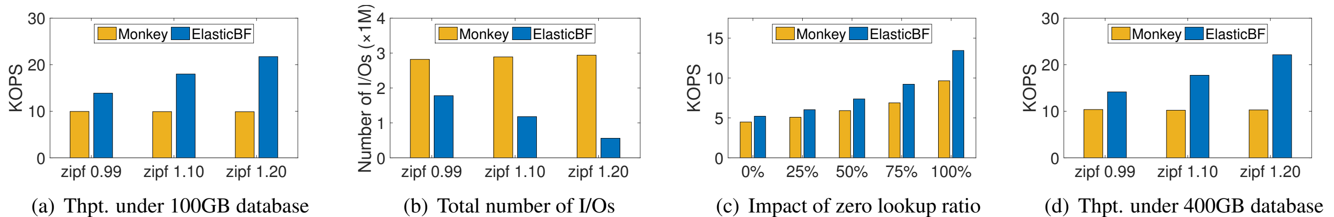
Now we evaluate the performance of ElasticBF with YCSB benchmarks, which provide a set of six workloads with different combinations of KV operations. Specifically, Workload A consists of 50% reads and 50% updates, Workload B consists of 95% reads and 5% updates, Workload C consists of 100% reads, Workload D consists of 95% reads and 5% inserts, Workload E consists of 95% scans and 5% inserts, and Workload F consists of 50% reads and 50% read-modify-writes. Note that Workload D uses the Latest distribution [9], while others follow Zipfian distribution. Each of the six workloads consists of 10M operations, which are issued on a 100GB database, and other settings are the same as before.

We first compare the performance of LevelDB, RocksDB and PebblesDB with and without ElasticBF. Figure 13(a), 13(b) and 13(c) show the throughput results. We can see that ElasticBF improves the performance for all workloads except for Workload E (95% scans), this is because Workload E is a scan-dominated workload, and ElasticBF does not affect the performance of write and scan. In particular, for read-only Workload C, ElasticBF achieves 1.99× - 2.11× throughput in different KV stores due to the optimized Bloom filter design. For Workload A (50% reads) and Workload B (95% reads), ElasticBF improves the throughput by 7.4% - 36.8% and 52.6% - 71.5% for different KV stores, respectively. The reason why the improvement under Workload A and B is smaller than that under Workload C is because the request keys are Zipfian distributed, and the updates make most of



(a) LevelDB (b) RocksDB (c) PebblesDB (d) MongoDB

Figure 13: Performance comparison of different KV stores with and w/o ElasticBF under YCSB benchmarks.



(a) Thpt. under 100GB database (b) Total number of I/Os (c) Impact of zero lookup ratio (d) Thpt. under 400GB database

Figure 14: Performance compared with Monkey under micro-benchmarks.

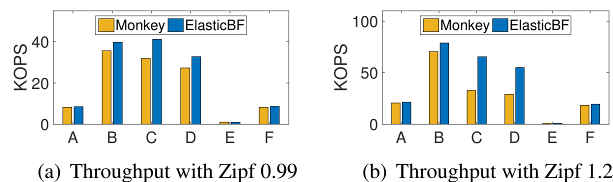
the accessed keys issued by Get are stored in lower levels, and thus leads to a smaller number of SSTables that need to be checked during read than that in read-only Workload C, so ElasticBF has a smaller improvement. The above reason also leads to the results under Workload F which has 50% reads and 50% read-modify-writes, and ElasticBF improves the throughput by 7.8% - 46.6%. Finally, for Workload D, ElasticBF increases the throughput by 47.9% - 93.0%.

We also study the performance impact of ElasticBF on MongoDB [29], which is a popular open-source NoSQL database using WiredTiger [41] and RocksDB as its storage engine. Since WiredTiger is not based on LSM-tree, we choose RocksDB as the storage engine, and evaluate the performance improvement when integrate ElasticBF in MongoDB. The client of YCSB benchmark is running on the same machine with the MongoDB server. Figure 13(d) shows the results. We find that the improvements are only about 11% - 15% except for the scan-dominated Workload E. This is because the YCSB workloads issue only one read/update/insert per request, while MongoDB adds a lot of latency in the critical path of read operations, e.g., the query planner, and thus the latency induced by RocksDB accounts for only about 20% of the total latency. As a result, optimization in the KV storage layer does not result in a large improvement, and this is also observed in PebblesDB [32]. However, we point out that MongoDB may issue batch reads to hide extra latency in real-world scenarios, and in this case, ElasticBF must bring in larger improvement.

4.4 Comparison with Monkey

Now we compare the performance of ElasticBF with Monkey [10], both are built atop LevelDB. As Monkey mainly focuses on zero lookups, which are very common in practice, e.g., the insert-if-not-exist queries, we also assume that all Get operations request non-existent items in the experiments.

We first evaluate the performance of micro-benchmarks. We conduct the evaluation by issuing 10M Get requests to 100GB KV stores. Figure 14(a) shows the results. We can see that ElasticBF increases the throughput to 1.39× - 2.20× across different workloads. In particular, the improvement ratio increases if the workload is more skewed, and this validates the efficiency of taking into account data locality. However, the performance of Monkey is flat across workloads, the reason is that each zero lookup will traverse all levels of the LSM-tree regardless of the access skewness, thus the number of I/Os caused by each Get request due to false positive keeps almost the same under the static setting in Monkey. To further justify, we also count the total number of I/Os issued by Get operations. As shown in Figure 14(b), ElasticBF reduces the number of I/Os by 36.9% - 80.9% compared with Monkey. We then study the impact of zero lookup ratio, and Figure 14(c) shows the result by fixing the Zipfian constant as 0.99. ElasticBF improves the throughput to 1.16× - 1.39×. In particular, as the number of I/Os to find the relevant items accounts for a higher proportion when there are fewer zero lookups, ElasticBF results in smaller benefits in the case of lower zero lookup ratio. Finally, we also study the performance impact on 400GB KV stores, as shown in Figure 14(d), ElasticBF preserves similar improvement, e.g., it increases the throughput to 1.36× - 2.15×.



(a) Throughput with Zipf 0.99 (b) Throughput with Zipf 1.2

Figure 15: Compared with Monkey under YCSB benchmarks.

Next, we study the performance of ElasticBF under the YCSB benchmarks with four threads, each workload of YCSB issues 10M operations on a 100GB KV store. To consider the impact of access skewness, we conduct two sets of experiments by setting the Zipfian constant as 0.99 and 1.2, respectively. Figure 15(a) and Figure 15(b) show the results. We can see that ElasticBF outperforms Monkey for all read-dominated workloads. In particular, for Workload C (100%

reads) and Workload D (95% reads and 5% inserts), when the Zipfian constant is 0.99, ElasticBF obtains 1.29× and 1.20× throughput, respectively, and the improvement ratios increase to 1.99× and 1.89× when the workload becomes more skewed. For other workloads, such as Workload A, B and F, the improvement of ElasticBF is small, this is because the updates in these workloads make most of the keys requested by Get be at lower levels, and Monkey can gain the benefits even with a level-based static scheme, and thus the further improvement of ElasticBF is small.

ElasticBF performs better than Monkey mainly because of the finer-grained hotness identification strategy, i.e., the segment-level hotness identification and Bloom filter adjustment. We will further evaluate the impact of the granularity of hotness identification in details by varying the segment size in the next subsection. Besides the performance improvement, ElasticBF is also a more general Bloom filter management scheme, e.g., it can be deployed in KV stores which use complicated compaction strategies [15, 18], while in these cases, the LSM-tree structure becomes hard to predict, so it is hard for Monkey to find the optimal setting of Bloom filters, and Monkey also fails to dynamically adjust the setting when the structure of the LSM-tree changes.

4.5 Impact of Different Configurations

In this subsection, we study the performance impact of different configurations on ElasticBF. We use one thread to run YCSB benchmark, and issue 10M Get requests to a 100GB database. Due to page limit, we only show the performance improvement over LevelDB, and improvements over RocksDB and PebblesDB are also similar.

Performance under HDD. Figure 16(a) shows the read throughput under HDD. We can see that ElasticBF achieves 2.31× - 2.38× better throughput for LevelDB, RocksDB and PebblesDB. Besides, we also note that the improvement ratio is similar to that under SSD. That is, ElasticBF can improve the read performance of KV stores for all the main-stream storage devices, including both SSD and HDD.

Impact of zero lookup ratio. Figure 16(b) studies the impact of different ratios of non-existent items. Specifically, the x-axis represents the ratio of Get requests which access non-existent keys, i.e., zero lookup. Specifically, ElasticBF increases the read throughput to 1.65× - 3.08× when the zero lookup ratio increases from 0% to 100%. Besides, we can see that with the increasing of zero lookup ratio, ElasticBF achieves larger improvement. This is because looking up non-existent keys leads to the search of all levels in the KV store, and so it needs to check more SSTables. Thus, optimizing the Bloom filter can bring larger benefit to reduce the I/Os, so ElasticBF can get a larger improvement from zero lookups.

Impact of block cache size. We study the impact of cache size. As mentioned before, we enable direct I/O in the experiments. Figure 16(c) shows the results with different block cache sizes, note that the default block cache size is 8MB [17], and we set its size as 64MB which is slightly larger than the amount of Bloom filters (50MB). We can see that with a larger block cache, the read performance improves. Besides, ElasticBF still improves the performance when cache is enabled, e.g., it increases the throughput to 1.43× - 2.08×.

Impact of KV pair size and database size. Figure 16(d) studies the impact of KV pair size. ElasticBF increases the read throughput for different KV pair sizes, e.g., it increases the throughput to 1.99× - 2.08× when we vary the KV pair size from 1KB to 128B. Similarly, Figure 16(e) shows that ElasticBF consistently increases the read throughput for large databases, e.g., it increases the throughput to 2.00× - 2.08× when we vary the database size from 100GB to 400GB.

Impact of segment size, `lifeTime` length and filter unit size. Finally, we study the impact of configuration parameters on the read performance of ElasticBF. First, we consider the impact of segment size, and Figure 16(f) shows the read throughput versus the segment size. Note that the SSTable size is 64MB, if the segment size is also set as 64MB, then it means that we measure hotness and adjust Bloom filters in unit of an SSTable. The results show that the improvement is the largest under the 4MB setting, e.g., the throughput under

the 4MB setting is 17.8% higher than that under the 64MB setting. The reason is that as the segment size decreases, ElasticBF can perform a finer-grained hotness recognition, so it can gain more benefits from the adjustment of Bloom filters. This also demonstrates the effectiveness of the finer-grained design in ElasticBF. However, if the size of each filter unit is too small (e.g., less than a block size), then each load of the filter unit is wasting for the I/Os, so the throughput drops. Second, from the results in Figure 16(g), which show the impact of `lifeTime` length, we can see that and the performance improvement has no big difference. That is, ElasticBF is not sensitive to the `lifeTime` parameter, e.g., we can simply set `lifeTime` according to the total number of segments. Finally, Figure 16(h) shows the impact of filter unit size, the x-axis represents the `bits-per-key` of each filter unit, and we configure the total `bits-per-key` of a filter group as 24 (or 25 for 5bit). The improvement is the largest when using 4bit. This is because if each filter unit uses fewer `bits-per-key`, then it can have more filter units for each SSTable, and this implies to have more hotness categories, but too many categories will also require more I/Os to load enough filter units to achieve low false positive rate.

To summarize this section, we find that ElasticBF can effectively boost the read performance of various KV stores under different storage mediums and database scales, but it mainly focuses on the memory-constrained environment. That is, if the memory capacity is not a bottleneck, then one can simply allocate more bits to each Bloom filter and keeps all of them in memory, in this case, the false positive rate can be very small and the benefit of ElasticBF is limited.

5 Related Work

In recent years, many studies have proposed new designs based on LSM-tree [30]. WiscKey [27] reduces the compaction I/Os by using key-value separation technique to manage keys and metadata in LSM-tree, while stores values into an appended-only log. HashKV [7] further optimizes the value management for key-value separation based design by using hash-based data organization. LSM-trie [42] focuses on small key value pairs, and organizes data into a hash-based trie structure to reduce write amplification. bLSM [35] uses a new merge scheduler to reduce the impact of the compaction on the front-end write performance, and also uses Bloom filters to help efficient lookup. TRIAD [5] reduces write I/Os by leveraging the skewed data popularity and delayed compaction strategy. PebblesDB [32] reorganizes the storage layout inspired from skip lists, thereby avoiding data rewriting in the same level to reduce the compaction overhead. We point out that these works mainly focus on improving the write performance, and they still follow the basic structure of LSM-tree and require Bloom filter, so our work is orthogonal to them, and can be used to further improve the read performance by adaptively adjusting Bloom filters.

Some other studies aim to better utilize the features of emerging storage devices to improve the performance of KV stores. For example, RocksDB [16] utilizes the parallelism of SSDs by scheduling multiple compaction operations concurrently. LOCS [40] leverages the multi-channel of SSDs to exploit the abundant parallelism for efficient compaction and data access. NVMKV [28] cooperates with FTL by mapping KV pairs in physical address space to decrease the redundant work between the store layer and the device layer. HiKV [43] also leverages NVRAM by using a hybrid index. In contract, ElasticBF mainly focuses on the Bloom filter design, and it can improve the read performance on both HDDs and SSDs.

At last, there are also several works considering Bloom filter optimization. In particular, RocksDB [15] uses prefix Bloom filter to reduce read amplification on range queries. SuRF [44] is based on a succinct data structure to reduce I/Os by filtering requests of point queries and range queries. Heterogeneous Bloom filter design is also considered to configure different Bloom filters for different levels or files [10, 45]. However, Monkey [10] adopts a coarse-grained scheme which allocates the same number of filters for SSTables within the same level and also fails to dynamically adjust according to hotness. ElasticBF further leverages the access locality in a finer granularity with dynamical adjustment, and our extensive experiments demonstrate its benefit, especially for skewed workloads. Finally, compared with our previously published workshop paper [45], we also make multiple novel optimizations: (1) we develop a fine-grained heterogeneous scheme by further differentiating segments within each SSTable, (2) we propose a hotness inheritance scheme to quickly obtain the accurate hotness information of the newly generated SSTables during compaction, (3) we implement ElasticBF on top of various KV stores and conduct extensive experiments to demonstrate its efficiency and generality, and (4) we also leverage multi-threading and parallel I/Os in the implementation for performance optimization.

6 Conclusion

In this paper, we developed a fine-grained heterogeneous Bloom filter management scheme called ElasticBF by leveraging the access skewness within workloads. ElasticBF measures the hotness information with a lightweight method and also supports dynamic adjustment of Bloom filters at a fine granularity. As a result, ElasticBF can greatly reduce the expected overall false positive rate without increasing the volume and memory overhead of Bloom filters, and thus speeds up the read performance in KV stores. Finally, we also conducted extensive experiments to demonstrate the efficiency of ElasticBF by building it atop of various KV stores.

Abstract

LSM-based KV stores are designed to offer good write performance, by capturing client writes in memory, and only later flushing them to storage. Writes are later compacted into a tree-like data structure on disk to improve read performance and to reduce storage space use. It has been widely documented that compactions severely hamper throughput. Various optimizations have successfully dealt with this problem. These techniques include, among others, rate-limiting flushes and compactions, selecting among compactions for maximum effect, and limiting compactions to the highest level by so-called fragmented LSMs.

In this paper we focus on latencies rather than throughput. We first document the fact that LSM KVs exhibit high tail latencies. The techniques that have been proposed for optimizing throughput do not address this issue, and in fact in some cases exacerbate it. The root cause of these high tail latencies is interference between client writes, flushes and compactions. We then introduce the notion of an I/O scheduler for an LSM-based KV store to reduce this interference. We explore three techniques as part of this I/O scheduler: 1) opportunistically allocating more bandwidth to internal operations during periods of low load, 2) prioritizing flushes and compactions at the lower levels of the tree, and 3) preempting compactions.

SILK is a new open-source KV store that incorporates this notion of an I/O scheduler. SILK is derived from RocksDB, but the concepts can be applied to other LSM-based KV stores. We use both a production workload at Nutanix and synthetic benchmarks to demonstrate that SILK achieves up to two orders of magnitude lower 99th percentile latencies than RocksDB and TRIAD, without any significant negative effects on other performance metrics.

1 Introduction

Latency-critical applications require data platforms that are able to deliver low latency and predictable throughput. Tail latency is especially important, because applications often exhibit high fan-out queries whose overall latency is determined by the response time of the slowest reply. Log-structured merge key-value stores (LSM KVs), such as RocksDB [18], LevelDB [14] and Cassandra [30], are widely adopted in production environments to provide storage beyond main memory for such latency-critical applications, especially for write-heavy workloads. At Nutanix, we use LSM KVs for storing the meta-data of our core enterprise platform, which serves thousands of customers with petabytes of storage capacity.

KV stores support a range of client operations, such as `Get()`, `Update()` and `Scan()`, to store and retrieve data. LSM KVs strive for good update performance by absorbing updates in an in-memory buffer [36, 37]. A tree-like structure is maintained on storage. In addition to client operations, LSM KVs implement two types of *internal operations*: *flushing*, which persists the content of in-memory buffers to disk, and *compaction*, which merges data from the lower into the higher levels of the tree.

In this paper we demonstrate that tail latencies in state-of-the-art LSM KVs can be quite poor, especially under heavy and variable client write loads. We introduce the notion of an *I/O scheduler for LSM KVs*. We implement this I/O scheduler in RocksDB, and we show up to two orders of magnitude improvements in tail latency.

Our work complements much recent work that has sought to improve the client throughput of LSM KVs (e.g., [4, 24, 28, 32, 34, 38, 39, 42, 43]). Client throughput is improved by reducing the cost of internal operations, but this does not suffice to reduce tail latency. Internal operations remain necessary, and client operations that arrive during ongoing internal operations experience increased latency because of interference with these internal tasks. The internal operations may be fewer in number and less costly, reducing the probability of latency spikes, but in practice they occur sufficiently often to influence the higher order percentiles of the latency distribution, especially if client load is bursty.

One may at first think that limiting the I/O bandwidth allocated to internal operations, as is commonly done in production systems, would avoid latency spikes due to interference between internal work and client load. On closer inspection, however, we find this not to be the case. As a simple example, consider a burst of client writes, triggering a burst of flushes. If a number of compactions is going on at the same time, the flushes have to share the limited bandwidth with the compactions, and they become slow. This leads to the in-memory component filling up and blocking further writes, hence producing latency spikes. Limiting the rate of compactions is also insufficient, because they can lead to the lowest level of the tree filling up, stalling flushes, and in turn stalling writes.

These and other observations lead us to the conclusion that reducing the cost of internal operations or limiting their bandwidth allocation does not suffice to avoid latency spikes, and that instead there is a fundamental need for coordination between the client load and the load imposed by different internal operations. To this end we introduce an *I/O scheduler* for an LSM-based KV store.

We build a new KV store, SILK, which we derive from RocksDB. The I/O scheduler in SILK (1) dynamically allocates bandwidth between client and internal operations, (2) gives preference to internal operations that may block client operations, and (3) allows preemption of less critical internal operations. Other techniques could possibly be included, but we have found these sufficient to get two orders of magnitude benefits in tail latency for write-heavy workloads, with no negative effects on throughput or average latency. Also, SILK does not produce significant negative effects in read- and scan-heavy workloads.

Contributions. The main contributions of this paper are:

1. An extensive empirical study that demonstrates the high tail latencies of current LSM KVs.
2. The introduction of an I/O scheduler for LSM KVs, and various scheduling techniques useful for reducing tail latency while maintaining good throughput.
3. An implementation of an LSM KV store I/O scheduler in an industry-standard LSM KV store (RocksDB).
4. An experimental evaluation demonstrating up to two orders of magnitude improvements in tail latency in our production workload, without significant negative effects on other performance metrics or workloads.

2 LSM KV background

2.1 LSM KV architecture

An LSM KV store has three main components: the memory component, the disk component, and the commit log.

Memory component. The memory component C_m is a sorted data structure that resides in main memory. Its size is typically small, around a few tens of MBs. The purpose of C_m is to temporarily absorb user updates. When C_m fills up, it is replaced by a new, empty component. The old memory component is then in the background flushed as is to level 0 (L_0) of the LSM disk component.

Disk component. The disk component C_{disk} is structured into multiple levels (L_0, L_1, . . . L_n), where each level is larger than the previous (lower) level by a configurable factor (e.g., 10). Each level contains multiple sorted files, called SSTables. The number of SSTables on a given level is limited by a configuration parameter, as is the maximum size of an individual file for a given level. SSTables on levels L_i $(i > 0)$ have disjoint key-ranges. L_0 allows overlapping key-ranges between files.

Commit log. The commit log C_{log} stores the updates that are made to C_m (in small batches) on stable storage. C_{log} is usually a few hundreds of MBs large. It is used if the application requires the data to be recoverable in case of a failure, but it is not mandatory. The techniques we propose in SILK apply regardless of whether C_{log} is active or not.

2.2 LSM KV operations

LSM KVs implement two main kinds of operations, which are executed by disjoint thread pools.

Client operations. The main client operations in LSM KVs are writes *(Update(k, v))*, reads *(Get(k))*, and range scans *(Scan(k1, k2))*. *Update(k, v)* associates value v to key k. Updates are absorbed in C_m, to achieve high write throughput. *Get(k)* returns the most recent value of k. The read first goes to C_m. If k is not found in C_m, the read continues to L_0, L_1, . . . L_n, until k is found. By design, at most one SSTable is checked on each level L_i for $i > 0$. On the contrary, more than one SSTable in L_0 may need to be checked because L_0 SSTables may contain the entire key-range. Per-SSTable Bloom filters [7, 25] are used to address this issue. Therefore, in practice, only one SSTable ends up being checked on L_0 most of the time. *Scan(k1, k2)* returns a range of key-value tuples with the keys ranging from $k1$ to $k2$. First, C_m is queried for keys in the $k1$–$k2$ range. Then, SSTables in C_{disk} that may contain the $k1$–$k2$ range are read, going down the levels, until all the keys are found. Client operations are enqueued and served in FIFO order by a fixed-size worker thread pool.

Internal operations. LSM KVs implement *flushing* and *compaction* as background processes. Flushing writes C_m as is to L_0. Because flushing speed affects the rate at which new memory components can be installed, memory components are written to disk without additional processing. As a result, L_0 allows overlapping key-ranges between files. Compaction is the operation that cleans up the LSM tree. It merges SSTa-

bles in level L_i of C_{disk} into SSTables with overlapping key-ranges in L_{i+1}, discarding older values in the process. When the size of L_i exceeds its maximum, an SSTable F in L_i is picked and merged into the SSTables in L_{i+1} that have overlapping key-ranges with F, in a way similar to a merge sort. Most LSM KVs support parallel compactions, apart from compactions from L_0 to L_1 which are not parallelized because of overlapping key-ranges on L_0. Compaction induces large I/O overhead by reading the SSTables and writing the new ones to disk.

The system maintains an internal FIFO work queue, where flushes and compactions are enqueued. When a new internal work request is enqueued, it is placed at the end of the internal work queue. A flush is enqueued when C_m fills up. A compaction operation may be enqueued after a flush completes, or after a compaction completes. A pool of internal worker threads serve the requests in the internal work queue. In current LSM KVs an internal operation is enqueued whenever the system deems it necessary in order to maintain the structure of the LSM tree (e.g., when the maximum size or maximum number of files is reached on a level).

2.3 State-of-the-art LSM-based systems

Our experimental study includes three state-of-the-art systems: RocksDB, TRIAD, and PebblesDB.

RocksDB [18] developed at Facebook, is a popular system in production environments, including ours. Its architecture follows the description above. In addition, RocksDB provides a rate limiter to restrict the I/O bandwidth for internal operations. The bandwidth can be set to a fixed value, or RocksDB can change it over time in a multiplicative-increase, multiplicative-decrease manner [19]. This *auto-tuned* version of the rate limiter adapts the bandwidth to the amount of internal work, allocating more bandwidth when there is more pending work.

TRIAD [4] reduces the overhead of internal operations through three techniques. First, TRIAD keeps frequently updated keys in C_m, decreasing internal operation overhead in skewed workloads. Second, TRIAD provides an improvement to the flushing operation, by leveraging data already written in C_{log}. Finally, at the disk level, TRIAD employs a cost-based approach to trigger compaction from L_0 to L_1. Compaction happens only when there is significant key-range overlap, reducing the frequency of compaction operations and amortizing their cost.

PebblesDB [39] avoids most of the compaction overhead of merging and rewriting SSTables, by allowing overlapping key-ranges on all but the highest tree level through the use of Fragmented LSM trees. PebblesDB orders SSTables by key-ranges on each level, and uses special pointers called *guards* to indicate where a given key-range is on a level. When the number of guards on a level reaches a threshold, the guards and the corresponding keys are moved to the next level, mostly without re-writing the SSTables. PebblesDB only requires compaction at the highest tree level, when the number of guards reaches a threshold.

3 Performance requirements for LSM KVs

LSM KVs should meet the following requirements:

1. **Low tail latency.** In environments where LSM KVs serve applications with high fan-out operations, in which the slowest reply within an operation determines the latency of the whole operation, low tail latency is a key requirement [15].

2. **Predictable throughput.** LSM KVs must deliver a throughput that matches the client load *at any time*. Throughput variability is a well-known problem in LSM KVs, mostly stemming from the interference between LSM internal work and client requests.

3. **Small main memory footprint.** Typically, LSM KVs are only one piece of a wider set of services that are accessed by an application. For example, a KV store that handles meta-data can co-exist on the same machine with other services that require large amounts of memory, making memory a constrained resource.

LSM issues. A common issue in LSM KVs is interference between LSM internal work and client operations when a sudden burst of client-side writes occurs in parallel with long-running, resource-intensive compaction tasks. Despite the fact that internal LSM work directly influences client latency, it is handled without being aware of the client load. For instance, large compactions (e.g., compacting tens of GBs) may occupy a large fraction of the I/O bandwidth for extended periods of time (e.g., tens of minutes). The resulting problem is two-fold. First, when flushes do not proceed in a timely manner, the memory component fills up, and incoming writes cannot be absorbed in the memory component. Second, slow L_0 to L_1 compactions lead to the accumulation of a large number of SSTables on L_0. In extreme situations, when the maximum number of SSTables on L_0 is reached, this dynamic brings the entire system to a halt. Both scenarios lead to severe spikes in client latency.

4 Experimental study of tail latency

We perform an extensive experimental study to show that established techniques used in industry and state-of-the-art research systems do not solve the issue of tail latency.

4.1 Experimental environment

We use the YCSB [11] update-intensive workload, corresponding to a 50:50 read:write ratio on 1 KB items (YCSB

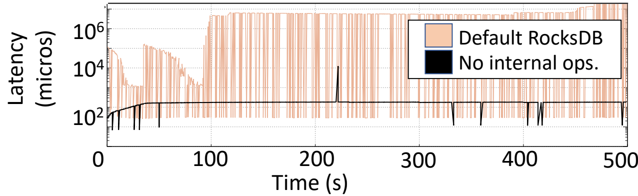

Figure 1: RocksDB compared to a RocksDB version with no internal operations. Internal operations lead to spikes in client request 99th percentile latency.

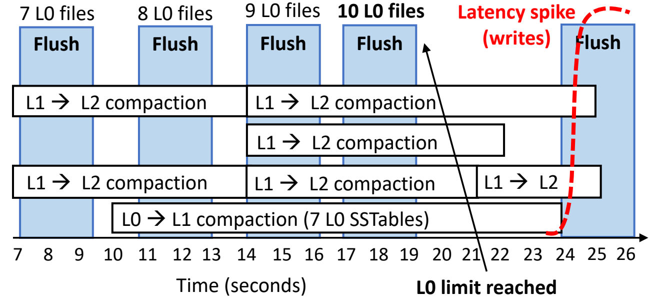

Figure 2: RocksDB. Timeline of internal operations during a writes latency spike (dashed red line) caused by L_0 reaching full capacity. L_0 reaches 10 SSTables at $t = 19$, so flushes are temporarily paused.

workload A), with a uniform data distribution. We choose this workload because it is representative for write-intensive workloads in LSM KVs. Furthermore, a uniform workload allows us to detect more quickly performance problems that in skewed workloads would remain hidden due to in-memory caching [4]. LSM KVs are notorious for having numerous tuning knobs. Throughout this study, we configure all the involved systems to the best of our abilities, following guidelines in [23, 39]. The hardware configuration we use in this study is described in Section 6.1.

Each experiment consists of a population phase followed by read and write operations issued at 18 Kops/sec. Unless stated otherwise, all experiments are run without I/O bandwidth rate limiting for internal operations. For RocksDB, unless stated otherwise, we use two memory components of 128MB each. For the rest of the systems we limit the memory use to 1GB. We configure the maximum number of concurrent internal operations to ten for all systems. The latency is measured every second. The 99th percentile latency is computed for every 1-second interval.

4.2 RocksDB

We first show the performance degradation of client operations caused by internal operations in RocksDB. To this end, we compare RocksDB with a modified version of RocksDB in which compaction and flushing are disabled. We disable internal operations by discarding C_m when it fills up (the data store is pre-populated with the full set of keys, so persistent storage is accessed by reads, if necessary).

Figure 1 shows the performance of the two systems over time. The 99th percentile latency of operations in RocksDB is 2 to 4 orders of magnitude higher than in the system without internal operations. These spikes are not present at the 50th and 90th percentiles of the latency distribution. Both reads and writes experience latency spikes at the same time and of the same magnitude, despite their different access paths in the LSM KV store (i.e., writes complete in-memory, while reads are typically served from persistent storage).

The main culprit for the latency spikes is the fact that writes get blocked by virtue of C_m filling up. The reads then get queued behind these writes in the threading architecture.

We identify two main reasons for write latency spikes, illustrated in Figures 2 and 3. The examples showcase real scenarios encountered while profiling RocksDB.

Figure 2 illustrates an example of a write latency spike (the red dashed line) occurring because L_0 reaches maximum capacity (10 SSTables in this example). Several compactions on levels L_0, L_1 and L_2 occur in parallel between $t = 14$ and $t = 23$. Even if many parallel compactions can run at higher levels (i.e., L_i to L_{i+1}, where $i > 0$), there can only be one L_0 to L_1 compaction running at a time. Since I/O bandwidth is spread equally over all compactions, L_0 to L_1 compaction is slowed down. Consequently, L_0 is not cleared fast enough, which, in turn, causes flushes from C_m to be temporarily halted.

A second cause for latency spikes is C_m filling up because of slow flushing, as illustrated in Figure 3. Here, L_0 does not fill up, reaching only 7 SSTables at $t = 5$. However, the flush starting at $t = 0$ takes an unusually long time (5 seconds compared to 1-2 seconds for a typical flush). The cause is that, by coincidence, a large number of compactions are running at the same time, which makes flushing slow because of limited available I/O bandwidth. There are 7 ongoing compactions at the time of the very slow flush.

4.3 Rate-limited RocksDB

Limiting the I/O bandwidth for internal operations is a popular technique to prevent them from consuming an excessive amount of I/O bandwidth, and hence to "shelter" client operations. We now report the results that we obtain when running RocksDB with limited I/O bandwidth for internal operations [22].

Figure 4 shows the 99th percentile latency of client operations over time when limiting the I/O bandwidth for internal operations to 50, 75 and 90 MB/s. For the sake of legibility, in Figure 4 we show the results of the experiment only up to the time that the tail latency greatly deteriorates (at 900s for 50MB/s, etc). The higher the bandwidth assigned to inter-

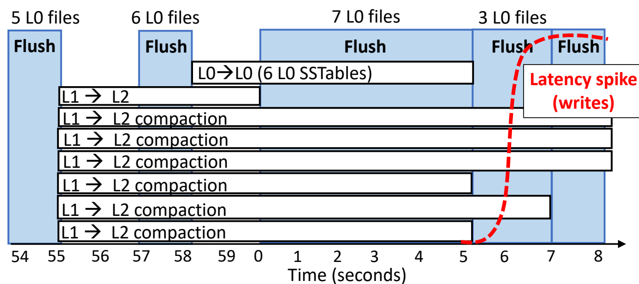

Figure 3: RocksDB. Timeline of internal operations during a writes latency spike caused by slow flushing. From $t = 0$ to $t = 7$, flushes are slowed down by many parallel L_1 to L_2 compactions monopolizing I/O bandwidth. Consequently, C_m fills up, not being able to absorb incoming updates.

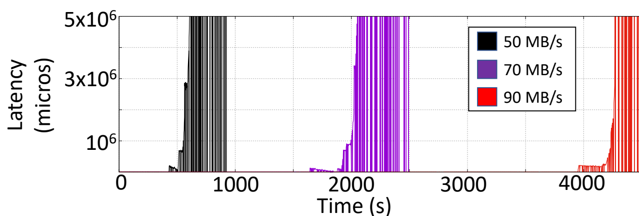

Figure 4: RocksDB. 99th percentile of client request latency when limiting the I/O bandwidth for internal operations.

nal operations, the longer the system is able to postpone the occurrence of latency spikes. However, restricting the bandwidth for internal operations results in slowing them down. This approach therefore increases the likelihood that at some later point many compactions are running at the same time, contending for the limited I/O bandwidth.

4.4 RocksDB with increased C_m

We investigate whether allocating larger memory buffers influences tail latencies in LSM KV. To this end, we run a series of experiments in RocksDB where we increase the total size of the memory component(s) to 1GB – a value close to the upper limit of what we can allow in our production environments (see Section 3). We distribute the memory first into two 500MB memory components and then into ten memory components of 100MB each. We also vary the maximum number of flushes, experimenting with one and ten parallel flushing threads. We find the setup with ten memory components and a single flushing thread to be the most efficient in postponing the latency spikes because the memory absorbs more updates and the data flow from memory to L_0 matches more closely the L_0 to L_1 compaction flow. However, we encounter tail latency spikes sooner or later in all of these cases, for similar reasons to the ones in the scenarios above.

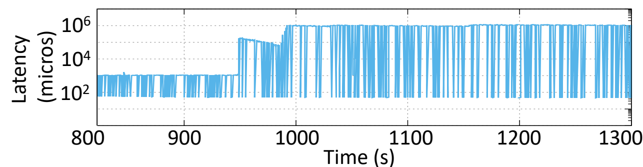

Figure 5: TRIAD. 99th percentile latency. Despite reducing internal operations overhead, TRIAD does not prevent latency spikes during resource-intensive compactions.

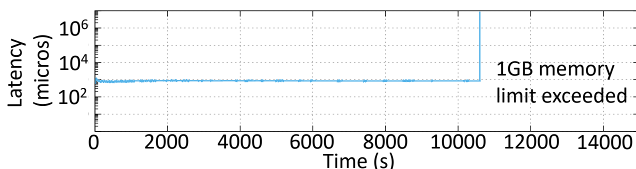

Figure 6: PebblesDB. 99th percentile latency. Postponing compaction keeps the latency low. Experiment ends because of high memory overhead.

4.5 TRIAD

Reducing the overhead of internal operations, as done by state-of-the-art systems [4, 12, 13, 17], is not enough to avoid resource interference. We use TRIAD [4] as a representative of such state-of-the-art systems in the next experiment. Figure 5 shows the 99th percentile latency of client operations over time. In this scenario, TRIAD reduces compaction overhead mainly by choosing when to run L_0 to L_1 compactions depending on key-range overlap. Postponing compactions at the lower levels (closer to C_m) results in postponing compactions at the higher levels. So, in the long term, TRIAD increases the likelihood of running many concurrent compactions. Consequently, the 99th percentile of client operations shows no spikes for the first $\approx$ 1,000 seconds but, after that point, shows frequent and significant spikes.

4.6 PebblesDB

Figure 6 shows PebblesDB's 99th percentile latency over time. The experiment stops after 10,500 seconds. Although we provide PebblesDB with more memory than RocksDB and TRIAD, it runs out of memory at this time. The memory consumption is due to the frequent creation of guards and Bloom filters in a write-intensive workload. During its uptime, PebblesDB provides very good tail latencies due to the absence of compactions. In other words, the LSM tree is restructured through the use of guards but no data compactions occurred.

To create a situation in which PebblesDB experiences compactions, we run it with a read-intensive workload (95:5) which reduces memory pressure. With this workload, tail latencies remain very good in the early going, but after around

8 hours, when compaction sets in, the system effectively comes to a halt. PebblesDB stalls client operations when it has to perform the very resource-demanding compaction on the highest level of the tree. When such compaction takes place, all threads for internal operations are busy, so they cannot push down guards and keys from the lower levels of the tree. Hence, to maintain the tree integrity, PebblesDB stalls client operations until compaction terminates.

4.7 Lessons learned

We gain three main insights from our experimental study.

Lesson 1) The main reason for high tail latency is the fact that writes get blocked by C_m filling up. There are two principal reasons for this. The first reason is that L_0 on disk is full, which causes flushes from C_m to be halted. L_0 reaches its capacity if L_0 to L_1 compaction cannot keep up. The second reason is that, by coincidence, a large number of compactions are happening concurrently, which causes flushing to be slow because of limited available bandwidth.

Lesson 2) Simply limiting bandwidth for internal operations does not solve the problem of limited bandwidth being available for flushes and can in fact exacerbate it in the long run. This approach effectively postpones compactions, and therefore increases the likelihood that at some later point many compactions occur at the same time.

Lesson 3) Recent approaches to improve throughput, such as being selective about starting compactions or only performing compactions at the highest level, avoid latency spikes in the short run, but aggravate the problem in the long run, because they too increase the likelihood of many concurrent compactions at some later point in time.

As a corollary to Lesson 1, we conclude that not all internal operations are equal. Internal operations on the lower levels of the tree (i.e., closer to C_m) are critical, because failing to complete them in a timely fashion may result in stalling client operations.

Finally, as a corollary to Lessons 2 and 3, it is essential to run performance tests for an extended amount of time, lest these issues go undetected.

5 SILK

5.1 SILK design principles

SILK integrates the lessons we learn from our experimental study into an *I/O scheduler* for internal and external work. SILK follows three core design principles.

1) Opportunistically allocating I/O bandwidth to internal operations. SILK leverages the fact that, in production workloads, the load of client-facing operations typically varies over time (see Figure 7). SILK allocates less I/O bandwidth to compactions on higher levels during peak

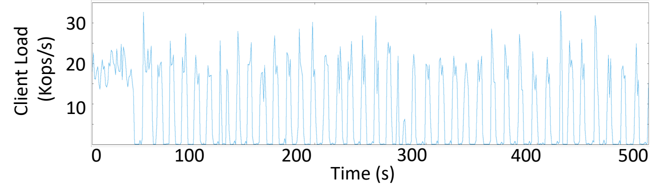

Figure 7: Client load in Nutanix production workload. Real workloads are not flat lines.

client load, and exploits transient low-load periods to boost the processing of internal operations. Dynamic I/O throttling enables SILK (1) to limit interference between internal operations and client-facing ones, and (2) to avoid accumulating over time too large a backlog of internal work, preventing overload conditions in the long term.

2) Prioritizing internal operations at the lower levels of the tree. SILK integrates Lesson 1 in its design by introducing prioritized execution of flushes and compactions from L_0 to L_1. SILK splits internal operations of LSM KVs into three categories with respect to the effect they have on client latencies: (1) SILK ensures that the flushes are fast, making room in memory to absorb incoming updates, which directly affects write latency, (2) SILK gives second priority to L_0 to L_1 compactions, ensuring that L_0 does not reach its full capacity, so that flushes can proceed, (3) SILK gives third priority to compactions on the levels below L_1 because, while they maintain the structure of the LSM tree, their timely execution does not significantly affect client operation latencies in the short term.

3) Preempting compactions. SILK implements a new compaction algorithm that allows internal operations on lower levels of the tree to preempt compactions on higher levels.

5.2 SILK implementation

5.2.1 Opportunistically allocating I/O bandwidth

SILK continuously monitors the bandwidth used by client operations and allocates the available leftover I/O bandwidth to internal operations. The client load monitoring and rate limiting are handled by a separate SILK thread. The monitoring granularity is a system parameter which depends on the frequency of fluctuations in the workload; the monitoring granularity in SILK is currently configured to 10 ms.

If the total I/O bandwidth available to the LSM KV store is T B/s, SILK measures the bandwidth C B/s used by the client requests and it continuously adjusts the internal operation bandwidth to $I = T - C - \varepsilon$ B/s , where ε is a small buffer. To adjust the I/O bandwidth, SILK makes use of a standard rate limiter (e.g., [22]). SILK maintains a minimum configurable I/O bandwidth threshold for flushing and L_0 to L_1 compactions, because these operations directly influence client latency.

To minimize overhead associated with changing the rate limit, SILK only adjusts the limit if the difference between the current value and the new measured value is significant. We empirically set this threshold to be 10 MB/s. We find that lower thresholds cause overly frequent changes in the rate limit. The role of ε is to account for small fluctuations in client load which are not significant enough to adjust internal operation bandwidth using the rate limiter.

5.2.2 Prioritizing and preempting internal operations

Recall that in LSM KVs internal work is handled by a pool of internal worker threads. Once a flush or a compaction is completed, the system checks whether more internal work is needed by assessing the size of the levels and the state of the memory component. If needed, more internal work tasks are scheduled in an internal work queue. SILK maintains two internal worker thread pools: a high-priority one for flushing, and a low-priority one for compactions.

Flushing has the highest priority among the internal operations. Flushes have their dedicated thread pool and always have access to the I/O bandwidth available for internal operations. The minimum flushing bandwidth is chosen to be sufficient to be able to flush the immutable memory component before the active one fills up. The current implementation of SILK allows two memory components (i.e., an immutable one, and an active one) and one flushing thread. If memory constraints allow it, having multiple memory components and flushing threads may help sustain longer client activity peaks.

$\mathbf{L_0}$ to $\mathbf{L_1}$ compaction. SILK needs L_0 to L_1 compactions to progress to ensure that there is enough room to flush on L_0. Unlike flushes, these compactions do not have a dedicated thread pool. If L_0 to L_1 compaction needs to proceed and all the threads in the compaction pool are running higher-level compactions, one of them is *preempted*. This way, L_0 to L_1 compactions do not wait behind higher-level compactions. In the current implementation the preempted compaction task is picked at random.

L_0 to L_1 compaction, like all internal operations is subject to dynamic I/O throttling. However, this type of compaction is never paused, even if SILK may choose to give no bandwidth to compactions. In order to keep L_0 to L_1 compaction running, SILK temporarily moves this job to the high priority thread pool and keeps it running via a high priority thread (i.e., same priority as the flush thread). In this case, the minimum flushing bandwidth mentioned above is shared by the flushing thread and the L_0 to L_1 compaction thread. At most one L_0 to L_1 compaction can run at a time, due to consistency issues caused by overlapping key-ranges. So, only one extra thread is added in the high priority thread pool. Recent versions of RocksDB support L_0 to L_0 compactions as an optimization to quickly reduce the number of SSTables on L_0 [21]. Since this optimization is beneficial for allowing flushes to proceed, SILK treats this case the same as L_0 to L_1 compactions.

Higher-level compactions. Compactions on levels higher than L_1 are scheduled in the low priority compaction thread pool. They make use of the I/O bandwidth available, as indicated by the dynamic rate limiter described in Section 5.2.1. SILK can pause and resume these larger compactions, either individually (because of L_0 to L_1 compaction preemption) or at the level of the thread pool (because of high user load).

It might happen that an L_1 to L_2 compaction is invalidated by the work done by an L_0 to L_1 compaction which preempted it. In this case, SILK discards the partial work done by the higher level compaction. We did not find this wasted work to significantly impact performance.

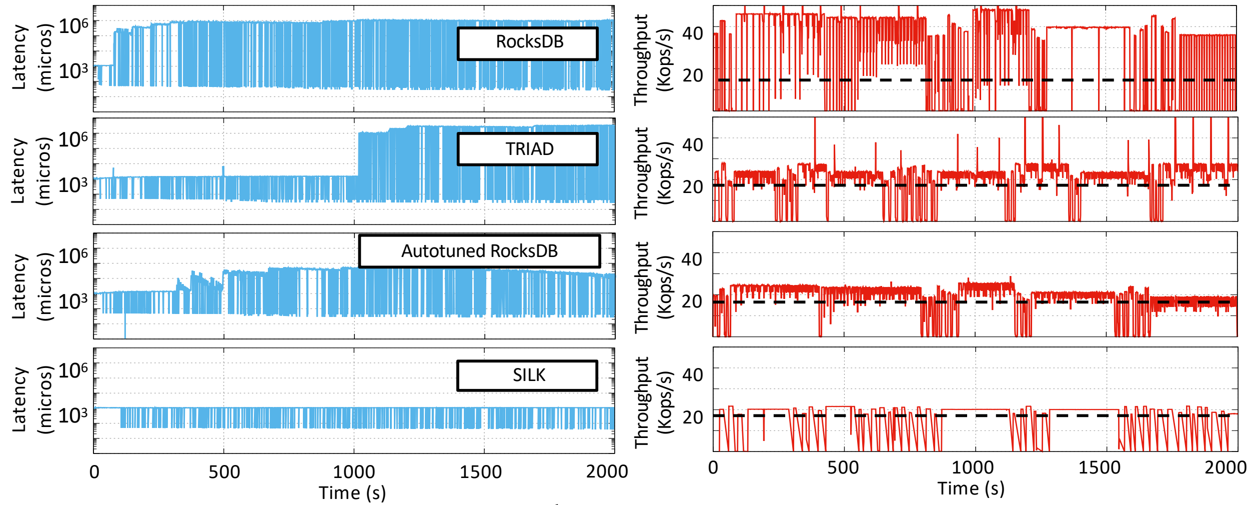
SILK supports parallel compaction, like most current LSM KVs. By default, and assuming equally aggressive compaction threads, each thread gets a similar share of the resources. LSM KVs do not allow parallel compactions from L_0 to L_1, so, if many parallel compactions are allowed, most of the compaction threads are working on the higher levels. This is detrimental to the client operation latencies, since L_0 to L_1 compactions are key to system performance and would benefit from getting the bulk of the resources. Reducing the size of the thread pool, together with SILK's compaction preempting scheme allows each internal worker thread to access a larger share of the resources, which results in faster completion of critical compactions.

The typical recommendation [23] is to set the number of compaction threads equal to the total number of cores. However, we find that the number of compaction threads should instead depend on the total drive I/O bandwidth and the amount of I/O bandwidth required by individual compaction operations. For instance, for a drive with 200MB/s bandwidth, four internal work threads is a suitable choice; even if all the threads happen to run in parallel, they are still allocated a large enough amount of bandwidth to finish the compaction operations fast, thus avoiding scenarios like the ones described in Section 4.

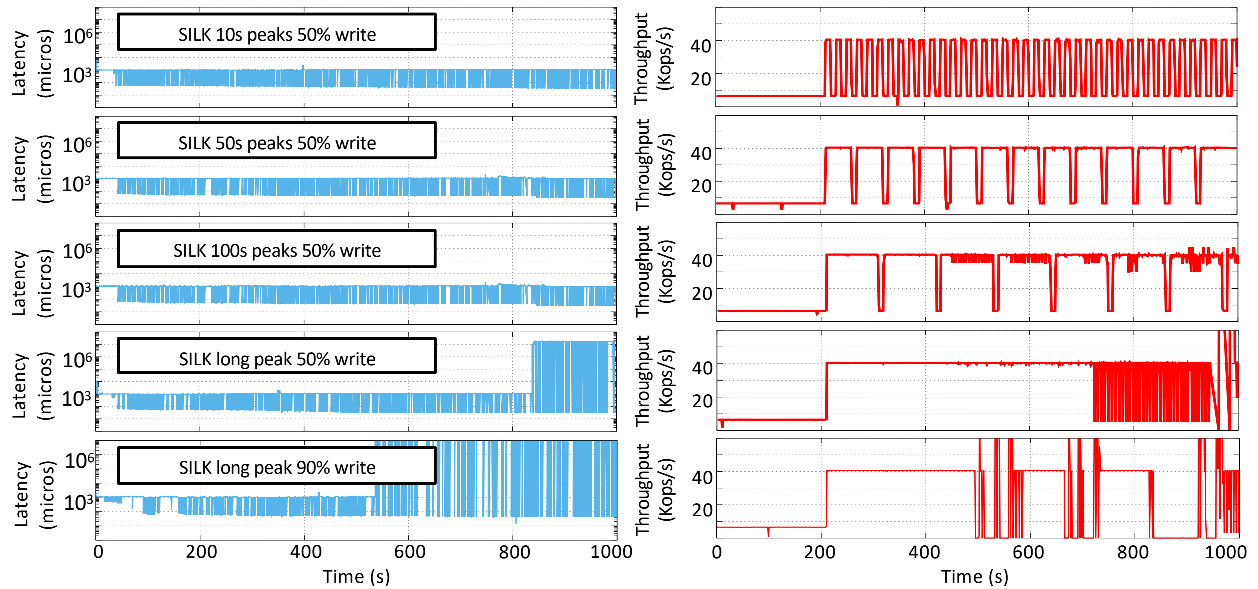
Currently, SILK controls the total I/O bandwidth allocated for compactions in the low priority thread pool. An interesting strategy to explore would be allocating different amounts of bandwidth to compactions at a finer granularity, depending on how urgent the compaction task is considered. We find the current approach to bring good improvements without this additional level of complexity.

6 Evaluation

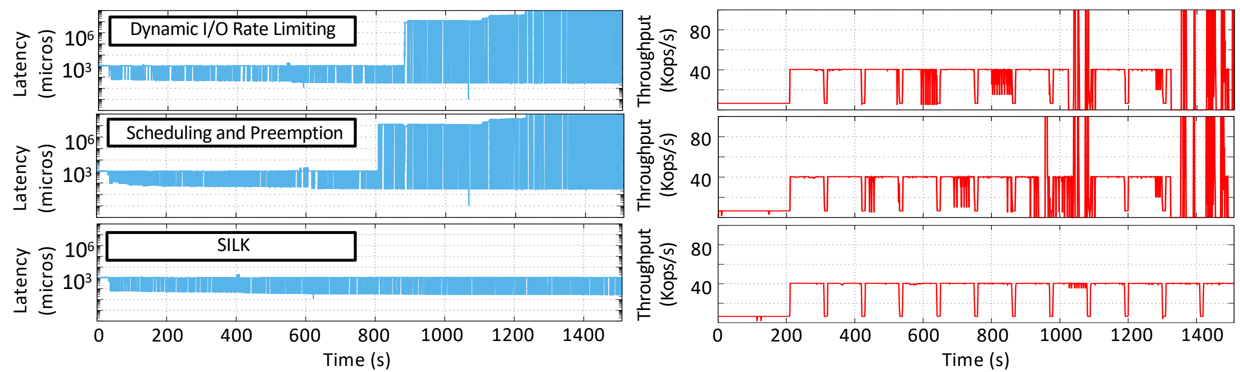
We implement SILK as an extension of RocksDB – used at Nutanix–, and of TRIAD. The source code of SILK is available at `https://github.com/theoanab/SILK-USENIXATC2019`. In what follows, we refer to the



A). Nutanix production workload. Left: 99th percentile latency, log scale on y-axis. Right: throughput. SILK maintains low and steady tail latency and its throughput closely follows the client load. Throughput presents high fluctuations in RocksDB and TRIAD. Average throughput is shown by the dashed black line.



B). Synthetic workloads. Degradation is faster during long peaks, as workloads get more write intensive.



C). Breakdown of SILK techniques. 50% write - 50% read workload, 100s peaks.
SILK's techniques complement each other in order to maintain low tail latency in the long run.

Figure 8: SILK performance in production and synthetic workloads.

RocksDB and the TRIAD extensions as RocksDB-SILK and TRIAD-SILK, respectively. An I/O scheduler could also be applied to PebblesDB, with suitable modifications for the fact that compactions only happen at the highest level. We do not extend PebblesDB with an I/O scheduler because of lack of familiarity with the code base and because PebblesDB's memory demands are not suitable in our environment.

We evaluate SILK with production and synthetic workloads, focusing on write-intensive workloads. We compare against TRIAD and RocksDB and show that:

- SILK achieves up to 2 orders of magnitude lower tail latency than state-of-the-art systems (Section 6.2).
- SILK's performance does not deteriorate over time in long running production workloads (Section 6.2).
- SILK provides stable throughput, close to the client load (Sections 6.2 and 6.4).
- SILK does not create any significant negative side effects on other important metrics such as average latency and read performance (Section 6.3).
- SILK can sustain long client activity peaks interrupted by short client activity lows (Section 6.4).
- The techniques used in SILK contribute to the results above in complementary ways (Section 6.5).

6.1 Experimental setup

Hardware. We perform the evaluation on a 20-core Intel Xeon, with two 10-core 2.8 GHz processors, 256 GB of RAM, and 960GB SSD Samsung 843T. All systems were restricted to run with 1GB of RAM using Linux control groups.

Benchmark. We compare the performance of RocksDB-SILK and TRIAD-SILK to RocksDB, TRIAD, and a version of RocksDB that uses the auto-tuned rate limiter [19]. All experiments are run through `db_bench`, one of RocksDB's standard benchmarking tools [20].

Measurements. Load-generator threads issue requests in an open loop according to the workload characteristics. They deposit the requests in the queues of the KV store worker threads. Latency is measured on the side of the load-generator threads, capturing both *queuing* time and *processing* time. We measure the 99th percentile tail latency and the throughput over one-second intervals (i.e., not cumulative over the entire experiment run). We report throughput and latency every second in the time-series plots.

Dataset. The dataset size for both the production and the synthetic workloads is approximately 500GB. The KV-tuple sizes vary between the production and the synthetic workloads. In all the experiments the data store is pre-populated with the entire dataset.

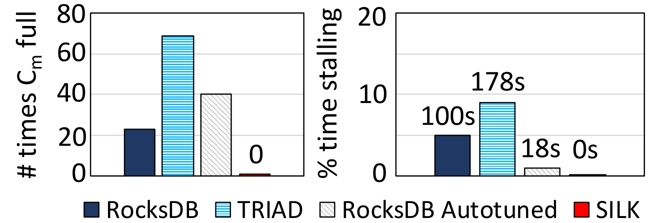


Figure 9: Production workload. Number of times C_m cannot be flushed (left) and time spent stalling writes (right).

KV store configuration. We use a 128MB memory component size and two memory components (i.e., one active and one immutable). In SILK, flushing and L_0 to L_1 compactions proceed at a rate of 50MB/s if SILK paused the other internal operations. The total I/O bandwidth allocated to the LSM KV store is 200MB/s. The `level0-slowdown` and `level0-stop` parameters (used to slow down or stop client writes once a maximum number of files is reached on L_0) are configured to very large values in all data stores so as not to artificially interfere with the measured latency. We use a thread pool of 4 threads for internal operations (including the flushing thread) for all the systems. All systems are pinned to 16 cores, out of which 8 are used by the worker threads, and 8 are used by the internal operations and other LSM threads (e.g., monitoring the client load in SILK). The load-generator threads run on separate dedicated cores.

Compression and commit logging are disabled in all reported measurements. While enabling them affects the absolute performance results, it does not impact the conclusions of our evaluation: the performance differences between RocksDB-SILK or TRIAD-SILK, on the one hand, and standalone RocksDB and TRIAD, on the other hand, remain similar. Using compression is equivalent to working with a smaller dataset. Commit logging takes the same amount of bandwidth in all systems. Therefore, from an experimental perspective, using C_{log} is roughly equivalent to working on a machine with smaller disk bandwidth.

6.2 Nutanix workload

Workload description. We sample one of our production workloads at Nutanix over 24h. It is a write-dominated workload, with a 57:41:2 write:read:scan ratio (a scan length is in the order of tens of keys). The client requests arrive in bursts (peaks of around 20K requests/s), separated by periods of low activity (valleys of around hundreds of requests/s or less). A typical duration of a valley is between 5s and 20s, with an average valley length being approximately 15s. Most peaks (approximately 90%) are short bursts between 10s and 20s. The longer peaks (>100s) make up the rest of the workload. The maximum peak lasts approximately 400s. The request sizes range between 250B and 1KB for

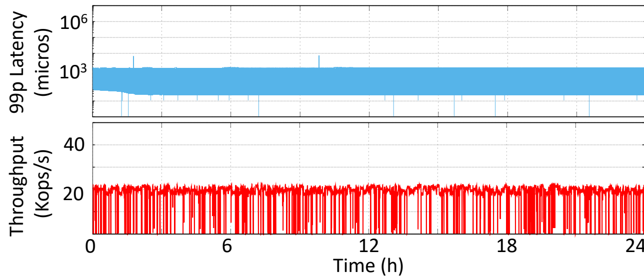

Figure 10: SILK in 24h Nutanix production workload. Top: 99th percentile latency, log scale on y-axis. Bottom: throughput. SILK maintains stable low latency and throughput close to the client load for extended time spans.

the single-point operations (i.e., reads and writes), with a median of 400B. We use a trace replay of the original workload, providing the input at the same rate as the original trace.

Results. Figure 8A shows the 99th percentile latency (left) and throughput (right) for RocksDB-SILK (bottom row), compared to state-of-the-art systems. Results obtained with TRIAD-SILK are similar.

SILK obtains two orders of magnitude lower tail latency than the auto-tuned RocksDB, and three orders of magnitude better than RocksDB and TRIAD, due to its combination of adjusting the I/O bandwidth and better internal work scheduling. Similar to their behavior described in Section 4, the tail latencies in RocksDB and TRIAD exhibit frequent spikes, due to stalling and contention for I/O bandwidth. The auto-tuned rate limiter in RocksDB achieves one order of magnitude better tail latency than both TRIAD and RocksDB, but does not avoid interference on shared resources as effectively as SILK (see Figure 8A, third row). The auto-tuner simply increases I/O bandwidth when there is more internal work to do, and it is oblivious of user load.

Throughput in SILK stays close to the offered client load, while throughput in RocksDB presents high fluctuations. Client operations build up in the worker thread queues because of interference with internal operations. When they can proceed, they are processed in bursts, which results in throughput spikes. TRIAD and the auto-tuned RocksDB stay closer to the offered client load, but still present throughput fluctuations, correlated to increases in tail latency.

Figure 9 shows the number of times C_m cannot be flushed right away (left) and the amount of time the writes are stalled, relative to the duration of the experiment (right). The statistics are collected for the experiment shown in Figure 8A. SILK never stalls writes and can always flush C_m as soon as it fills up. TRIAD has the most problems flushing C_m on time – the flush is delayed 69 times – because of its $L_0 - L_1$compaction strategy. The auto-tuned version of RocksDB does better, but it still spends a significant amount of the time stalling writes, consisting of 1% of the total experiment time.

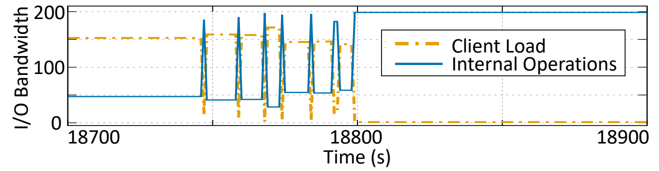

Figure 11: Detail of RocksDB-SILK I/O bandwidth allocation. SILK boosts internal work when client load decreases.

24h production workload. Figure 10 presents the 99th percentile latency and throughput time series of RocksDB-SILK for a 24h run of our production workload. SILK maintains stable performance over the extended period of time. Figure 11 shows a detail of the I/O bandwidth allocation in RocksDB-SILK during 200s of the production workload. Internal work may be temporarily postponed, but is eventually completed in the long term. RocksDB-SILK compacts approximately 3TB of data over the 24h and never has more than three compaction operations waiting to be scheduled. The worker threads experience no write stalls and have less than three operations enqueued throughout the experiment.

6.3 YCSB benchmarks

To evaluate the performance of SILK for a wide range of workloads, we now present results with the the full YCSB benchmark. From this point forward, we show results obtained with TRIAD-SILK. We report that the results for RocksDB-SILK are similar.

Workload description. YCSB provides six core workloads, described in Table 1. We use 8B keys and 1024B values. We evaluate SILK in the zipfian and uniform key distributions and show that SILK reduces tail latency in write-dominated workloads without inducing significant performance degradation in other scenarios.

Results. Figure 12 shows the average throughput of TRIAD and TRIAD-SILK, for the uniform (top) and zipfian (bottom) key distributions. SILK has low impact on throughput for both key distributions, amounting to at most 7%. As expected, SILK incurs the highest overhead for the uniform key distribution for the write-dominated workloads (i.e., YCSB F), because it entails frequent compactions and therefore frequent scheduling interventions by SILK. Reads do not suffer significantly compared to the baseline because of L0 read optimizations in TRIAD (and RocksDB): (1) there is a Bloom filter for each L0 file, and (2) reads return after the KV tuple is first found on L0, without checking all the L0 files. Because of these two optimizations, most of the time only one L0 file is read. So, even if SILK postpones L0 – L1 compactions, it has little impact on read performance. With a zipfian key distribution, most requests are served from memory in the entire benchmark, leading to less compaction. Here, SILK's overhead is at most 4%. Similarly, read-dominated workloads (YCSB B, C, D and E) are less impacted by com-

Workload	Description
YCSB A	write-intensive: 50% updates, 50% reads
YCSB B	read-intensive: 5% updates, 95% reads
YCSB C	read-only: 100% reads
YCSB D	read-latest: 5% updates, 95% reads
YCSB E	scan-intensive: 5% updates, 95% scans; average scan length 50 elements
YCSB F	50% read-modify-write, 50% reads

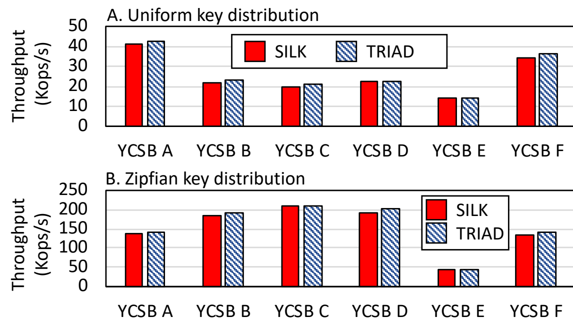

Figure 12: Average throughput of TRIAD and TRIAD-SILK in YCSB. Using SILK has minimal impact on throughput in read- and write- dominated workloads.

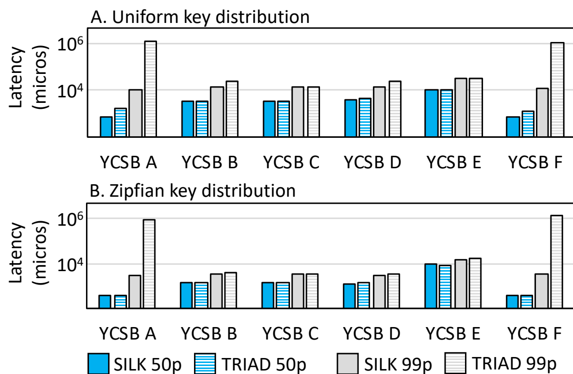

Figure 13: Latency of TRIAD and TRIAD-SILK in YCSB. Log-scale on Y-axis. SILK decreases 99p latency by two orders of magnitude in write-dominated workloads, while maintaining similar median latency across all workloads.

pactions, leading to less overhead (at most 5% in the uniform key distribution).

Figure 13 shows the median and 99 percentile latency for TRIAD and TRIAD-SILK. Generally, SILK's median latency is on par with that of TRIAD, or slightly lower. The only workload where SILK experiences higher median latency than TRIAD is YCSB E with a zipfian key distribution, where SILK surpasses TRIAD by 5%. Tail latency is lower with SILK across all workloads, by at least 5% (in YCSB E). SILK's benefits in terms of tail latency are most pronounced in write-dominated workloads, where the latency is decreased by up to two orders of magnitude.

6.4 Stress testing for long peaks

Workload description. In this section we focus on workloads in the style of YCSB core workload A (see Table 1), where we vary the ratio between the length of the client load peaks and valleys (gradually increasing peak duration, while keeping valley duration constant). We use 8B keys, 1024B values and a uniform key distribution. Client load during low activity periods is approximately 10 Koperations/second and approximately 40 Koperations/s during peaks. The offered load is higher for both the peaks and the valleys than our production workload, in order to stress the system.

Results. Figure 8B shows the 99th percentile latency (left) and the throughput (right) of TRIAD-SILK. The first three rows show a 50:50 write:read workload, where the ratio of peak:valley length is varied: peaks last 10, 50, and 100 seconds, while the valleys last 10 seconds. SILK easily sustains these peaks and valleys in the client load, keeping tail latency low and the throughput steady.

On the last two rows of the figure we show the results of an experiment with a long peak, to see at what point SILK's performance starts to degrade. The fourth row shows the results with a 50:50 write:read workload and the last row with a 90:10 write:read workload. Despite the prioritization of critical internal work, if the peak load is high and the peak duration long, the system cannot allocate enough resources to the internal work, and the performance eventually starts to degrade. Also, as expected, the proportion of writes influences the amount of time the peaks can be sustained. SILK's performance starts to degrade at around 500 seconds (300 seconds of peak) for the 90% writes workload, while the peak can be sustained up to around 700 seconds (500 seconds of peak) for the 50% writes scenario. Despite showing performance degradation, SILK is able to handle challenging workloads that are representative of real applications. Our production workload has at most 400s peaks, 50% writes and load peaks reaching only half the load of the synthetic workload peaks (Figure 10).

6.5 Breakdown

Figure 8C shows 99th percentile latency (left) and throughput (right) for the following variants of SILK. The first row shows a version where we enable SILK's dynamic I/O bandwidth rate limiting, but where the priorities and preemption are disabled. The second row shows the complementary version which uses priorities and preemption but where the I/O bandwidth is not controlled. The final row shows SILK. On their own, neither of the two techniques is able to sustain the client load.

In the first case (top row), the dynamic bandwidth allocation ensures that internal and external work interference is low. However, as the experiment progresses and larger compactions need to take place, the urgent internal operations are slowed down.

In the second case (middle row), good prioritization maintains the tree structure at the levels close to the memory component, allowing flushes and $L_0 - L_1$ compactions to proceed without slowdowns. However, as larger compactions need to take place, the fact that the bandwidth is not controlled leads to negative interference between internal and external work.

7 Related work

Reducing compaction overhead. Many systems reduce the overhead of compaction algorithms used in production systems, such as RocksDB [18], LevelDB [14] and Cassandra [30]. WiscKey [32], HashKV [10] and LWC-tree [44] separate keys from values, and only store keys in the LSM tree, reducing data movement in compaction operations. TRIAD [4] keeps hot data in memory, avoids duplicate writes of the log component, and compacts an SSTable only when there is sufficient overlap with lower-level SSTables. SlimDB [40] allows overlapping key-ranges on each level of the LSM tree to reduce the amount of data that is rewritten, and uses new index blocks and cuckoo filters to perform fast key lookup. Monkey [12], Dostoevsky [13], Lim et al. [31], Dong et al. [17] tune the parameters of the LSM tree, in order to limit the amount of maintenance work and to achieve better performance. Accordion [8] optimizes the layout of the in-memory component by means of a hierarchical structure and in-memory compactions. SifrDB [33] employs different compaction algorithms on different levels of the LSM tree.

These techniques decrease the amount of work performed during internal operations, with the result of increasing throughput. However, they do not avoid the interference with user operations *while* internal operations execute. By contrast, SILK schedules internal operations so as to avoid interference on user operations, thus avoiding latency spikes for user operations and improving tail latencies. The techniques of SILK can be applied to existing designs, thereby preserving their improvements in terms of internal operation overhead. We show this by applying SILK techniques on top of two systems: RocksDB and TRIAD.

Compaction variants and alternatives. PebblesDB [39] allows overlapping key ranges in the lower LSM tree levels to avoid SSTable merges, and uses a skip-list-like structure to allow efficient key lookups. PebblesDB achieves remarkable performance, but its last-level compaction may lead to prolonged service unavailability (Section 4). SILK techniques can be applied to PebblesDB to improve its robustness.

Tucana [38] and ForestDB [2] use variants of the B-ε tree [6, 9, 27] and of the B+ tree, respectively. Unlike LSM trees, these systems do not maintain large sorted files and hence do not implement flushing and compaction. However, they implement operations such as leaf splitting, leaf merging and tree re-balancing to preserve the structure of the tree. These operations result in random accesses that increase write amplification and affect the latency of user operations by contending for I/O. SILK targets LSM tree-based systems, which favor sequential I/O, absorb writes in memory, and leverage sorted SSTables for efficient range scans.

Ahmad and Kemme [1] offload compaction to a dedicated server. Atlas [29] uses different servers to store keys and values. Using a different server for compactions is an effective way to address latency spikes, since this approach removes interference between client and internal operations. However, this solution substantially changes the architecture of the KV store from a standalone system to a distributed one, which results in higher operational costs and increased complexity. Moreover, the transfer of SSTables between the compaction server and the client-facing servers puts additional load on the network, which can generate interference on co-located applications.

Data structure and algorithm improvements. FloDB [5], cLSM [24], HyperLevelDB [26], Nibble [35] and BespoKV [3] improve scalability by alleviating contention bottlenecks. NoveLSM [28] reduces logging overhead by supporting in-place updates to a component stored on NVM, and performs parallel reads. These techniques are orthogonal to SILK's. Minos [16] reduces tail latency for in-memory KVs focusing on workloads with heterogeneous item sizes. To this end, Minos serves similar-sized requests on the same cores. Similar approaches could be implemented in LSM KVs to further reduce tail latency in heterogeneous workloads, and they can co-exist with SILK. bLSM [41] aims to avoid stalling at a level L of the tree by ensuring that operations at lower levels have completed by the time level L has to push data to lower levels. bLSM achieves this goal by throttling internal operation rates. bLSM, however, may throttle user writes as the memory component fills up. Instead of artificially throttling requests, SILK performs internal operations during off-peak periods, and prioritizes higher-level internal operations to avoid stalling user operations.

8 Conclusion

In this paper we presented SILK, a new LSM KV store designed to prevent client request latency spikes. SILK uses an I/O scheduler to manage external client load and internal LSM maintenance work. We implemented SILK in two state-of-the-art LSM KVs and demonstrated order-of-magnitude improvements in latency at the 99th percentile in synthetic and production workloads from Nutanix.

Abstract

Efficiently exchanging temporary data between tasks is critical to the end-to-end performance of many data processing frameworks and applications. Unfortunately, the diverse nature of temporary data creates storage demands that often fall between the sweet spots of traditional storage platforms, such as file systems or key-value stores.

We present NodeKernel, a novel distributed storage architecture that offers a convenient new point in the design space by fusing file system and key-value semantics in a common storage kernel while leveraging modern networking and storage hardware to achieve high performance and cost-efficiency. NodeKernel provides hierarchical naming, high scalability, and close to bare-metal performance for a wide range of data sizes and access patterns that are characteristic of temporary data. We show that storing temporary data in Crail, our concrete implementation of the NodeKernel architecture which uses RDMA networking with tiered DRAM/NVMe-Flash storage, improves NoSQL workload performance by up to 4.8× and Spark application performance by up to 3.4×. Furthermore, by storing data across NVMe Flash and DRAM storage tiers, Crail reduces storage cost by up to 8× compared to DRAM-only storage systems.

1 Introduction

Managing temporary data efficiently is key to the performance of cluster computing workloads. For example, application frameworks often cache input data or share intermediate data, both both within a job (e.g., shuffle data in a map-reduce job) and between jobs (e.g., pre-processed images in a machine learning training workflow). Temporary data storage is also increasingly important in serverless computing for exchanging data between different stages of tasks [17].

Storing temporary data efficiently is challenging as its characteristics typically lie between the design points of existing storage platforms, such as distributed file systems and key-value stores. For instance, shuffle data in a map-reduce job may consist of a large number of files which are organized hierarchically, vary widely in size, are written randomly, and read sequentially. While file systems (e.g., HDFS) offer a convenient hierarchical namespace and efficiently store large datasets for sequential access, distributed key-value stores are optimized for scalable access to a large number of small objects. Similarly, DRAM-based key-value stores (e.g., Redis) offer the required low latency, but persistent storage platforms (e.g, S3) are more suitable for high capacity at low cost. Overall, we find that existing storage platforms are not able to satisfy all the diverse requirements for temporary data storage and sharing in distributed data processing workloads.

In this paper we present *NodeKernel*, a new distributed storage architecture designed from the ground up to support fast and efficient storage of temporary data. As its most distinguishing property, the NodeKernel architecture fuses file system and key-value semantics while leveraging modern networking and storage hardware to achieve high performance. NodeKernel is based on two key observations. First, many features offered by long-term storage platforms, such as durability and fault-tolerance, are not critical when storing temporary data. We observe that under such circumstances, the software architectures of file systems and key-value stores begin to look surprisingly similar. The fundamental difference is that file systems require an extra level of indirection to map offsets in file streams to distributed storage resources, while key-value stores map entire key-value pairs to storage resources. The second observation is that low-latency networking hardware and multi-CPU many-core servers dramatically reduce the cost of this indirection in a distributed setting by enabling scalable RPC communication at latencies of a few microseconds.

Based on these insights we develop the NodeKernel architecture by implementing file system and key-value semantics as thin layers on top of a common storage kernel. The storage kernel operates on opaque data objects called "nodes" in a unified namespace. Applications can store arbitrary size data in nodes, arrange nodes in a hierarchical namespace, and obtain file system or key-value semantics through specialized

node types if needed. For instance, key-value and table nodes permit concurrent creation of nodes with the same name, offering last-put-wins semantics. On the other hand, file and directory nodes permit efficient enumeration of data sets at a given level in the storage hierarchy. By splitting functionality in a common storage kernel and custom node types, NodeKernel enables applications to use a single platform to store data that may require different semantics, while generally offering good performance for a wide range of data sizes and access patterns.

NodeKernel is designed explicitly with modern hardware in mind. Following strict separation of concerns, the storage kernel is composed of a lightweight and scalable metadata plane tailored to low-latency networking hardware and an efficient data plane that provides access to multiple tiers of network-attached storage resources. The metadata plane is trimmed down to offer only the most critical functionality, with low overhead. The data plane runs a lightweight software stack and leverages modern networking and storage hardware to achieve fast access to arbitrary size data sets while also optimizing cost efficiency. For instance, data attached to "nodes" may either be pinned to a particular storage technology tier or may spill from one storage tier to another depending on performance and cost requirements.

Crail is our concrete implementation of the NodeKernel architecture using RDMA networking and two storage tiers based on DRAM and NVMe SSDs respectively. We evaluated Crail on a 100Gb/s RoCE cluster equipped with Intel Optane NVMe SSDs using raw storage microbenchmarks as well as using the NoSQL YCSB benchmark and different Spark workloads. Our results show that Crail matches the performance of current state-of-the-art file systems and key-value stores when operated in their sweet spot, and outperforms existing systems up to 3.4× for data accesses outside the sweet spot of file systems and key-value stores. Moreover, Crail creates new opportunities to reduce cost and gain flexibility with almost no performance penalties by using NVMe Flash in addition to DRAM. For instance, using Crail to store shuffle data in Spark allows us to adjust the ratio between DRAM and Flash with only a minimal increase in job runtimes.

In summary, this paper makes the following contributions:

- We propose NodeKernel, a new storage architecture fusing file system and key-value semantics to best meet the needs of temporary data storage in data processing workloads.

- We present Crail, a concrete implementation of the NodeKernel architecture using RDMA, DRAM, and NVMe Flash.

- We show that storing temporary data in Crail reduces the runtime and cost of data processing workloads. For instance, Crail improves performance up to 4.8× for NoSQL workloads. When integrated in Spark's shuffle and broadcast services, Crail improves application performance up to 3.4× and reduces cost up to 8×.

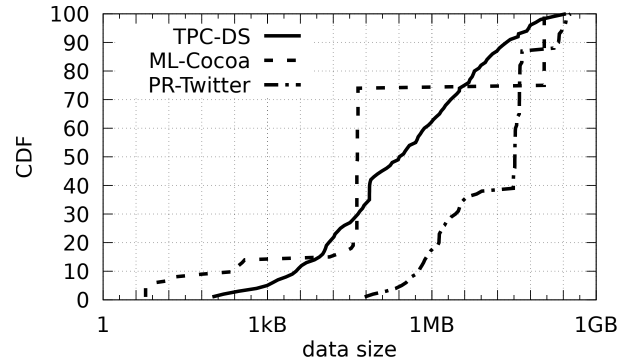

Figure 1: CDF of the size of intermediate data written or read per compute task in Spark for different workloads.

Crail is an open source Apache project [2, 3] with the code available for download from the project website as well as directly from GitHub at https://github.com/apache/incubator-crail. Further, all benchmarks used in this paper are open source.

2 Background and Motivation

Temporary data represent a large and important class of in-processing data in analytics frameworks. For example, Zhang et al. report that over 50% Spark jobs executed at Facebook contain at least one shuffle operation, generating significant amounts of temporary data [37].

We define temporary data as the multitude of all application data being created, handled, or consumed during processing, excluding the original input and final output data. Specifically, we identify three distinct classes of temporary data: intra-job, inter-job, and cached input/output datasets. Intra-job temporary data is generated within a framework when executing a single job like page-rank, or a SQL query. Common examples are datasets generated during shuffle or broadcast operations in frameworks like Spark, Hadoop or Flink. Such data is typically generated and consumed by the same job, which puts a bound on the lifetime of the data. Inter-job temporary data are intermediate results in multi-job pipelines. For example, there are many pre-processing and post-processing jobs in a typical machine learning pipeline [35], where the output of one job becomes the input of another job. Lastly, examples of cached input/output data are mostly read-only datasets that are pulled into a cache for fast repetitive processing. For instance, users may run many SQL queries on the same table (or a view) over a short period of time. In this case, a copy of the input table might be cached on a fast storage media.

Technology	Local Latency	Remote Latency	Bandwidth	Price
DRAM	80ns	2us	10s GB/s	5$/GB
3D XPoint	5us	10us	2-3 GB/s	1.25$/GB
NAND Flash	50us	55us	2-3 GB/s	0.63$/GB

Table 1: Price and performance of DRAM (DDR4), 3D XPoint (NVMe) and NAND Flash (NVMe). Remote DRAM latency for RDMA, remote 3D XPoint and NAND Flash latency for NVMf.

Building an efficient storage platform for the different types of temporary data requires careful consideration of application demands, data characteristics and hardware opportunities. In the following section we discuss several requirements for a temporary storage platform and provide an overview of current state-of-the-art solutions.

2.1 Requirements and Challenges

Size, API, and Abstractions Diversity: Temporary data in data processing workloads can vary substantially with regard to the data size. In Figure 1 we show the size distribution (CDF) of temporary data generated per task during the execution of (a) PageRank on the Twitter graph; (b) SQL queries on a TPC-DS dataset; and (c) Cocoa machine learning on a sparse matrix dataset [24]. As shown, the per-task data sizes are ranging from a few bytes (for machine learning) to a GB (for TPC-DS). Historically, different storage systems are used to handle the two ends of this spectrum. Distributed key-value stores (e.g., RAMCloud, memcached, etc.) have an object API and are optimized to store small values efficiently for fast random lookups [20, 33]. In contrast, file systems like HDFS or Ceph, can store large datasets (GBs) efficiently by partitioning the dataset and maintaining indexes for lookups. Moreover, filesystem abstractions of appendable files, enumerable hierarchical namespace, and a streaming-byte interface for I/O provide additional support for an easy mapping of temporary datasets, such as all-to-all shuffle, to the underlying storage.

A temporary storage platform should be able to store small and large values efficiently, with the unified benefit of file and key-value abstractions in a single system.

Performance: Temporary data often lies in the critical path of data processing, hence it is imperative that access to the temporary data is fast. As with the size, the access pattern also varies widely. For example, as there is no global order, shuffle data is often written randomly [11], whereas SQL tables are read in large sequential scans [32]. Hence, one requirement a storage platform for temporary data has to fulfill is that it should be capable of performing well on the entire spectrum of data sizes for any access pattern.

Fortunately, over the last decade, I/O devices have evolved rapidly to support high-bandwidth (100s of Gbps), ultra low-latencies (less than 10 usec), with millions of IOPS. In order to meet data processing demands, these devices are now being deployed in the cloud (AWS, Azure), and used inside data processing frameworks. Consequently, an ideal temporary storage system should be able to run efficiently on modern networking and storage hardware while delivering close to bare-metal performance.

Beyond In-Memory Storage: The total amount of temporary data that is generated or consumed by data processing workloads can be large. For instance, between the workloads whose temporary data object size CDFs are shown in Figure 1, the collective total volume of data differs by 100s of GBs (10-100% of the input dataset size, not shown in the figure). Efficiently storing large volumes of data while offering good data access performance is difficult. For instance, storing all the data in DRAM is preferred from a performance standpoint but doing so typically is too costly. Thankfully, over the past years different media types such as NAND Flash, and PCM storage, have emerged to store data at a different cost, performance, and energy price point. Hence, an efficient storage platform for temporary data should integrate multiple storage technologies that offer different performance cost trade-offs, and allow applications to choose between different points in the trade-off space. A comparison of different storage technologies with respect to price and performance is given in Table 1.

Non-Requirements: We observe that in the specific case of temporary data storage, many traditional storage features such as durability and fault-tolerance are not a priority. Durability, for instance, is of low importance due to the short lifetime of temporary data. While fault-tolerance is generally useful for short-lived data, it still is not a high priority for temporary data storage. Today, fault tolerance is often implemented at the level of the compute framework, in a coarse grained manner. For instance, Spark [36] and Ray [25] use lineage tracking to re-compute data in case of data loss by relaunching tasks.

2.2 Limitations of Existing Approaches

We review current state-of-the-art storage systems with regard to the design goals listed in the previous section. We classify the systems discussed into the following three categories.

Key-Value Stores: Memcached [4] and Redis [5] are two of the most popular key-value stores designed to store data in DRAM. Network-optimized KVs like MICA [21], Herd [14], FaRM [12], KVDirect [19] and RAMCloud [26] use RDMA operations to provide high-performance data accesses but cannot easily integrate data storage to different tiers beyond DRAM. Redis has an extension to spill data to Flash, however keys are still stored in DRAM, and hence are limited by the DRAM capacity. Storage-optimized KVs such as Aerospike [30] or BlueCache [34], use NAND Flash for storage. Hence, their performance is bounded by the performance of Flash, and they are not optimized for the next-generation

of NVM storage devices like Optane (see Section 5.1). Other systems, like HiKV [33], have hybrid DRAM-Flash indexes but only target a single node deployment, hence limiting their applications to a wider class of operations such as shuffling. Furthermore, the design of these KV stores is tailored to very small data sets of a few hundred bytes up to a few MB maximum, thus, limiting their operational window to these object sizes.

Distributed Data Stores: Storage systems such as Cephover-Accelio [8] and Octopus [23] are high-performance distributed file systems used for fast network and NVM devices. However, due to the focus on providing fault-tolerant, durable storage their performance for small objects is poor (see Section 5). The recently proposed Regions system provides a file abstraction to remote memory [6]. As with other in-memory storage systems, however, Regions is not a cost-effective solution for storing large data sets. Systems like Alluxio [1] and Pocket [17] provide support for multiple storage technology types. But Alluxio does not deliver the performance of high-end hardware, and is targeted towards building local caches. Pocket shares our aim of a dedicated storage system for temporary data and its design has similarities with the NodeKernel architecture. However, the focus of Pocket is on providing efficient and elastic temporary storage on commodity hardware in the cloud whereas NodeKernel is designed for low-latency high-bandwidth network and storage hardware. Moreover, Pocket has only an object based I/O interface which is well suited for data sharing in serverless workloads. In contrast, NodeKernel's unified API provides semantics like "append" and "bag" to support storing a wide range of temporary data in different workloads.

Temporary-data specific operations: A number of works accelerate specific storage operations in data processing workloads. For instance, Riffle [37] is an optimized shuffle server that aims to reduce overheads associated with large fanouts. Sailfish [27] is a framework that introduced I-files which are shuffle optimized data containers. ThemisMR [28] also aims to optimize shuffle and target small rack-scale deployments. In general, the aim of these systems is to optimize disk-based, file-oriented shuffle data management for map-reduce type workloads. It is not clear how their design can support other communication patterns, such as broadcast and multicast, or integrate different storage types to optimize for different access patterns. Parallel databases [7, 22] use RDMA-optimized shuffling operations for database operators. These works, however, are highly database specific and do not extend naturally to other data processing workloads or other forms of temporary data.

3 The NodeKernel Architecture

We present the NodeKernel, a new storage architecture designed to match the diverse and complex demands of temporary data storage in data processing workloads. The NodeKernel tackles this challenge by fusing storage semantics that are otherwise available separately in file systems and key-value stores, such as hierarchical naming, scalability, multiple storage tiers, fast enumeration of datasets, and support for both tiny and large data sizes (Figure 2). The NodeKernel architecture is guided by three design principles:

1. Distill higher-level storage semantics into thin layers on top of a common storage kernel.
2. Separate data management concerns into a lightweight metadata plane and a "dumb" data plane optimized for modern networking and storage hardware.
3. Leverage multiple storage technologies for efficient storage of large datasets.

We discuss each of these design principles in more detail below before describing Crail, a concrete implementation of the NodeKernel architecture, in Section 4.

3.1 Storage Kernel and Node Types

In the NodeKernel architecture, higher-level storage semantics are implemented as thin layers – or more precisely, as specialized data types – on top of a shared storage kernel exporting a hierarchical namespace of opaque data "nodes". Nodes are objects of an abstract type `Node` as shown in the following code snippet.

```
abstract class Node {
protected:
  /*implemented by derived types*/
  abstract bool addChild(Node child);
  abstract bool removeChild(Node child);
  /*implemented by the storage kernel*/
  future<int> read(byte[] buf);
  future<int> append(byte[] buf);
  future<int> update(byte[] buf, int off);
  string getPath();
  int size();
  ...
}
```

The kernel is responsible for allocating storage resources on behalf of nodes, manipulating the hierarchical namespace, and implementing basic data access operations such as `read`, `append` and `update`. Applications interface with the storage kernel to create data nodes at a given location in the hierarchy, attach data of arbitrary size to a node, look up nodes, and fetch the associated dataset from a node. Nodes are identified using path names encoding the location in the storage hierarchy, similar to files and directories in a file system.

Applications do not create raw `Node` objects directly, instead they create objects of derived types offering specialized functionality. These so-called custom types implement higher-level storage semantics by extending `Node` in two ways. First,

custom types provide implementations for the abstract operations addChild and removeChild. These operations are called by the kernel whenever a new node is inserted or removed to/from the storage hierarchy. Second, custom data types provide specialized data access operations implemented using read and append available in Node.

NodeKernel defines five custom node types, each offering slightly different semantics and operations:

- File and KeyValue: Both node types provide read and append interfaces by exposing the corresponding operations in Node. The two types, however, provide different semantics during the creation and insertion of new nodes, controlled via the implementation of addChild and removeChild. For File nodes, the first create operation for a given path name succeeds and subsequent create operations on the same path name fail. For KeyValue nodes, subsequent create operations on a path name representing an existing node will succeed, replacing the existing node. As we will see in Section 5, KeyValue nodes are useful to cache input datasets in NoSQL workloads, permitting concurrent updates of the data, whereas File nodes are a better match to cache read-only input data in Spark workloads.

- Directory and Table: Those node types are containers for File and KeyValue nodes respectively. Directory and Table nodes store the name components of all of their children as part of their data (implemented using append and update operations available in Node). For instance, the data segment of a Directory with path name "/a/b" storing two files with path names "/a/b/c1" and "/a/b/c2" consists of the two name components "c1" and "c2". Both Directory and Table nodes offer operations to enumerate the names of all of their children (implemented using read available in Node). Tables can optionally be configured as "non-enumerable" in which case no name components are stored and enumeration returns the empty set. Creating KeyValue nodes in a non-enumerable table is typically faster because it eliminates the step of updating the name component (as described in Section 4.1).

- Bag: The Bag node type is designed to support efficient sequential reading of data spread across many data nodes. A Bag behaves like a directory such that it acts as a container for File nodes. Applications create and write files in a Bag just like they create and write files in a Directory. When reading a Bag, however, the Bag appears to the application like a single file. Using a Bag's read operation allows applications to sequentially read through the full set of files in the bag. Generally, the read operation of a Bag offers better performance than reading each File node separately, due to more efficient metadata access at file boundaries. As we will see in Section 5, Spark applications can use Bags to store shuffle data, allowing reduce tasks to efficiently fetch data written by map tasks. The Bag type in NodeKernel is similar in spirit than bags in Hurricane, a recent work on taming skew in data processing workloads [9].

NodeKernel restricts the way node types can be stacked. For instance, KeyValue nodes can only be attached to Table nodes, whereas File nodes can only be attached to Bag and Directory nodes. Moreover, directories can be arbitrarily nested, whereas bags and tables implement a flat namespace. The permitted combinations of node types match the specific use cases of temporary data storage. At the same time, preventing arbitrary combinations of node types ensures the architecture is not over-designed and simple to implement. For instance, Bags are mainly used to store shuffle data which is organized in flat per-reducer buckets, thus, enabling arbitrarily nested bags seemed unnecessary. At the time, a read operation on flat Bags is easier to implement than a read operation on an arbitrarily nested Bag.

Why provide a single unified storage namespace? By splitting functionality in a common storage kernel and a set of custom data types, the NodeKernel achieves two things. First, it permits different types of temporary data requiring different semantics to be managed by a single storage platform. For instance, as we will see later, Spark applications can use Crail for storing both broadcast and shuffle data, as well as for caching RDDs. Second, decoupling core data access from storage semantics allows applications to choose a particular node type based on the semantics they need (key/value vs file) rather than based on the size of the data or the access pattern. As discussed in Section 2.1, temporary data often varies in terms data size and access pattern even within a single workload, making it difficult to store the data efficiently in a storage platform like a filesystem or a key-value store. By contrast, node types in NodeKernel have no size limitation and provide efficient data access for different access patterns as we will see later in Section 5.

3.2 System Architecture

Figure 2 illustrates the NodeKernel system architecture. At the data management level, NodeKernel's architecture resembles the architecture of distributed file systems like HDFS or GFS, consisting of a set of metadata and storage servers deployed across a cluster. Data attached to a "node" in the storage hierarchy appears to clients as a stream, but internally the data is composed of a sequence of blocks. A block refers to a fixed sequence of bytes stored in one of the storage servers. Metadata servers maintain the hierarchical storage namespace as well as block metadata, i.e., a mapping between storage blocks and storage servers. Storage servers allocate a large set of storage blocks at startup and register them with

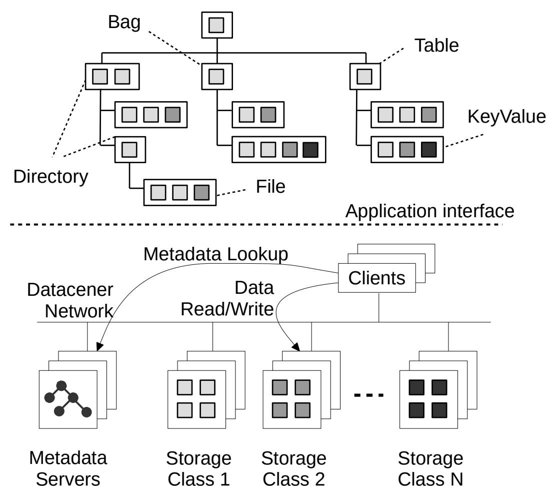

Figure 2: The NodeKernel storage architecture.

one of the metadata servers. Metadata servers maintain a free list with blocks that are not assigned to a particular node, and move blocks from the free list to a per node list during data writes and appends. When accessing data, clients first contact one of the metadata servers and request the metadata for the corresponding block. Based on this information clients then contact the given storage server to read or write the data.

The `Node` abstract data type exports two abstract operations, `addChild` and `removeChild`, to be implemented by the derived types described in Section 3.1. Those operations are executed at the metadata server each time a new node is created or removed. The `Node` further exports functions to manipulate data such as `read`, `append` or `update`. Those functions are implemented as part of the client library and require interactions with both metadata and storage servers. Finally, the basic metadata operations such as `getPath` or `size` are also implemented by the client library returning cached values if possible.

Target deployment: NodeKernel targets temporary data which is short-lived and simple to regenerate. Furthermore, NodeKernel targets small to medium size deployments consisting of few compute racks. Considering the target deployments and the nature of the data to be stored, NodeKernel prioritizes performance over fault tolerance. However, if deemed necessary, additional fault-tolerance mechanism such as replication, erasure-coding, etc., can be added. The lack of these features is not fundamental to the design.

Performance challenges: The main challenge in NodeKernel was to come up with a system architecture that can serve the full spectrum of demands discussed in Section 2.1. In particular, the architecture should be scalable like a key-value store despite offering a convenient hierarchical namespace. Furthermore, the architecture should support both low-latency key-value style access, as well as high-bandwidth file system like data access. In the following we discuss in how we accommodate these requirements in the NodeKernel architecture.

3.2.1 Low-latency metadata operations

Fusing file system and key-value semantics into a single storage kernel primarily requires a fast metadata access. In Section 2.1, we observed that software architectures of distributed file systems fundamentally differ from key-value stores only by an extra metadata operation required to map offsets in file streams to storage resources (e.g., blocks on storage servers). Thus, keeping the overheads of metadata operations low will make NodeKernel's architecture amenable to key-value style operations on small datasets, while also improving the efficiency of large data accesses.

Today, modern low-latency networking hardware enables RPC communication at latencies of a few microseconds [13, 16]. The NodeKernel features a lightweight metadata plane that matches well with low-latency networking hardware. For one, the metadata plane is trimmed down to offer only the most critical functionality consisting of six key RPC operations: `create` to create a new node, `lookup` to retrieve the metadata of a node, `remove` to delete an existing node, `move` to move a node to a different location in the storage hierarchy, `map` to map a logical offset in a node's data stream to a storage resource, and `register` used by storage servers to register storage resources with the metadata server. All these operations have low compute and I/O intensity and can be implemented at the latency of a few microseconds on a high-performance network fabric. We deliberately move data intensive metadata operations like `enumeration` to the data plane to avoid interference (see Section 3.1 and 4).

3.2.2 Metadata partitioning

The scalability of NodeKernel heavily depends on the throughput and scalability of its metadata RPC subsystem. Recent work has shown that RPC systems can be scaled to millions of operations per second on a single server using high-performance networking hardware on the one hand [15], but also using efficient software stacks on commodity hardware [13]. The lightweight RPC interface in NodeKernel is designed for high throughput and can drive up to 10 million metadata operations per second using a single metadata server, as shown later in Section 5. Up to now in all of our deployments we have never had a situation where a single metadata server would reach its limit. In fact, in one of our largest deployments on 128 nodes the metadata throughout reached 4.5 million operations per second, thus, roughly half of what a single metadata server can support.

Nevertheless, for the case where a single metadata server

is not sufficient, NodeKernel permits partitioning the metadata space over multiple servers. Thereby, the top-level root namespace is hash-partitioned among an ordered list of metadata servers. Using metadata partitioning, one can scale the metadata plane horizontally assuming a sufficiently large top level fan out.

One drawback of static of partitioning based on top-level namespaces is that load may be unevenly distributed among the metadata servers depending on the size of the subtree and the activity within the subtree. One alternative approach would be dynamic partitioning at a more fine grained level. For instance, past work has proposed a partitioning scheme for file systems where metadata partitioning is implemented at the directory level, with an option to split large directories on-demand as they grow too big and distribute the splits over multiple metadata servers [29]. Even though such an approach creates a more even load distribution, it comes at a significant performance cost as it requires multiple RPC invocations during path lookup and traversal. Given the performance target of 5-10 μs in NodeKernel we ultimately decided to adopt the simpler partitioning scheme where node paths are always local to a metadata server.

3.2.3 Hardware-accelerated storage

NodeKernel's data plane is designed to work well with modern networking and storage hardware. The goal is to keep the storage interface simple to avoid excessive software overheads and permit as much of the data access functionality to be implemented in hardware. Clients in NodeKernel interact with local and remote storage servers via two interfaces: `read(blockid, offset, length, buffer)` to fetch a certain number of bytes from a block, and `write(blockid, offset, buffer, length)` to write a data stored in a buffer to a block. Later in Section 4 we show that `read` and `write` operations in Crail can almost completely be offloaded to networking and storage hardware for both DRAM and Flash. Also note that the storage interface explicitly supports byte addressable storage hardware by defining the access granularity at the byte level as opposed to block level.

3.2.4 Tiered storage

NodeKernel employs a simple tiered storage design to accommodate large datasets that cannot be stored in DRAM in a cost-effective manner. Storage servers are grouped into different classes (see Figure 2), typically a class per storage technology (DRAM, NVMe SSDs, HDD, etc.). A storage server is a logical entity, i.e., one physical or virtual machine may host multiple storage servers of different types. For instance, a common deployment is to run two storage servers per host, one exporting some amount of local DRAM and one exporting storage space on the local NVMe SSD. In principle, storage classes are user-defined sets of storage servers.

Object type	Methods
Crail	**create**<T extends Node>(*path*, *sc*) → future(*T*)
	creates a data node of type T
	lookup<T extends Node>(*path*) → future(*T*)
	lookup of an existing node
	delete(*path*) → future(*boolean*)
	deletes an existing node at the given *path*
	move(*src*, *dst*) → future(*boolean*)
	moves node *src* to new location *dst*
File & KeyValue	**read**(*offset*, *buffer*, *length*) → future(*Int*)
	reads data at given offset
	append(*buffer*, *length*) → future(*Int*)
	appends application buffer to data
Bag	**read**(buffer, length) → future(*Int*)
	sequentially reads through all subfiles
Directory & Table	**enumerate**() → iterator(*Node*)
	enumerates all nodes in a given directory

Table 2: Application programming interface of Crail.

A storage server always belongs to exactly one storage class. In our evaluation we configure two storage classes, one for DRAM servers and one of NVMe SSD servers.

The traditional approach to storage tiering is to migrate data to more cost effective storage classes as the faster storage classes fill up. We found this strategy to be ineffective for temporary data due to the short lifetime of the data. Instead, we opted for a simpler approach where storage classes are filled up according to a user-defined order – typically DRAM first followed by Flash and hard disk – without ever migrating data between the tiers. Specifically during data write operations, metadata servers try to allocate DRAM blocks first, turning to lower priority storage tiers only once no higher priority storage blocks are available across the entire cluster.

4 Crail

Crail is a concrete implementation of the NodeKernel architecture. We implemented Crail in about 10K lines of Java and C++ code. Table 2 shows the application interface of Crail. The top level data type in Crail is `CrailStore`. Applications use `CrailStore` to `create`, `lookup` and `delete` data nodes, or to `move` data nodes to a different location in the storage hierarchy. Nodes are identified using path names similar to file systems. When creating a new node using `create`, applications may choose a preferred storage class for the data to be stored (parameter "sc" in Table 2). We also refer to the storage class preference as storage affinity because it allows users to specify affinity for a particular set of data to a particular set of storage servers or storage media.

Crail implements the full set of node types discussed in Section 3.1. Note that all operations in Crail are non-blocking and asynchronous (returning a `future` object). Crail's asyn-

chronous API matches well with asynchronous software interfaces for modern networking and storage hardware. In fact, almost all of Crail's high-level operations can be mapped directly to a set of non-blocking and asynchronous network and storage operations. Failures of Crail API calls are communicated either via invalid `futures` or exceptions (not shown in Table 2). For instance, an attempt to `lookup` a node that does not exist will result in an invalid `future` (`nullpointer`), while an attempt to `read` data from a node beyond the node's capacity will result in an exception.

Crail can be operated either as a shared storage service or in the form of per-user or per-application deployments. The current implementation of Crail, however, does not provide any tools to virtualize, protect and isolate multiple tenants from each other.

4.1 Metadata plane

Crail metadata servers maintain an in-memory representation of (a) the storage hierarchy, (b) the set of free-blocks, and (c) the assignments of blocks to "nodes". Specifically, each metadata server maintains a per storage class list of free blocks. Storage classes are ordered according to a user-defined preference. As discussed in Section 3.2, if during a write operation the current write position does not yet point to an allocated block, a client requests a fresh new block by calling the metadata `map` RPC operation. The metadata server selects a free block based on the selected storage affinity (or "sc" in Table 2). If there are no free blocks in the selected storage class, the metadata server attempts to allocate a block from the next storage class in the priority list. When selecting a block in a storage class, the metadata server uses round-robin over all storage servers in the given storage class to make sure data is distributed uniformly in the cluster. If no free block is available in any of the storage classes the write operation at the client will fail.

Crail partitions metadata across an array of metadata servers as discussed in Section 3.2.1, meaning, each metadata server is responsible for a partition of the storage hierarchy. Each individual server is implemented as a lightweight RPC service using DaRPC [31], an asynchronous low-latency RPC library based on RDMA send/recv. To achieve high throughput, client connections are partitioned across the different CPU cores. Each core manages a subset of the client connections in-place within a single process context to avoid context-switching overheads. All the memory for RPC buffers is allocated local to the NUMA node associated with the given CPU core that is responsible for the particular connection. Figure 3 illustrates the different aspects of the metadata processing in Crail.

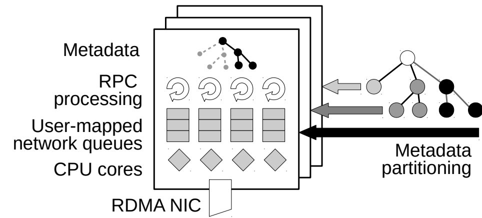

Figure 3: Lightweight metadata plane in Crail.

Enumeration: In Section 3.1 we discussed how container nodes (`Table`, `Directory`, `Bag`) maintain a list of the names of all child nodes as part of their data. The rational behind this design is that it allows us to implement container enumeration efficiently in the data plane. We have seen use cases where storing Spark shuffle data in Crail generated close to hundred thousand `File` nodes in a `Bag`. Implementing enumeration at the metadata server would lead to substantial data transfers between clients and metadata servers and in many cases would require multiple rounds of RPC to enumerate all of the nodes.

Crail's file format for container nodes is structured as an array of fixed-size records consisting of the children's name component along with a valid flag. Upon creating a new node, the metadata server assigns a unique offset within the array based on which the client writes the corresponding record. During a delete operation, after the metadata server has removed the node entry, a client clears the valid flag of the corresponding record (by zeroing the valid bit in the record). Note that the node record inside a container's data is only considered supplementary information. The metadata server always serves as the authority for validating the existence of a node. Thus, an enumerate operation running concurrently with a delete operation may lead to a situation where a node's record in the directory file is still valid, but the node's metadata state at the metadata server has already been deleted. In that case, the node is considered deleted and no read or write operations will be permitted.

4.2 Data plane

Crail implements two storage classes, one for DRAM and one for NVMe-based SSDs. An implementation of a storage class consists of a server part exporting a storage resource (see Section 3.2.3), and a client part implementing efficient data access.

RDMA storage class: A storage server in the RDMA storage class exports large regions of RDMA registered memory to the metadata server. Metadata for RDMA based storage blocks contains the necessary RDMA credentials such as address, length and stag and allows clients to directly read or write a storage block using RDMA one-sided read/writes.

NVMe-over-Fabrics storage class: NVMe-over-Fabrics (NVMf) is a recent extension to the NVMe standard that enables access to remote NVMe devices over RDMA-capable

networks. It eliminates unnecessary protocol translations along the I/O path to a remote device, exposing the multiple paired queue design of NVMe directly to clients. As with RDMA, the queue pairs can directly be mapped into the application context to avoid kernel overheads.

A Crail NVMf storage server acts as a control plane for a NVMf controller by connecting to the controller and reporting its credentials like NVMe qualified name, size, etc., to the metadata server. With the credentials provided by the metadata server, the clients can directly connect to the NVMf controller and perform block read and write operations.

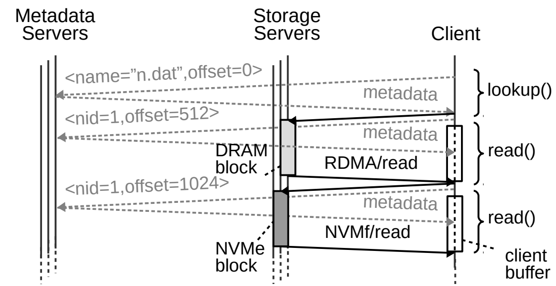

Figure 4: Anatomy of file read/write operations in Crail.

4.3 Failure semantics and persistence

Crail does not currently implement mechanisms for fault-tolerance (see Section 3.2) and therefore does not protect against machine or hardware failures. On a crash of a storage server the corresponding data blocks are lost. On a crash of a metadata server the correponding metadata partition is lost. Metadata servers remove inaccessible storage servers from the list of active servers based on keep-alive messages and make sure only active servers are considered during block allocation.

Crail provides optional mechanisms to persist data stored in DRAM, shut down a Crail deployment and to start a Crail deployment from a previously persisted state. Persistence is implemented via operation logging at the metadata servers and the use of memory mapped persistent storage at storage servers.

4.4 Anatomy of data access

Figure 4 illustrates how a Crail client interacts with storage and metadata servers on behalf of an application reading data from a `File` or `KeyValue` node. The application first calls `lookup` to retrieve a node handle, causing Crail to fetch the necessary metadata via RPC from the metadata server. The metadata contains information about the node such as the size of the data and the location of the first block. Following a successful `lookup` call, the application issues a `read` operation to read a certain number of bytes from the node. The requested number of bytes may be less than a block. In that case a single RDMA or NVMf operation will be sufficient to complete the request. If the requested number of bytes spawns multiple blocks, as it is case in the example, Crail immediately issues the data transfer for the first block, while in parallel requesting the metadata for the next block. Under normal circumstances – due to the low latency RDMA-based protocol between the client and the metadata server – the metadata request will complete ahead of the current block transfer and guarantee a continued data transfer without the client ever having to wait for missing metadata information.

5 Evaluation

In our evaluation we assess if Crail meets the requirements for a temporary storage platform discussed in Section 2.1. Specifically we answer the following questions:

1. Does the unified abstraction of Crail, with its extra indirection layer, perform well for a wide spectrum of data sizes on high-performance devices? (Section 5.1)

2. How simple is it to map higher-level workloads (with their temporary data accesses) to Crail? (Section 5.2)

3. How big are the performance and cost benefits of a mixed-media storage system for data-processing frameworks? (Section 5.3)

Cluster configuration: We use a cluster of eight x64 nodes with two Intel(R) Xeon(R) CPU E5-2690 v1 @ 2.90GHz CPUs, 96GB DDR3 DRAM and a 100 Gbit/s Mellanox ConnectX-5 RoCE RDMA network card. For the client server microbenchmarks, the server is configured with 4 Intel Optane 900P SSDs, except for the IOPS experiments where we only use 2 Optane drives per server. For the larger cluster experiments, all 8 nodes are equipped with 4 Samsung 960 Pro SSDs. The nodes run Ubuntu 16.04.3 LTS (Xenial Xerus) with Linux kernel version 4.10.0-33-generic and Java 8.

5.1 Microbenmarks

Small and medium-size values: We first start by evaluating Crail's performance for storing small to medium size values, a use case typically well served by key-value stores. Consequently, we compare Crail's performance (latency and IOPS) with two state-of-the-art open-source key-value stores, namely, RAMCloud (for DRAM storage) and Aerospike (for NVM Optane). Figure 5 shows the performance for `get` and `put` operations for different data sizes. In Crail, a put operation is implemented by creating a `KeyValue` node using the `create` API call (see Table 2), followed by an `append` operation. The get operation is implemented using a `lookup` call followed by a `read` on the `KeyValue` node – similar to

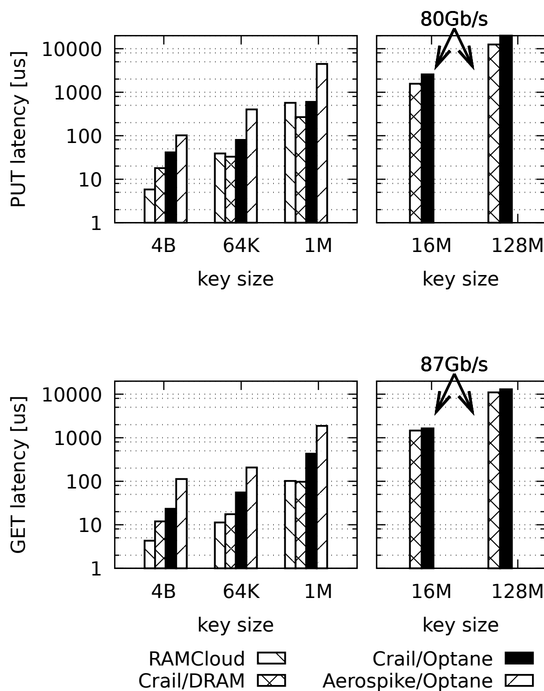

Figure 5: Put/Get latencies in Crail, RAMCloud and Aerospike for datasets of different sizes.

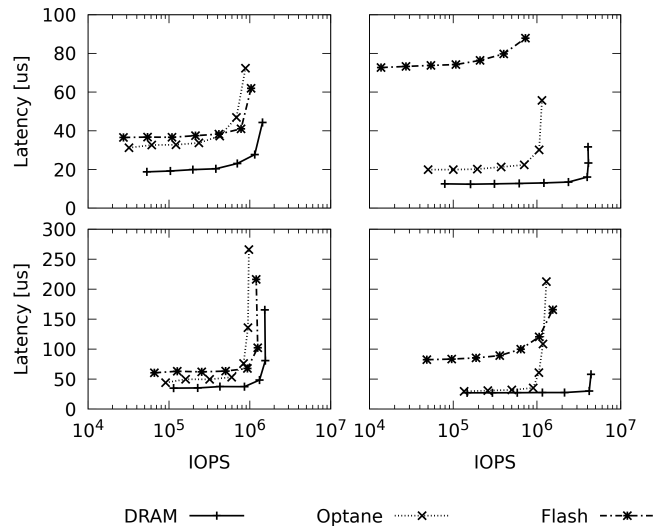

Figure 6: Media-specific loaded latency profile. Top left: Put, queue depth 1. Top right: Get, queue depth 1. Bottom left: Put, queue depth 4. Bottom right: Get, queue depth 4.

the scenario shown in Figure 4. For small datasets (4 bytes), Crail performs slightly worse than RAMCloud for DRAM storage (12 μs vs 6 μs), but outperforms Aerospike on Optane NVM by a margin of $2-4\times$ (23-40 μs for Crail vs. 100 μs for Aerospike). The difference between Aerospike and Crail comes from differences in their I/O execution. Aerospike uses synchronous I/O and multiple I/O threads, which cause contention and spend a significant amount of execution time in synchronization functions [18]. Crail uses asynchronous I/O and executes I/O requests in one context, avoiding context switching and synchronization completely. The latency difference between Crail and RAMCloud is acceptable considering that RAMCloud is a system optimized for small values. For medium sized values (64KB-1MB), Crail outperforms RAMCloud and Aerospike by a margin of $2-6.8\times$. For instance, a 1MB Put on Crail takes around 590 μs, versus 4 *ms* in Aerospike. These performance gains come from the efficient use of RDMA one-sided operations (for both DRAM and NVM), which eliminates data copies at both client and server ends and generally reduces the code path that is executed during put/get operations. While Crail natively supports arbitrary size datasets – by distributing the blocks over multiple storage servers – storing such large values in systems like RAMCloud or Aerospike is either difficult or prohibited. For instance, Aerospike limits individual key/value pairs to 1MB. RAMCloud does not have a strict size limitation but failed to store values larger than 4MB.

For sake of completeness, Figure 5 also shows put/get latencies for extra large values of 16MB and 128MB. As we can see, it takes around to 12 *ms* to store a 128MB value in Crail's DRAM tier, and 20 *ms* to store the same dataset in Crail's Optane tier. Storing such large values in Crail is entirely a matter of throughput. Consequently, the remote DRAM latency is limited by the 100 Gb/s network bandwidth, while the NVM latency is the determined by the bandwidth of the storage device. The aggregated bandwidth of the 4 Optane drives is around 10-12 GB/s. Hence, the resulting data access bandwidth for large datasets stored in Crail's NVM tier is 80-87 Gb/s.

IOPS scaling: So far we have discussed unloaded latencies. Figure 6 shows the latency profile for 256 bytes values for a loaded Crail system for different media types. In this setup, we increase the number of clients from 1 to 64. The clients are running on 16 physical machines, issuing put/get operations in a tight loop. We use only one storage server and one metadata server in this setup, configured either to serve DRAM, Optane NVM or Flash. The top row in Figure 6 show the case for a queue depth of 1, meaning, each client always has only one operation in flight. As shown in the figure, Crail delivers stable latencies up to a reasonably high throughput. For DRAM, the get latencies (top right in Figure 6) stay at 12-15 μs up to 4M IOPS, at which point the metadata server became the bottleneck. We ran the same experiment with multiple metadata servers and verified that the system throughput was scaling linearly (shown later in Figure 7 on top). For the Optane NVM configuration, latencies stay at 20 μs up until almost 1M IOPS, which is very close to the device limit. The Flash latencies are higher but the Samsung drives also have a higher throughput limit. In fact, 64 clients with queue depth 1 cannot saturate the Samsung devices. In order to generate

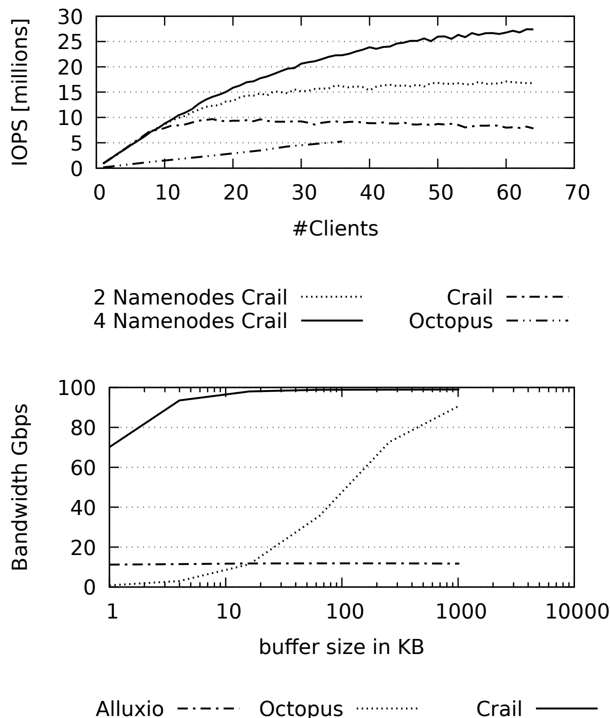

Figure 7: Top: metadata performance in Crail compared to Octopus (we could not run Octopus reliably after 36 clients). Bottom: sequential read performance in Crail and Octopus for large datasets and different buffer sizes.

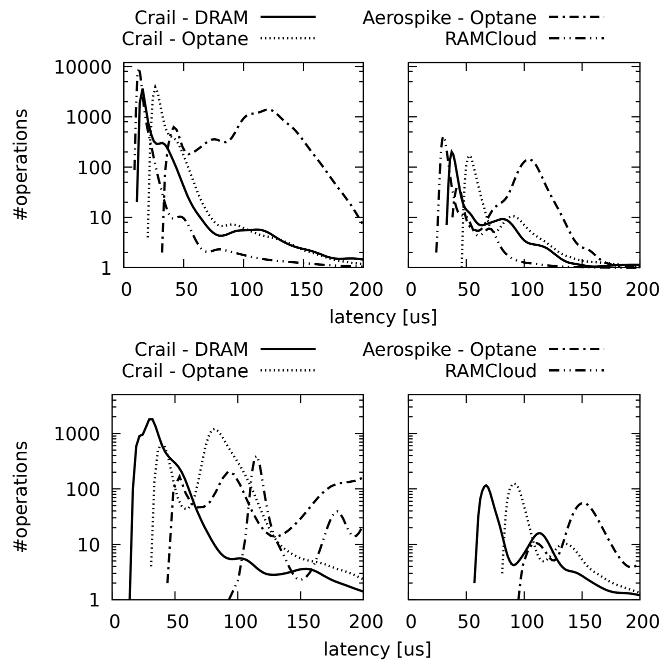

Figure 8: YCSB benchmark performance. Top: small value (1K per KV pair) read (left) and update (right) latencies. Bottom: large value (100K per KV pair) read and update latencies.

a higher load, we measured throughput and latencies for the case where each client always has four operations in flight (queue depth 4, bottom row in Figure 6). As shown, queue depth 4 generally achieves a higher throughput up to a point where the hardware limit is reached, the device queues are overloaded (e.g., for NVM Optane) and latencies sky rock. For instance, at the point before the exponential increase in the latencies, Crail delivers get latencies (Figure 6 bottom right) of 30.1 μs at 4.2M IOPS (DRAM), 60.7 μs for 1.1M IOPS (Optane), and 99.86 μs for 640.3K IOPS (Flash). The situation for put is similar, though generally with lower performance.

Metadata performance: In Figure 7 (top), we benchmark the performance of a simple `lookup` metadata operation which is used to retrieve node metadata in Crail, and compare it with the performance of a similar metadata operation `getattr` in Octopus [23] (an RDMA-optimized NVM file system running in DRAM). There are two main observations here. First, for the single namenode case, Crail outperforms Octopus by $1.7-5.9\times$. A single namenode in Crail peaks around 9.3M lookups/sec. Second, Crail can very efficiently scale the single namenode performance to multi-namenode setups. The system can deliver up to 16.7M and 27.4M lookups/sec for 2 and 4 namenode configurations.

Accessing large datasets: Figure 7 (bottom) shows the bandwidth (y-axis) measured when reading large datasets of `File` nodes in Crail, in comparison to file read operations in Octopus and Alluxio. The x-axis in Figure 7 refers to the size of the application buffer the client is using during read operations. Crail with its efficient data and metadata plane, and overlapping of lookup RPCs and data fetching quickly reaches the network bandwidth limit even for relatively small buffer sizes (just over 1kB). Alluxio performance is bottlenecked by the CPU due to data copies and inefficiencies in the network stack implementation. Octopus performs better than Alluxio, and gradually for large buffers (close to 1MB) reaches the line speed of 98 Gb/s. Note that Crail's peak bandwidth (98 Gb/s) in Figure 7 is better than the peak bandwidth (87 Gb/s) in Figure 5 because for the KV experiments each `KeyValue` node is opened, read, and closed whereas for the file experiments those accesses are amortized.

Summary: In this section we have shown that Crail can store a large spectrum of values effectively while offering comparable or superior performance than the other state-of-the-art systems that are optimized for a particular data range.

5.2 Systems-level Benchmarks

5.2.1 NoSQL workloads

The Yahoo! Cloud Serving Benchmark (YCSB) is an open standard designed to compare the performance of NoSQL databases [10]. It comes with five workloads that stress different properties, e.g. workload A is update heavy whereas workload C is read heavy. We choose workload B to compare Crail to RAMCloud and Aerospike. Workload B has 95% read and 5% update operations and the records are selected with a Zipfian distribution. All systems run in a single namenode/datanode configuration. The purpose of this experiment is to evaluate the latency profile of Crail for a realistic workload beyond microbenchmarks presented in the last section.

Figure 8 (top part) shows the read and update latency distributions for workload B using a single client for the default setup of 10 fields of 100 bytes per record (1K per KV pair). The left part of the figure shows the read performance, and the right part shows the update performance. As shown for this default setup, the largest number of read operations observe a latency of 14 μs (95% and 99% percentile are at 37 and 84 μs) and 26 μs (95% and 99% percentile are at 47 and 81 μs) for DRAM and Optane respectively. Crail on Optane has an average latency of 38 μs and thus is only 15 μs slower than Crail on DRAM. On the other hand, Aerospike with Optane delivers an average latency of 108.7 μs, which is 2.84$\times$ worse than the average Crail latency (38.03 μs). Comparing Crail's DRAM performance to RAMCloud shows that RAMCloud is slightly faster than Crail. However, as we move to larger values of 10 fields of 10KB each (100KB per KV pair) in Figure 8 (bottom) Crail is almost $2.6-4.8\times$ better than Aerospike and RAMCloud, respectively.

Summary: Our experiments using the YCSB benchmark have demonstrated that (a) Crail can successfully translate the raw DRAM/NVMe performance advantages into workload level gains, and (b) Crail effectively deals with both small and large datasets while RAMCloud and Aerospike perform their best in a specific operating range.

5.2.2 Spark Integration

We present the evaluation of Crail with Spark, one of the most popular data processing engines. Spark executes workloads as a series of map-reduce steps while sharing performance critical data in each step. There are multiple points in the Spark data processing pipeline where temporary datasets are generated. In this section, we show performance measurements specifically for two: shuffle and broadcast. Both subsystems can easily be implemented as plugin modules for Spark.

Broadcast: We implemented broadcast using Crail by storing broadcast data as `KeyValue` nodes in a non-enumerable `Table`. A broadcast writer creates a new `KeyValue` node, appends the broadcast data to the node, and passes the node "name" to the readers. Readers, which are distributed over multiple machines inside Spark executors, do a lookup on the "name" and read the data from Crail. Figure 10a shows the result. The x-axis shows the latency as observed by different broadcast readers in the Spark job, while the y-axis shows the percentage of readers. The solid vertical line represent the baseline latency of 12 μs, which we demonstrated in our microbenchmarks. As shown, most of the Crail broadcast readers observe latency very close to the minimum possible. A few observe a latency lower than 12 μs because some of these readers are co-located on the same physical machine where the values are stored. For those nodes, even though they still read the data using the local network interface, there is no actual network transfer happening, hence, their read performance is not limited by the network. In summary, Crail broadcast performance is 1-2 orders of magnitude better than the default Spark implementation.

Shuffle: In Spark, a shuffle writer continuously generates shuffle data during the map phase as it processes the input dataset and classifies data into different buckets that are later read by reducers. Due to the large fan-in and fan-out access pattern, we implemented shuffle using Crail `Bag` nodes. There is one `Bag` node per reducer and each shuffle writer appends data to an array of privately owned `File` nodes, one `File` node per writer per bag. After the map phase, each reducer reads its associated bag using the optimized read interface available in the `Bag` node type (see Section 3.1). We generated a large amount of data (512 GB) and triggered the shuffle operation using the GroupBy benchmark available in the Spark source code. Figures 10b and 10c show the performance (runtime on the x-axis) and the observed network throughput (y-axis) for various configurations. The values 1, 4, or 8 represent the number of cores given to each Spark executor. A quick comparison of the two figures shows that the Crail-accelerated Spark observes higher network throughput (for a corresponding core count) and, thus, as a result better runtimes (1 core 5x, 4 cores 2.5x and 8 cores 2x).

Summary: In this section we have demonstrated that Crail is able to successfully accelerate temporary data access in Spark for small values (e.g., broadcast) as well as large values

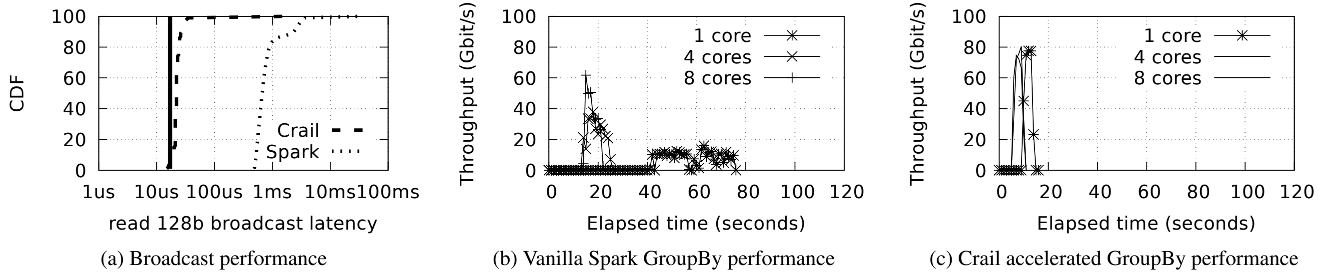

Figure 10: Spark broadcast and GroupBy performance, using Vanilla Spark vs. Crail temporary storage.

(e.g., shuffle) by taking advantage of the different node types (`KeyValue` and `Bag`) in Crail.

5.3 Efficiency of hybrid DRAM/NVM setup

As the last part of our evaluation, we quantify how Crail's tiered data plane helps with regard to performance and cost objectives. We consider the Terasort workload, which is one of the most I/O intensive applications on Spark. We implement Terasort as an external range-partition sort algorithm in two stages. The first stage maps the incoming key-value pairs (10 bytes keys and 90 bytes value) into external buckets. These buckets are then shuffled and sorted by individual reduce tasks. For this evaluation we use the accelerated shuffle and broadcast plugins that we previously developed.

In Figure 9, we explore the performance/cost trade-off of using NVM instead of DRAM to store shuffle data in a 200 GB Spark sorting workload. For this we configure Crail with different storage limits for the DRAM and the Flash storage tiers. The x-axis indicates what fraction of the total shuffle data is stored in DRAM versus Flash. Note that in this experiment we are using the Samsung Flash-based SSDs rather than the Optane devices. A configuration of 10/90 means that 10% of the data is held in DRAM, while 90% is held in Flash. The figure also shows the performance of vanilla Spark (first bar of the figure) that runs on its default shuffle engine completely in DRAM (using tmpfs as a storage backend). There are two key observations here. First, in comparison to vanilla Spark, the use of Crail for the shuffle backend already reduces the runtime by a factor of 3.4. This performance gain can be attributed to the efficient use of high-performance networking and storage hardware in Crail. For instance, during the reduce phase we measured an all-to-all network throughput of 70 Gb/s/machine. Second, as we decrease the fraction of DRAM in Crail in favor of Flash, Spark graciously and automatically spills shuffle data into the Flash tier. In the extreme configuration, where all shuffle data is stored in Flash, the performance degrades to 46.49 second (48% increase), while to total cost for storage is reduced by 8× from 1,000$ to 126$ (to store 200 GB of data based on the numbers in Table 1). The gradual spilling of data from DRAM to Flash happens transparently. Even in the all-Flash configuration, the performance of the Crail-integrated Spark Terasort is half of the completely-in-DRAM vanilla Spark performance. These results validate the design choices we made in Crail that permit trading performance for storage cost.

Summary: In this section, we demonstrated that the use of Crail in Spark (i) leads to better performance due to its efficient I/O path; (ii) reduces the cost of storage, and increases the performance due the hybrid DRAM-NVMe architecture.

6 Conclusion

Storing and accessing temporary data efficiently in data processing workloads is critical for performance, yet challenging due to complex storage demands that fall between the lines of existing storage systems like file systems or key-value stores. We presented NodeKernel, a novel storage architecture offering a new point in the storage design space by combining hierarchical naming with scalability and excellent performance for a wide range of data sizes and access patterns that are typical for temporary data. The NodeKernel architecture is driven by opportunities of modern networking and storage hardware that enabled us to reduce overheads that made such a design impractical in the past. We showed that storing temporary data in Crail, our concrete implementation of the NodeKernel architecture leveraging RDMA networking and NVMe storage, can improve NoSQL workloads by up to 4.8× and Spark application performance by up to 3.4×. Crail's use of NVMe Flash further reduces storage cost by up to 8× compared to storage systems that only use DRAM.

Evaluating File System Reliability on Solid State Drives

Shehbaz Jaffer* University of Toronto
Stathis Maneas* University of Toronto
Andy Hwang University of Toronto
Bianca Schroeder University of Toronto

Abstract

As solid state drives (SSDs) are increasingly replacing hard disk drives, the reliability of storage systems depends on the failure modes of SSDs and the ability of the file system layered on top to handle these failure modes. While the classical paper on IRON File Systems provides a thorough study of the failure policies of three file systems common at the time, we argue that 13 years later it is time to revisit file system reliability with SSDs and their reliability characteristics in mind, based on modern file systems that incorporate journaling, copy-on-write and log-structured approaches, and are optimized for flash. This paper presents a detailed study, spanning ext4, Btrfs and F2FS, and covering a number of different SSD error modes. We develop our own fault injection framework and explore over a thousand error cases. Our results indicate that 16% of these cases result in a file system that cannot be mounted or even repaired by its system checker. We also identify the key file system metadata structures that can cause such failures and finally, we recommend some design guidelines for file systems that are deployed on top of SSDs.

1 Introduction

Solid state drives (SSDs) are increasingly replacing hard disk drives as a form of secondary storage medium. With their growing adoption, storage reliability now depends on the reliability of these new devices as well as the ability of the file system above them to handle errors these devices might generate (including for example device errors when reading or writing a block, or silently corrupted data). While the classical paper by Prabhakaran et *al.* [45] (published in 2005) studied in great detail the robustness of three file systems that were common at the time in the face of hard disk drive (HDD) errors, we argue that there are multiple reasons why it is time to revisit this work.

The first reason is that failure characteristics of SSDs differ significantly from those of HDDs. For example, recent field studies [39, 43, 48] show that, while their replacement rates (due to suspected hardware problems) are often by an order of magnitude lower than those of HDDs, the occurrence of partial drive failures that lead to errors when reading or writing a block or corrupted data can be an order of magnitude higher. Other work argues that the Flash Translation Layer (FTL) of SSDs might be more prone to bugs compared to HDD firmware, due to their high complexity and less maturity, and demonstrate this to be the case when drives are faced with power faults [53]. This makes it even more important than before that file systems can detect and deal with device faults effectively.

Second, file systems have evolved significantly since [45] was published 13 years ago; the ext family of file systems has undergone major changes from the ext3 version considered in [45] to the current ext4 [38]. New players with advanced file-system features have arrived. Most notably Btrfs [46], a copy-on-write file system which is more suitable for SSDs with no in-place writes, has garnered wide adoption. The design of Btrfs is particularly interesting as it has fewer total writes than ext4's journaling mechanism. Further, there are new file systems that have been designed specifically for flash, such as F2FS [33], which follow a log-structured approach to optimize performance on flash.

The goal of this paper is to characterize the resilience of modern file systems running on flash-based SSDs in the face of SSD faults, along with the effectiveness of their recovery mechanisms when taking SSD failure characteristics into account. We focus on three different file systems: Btrfs, ext4, and F2FS. ext4 is an obvious choice, as it is the most commonly used Linux file system. Btrfs and F2FS include features particularly attractive with respect to flash, with F2FS being tailored for flash. Moreover, these three file systems cover three different points in the design spectrum, ranging from journaling to copy-on-write to log-structured approaches.

The main contribution of this paper is a detailed study, spanning three very different file systems and their ability to detect and recover from SSD faults, based on error injection targeting all key data structures. We observe huge differences across file systems and describe the vulnerabilities of each in detail.

*These authors contributed equally to this work.

Over the course of this work we experiment with more than one thousand fault scenarios and observe that around 16% of them result in severe failure cases (kernel panic, unmountable file system). We make a number of observations and file several bug reports, some of which have already resulted in patches. For our experiments, we developed an error injection module on top of the Linux device mapper framework.

The remainder of this paper is organized as follows: Section 2 provides a taxonomy of SSD faults and a description of the experimental setup we use to emulate these faults and test the reaction of the three file systems. Section 3 presents the results from our fault emulation experiments. Section 4 covers related work and finally, in Section 5, we summarize our observations and insights.

2 File System Error Injection

Our goal is to emulate different types of SSD failures and check the ability of different file systems to detect and recover from them, based on which part of the file system was affected. We limit our analysis to a local file system running on top of a single drive. Note that although multi-drive redundancy mechanisms like RAID exist, they are not general substitutes for file system reliability mechanisms. First, RAID is not applicable to all scenarios, such as single drives on personal computers. Second, errors or data corruption can originate from higher levels in the storage stack, which RAID can neither detect nor recover.

Furthermore, our work only considers *partial* drive failures, where only part of a drive's operation is affected, rather than *fail-stop* failures, where the drive as a whole becomes permanently inaccessible. The reason lies in the numerous studies published over the last few years, using either lab experiments or field data, which have identified many different SSD internal error mechanisms that can result in partial failures, including mechanisms that originate both from the flash level [10, 12, 13, 16–19, 21, 23, 26, 27, 29–31, 34, 35, 40, 41, 47, 49, 50] and from bugs in the FTL code, e.g. when it is not hardened to handle power faults correctly [52, 53].

Moreover, a field study based on Google's data centers observes that partial failures are significantly more common for SSDs than for HDDs [48].

This section describes different SSD error modes and how they manifest at the file system level, and also our experimental setup, including the error injection framework and how we target different parts of a file system.

2.1 SSD Errors in the Field and their Manifestation

This section provides an overview over the various mechanisms that can lead to partial failures and how they manifest at the file system level (all summarized in Table 1).

Uncorrectable Bit Corruption: Previous work [10, 12, 13, 16–19, 21, 26, 27, 29, 34, 35, 41] describes a large number of error mechanisms that originate at the flash level and can result in *bit corruption*, including retention errors, read and program disturb errors, errors due to flash cell wear-out and failing blocks. Virtually all modern SSDs incorporate error correcting codes to detect and correct such bit corruption. However, recent field studies indicate that *uncorrectable bit corruption*, where more bits are corrupted than the error correcting code (ECC) can handle, occurs at a significant rate in the field. For example, a study based on Google field data observes 2-6 out of 1000 drive days with uncorrectable bit errors [48]. Uncorrectable bit corruption manifests as a read I/O error returned by the drive when an application tries to access the affected data ("Read I/O errors" in Table 1).

Silent Bit Corruption: This is a more insidious form of bit corruption, where the drive itself is not aware of the corruption and returns corrupted data to the application ("Corruption" in Table 1). While there have been field studies on the prevalence of silent data corruption for HDD based systems [9], there is to date no field data on silent bit corruption for SSD based systems. However, work based on lab experiments shows that 3 out of 15 drive models under test experience silent data corruption in the case of power faults [53]. Note that there are other mechanisms that can lead to silent data corruption, including mechanisms that originate at higher levels in the storage stack, above the SSD device level.

FTL Metadata Corruption: A special case arises when silent bit corruption affects FTL metadata. Among other things, the FTL maintains a mapping of logical to physical (L2P) blocks as part of its metadata [8]; metadata corruption could lead to "Read I/O errors" or "Write I/O errors", when the application attempts to read or write a page that does not have an entry in the L2P mapping due to corruption. Corruption of the L2P mapping could also result in wrong or erased data being returned on a read, manifesting as "Corruption" to the file system. Note that this is also a silent corruption - i.e. neither the device nor the FTL is aware of these corruptions.

Misdirected Writes: This refers to the situation where during an SSD-internal write operation, the correct data is being written to flash, but at the wrong location. This might be due to a bug in the FTL code or triggered by a power fault, as explained in [53]. At the file system level this might manifest as a "Corruption", where a subsequent read returns wrong data, or a "Read I/O error". This form of corruption is silent; the device does not detect and propagate errors to the storage stack above until invalid data or metadata is accessed again.

Shorn Writes: A shorn write is a write that is issued by the file system, but only partially done by the device. In [53], the authors observe such scenarios surprisingly frequently during power faults, even for enterprise class drives, while issuing properly synchronized I/O and cache flush commands to the device. A shorn write is similar to a "torn write", where only part of a multi-sector update is written to the disk, but it applies to sector(s) which should have been fully persisted due to the use of a cache flush operation. One possible expla-

nation is the mismatch of write granularities between layers. The default block size for file systems is larger (e.g. 4KB for ext4/F2FS, and 16KB for Btrfs) than the physical device (e.g. 512B). A block issued from the file system is mapped to multiple physical blocks inside the device. As a result, during a power fault, only some of the mappings are updated while others remain unchanged. Even if physical block sizes match that of the file system, another possible explanation is because SSDs include on-board cache memory for buffering writes, shorn writes may also be caused by alignment and timing bugs in the drive's cache management [53]. Moreover, recent SSD architectures use pre-buffering and striping across independent parallel units, which do not guarantee atomicity between them for an atomic write operation [11]. The increase in parallelism may further expose more shorn writes.

At the file system level, a shorn write is not detected until its manifestation during a later read operation, where the file system sees a 4KB block, part of which contains data from the most recent update to the block, while the remaining part contains either old or zeroed out data (if the block was recently erased). While this could be viewed as a special form of silent bit corruption, we consider this as a separate category in terms of how it manifests at the file system level (called "Shorn Write" corresponding to column (d) in Table 1) as this form of corruption creates a particular pattern (each sequence of 512 bytes within a 4KB block is either completely corrupted or completely correct), compared to the more random corruption event referred to by column (c).

In [53], the authors observe shorn writes manifesting in two patterns, where only the first 3/8th or the first 7/8th of a block gets written and the rest is not. Similarly in our experiments, we keep only the first 3/8th of a 4KB block. We assume the block has been successfully erased, so the rest of the block remains zeroed out. Our module can be configured to test other shorn write sizes and patterns as well.

Dropped writes: The authors in [53] observe cases where an SSD internal write operation gets dropped even after an explicit cache flush (e.g. in the case of a power fault when the update was in the SSD's cache, but not persisted to flash). If the dropped write relates to FTL metadata, in particular to the L2P mapping, this could manifest as a "Read I/O error", "Write I/O error" or "Corruption" on a subsequent read or write of the data. If the dropped write relates to a file system write, the result is the same as if the file system had never issued the corresponding write. We create a separate category for this manifestation which we refer to as "Lost Write" (column (e) in Table 1).

Incomplete Program operation: This refers to the situation where a flash program operation does not fully complete (without the FTL noticing), so only part of a flash page gets written. Such scenarios were observed, for example, under power faults [53]. At the file system level, this manifests as a "Corruption" during a subsequent read of the data.

Incomplete Erase operation: This refers to the situation where a flash erase operation does not completely erase a flash erase block (without the FTL detecting and correcting this problem). Incomplete erase operations have been observed under power faults [53]. They could also occur when flash erase blocks wear-out and the FTL does not handle a failed erase operation properly. Subsequent program operations to the affected erase block can result in incorrectly written data and consequently "Corruption", when this data is later read by the file system.

SSD/Flash Errors	(a)	(b)	(c)	(d)	(e)
Uncorrectable Bit Corruption	✓				
Silent Bit Corruption			✓		
FTL Metadata Corruption	✓	✓	✓		
Misdirected Writes	✓		✓		
Shorn Writes				✓

Incomplete Program Operation			✓	✓	
Incomplete Erase Operation			✓		

Table 1: *Different types of flash errors and their manifestation in the file system. (a) Read I/O error (b) Write I/O error (c) Corruption (d) Shorn Write (e) Lost Write.*

2.2 Comparison with HDD faults

We note that there are also HDD-specific faults that would manifest in a similar way at the file system level. However, the mechanisms that cause faults within each media are different and can for example affect the frequency of observed errors. One such case are uncorrectable read errors which have been observed at a much higher frequency in production systems using SSDs than HDDs [48] (a trend that will likely only get worse with QLC). There are faults though whose manifestation does actually differ from HDDs to SSDs, due to inherent differences in their overall design and operation. For instance, a part affected by a shorn write may contain previously written data in the case of an HDD block, but would contain zeroed out data if that area within the SSD has been correctly erased. In addition, the large degree of parallelism inside SSDs makes correctness under power faults significantly more challenging than for HDDs (for example, ensuring atomic writes across parallel units). Finally, file systems might modify their behavior and apply different fault recovery mechanisms for SSDs and HDDs; for example, Btrfs turns off metadata duplication by default when deployed on top of an SSD.

2.3 Device Mapper Tool for Error Emulation

The key observation from the previous section is that all SSD faults we consider manifest in one of five ways, corresponding to the five columns (a) to (e) in Table 1. This section describes a device mapper tool we created to emulate all five scenarios.

In order to to emulate SSD error modes and observe each individual file system's response, we need to intercept the block I/O requests between the file system and the block device. We leverage the Linux *device mapper* framework to create a virtual block device that intercepts requests between the file system and the underlying physical device. This allows

Programs
mount, umount, open, creat, access, stat, lstat, chmod, chown, utime, rename, read, write, truncate, readlink, symlink, unlink, chdir, rmdir, mkdir, getdirentries, chroot

Table 2: *The programs used in our study. Each one stresses a single system call and is invoked several times under different file system images to increase coverage.*

ext4	
Data Structure	**Approach**
super block, group descriptor, inode blocks, block bmap, inode bmap	dumpe2fs
dir_entry	debugfs, get block inode, stat on inode number, check file type
extent	debugfs, check for extent of a file or directory path
data	debugfs, get block inode, stat on inode number, check file type
journal	debugfs, check if parent inode number is 8
Btrfs	
Data Structure	**Approach**

DIR_ITEM DIR_INDEX INODE_REF INODE_DATA EXTENT_DATA	btrfs-debug-tree
F2FS	
superblock, checkpoint, SIT, NAT, inode, d/ind node, dir. block, data	device mapper module

Table 3: *The approach to type blocks collected using either* `blktrace` *or our own device mapper module.*

us to operate on block I/O requests and simulate faults as if they originate from a physical device, and also observe the file system's reaction without modifying its source code. In this way, we can perform tracing, parse file system metadata, and alter block contents online, for both read and write requests, while the file system is mounted. For this study, we use the Linux kernel version 4.17.

Our module can intercept read and write requests for selected blocks as they pass through the block layer and return an error code to the file system, emulating categories (a) "Read Error" and (b) "Write Error" in Table 1. Possible parameters include the request's type (read/write), block number, and data structure type. In the case of multiple accesses to the same block, one particular access can be targeted. We also support corruption of specific data structures, fields and bytes within blocks, allowing us to emulate category (c) "Corruption". The module can selectively shear multiple sectors of a block before sending it to the file system or writing it on disk, emulating category (d) "Shorn Write". Our module can further drop one or more blocks while writing the blocks corresponding to a file system operation, emulating the last category (e) "Lost Write". The module's API is generic across file systems and can be expanded to different file systems. Our module can be found at [6].

2.4 Test Programs

We perform injection experiments while executing test programs chosen to exercise different parts of the POSIX API, similar to the "singlets" used by Prabhakaran et *al.* [45]. Each individual program focuses on one system call, such as `mkdir` or `write`. Table 2 lists all the test programs that we used in our study. For each test program, we populate the disk with different files and directory structures to increase code coverage. For example, we generate small files that are stored inline within an inode, as well as large files that use indirect blocks. All our programs pedantically follow POSIX semantics; they call `fsync(2)` and `close(2)`, and check the return values to ensure that data and metadata has successfully persisted to the underlying storage device.

2.5 Targeted Error Injection

Our goal is to understand the effect of block I/O errors and corruption in detail depending on which part of a file system is affected. That means our error injection testbed requires the ability to target specific data structures and specific fields within a data structure for error injection, rather than randomly injecting errors. We therefore need to identify for each program which data structures are involved and how the parts of the data structure map to the sequence of block accesses generated by the program.

Understanding the relationship between the sequence of block accesses and the data structures within each file system required a significant amount of work and we had to rely on a combination of approaches. First, we initialize the file system to a clean state with representative data. We then run a specific test program (Table 2) on the file system image, capturing traces from `blktrace` and the kernel to learn the program's actual accessed blocks. Reading the file system source code also enables us to put logic inside our module to interpret blocks as requests pass through it. Lastly, we use offline tools such as `dumpe2fs`, `btrfs-inspect`, and `dump.f2fs` to inspect changes to disk contents. Through these multiple techniques, we can identify block types and specific data structures within the blocks. Table 3 summarizes our approach to identify different data structures in each of the file systems.

After identifying all the relevant data structures for each program, we re-initialize the disk image and repeat test program execution for error injection experiments. We use the same tools, along with our module, to inject errors to specific targets. A single block I/O error or data corruption is injected into a block or data structure during each execution. This allows us to achieve better isolation and characterization of the file system's reaction to the injected error.

Our error injection experiments allow us to measure both immediate and longer-term effects of device faults. We can observe immediate effects on program execution for some cases, such as user space errors or kernel panics (e.g. from write I/O errors). At the end of each test program execution, we unmount the file system and perform several offline tests to verify the consistency of the disk image, regardless of whether the corruption was silent or not (e.g. persisting lost/shorn writes): we invoke the file system's integrity checker (*fsck*), check if the file system is mountable, and check whether

Symbol	Level	Description
○	$\mathbf{D_{Zero}}$	No detection.
–	$\mathbf{D_{ErrorCode}}$	Check the error code returned from the lower levels.
\	$\mathbf{D_{Sanity}}$	Check for invalid values within the contents of a block.
/	$\mathbf{D_{Redundancy}}$	Checksums, replicas, or any other form of redundancy.
|	$\mathbf{D_{Fsck}}$	Detect error using the system checker.
○	$\mathbf{R_{Zero}}$	No attempt to recover.
/	$\mathbf{R_{Retry}}$	Retry the operation first before returning an error.
|	$\mathbf{R_{Propagate}}$	Error code propagated to the user space.
\	$\mathbf{R_{Previous}}$	File system resumes operation from the state exactly before the operation occurred.
–	$\mathbf{R_{Stop}}$	The operation is terminated (either gracefully or abruptly); the file system may be mounted as read-only.
■ (red)	$\mathbf{R_{Fsck_Fail}}$	Recovery failed, the file system cannot be mounted.
■ (orange)	$\mathbf{R_{Fsck_Partial}}$	The file system is mountable, but it has experienced data loss in addition to operation failure.
■ (yellow)	$\mathbf{R_{Fsck_Orig}}$	Current operation fails, file system restored to pre-operation state.
■ (green)	$\mathbf{R_{Fsck_Full}}$	The file system is fully repaired and its state is the same with the one generated by the execution where the operation succeeded without any errors.

Table 4: *The levels of our detection and recovery taxonomy.*

the program's operations have been successfully persisted by comparing the resultant disk image against the expected one. We also explore longer-term effects of faults where the test programs access data that were previously persisted with errors (read I/O, reading corrupted or shorn write data).

In this study, we use *btrfs-progs v4.4*, *e2fsprogs v1.42.13*, and *f2fs-tools v1.10.0* for our error injection experiments.

2.6 Detection and Recovery Taxonomy

We report the *detection* and *recovery* policies of all three file systems with respect to the data structures involved. We characterize each file system's reaction via all observable interfaces: system call return values, changes to the disk image, log messages, and any side-effects to the system (such as kernel panics). We classify the file system's detection and recovery based on a taxonomy that was inspired by previous work [45], but with some new extensions: unlike [45], we also experiment with file system integrity checkers and their ability to detect and recover from errors that the file system might not be able to deal with and as such, we add a few additional categories within the taxonomy that pertain to file system checkers. Also, we create a separate category for the case where the file system is left in its previous consistent state prior to the execution of the program ($R_{Previous}$). In particular, if the program involves updates on the system's metadata, none of it is reflected to the file system. Table 4 presents our taxonomy in detail.

A file system can detect the injected errors online by checking the return value of the block I/O request ($D_{ErrorCode}$), inspecting the incoming data and performing some sanity checks (D_{Sanity}), or using redundancies, e.g. in the form of checksums ($D_{Redundancy}$). A successful detection should alert the user via system call return values or log messages.

To recover from errors, the file system can take several actions. The most basic action is simply passing along the error code from the block layer ($R_{Propagate}$). The file system can also decide to terminate the execution of the system call, either gracefully via transaction abort, or abruptly such as crashing the kernel (R_{Stop}). Lastly, the file system can perform retries (R_{Retry}) in case the error is transient, or use its redundancy data structures to recover the data.

It is important to note that for block I/O errors, the actual data stored in the block is not passed to the disk or the file system. Hence, no sanity check can be performed and D_{Sanity} is not applicable. Similarly, for silent data corruption experiments, our module does not return an error code, so $D_{ErrorCode}$ is not relevant.

We also run each file system's *fsck* utility and report on its ability to detect and recover file systems errors offline, as it may employ different detection and recovery strategies than the online file system. The different categories for *fsck* recovery are shown in Table 4.

3 Results

Tables 5 and 6 provide a high-level summary of the results from our error injection experiments following the detection and recovery taxonomy from Table 4. Our results are organized into six columns corresponding to the fault modes we emulate. The six tables in each column represent the fault detection and recovery results for each file system under a particular fault. The columns (a-w) in each table correspond to the programs listed in Table 2, which specify the operation during which the fault mode was encountered, and rows correspond to the file system specific data structure, that was affected by the fault.

Note that the columns in Tables 5 and 6 have a one-to-one correspondence to the fault modes described in Section 2 (Table 1), with the exception of *shorn writes*. After a shorn write is injected during test program execution and persisted to the flash device, we examine two scenarios where the persisted partial data is accessed again: during fsck invocation (*Shorn Write + Fsck* column) and test program execution (*Shorn Write + Program Read* column).

3.1 Btrfs

We observe in Table 5 that Btrfs is the only file system that consistently detects all I/O errors as well as corruption events, including those affecting data (rather than only metadata). It achieves this through the extensive use of checksums.

However, we find that Btrfs is much less successful in recovering from any issues than the other two file systems. It is the only file system where four of the six error modes can lead to a kernel crash or panic and subsequently a file system that cannot be mounted even after running `btrfsck`. It also has the largest number of scenarios that result in an unmountable file system after `btrfsck` (even if not preceded by a kernel crash). Furthermore, we find that node level checksums, although good for detecting block corruption, they remove an entire node even if a single byte becomes corrupted. As a result, large chunks of data are removed, causing data loss.

Before we describe the results in more detail below, we provide a brief summary of Btrfs data structures. The Btrfs

file system arranges data in the form of a forest of trees, each serving a specific purpose (e.g. file system tree (*fstree*) stores file system metadata, checksum tree (*csumtree*) stores file/directory checksums). Btrfs maintains checksums for all metadata within tree nodes. Checksum for data is computed and stored separately in a checksum tree. A *root tree* stores the location of the root of all other trees in the file system. Since Btrfs is a copy-on-write file system, all changes made on a tree node are first written to a different location on disk. The location of the new tree nodes are then propagated across the internal nodes up to the root of the file system trees. Finally, the *root tree* needs to be updated with the location of the other changed file system trees.

3.1.1 Read errors

All errors get detected ($D_{\text{ErrorCode}}$) and registered in the operating system's message *log*, and the current operation is terminated (R_{Stop}). `btrfsck` is able to run, detect and correct the file system in most cases, with two exceptions. When the *fstree* structure is affected, `btrfsck` removes blocks that are not readable and returns an I/O error. Another exception is when a read I/O error is encountered while accessing key tree structures during a `mount` procedure: `mount` fails and `btrfsck` is unable to repair the file system.

3.1.2 Corruption

Corruption of any B-tree node. Checksums inside each tree node enable reliable detection of corruption; however, Btrfs employs a different recovery protocol based on the type of the underlying device. When Btrfs is deployed on top of a hard disk, it provides recovery from metadata corruption using metadata replication. Specifically, reading a corrupted block leads to `btrfs-scrub` being invoked, which replaces the corrupted primary metadata block with its replica. Note that `btrfs-scrub` does not have to scan the entire file system; only the replica is read to restore the corrupted block. However, in case the underlying device is an SSD, Btrfs turns off metadata replication by default for two reasons [7]. First, an SSD can remap a primary block and its replica internally to a single physical location, thus deduplicating them. Second, SSD controllers may put data written together in a short time span into the same physical storage unit (i.e. cell, erase block, etc.), which is also a unit of SSD failures. Therefore, `btrfs-scrub` is never invoked in the case of SSDs, as there is no metadata duplication. This design choice causes a single bit flip of *fstree* to wipe out files and entire directories within a *B-Tree* node. If a corrupted tree node is encountered while `mount` reads in all metadata trees into memory, the consequences are even more severe: the operation fails and the disk is left in an inconsistent and irreparable state, even after running `btrfsck`.

Directory corruption. We observe that when a node corruption affects a directory, the corruption could actually be recovered, but Btrfs fails to do so. For performance reasons, Btrfs maintains two independent data structures for a directory (`DIR_ITEM` and `DIR_INDEX`). If one of these two becomes corrupted, the other data structure is not used to restore the directory. This is surprising considering that the existing redundancy could easily be leveraged for increased reliability.

3.1.3 Write errors

Superblock & Write I/O errors: Btrfs has multiple copies of its superblock, but interestingly, the recovery policy upon a write error is not identical for all copies. The superblocks are located at fixed locations on the disk and are updated at every write operation. The replicas are kept consistent, which differs from ext4's behavior. We observe that a write I/O error while updating the primary superblock is considered severe; the operation is aborted and the file system remounts as *read-only*. On the other hand, write I/O errors for the secondary copies of the superblock are detected, but the overall operation completes successfully, and the secondary copy is not updated. While this allows the file system to continue writing, this is a violation of the implicit consistency guarantee between all superblocks, which may lead to problems in the future, as the system operates with a reduced number of superblock copies.

Tree Node & Write I/O errors: A write I/O error on a tree node is registered in the operating system's message *log*, but due to the file system's asynchronous nature, errors cannot be directly propagated back to the user application that wrote the data. In almost all cases, the file system is forced to mount as *read-only* (R_{Stop}). A subsequent `unmount` and `btrfsck` run in repair mode makes the device unreadable for *extentTree*, *logTree*, *rootTree* and the root node of the *fstree*.

3.1.4 Shorn Write + Program Read

We observe that the behavior of Btrfs during a read of a shorn block is similar to the one we observed earlier for corruption. The only exception is the superblock, as its size is smaller than the 3/8th of the block and it does not get affected.

3.1.5 Shorn Write + Fsck

Shorn writes on *root tree* cause the file system to become unmountable and unrecoverable even after a `btrfsck` operation. We also find kernel panics during shorn writes as described in Section 3.1.7.

3.1.6 Lost Writes

Errors get detected only during `btrfsck`. They do not get detected or propagated to user space during normal operation. `btrfsck` is unable to recover the file system, which is rendered unmountable due to corruption. The only recoverable case is a lost write to the superblock; for the remaining data structures, the file system eventually becomes unmountable.

3.1.7 Bugs found/reported.

We submitted 2 bug reports for Btrfs. The first bug report is related to the corruption of a `DIR_INDEX` key. The file system was able to detect the corruption but deadlocks while listing

the directory entries. This bug was fixed in a later version [1]. The second bug is related to read I/O errors specifically on the root directory, which can cause a kernel panic for certain programs. We encountered 2 additional bugs during a shorn write that result in a kernel panic, both having the same root cause. The first case involves a shorn write to the root of the *fstree*, while the second case involves a shorn write to the root of the *extent tree*. In both cases, there is a mismatch in the leaf node size, which forces Btrfs to print the entire tree in the operating system's message *log*. While printing the leaf block, another kernel panic occurs where the size of a Btrfs *item* does not match the Btrfs *header*. Rebooting the kernel and running `btrfsck` fails to recover the file system.

3.2 ext4

ext4 is the default file system for many widely used Linux distributions and Android devices. It maintains a *journal* where all metadata updates are sequentially written before the main file system is updated. First, data corresponding to a file system operation is written to the in-place location of the file system. Next, a transaction log is written on the *journal*. Once the transaction log is written on the *journal*, the transaction is said to be *committed*. When the *journal* is full or sufficient time has elapsed, a *checkpoint* operation takes place that writes the in-memory metadata buffers to the in-place metadata location on the disk. On the event of a crash before the transaction is committed, the file system transaction is discarded. If the commit has taken place successfully on the *journal* but the transaction has not been checkpointed, the file system replays the *journal* during remount, where all metadata updates that were committed on the *journal* are recovered from the journal and written to the main file system.

ext4 is able to recover from an impressively large range of fault scenarios. Unlike Btrfs, it makes little use of checksums unless *metadata_csum* feature is enabled explicitly during file system creation. Further, it deploys a very rich set of sanity checks when reading data structures such as directories, inodes and extents[1], which helps it deal with corruptions.

It is also the only one of the three file systems that is able to recover lost writes of multiple data structures, due to its in-place nature of writes and a robust file system checker. However, there are a few exceptions where the corresponding issue remains uncorrectable (see the red cells in Table 6 associated with ext4's recovery).

Furthermore, we observe instances of data loss caused by shorn and lost writes involving write programs, such as `create` and `rmdir`. For shorn writes, ext4 may incur silent errors, and not notify the user about the errors.

Before describing some specific issues below, we point out that our ext4 results are very different from those reported for ext3 in [45], where a large number of corruption events and several read and write I/O errors were not detected or handled properly. Clearly, in the 13 years that have passed since then, ext developers have made improvements in reliability a priority, potentially motivated by the findings in [45].

I/O errors, corruption and shorn writes of Inodes: The most common scenario leading to data loss (but still a consistent file system) is a fault, in particular read I/O error, corruption or shorn write, that affects an inode, which results in the data of all files having their inode structure stored inside the affected inode block becoming inaccessible.

Read I/O errors, corruption and shorn writes of Directory blocks: A shorn write involving a directory block is detected by the file system and eventually, the corresponding files and directories are removed. Empty files are completely removed by *e2fsck* by default, while non-empty files are placed into the *lost+found* directory. However, the parent-child relationship is lost, which we encode as $R_{Fsck_Partial}$.

Write I/O errors and group descriptors: There is only one scenario where `e2fsck` does not achieve at least partial success: When `e2fsck` is invoked after a write error on a group descriptor, it tries to rebuild the group descriptor and write it to the same on-disk location. However, as it is the same on-disk location that generated the initial error, `e2fsck` encounters the same write error and keeps restarting, running into an infinite loop for 3 cases (see R_{Fsck_Fail}).

Read I/O error during mount: ext4 fails to complete the `mount` operation if a read I/O error occurs while reading a critical metadata structure. In this case, the file system cannot be mounted even after invoking `e2fsck`. We observe similar behavior for the other two file systems as well.

3.3 F2FS

F2FS is a log-structured file system designed for devices that use an FTL. Data and metadata are separately written into 6 active *logs* (default configuration), which are grouped by data/metadata, files/directories, and other heuristics. This *multi-head logging* allows similar blocks to be placed together and increases the number of sequential write operations.

F2FS divides its logical address space into the *metadata region* and the *main area*. The metadata region is stored at a fixed location and includes the Checkpoint (CP), the Segment Information Table (SIT), and the Node Address Table (NAT). The checkpoint stores information about the state of the file system and is used to recover from system crashes. SIT maintains information on the *segments* (the unit at which F2FS allocates storage blocks) in the main area, while NAT contains the block addresses of the file system's *nodes*, which comprise of file/directory inodes, direct, and indirect nodes. F2FS uses a two-location approach for these three structures. In particular, one of the two copies is "active" and used to initialize the file system's state during `mount`, while the other is a shadow copy that gets updated during the file system's execution. Finally, each copy of the checkpoint points to its

[1] We report failure results for both directory and file extents together. Since our pre-workload generation creates a number of files and directories in the root directory, at least 1 extent block corresponding to the root directory gets accessed by all programs.

corresponding copy of SIT and NAT.

F2FS's behavior when encountering read/write errors or corruption differs significantly from that of ext4 and Btrfs. While read failures are detected and appropriately propagated in nearly all scenarios, we observe that F2FS consistently fails to detect and report any write errors, independently of the operation that encounters them and the affected data structure. Furthermore, our results indicate that F2FS is not able to deal with lost and shorn writes effectively and eventually suffers from data loss. In some cases, a run of the file system's checker (called `fsck.f2fs`) can bring the system to a consistent state, but in other cases, the consequences are severe. We describe some of these cases in more detail below.

3.3.1 Read errors

Checkpoint / NAT / SIT blocks & read errors. During its `mount` operation, if F2FS encounters a read I/O error while trying to fetch any of the checkpoint, NAT, or SIT blocks, then it mounts as *read-only*. Additionally, F2FS cannot be mounted if the inode associated with the root directory cannot be accessed. In general, `fsck.f2fs` cannot help the file system recover from the error since it terminates with an assertion error every time it cannot read a block from the disk.

3.3.2 Write errors & Lost Writes

We observe that F2FS does not detect write errors (as injected by our framework), leading to different issues, such as corruption, reading garbage values, and potentially data loss. As a result, during our experiments, newly created or previously existing entries have been completely discarded from the system, applications have received garbage values, and finally, the file system has experienced data loss due to an incomplete recovery protocol (i.e. when `fsck.f2fs` is invoked). Considering that F2FS does not detect write I/O errors, lost writes end up having the same effect, since the difference between the two is that a lost write is silent (i.e. no error is returned).

3.3.3 Corruption

Data corruption is reliably detected only for inodes and checkpoints, which are the only data structures protected by checksums, but even for those two data structures, recovery can be incomplete, resulting in the loss of files (and the data stored in them). The corruption of other data structures can lead to even more severe consequences. For example, the corruption of the superblock can go undetected and lead to an unmountable file system, even if the second copy of the superblock is intact. We have filed two bug reports related to the issues we have identified and one has already resulted in a fix. Below we describe some of the issues around corruption in more detail.

Inode block corruption. Inodes are one of only two F2FS data structures that are protected by checksums, yet their corruption can still create severe problems. One such scenario arises when the information stored in the *footer* section of an inode block is corrupted. In this case, `fsck.f2fs` will discard the entry without even attempting to create an entry in the *lost_found* directory, resulting in data loss.

Another scenario is when an inode associated with a directory is corrupted. Then all the regular files stored inside that directory and its sub-directories are recursively marked as *unreachable* by `fsck.f2fs` and are eventually moved to the *lost_found* directory (provided that their inode is valid). However, we observe that `fsck.f2fs` does not attempt to recreate the structure of sub-directories. It simply creates an entry in the *lost_found* directory for regular files in the sub-directory tree, not sub-directories. As a result, if there are different files with the same name (stored in different paths of the original hierarchy), then only one is maintained at the end of the recovery procedure.

Checkpoint corruption. Checkpoints are the other data structure, besides inodes, that is protected by checksums. We observe that issues only arise if both copies of a checkpoint become corrupted, in which case the file system cannot be mounted. Otherwise, the uncorrupted copy will be used during the system's `mount` operation.

Superblock corruption. While there are two copies of the superblock, the detection of corruption to the superblock relies completely on a set of sanity checks performed on (most) of its fields, rather than checksums or comparison of the two copies. If sanity checks identify an invalid value, then the backup copy is used for recovery. However, our results show that the sanity checks are not capable of detecting all invalid values and thus, depending on the corrupted field, the reliability of the file system can suffer.

One particularly dangerous situation is a corruption of the *offset* field, which is used to calculate a checkpoint's starting address inside the corresponding *segment*, as it causes the file system to boot from an invalid checkpoint location during a `mount` operation and to eventually hang during its `unmount` operation. We filed a bug report which has resulted in a new patch that fixes this problem during the operation of `fsck.f2fs`; specifically, the patch uses the (checksum-protected) checkpoint of the system to restore the correct value. Future releases of F2FS will likely include a patch that enables checksums for the superblock.

Another problem with superblock corruption, albeit less severe, arises when the field containing the counter of supported file extensions, which F2FS uses to identify *cold data*, is corrupted. The corruption goes undetected and as a result, the corresponding file extensions are not treated as expected. This might lead to file system performance problems, but should not affect reliability or consistency.

SIT corruption. SIT blocks are not protected against corruption through any form of redundancy. We find cases where the corruption of these blocks severely compromises the consistency of the file system. For instance, we were able to corrupt a SIT block's bitmap (which keeps track of the allocated blocks inside a *segment*) in such a way that the file system hit a bug during its `mount` operation and eventually,

became unmountable.

NAT corruption. This data structure is not protected against corruption and we observe several problems this can create. First, the node ID of an entry can be corrupted and thus, point to another entry inside the file system, to an invalid entry or a non-existing one. Second, the block address of an entry can be corrupted and thus, point to another entry in the system or an invalid location. In both cases, the original entry is eventually marked as *unreachable* by `fsck.f2fs`, since the reference to it is no longer available inside the NAT copy, and placed in the *lost_found* directory. As already mentioned, files with identical names overwrite each other and eventually only one is stored inside the *lost_found* directory.

Direct/Indirect Node corruption. These blocks are used to access the data of large files and also, the entries of large directories (with multiple entries). Direct nodes contain entries that point to on-disk blocks, while indirect nodes contain entries that point to direct nodes. Neither single nor double indirect nodes are protected against corruption. We observe that corruption of these nodes is not detected by the file system. Even when an invocation of `fsck.f2fs` detects the corruption problems can arise. For example, we find a case where after the invocation of `fsck.f2fs` the system kept reporting the wrong (corrupted) size for a file. As a result, when we tried to create a copy of the file, we received a different content.

Directory entry corruption. Directory entries are stored and organized into blocks. Currently, there is no mechanism to detect corruption of such a block and we observe numerous problems this can create. For example, when the field in a directory entry that contains the length of the entry's name is corrupted the file system returns garbage information when we try to get the file's status. Moreover, the field containing the node ID of the corresponding inode can be corrupted and as a result point to any node currently stored in the system. Finally, an entry can "disappear" by storing a zero value into the corresponding index inside the directory's bitmap.

In the last two cases, any affected entry is eventually marked as *unreachable* by `fsck.f2fs`, since their parent directory does no longer point to it. As already mentioned, files with identical names overwrite each other and eventually only one is stored inside the *lost_found* directory.

3.3.4 Shorn Write + Program Read

The results when a program reads a block previously affected by a shorn write are similar to those for corruption, since shorn writes can be viewed as a special type of corruption. The only exception is the superblock, as it is a small data structure that happened not to be affected by our experiments.

3.3.5 Shorn Write + Fsck

Directory entries and shorn writes. Blocks that contain directory entries are not protected against corruption. Therefore, a shorn write goes undetected and can cause several problems. First, valid entries of the system "disappear" after invoking `fsck.f2fs`, including the special entries that point to the current directory and its parent. Second, in some cases, we additionally observed that after re-mounting the file system, an attempt to list the contents of a directory resulted in an infinite loop. In both cases, the affected entries were eventually marked as *unreachable* by `fsck.f2fs` and were dumped into the *lost_found* directory. As we have already mentioned, files with identical names in different parts of the directory tree conflict with each other and eventually, only one makes it to the *lost_found* directory. In some cases, `fsck.f2fs` is not capable of detecting the entire damage a shorn write has caused; we ran into a case where after remounting the file system, all the entries inside a directory ended up having the same name, eventually becoming completely inaccessible.

3.3.6 Bugs found/reported

We have filed two bug reports related to the issues we have identified around handling corrupted data and one has already resulted in a fix [2, 4]. Moreover, we have reported F2FS's failure to handle write I/O errors [3].

4 Related Work

Our work is closest in spirit to the pioneering work by Prabhakaran et *al.* [45], however our focus is very different. While [45] was focused on HDDs, we are specifically interested in SSD-based systems and as such consider file systems with features that are attractive for usage with SSDs, including log-structured and copy-on-write systems. None of the file systems in our study existed at the time [45] was written and they mark a significant departure in terms of design principles compared to the systems in [45]. Also, since we are focused on SSDs, we specifically consider reliability issues that arise from the use of SSDs. Additionally, we provide some extensions to the work in [45], such as exploring whether *fsck* is able to detect and recover from those issues that the file systems cannot handle during their online operation.

Gunawi et *al.* [28] make use of static analysis and explore how file systems and storage device drivers propagate error codes. Their results indicate that write errors are neglected more often than read errors. Our study confirms that write errors are still not handled properly in some file systems, especially when lost and shorn writes are considered. In [51], the authors conduct a performance evaluation on the transaction processing system between ext2 and NILFS2. In [42], the authors explore how existing file systems developed for different operating systems behave with respect to features such as crash resilience and performance. Nonetheless, the provided experimental results only present the performance of read and write operations. Recently, two new studies presented their reliability analysis of file systems in a context other than the local file system. Ganesan et *al.* [25] present their analysis on how modern *distributed storage systems* behave in the presence of file-system faults. Cao et *al.* [20] present their study on the reliability of *high-performance parallel systems*.

In contrast, in our work, we focus on local file systems and explore the effect of SSD related errors.

Finally, different techniques involving hardware or modifications inside the FTL have been proposed to mitigate existing errors inside SSDs [14, 15, 22, 35–37, 44].

5 Implications

• ext4 has significantly improved over ext3 in both detection and recovery from data corruption and I/O injection errors. Our extensive test suite generates only minor errors or data losses in the file system, in stark contrast with [45], where ext3 was reported to silently discard write errors.
• On the other hand, Btrfs, which is a production grade file system with advanced features like snapshot and cloning, has good failure detection mechanisms, but is unable to recover from errors that affect its key data structures, partially due to disabling metadata replication when deployed on SSDs.
• F2FS has the weakest detection against the various errors our framework emulates. We observe that F2FS consistently fails to detect and report any write errors, regardless of the operation that encounters them and the affected data structure. It also does not detect many corruption scenarios. The result can be as severe as data loss or even an unmountable file system. We have filed 3 bug reports; 1 has already been fixed and the other 2 are currently under development.
• File systems do not always make use of the existing redundancy. For example, Btrfs maintains two independent data structures for each directory entry for enhanced performance, but upon failure of one, does not use the other for recovery.
• We notice potentially fatal omissions in error detection and recovery for all file systems except for ext4. This is concerning since technology trends, such as continually growing SSD drive capacities and increasing densities as QLC drives which are coming on the market, all seem to point towards increasing rather than decreasing SSD error rates in the future. In particular for flash-focused file systems, such as F2FS, where for a long time focus has been on performance optimization, an emphasis on reliability is needed if they want to be a serious contender for ext4.
• File systems should make every effort to verify the correctness of metadata through sanity checks, especially when the metadata is not protected by a mechanism, such as checksums. The most mature file system in our study, ext4, does a significantly more thorough job at sanity checks than for example F2FS, which has room for improvement. There have also been recent efforts towards this direction in the context of a popular enterprise file system [32].
• Checksums can be a double-edged sword. While they help increase error detection, coarse granularity checksums can lead to severe data loss. For instance, manipulation of even 1 byte of the checksummed file system unit leads to discard of the entire file system unit in the case for Btrfs. Ideally having a directory or a file system level checksum that discards only 1 entity instead of all co-located files/directories should be implemented. A step in this direction is File-Level Integrity proposed for Android [5, 24]. The tradeoff of adding fine-grained checksums is the space and performance overhead, since a checksum protects a single inode instead of a block of inodes. Finally, note that checksums can only help with detecting corruption, but not with recovery (ideally a file system can both detect corruption and recover from it). These points have to be considered together when implementing checksums inside the file system.
• One might wonder whether added redundancy as described in the Iron file system paper [45] might resolve many of the issues we observe. We hypothesize that for flash-based systems, redundancy can be less effective in those (less likely) cases where both the primary and replica blocks land in the same fault domain (same erase block or same flash chip), after being written together within a short time interval. Even though modern flash devices keep multiple erase blocks open and stripe incoming writes among them for throughput, this does not preclude the scenario where both the primary and replica blocks land in the same fault domain.
• Maybe not surprisingly, a few key data structures (e.g. the journal's *superblock* in ext4, the root directory *inode* in ext4 and F2FS, the root node of *fstree* in Btrfs) are responsible for the most severe failures, usually when affected by a silent fault (e.g. silent corruption or silently dropped write).It might be worthwhile to perform a series of sanity checks for such key data structures before persisting them to the SSD e.g. during an `unmount` operation.

6 Limitations and Future Work

Some of the fault types we explore in our study are based on SSD models that are several years old by now, whose internal behavior could have changed since then. However, we observe that some issues are inherent to flash and therefore likely to persist in new generations of drives, such as retention and disturb errors, which will manifest as read errors at the file system level. The manifestation of other faults, e.g. those related to firmware bugs or changes in page and block size, might vary for future drive models. Our tool is configurable and can be extended to test new error patterns.

File systems must remain consistent in the face of different types of faults. As part of future work, we plan to extend our device mapper module to emulate additional fault modes, such as timeouts. Additionally, our work can be expanded to include additional file systems, such as XFS, NTFS and ZFS. Finally, another extension to our work could be exploring how file systems respond to timing anomalies as those described in [26], where I/Os related to some blocks can become slower, or the whole drive is slow.

Alleviating Garbage Collection Interference through Spatial Separation in All Flash Arrays*

Jaeho Kim Kwanghyun Lim[‡] Young-Don Jung[†] Sungjin Lee[†] Changwoo Min Sam H. Noh[⋆]

Virginia Tech [‡]*Cornell University* [†]*DGIST* [⋆]*UNIST*

Abstract

We present SWAN, a novel All Flash Array (AFA) management scheme. Recent flash SSDs provide high I/O bandwidth (e.g., 3-10GB/s) so the storage bandwidth can easily surpass the network bandwidth by aggregating a few SSDs. However, it is still challenging to unlock the full performance of SSDs. The main source of performance degradation is garbage collection (GC). We find that existing AFA designs are susceptible to GC at SSD-level and AFA software-level. In designing SWAN, we aim to alleviate the performance interference caused by GC at both levels. Unlike the commonly-used *temporal separation approach* that performs GC at idle time, we take a *spatial separation approach* that partitions SSDs into the front-end SSDs dedicated to serve write requests and the back-end SSDs where GC is performed. Compared to temporal separation of GC and application I/O, which is hard to be controlled by AFA software, our approach guarantees that the storage bandwidth always matches the full network performance without being interfered by AFA-level GC. Our analytical model confirms this if the size of front-end SSDs and the back-end SSDs are properly configured. We provide extensive evaluations that show SWAN is effective for a variety of workloads.

1 Introduction

With the advent of the IoT and big data era, the amount of data generated, manufactured, and processed is expected to grow at rates that were previously unimaginable [20, 25, 36, 44, 52]. Such explosive growth of data will impose considerable stress on storage systems in data centers. All Flash Array (AFA) storage, which solely uses an array of SSDs, seems to be a viable storage solution that is capable of satisfying such a high demand. AFA has been recently receiving a lot of attention because of its high performance, low power consumption, and high capacity per volume.

While flash SSD is relatively new and its characteristics are different from HDD, the overall architecture of an AFA system is not much different from traditional HDD-based storage servers [9, 18, 21, 30, 35, 58]. This is because, instead of architecting a new SSD-based storage server from scratch, existing HDD-based storage servers have evolved to embrace high-speed SSDs. For example, an array of SSDs inside an AFA are grouped by variants of RAID architectures (e.g., RAID4, RAID5, or Log-RAID, which is based on log-structured writing that we describe in more detail in Section 2).

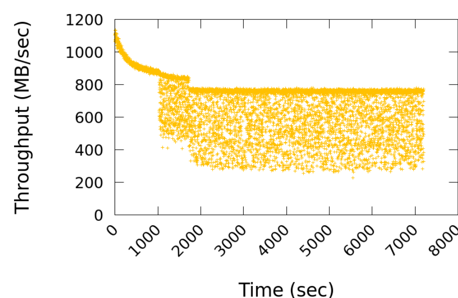

Figure 1: Performance of AFA consisting of eight SSDs under random write workloads. Performance fluctuation starts to occur (at around 1000 seconds) when the size of user write request approaches the capacity of AFA, roughly 1 TB in this configuration.

This naive AFA design, which replaces HDDs with SSDs, is not adequate to take full advantage of high-speed SSDs in two reasons. First, we observe significant performance drop as we run the FIO tool [6] that generates 8 KB random writes. Figure 1 shows the throughput of AFA with eight SATA SSDs (Samsung's 850 PRO) grouped as Log-RAID [9, 10, 21], where each SSD exhibits an effective write throughput of 140 MB/s. We find that garbage collection (GC) of AFA interfere with user I/O. Specifically, for the first 1,000 seconds, the system maintains high throughput that is close to the accumulated throughput of the eight SSDs. However, after 1,000 seconds, owing to interference with GC, the throughput drops considerably and oscillates between 300 MB/s and 750 MB/s, which is much lower than its full performance for 8 KB random I/Os.

*This work was initiated while Jaeho Kim was a postdoc at UNIST.

Table 1: Comparison of All-Flash-Array products

		EMC XtremIO [1]	NetApp SolidFire [4]	HPE 3PAR [2]	Hynix AFA [22]
SSD Array	Capacity	36∼144TB	46TB	750TB	552TB
	# of SSDs	18∼72	12	120 (max)	576
Network	Network Ports	4∼8×10Gb iSCSI	2×25Gb iSCSI	4∼12×16Gb FC	3×Gen3 PCIe
	Aggr. Network Throughput	5∼10 GB/s	6.25 GB/s	8∼24 GB/s	48 GB/s

Second, we find that storage bandwidth and network bandwidth are unbalanced. Typically, AFA is composed of multiple bricks, which is a 1U storage node to scale out capacity. As shown in Table 1, each brick is composed of a large number of SSDs and multiple network ports. Given the storage capacity and the number of installable SSDs, the aggregated write throughput of SSDs easily surpasses the aggregated network throughput. Taking EMC's XtremIO in Table 1 as an example, its 10GB/s network throughput can be easily saturated with four high-end SSDs with 2.5GB/s write throughput [48] out of the 18∼72 SSDs. This matches with observations of other recent work [12, 15, 37, 40].

The above two observations lead us to propose a new architecture for AFA systems. Given the maximum network or user-required throughput, our goal is to derive a balanced AFA system that *satisfies* the required throughput all the time without being interfered with foreground GC. To this end, we present *SWAN*, which stands for Spatial separation Within an Array of SSDs on a Network. In contrast to RAID that manages *all* the SSDs in parallel, SWAN manages the SSDs through several spatially separated groups. That is, only *some* spatially segregated SSDs out of all the SSDs, are in use at a single point in time to serve write requests over the network.

The rationale behind such segregated management is that, even if a large number of SSDs are available in the system, all the SSDs are not necessary to fully saturate the network bandwidth of the AFA. Using more SSDs in parallel does not help the clients in terms of performance. However, even with such a small number of SSDs being used, providing ideal, consistent performance is impossible with GC interference. The only way to achieve such ideal performance is hiding the GC effect. To hide the GC effect in SWAN, we partition the SSDs in the array into two *spatially* exclusive groups, that is, the front-end and the back-end SSDs, of which the front-end is composed of enough SSDs to saturate the bandwidth specification of an AFA. Then, SWAN manages these SSDs such that all writes are sequentially written to the front-end SSDs and those SSDs are never involved in GC. While the front-end SSDs are busy handling the user writes, the back-end SSDs perform GC in the background. Once the front-end SSDs become full with user data, the cleaned back-end SSDs become the new front-end to keep serving the user writes without foreground GC. By so doing, performance interference due to GC can be hidden.

This unique organization and operational behavior of SWAN gives us insight in deriving its balanced design. The number of SSDs belonging to the front-end SSDs should be large enough to fully saturate the required throughput. If not, users' performance demand cannot be satisfied. To give enough time for back-end SSDs to be completely cleaned up before they become frond-end SSDs, we should provision enough SSDs in the front-end and back-end SSD pool. Otherwise, foreground GC becomes unavoidable. The number of SSDs in the frond-end and back-end groups can be estimated by referring to the required throughput and worst-case GC cost models [31, 38, 53].

In summary, this paper makes the following contributions:

- We present a two-dimensional SSD organization as a new AFA architecture, which we refer to as SWAN. We show that such an organization allows for spatial separation of arrays of SSDs so that consistent throughput that is not influenced by GC can be provided.
- We provide an analytic model that decides the best number of SSDs in the frond-end SSD group and in the back-end SSD group. This provides guidance on deriving a balanced system when designing SWAN-based AFAs.
- We conduct comprehensive evaluations using various workloads, including both synthetic and realistic workloads, and demonstrate that SWAN outperforms existing storage management techniques such as RAID0, RAID4, RAID5, and Log-RAID [9, 10, 21]

The remainder of this paper is organized as follows. In the next section, we review existing AFA systems. Then, in Section 3, we present the design of SWAN in detail and an analytic model to completely hide the performance interference by GC. After discussing the implementation issues of SWAN in Section 4, we describe our experimental setup and present detailed results with various workloads in Section 5. We discuss the influence on SWAN on SSD design and other relevant issues in Section 6, . We review prior studies related to this work, comparing them with SWAN in Section 7. Finally, we conclude the paper with a summary in Section 8.

2 Background: All Flash Array

Existing AFA systems can be roughly categorized into two types depending on their write strategies, in-place write AFAs and log write AFAs, as summarized in Table 2.

Table 2: Comparison of existing approaches for managing All-Flash-Array storage

	Write Strategy	GC Interference	Media type	Modification	Disk Organization
Harmonia [30]	In-place write	●	SSDs	Array controller	RAID-0
HPDA [35]	In-place write	●	SSDs & HDDs	Host layer	RAID-4
GC-Steering [58]	In-place write	●	SSDs	Host layer	RAID-4/5
SOFA [9]	Log write	●	SSDs	Host layer	Log-RAID
SALSA [21]	Log write	●	SSDs & SMR	Host layer	Log-RAID
Purity [10]	Log write	●	SSDs	Host layer	Log-RAID
SWAN (proposed)	Log write	▲	SSDs	Host layer	2D Array

GC Interference: Interference between GC of SSD/AFA-level and user's I/O ●: Heavy interference ▲: Alleviated interference

In-place Write AFAs. Approaches with the in-place write strategy heavily rely on the traditional RAID architecture, but attempts have been made to improve performance by modifying data placement and the GC mechanism. The most well-known ones are Harmonia [30], HPDA [35], and GC-Steering [58].

Harmonia is based on the RAID0 architecture that groups all SSDs in an array in parallel without any parity disks [30]. To minimize high I/O fluctuation caused by SSD-level GC that independently happens in individual SSDs, it proposes a globally-coordinated GC algorithm that synchronizes the GC invocations across all the SSDs in the array. If GC is invoked in one SSD, it intentionally triggers GC in all the others, so that all the SSDs in the array are garbage collecting. This approach minimizes user-perceived I/O fluctuation through frequent GC invocations, but cannot completely eliminate performance interference by GC.

HPDA (Hybrid Parity-based Disk Array) takes an SSD-HDD hybrid architecture based on RAID4 [35]. By using a few HDDs as temporary storage to keep parity information, it mitigates performance and lifetime degradations of SSDs caused by frequent updates of parity data. While it is effective in lowering parity overhead, it does not propose any technique to hide GC interference.

GC-Steering is similar to SWAN [58]. It spatially dedicates few SSDs, called staging disks, to absorb the host writes while the other SSDs are busy performing GC. Since host writes can be served by staging disks, GC-Steering can prevent clients from being influenced by GC. However, once the staging disks become full and run out of free space to service host writes, foreground GC becomes unavoidable. To be more specific, it differs from SWAN in that it inherits the limitation of a cache. The staging space is divided into read and write regions, and hot data needs to be migrated to the space for read requests. Space constraints in the staging space not only make it impossible for all reads to avoid collision with GC, but it also causes migration overhead.

Log Write AFAs. While using the traditional RAID architecture (e.g., RAID4 or 5) for the purpose of fault-tolerance, some studies adopt log-structured writing, fundamentally changing its storage management policy, so as to generate sequential write requests that are more suitable for flash-based SSDs. To distinguish them from traditional ones, in this paper, we call AFA systems with log writing a log-structured RAID (Log-RAID).

SOFA is one of the first attempts to use the log-structured approach for AFAs [9]. SOFA integrates volume management, flash translation layer (FTL), and RAID logic together and runs them all in the host level. This integration enables global management of GC and wear-leveling, resulting in overhead associated with storage maintenance tasks being considerably reduced.

SALSA is similar to SOFA in that it offloads almost all of the functions that are typically performed inside storage devices to the host level [21]. However, unlike SOFA, SALSA's primary aim is in building a general-purpose storage platform that supports various types of storage media that are incapable of supporting in-place updates such as SSD and SMR.

Purity is an AFA appliance developed by Pure Storage [10]. Purity adopts log-structured indexes and data layouts that are based on the LSM-tree algorithm [43] to ensure that data is written in large sequential chunks. For better utilization of disk capacity, it also incorporates compression and deduplication algorithms into their system.

SWAN shares the same advantages of the aforementioned techniques as it runs its log-structured storage management logic at the host level. However, SWAN takes it one step further by minimizing the performance interference caused by GC while considering an AFA design that balances storage media and network interface performance.

3 Design of SWAN

3.1 Design Goal and Approach

The primary design goal of SWAN is to provide sustainable high performance for All Flash Array (AFA). More specifically, so that storage does not become the bottleneck, we aim to guarantee AFA storage performance to always be higher than or equal to the network interface bandwidth of AFA.

At a glance, this looks easy to achieve by simply using a RAID of multiple SSDs because even consumer-grade SSDs provide more than 1 GB/s bandwidth. As shown in Figure 2(a), RAID can be used to improve performance and reliability of AFA by composing multiple SSDs in parallel.

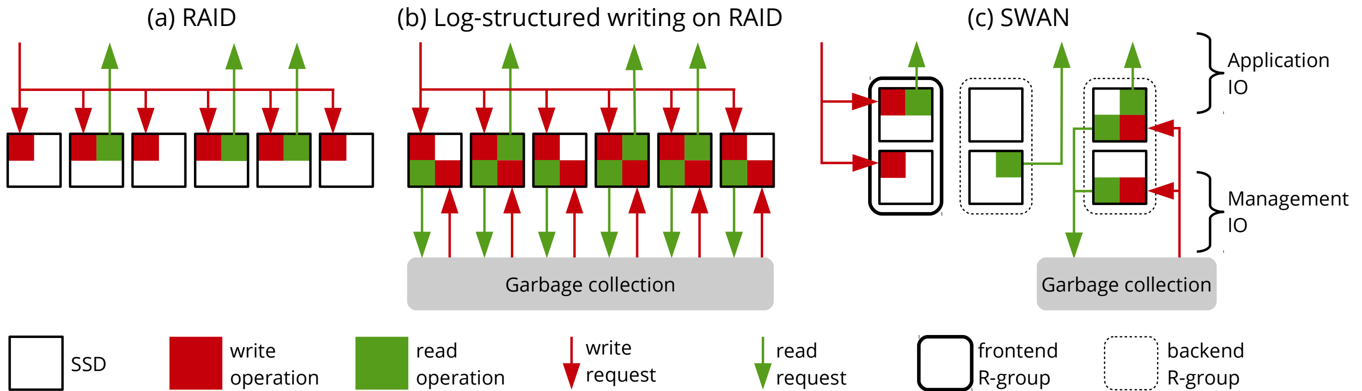

Figure 2: Comparison of All Flash Array (AFA) design. Existing AFA roughly follow either (a) RAID or (b) log-structured writing on RAID (Log-RAID) approaches. We propose (c) SWAN, a spatial separation approach to AFA.

However, its design is susceptible to gradual performance degradation due to high GC overhead inside SSDs. In fact, it turns out that such *SSD-level GC* can significantly degrade performance and incur latency spikes in AFA [30, 51].

To mitigate the internal SSD-level GC overhead, log-structured writing on RAID (Log-RAID), as depicted in Figure 2(b), has been widely adopted in AFA [9, 10, 21]. It generates SSD-friendly write requests by transforming small, random write requests to a bulk, sequential write stream thereby reducing the internal GC overhead in SSDs. However, the I/O operations for *AFA-level GC* (not SSD-level) may significantly interfere with application I/O and degrade performance by constantly issuing read/write requests. In particular, if an application tries to read a sector on an SSD where AFA-level GC is in progress, read latency could increase by several orders of magnitude [21, 23, 51]. A common approach to mitigate such interference is to perform AFA-level GC at idle time by *temporally separating* application I/O and AFA-level GC I/O, that is, segregate the two I/Os in terms of time. However, temporal separation of application I/O and AFA-level GC I/O is hard to control in reality because high performance AFAs are designed to handle multiple concurrent clients.

The key idea of our approach is the *spatial separation* of application I/O and AFA-level GC I/O to minimize such interference by organizing the SSDs into a two-dimensional array as depicted in Figure 2(c). Like Log-RAID, we adopt log-structured writing on RAID to minimize the performance degradation caused by heavy SSD-level GC while providing high performance and reliability using RAID. However, unlike Log-RAID, we spatially separate SSDs into two pools, the front-end and back-end pools. The front-end pool will serve write requests from applications in a log-structured manner, while the back-end pool is used for *SWAN-level GC*, which is GC that occurs only at the back-end pool. Thus, SWAN-level GC does not interfere with application write requests. When the front-end pool SSDs become full, a pool of SSDs from the back-end becomes the front-end and the old front-end SSDs return to the back-end. This design also has the advantage that application read requests are less interfered by SWAN-level GC operations. Recall that as SWAN uses commodity SSDs, it does not have direct control over SSD-level GC. However, we take a best effort approach given the conventional SSD interface.

3.2 Flash Array Organization

SWAN exposes linear 4KB logical blocks such that upper-level software just considers SWAN as a large block device. The SWAN software module is implemented as a part of the Linux kernel in the block I/O layer, where a logical volume manager or a software RAID layer is implemented. SWAN groups multiple SSDs into a single physical volume, which is then divided into fixed-size segments. It manages each segment in a log-structured manner, with new data always being sequentially appended. A segment is the unit for writing a chunk of data as well as for cleaning of obsolete data. Similar to other log-structured systems, therefore, SWAN manages mapping between logical blocks and segments, and, when necessary, it performs GC to secure free segments.

The overall architecture of SWAN is like a big host-level FTL supporting multiple SSDs, but it is the management mechanism in SWAN that differs from typical systems. Typical RAID systems manage an SSD array in a one-dimensional manner, that is, all the SSDs are arranged horizontally and incoming writes are evenly striped over all of them. Unlike RAID, in SWAN, an array of SSDs is organized as a *two-dimensional array*. Then, SSDs belonging to the same column are grouped in a RAID manner and are used in parallel. This group of SSDs is called a *RAID group (R-group)* as this is where redundancy is manifested to prevent data loss in the event of hardware or power failure. The R-group is also where the size can be set such that its aggregate throughput surpasses the network interface provided by AFA. That is, for AFA providing higher network interface bandwidth, we can increase the number of SSDs within the

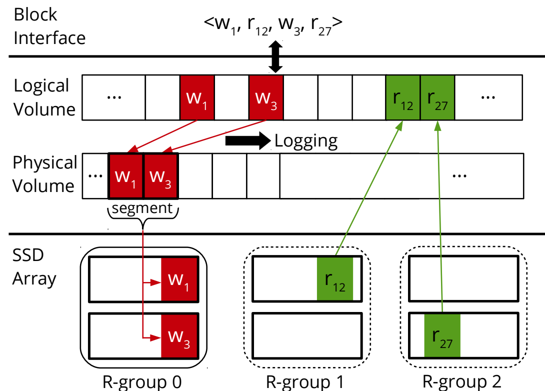

Figure 3: Example of handling read/write requests in SWAN where R-group 0 is the front-end R-group and R-groups 1 and 2 are in the back-end pool. SWAN appends writes to the log and issues write requests to the front-end R-group in segment units. Read requests will be served by any R-group holding the requested blocks.

R-group to match the network bandwidth. We further discuss optimizing the configuration of SWAN in Section 3.5.

3.3 Handling Application I/O Requests

As discussed, SWAN organizes SSDs into two or more R-groups, and each R-group is either a front-end or belongs to the back-end pool at a certain point in time. SWAN manages the movement of the R-groups such that each R-group takes turns being the front-end R-group, while the rest belong to the back-end pool.

Only the front-end R-group serves the incoming writes in a log-structured manner, consuming its free space. Once free space of SSDs in the R-group in the front-end pool is exhausted, SWAN moves this R-group to the back-end pool and selects a new R-group in the back-end pool that has enough free space to become the front-end R-group to serve writes coming in from the network. Incoming read requests are served by any SSD holding the requested blocks.

Figure 3 shows an example of how SWAN handles the I/O sequence $< w_1, r_{12}, w_3, r_{27} >$ arriving from the network, where w_i and r_i are the write and read of block i, respectively. The writes are appended to a segment, but are actually distributed across SSDs in the front-end R-group and are written in parallel. Reads, in contrast, will be served by any of the three R-groups. To alleviate read delays due to GC, we can employ methods such as RAIN as suggested by Yan et al. [60], which we do not consider in this study and leave for future work. However, as we show later, even without such optimizations, SWAN read performance does not suffer from delays as it is always given highest priority. Thus, read performance is comparable with conventional methods, while write performance is significantly improved.

3.4 Garbage Collection in SWAN

SWAN performs GC to secure free segments like other log-structured systems. SWAN chooses victim segments from one of the back-end R-groups and writes valid blocks within the chosen R-group. That is, GC is performed internally within a single back-end R-group. Also, while any victim selection policy could be used [13, 16], in this paper, we use the greedy policy that chooses a segment that has the least number of valid blocks as the victim. Such GC creates a free segment in the chosen R-group. When the front-end R-group becomes full, SWAN chooses an R-group in the back-end to be the next front-end, then moves the old front-end to the back-end group. SWAN completely decouples normal I/O from GC I/O by spatially separating SSDs into the front-end R-group and the back-end R-groups, so as to eliminate interference by GC I/O upon user writes.

3.5 Optimizing SWAN Configuration

The key insight behind the SWAN design is that given the many SSDs in AFA, only a portion of these SSDs (which forms the R-group) are sufficient to saturate the network interface bandwidth of an AFA. However, to realize and achieve sustainable high performance in SWAN, it is important to properly decide the configuration knobs: 1) the number of SSDs in an R-group and 2) the minimum number of R-groups in an SSD array.

Determining the number of SSDs in an R-group. The aggregated throughput of the SSDs in one R-group must be high enough to fully saturate the AFA network interface bandwidth. Thus, we determine the number of SSDs in an R-group such that the aggregated write throughput[1] of the SSDs in an R-group is higher than the aggregated AFA network interface bandwidth. For example, using an AFA configuration such as the EMC XtremIO in Table 1, given the aggregate network throughput of 10 GB/s and assuming the maximum write throughput of an SSD to be 2.5 GB/s [48], four SSDs (three for data and one for parity) must be assigned to the R-group to support RAID4 in SWAN.

Determining the minimum number of R-groups. Besides the raw aggregated throughput of an R-group, another important factor to decide the maximum write throughput of SWAN is GC overhead. If consuming a segment in a front-end R-group is faster than generating a free segment in the back-end R-groups, SWAN-level GC will be a performance bottleneck, limiting its performance. Thus, the number of the back-end R-groups should be large enough for SWAN-level GC not to fall behind. We provide an *analytic model* to calculate the minimum number of R-groups, which determines the number of back-end R-groups, to avoid cases where GC falls behind the front-end writing. In our analytic model, we only consider operations that dominate the execution time

[1] We consider only the write throughput of an SSD because read is faster than write.

such as read, write, and garbage collection and do not consider SSD-level optimizations such as the write buffer in the SSD that could further improve SSD performance.

Since SWAN manages the SSD array in a log-structured fashion, it divides the SSD space into fixed-size segments, and all the write and cleaning operations are done in segment units. Let T_w and T_r denote the elapsed times for writing and reading a segment to and from an SSD, respectively. Let T_e be the time for erasing flash blocks in a segment when all the data in it are invalid.

SWAN writes new data over the network to a front-end R-group. Once the front-end R-group fills up, it is moved to the back-end. To perform GC for a segment that has both valid and invalid pages in the back-end, the valid pages must first be read and then written to a free segment. Of course, all flash blocks in the free segment must be erased before writing valid pages. Therefore, time to finish GC of an R-group is $S \cdot (T_e + u \cdot (T_r + T_w))$ where S is the number of segments in an R-group and u is the ratio of valid pages in a segment (i.e., segment utilization). After finishing GC of an R-group, we will have $S \cdot (1-u)$ free space for this R-group. That R-group will be moved to the front-end later at some time. It will take $S \cdot (1-u) \cdot T_w$ to completely consume the free segments in that R-group.

In SWAN, all R-groups are independent of each other; either they service writes and reads as the one in the front-end or they perform GC and reads as ones in the back-end. Once an R-group is moved to the back-end pool, it will not be chosen as a front-end R-group until all previous R-groups in the back-end are consumed. This implies that, after an R-group moves to the back-end pool, it will return as the front-end R-group after $(N-1) \cdot (S \cdot (1-u) \cdot T_w)$ time at the earliest, where N is the number of R-groups in a SWAN array. This is when data are written to the front-end R-group SSDs at maximum throughput; it will take longer to return if the throughput is lower.

This tells us that, if the GC time of an R-group is equal to or shorter than the time that R-group is recycled, SWAN can finish GC of an R-group before moving it to the front-end. Conversely, if the above condition is not met, SSDs in the front-end R-group may need to delay writes as it waits for free segments to become available.

Consequently, the condition

$$S \cdot (T_e + u \cdot (T_r + T_w)) \leq (N-1) \cdot S \cdot (1-u) \cdot T_w$$

must hold to guarantee that SWAN-level GC does not interfere application writing at the front-end. This can be simplified as follows:

$$T_e + u \cdot (T_r + T_w) \leq (N-1) \cdot (1-u) \cdot T_w$$

From here, we get

$$\frac{T_e}{T_w} \cdot \frac{1}{1-u} + \left(\frac{T_r}{T_w} + 1\right) \cdot \frac{u}{1-u} + 1 \leq N \tag{1}$$

Note that Equation 1 is independent of the number of SSDs per R-group and dependent on the specifications of the SSDs and the utilization. Previous studies [31, 38, 53] have shown that in a log-structured scheme, $u_d = \frac{u-1}{\ln u}$ holds, where u_d is the disk utilization. This tells us that even for heavy loaded storage systems where the disk utilization (u_d) is 60% to 70%, u will be below 0.5.

Let us now consider applying the model. Given an array of SSDs, let T_e, $T_w = t_w \cdot B$, and $T_r = t_r \cdot B$ be constants, where T_e, t_w, t_r, and B are the time to erase a segment, write a block, read a block, and the number of blocks in a segment, respectively. From our AFA prototype, our measurements show that segment erase time is roughly 4 milliseconds, block read and write time is 15.6 and 19.5 microseconds, respectively, and the number of blocks per segment is 256. Taking these numbers and with a storage device that is ($u_d =$) 60% utilized, which results in roughly $u = 0.33$, then we can calculate N to be roughly 1.89. This tells us that with SWAN composed of two R-groups, we will be able to sustain the full network interface bandwidth performance and see no GC affects throughout its services. We believe that the modeling results based on our measurement-based parameter estimations effectively reflects the underlying system architecture as the impact of realistic factors such as queuing delays and resource contention are being reflected in the measured parameters.

Applying these results to a realistic setting, let us, once again, take a configuration such as EMC's XtremIO in Table 1, assuming an SSD with 2.5 GB/s write bandwidth. If we can configure each R-group to be of four SSDs, which is enough to saturate the network bandwidth, then we have, in the smallest configuration case (18 SSDs), three back-end R-groups (plus two spare SSDs), which will be more than sufficient to allow full sustained write performance.

One factor that we did not consider in our analysis is the bandwidth consumed by read requests to the back-end R-group. However, in reality, as the number of back-end R-groups are sufficiently high, these reads will not have a real effect on GC time needed to return as a front-end R-group.

Our analysis shows that with our SWAN approach, once we have set the number of SSDs within the R-group to match the network bandwidth, the total number of SSDs to maintain high, sustained performance can be determined. Also, extra SSDs for larger capacity will further ensure that SWAN-level GC will not interfere user writes at the front-end.

4 Implementation

We implement SWAN and Log-RAID in the block I/O layer, where the I/O requests are redirected from the host to the storage devices, in Linux kernel-3.13.0. For our implementation, we extend the SSD RAID Cache implementation in the Device Mapper (DM) [42] to accommodate AFA storage. To implement RAID0, RAID4, and RAID5, we use `mdadm`, which is a GNU/Linux utility used to manage and monitor

software RAID devices [54].

4.1 Metadata Management

SWAN and Log-RAID maintain basically the same metadata. They manage two types of metadata: 1) a mapping table from the logical volume to the physical volume mapping table (L2P) for address translation, and 2) the segment summary information. Each entry in the table, which takes up 5 bytes, corresponds to a 4 KB block in an SSD array. Thus, the metadata size for the mapping table is roughly 0.12% of the total storage capacity (i.e., 5 bytes per 4 KB).

The segment summary metadata contains information about each segment such as the segment checksum, sequence number, and the physical to logical mapping (P2L) for GC. It is located in the last block of a segment taking up 4 KB per segment. The metadata overhead for segment summary depends on SWAN's configuration. For example, for a 1 MB segment size, which is the size used in our experiments, segment summary takes up 0.39% of the storage space (i.e., 4 KB per 1 MB).

In the SWAN and Log-RAID prototypes, we maintain the entire metadata structures in DRAM, assuming that their contents are backed up by built-in batteries in the server. Owing to their huge size, however, keeping all of the data structures in DRAM could be burdensome, in terms of cost and energy. To address this, on-demand mapping that only keeps popular mapping entries in DRAM while storing the rest in SSDs can be considered. However, we do not consider this in this study.

4.2 Optimizing GC using TRIM

TRIM is used to further optimize GC. Once valid pages in a victim segment are written back to the new segment, then the victim segment is TRIMmed. This is efficient as the writing of the segments occur in a sequential manner and also, as the TRIM unit is large. With large segments being TRIMmed, the SSD firmware will perform erasures in an efficient manner. Thus, it helps SWAN achieve high performance regardless of SSD manufacturer.

5 Evaluation

In this section, we first present the evaluation results of micro-benchmarks to see how our design choices affect the behavior of SWAN and help to avoid GC interference. We then present the evaluation results of real-world workloads and compare the performance of SWAN to the traditional RAID0, RAID4, RAID5, and Log-structured management schemes (Log-RAID0 and 4) for an array of SSDs.

We evaluate SWAN on a Dell R730 server equipped with two Xeon E5-2609 CPUs and 64GB DRAM. We use 120GB Samsung 850 PRO SSDs of which measured peak read and write throughput is roughly 500MB/s and 400MB/s, respectively. The number of SSDs used differ from experiment to experiment as we describe later. We measure performance at the host system. Before any experiments for a particular

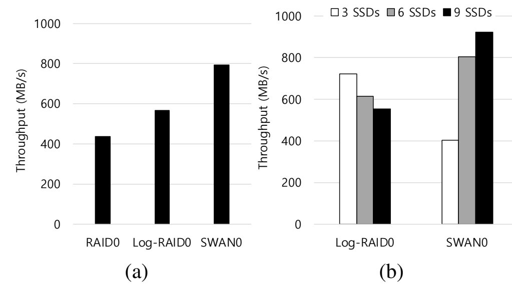

Figure 4: (a) Performance comparison of RAID0, Log-RAID0 and SWAN0 with 8 SSDs with SWAN0 configured as 4R-2SSD and (b) performance trend for Log-RAID0 and SWAN0 with 3, 6, 9 SSDs with SWAN configured as 3 R-groups with 1, 2, and 3 SSDs.

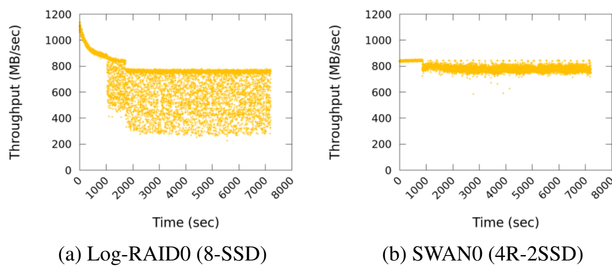
configuration, we go through a systematic cleaning and aging process; each SSD is first cleaned through formatting and TRIMming, and then the SSD is aged by making random writes to roughly 60% of the storage capacity.

5.1 Micro-benchmarks

We compare the performance of SWAN with two other AFA schemes, RAID and Log-RAID, all with RAID0 configurations. We denote each of these configurations as SWAN0, RAID0, and Log-RAID0, and the convention of attaching the suffix number representing the RAID type to the configuration will be used throughout hereafter. To understand their behavior especially under heavy GC, we make use of the FIO [6] benchmark issuing 8 KB random write (only) requests. To observe the raw performance, we disable any caching layers and directly issue writes to each scheme. Each experiment is conducted for two hours and its total footprint is roughly 12 TBs. Each experiment is performed more than 3 times and all results are within 6% of each other.

Figure 4(a) shows the results with 8 SSDs and SWAN configured as 4 R-groups of 2 SSDs each, which we denote as 4R-2SSD. Hereafter, this numbering convention will be used to represent SWAN configurations. The results show that RAID0 shows worst performance because it generates random writes and incurs high GC overhead inside the SSD. While Log-RAID0 transforms random writes to bulk, sequential writes, its performance is slower than SWAN0. The reason is Log-RAID0 requires GC to reuse log space, which issues read and write operations to all SSDs as illustrated in Figure 2. These GC related operations significantly degrade normal I/O operations. In contrast, SWAN0 shows close to full SSD throughput.

We then compare the performance of Log-RAID0 and SWAN0 with varying number of SSDs to understand how our partial aggregation of SSDs affects performance. We make use of 3, 6, 9 SSDs to configure Log-RAID0 and SWAN0, which, in turn, is configured as 3R-1SSD, 3R-2SSDs, and 3R-3SSDs using 3, 6, and 9 SSDs, respectively. As Figure 4(b) shows, surprisingly, the throughput of Log-



(a) Log-RAID0 (8-SSD) (b) SWAN0 (4R-2SSD)

Figure 5: Throughput of Log-RAID0 and SWAN0 over time

RAID0 degrades as more SSDs are used, while performance of SWAN0 improves. The reason behind this can be explained by the results shown in Figure 5, which shows (a) 8 SSDs configured as Log-RAID0 and (b) SWAN0 as 4R-2SSD. The results in this figure show that even with only 2 SSDs for SWAN, performance is actually better than Log-RAID0 with 8 SSDs. Furthermore, it shows that the throughput of Log-RAID0 fluctuates significantly, while SWAN0 shows high, sustained write performance that is proportional to the 2 SSDs in the R-group. The reason for throughput degradation with Log-RAID is that normal I/O and GC I/O interfere with each other. When normal I/O and GC I/O requests are being served by the same SSD, the latency of each I/O operation increases. As more SSDs get involved, the throughput of Log-RAID0 degrades because GC performance is limited by the slowest SSD [18].

5.2 Analysis of GC Behavior

We further analyze the performance degradation caused by AFA-level GC. For the random write workload of Figure 5, we plot the read/write throughput of each SSD for Log-RAID0 and SWAN0 in Figure 6. Note that all reads here are those issued for GC, and thus, we can observe the negative effect on overall performance due to such read operations.

Figure 6(a) shows the results for Log-RAID0. We see that all SSDs are involved in write operations throughout its execution. GC operations of Log-RAID begins from ⓐ in the figure, and performance starts to fluctuate from that point. This is also the point where read maintains a steady bandwidth overhead. (Though there is a line for read before this point, the value is 0.) The total amount of write requests up to this point closely coincides with the total RAID capacity. Once disk space becomes exhausted, GCs are triggered, and we observe performance deterioration and fluctuation. This observation lasts until the end of our experiment.

Figure 6(b) shows the performance for SWAN0. Here, in contrast to those of Figure 6(a), we see that the throughput of SSDs 1 and 2 that comprise the front-end R-group is close to 400MB/s, the maximum throughput of the SSD, as they are the ones receiving the write requests. The performance offered to the user is the aggregate of the two SSDs, which is roughly 800MB/s. Once the free segments in the first two SSDs are exhausted, SSD 3 and 4 become the front-end R-group and the old front-end R-group becomes the back-end. When SSD 7 and 8 become the front-end R-group, SWAN starts performing GC by selecting the SSDs with victim segments based on the greedy policy. In the figure, the R-group denoted by ⓑ is the front-end and the one denoted ⓒ is the selected back-end R-group that is performing GC. Note from ⓒ (and the magnified circle) that only SSDs performing garbage collection is incurring reads. All other SSDs neither incur reads or writes (except the ones of the front-end R-group). These front-end and back-end transitions are repeated throughout the experiments.

To quantitatively understand how SWAN GC behaves in runtime, we analyze the utilization of victim segments (i.e., the ratio of valid pages in a victim segment) and the number of free segments in the SWAN array for 80 minutes. Recall that as our workload continuously writes to the front-end R-group and GC on the back-end must continuously be performed in the background to maintain stable performance. From Figure 6(b), we observe that starting from around 800 seconds, GC starts to occur. Figure 7 shows that initially the utilization of the selected victim segments are 0, but then start to increase. The results show that, eventually, the utilization of the victim segment and the number of free segments are converging. This is because data is being overwritten and thus, the back-end R-group is likely to have many obsolete data. Such convergence shows that free segment generation through GC in SWAN is stable and does not interfere with the writes occurring in the front-end R-group.

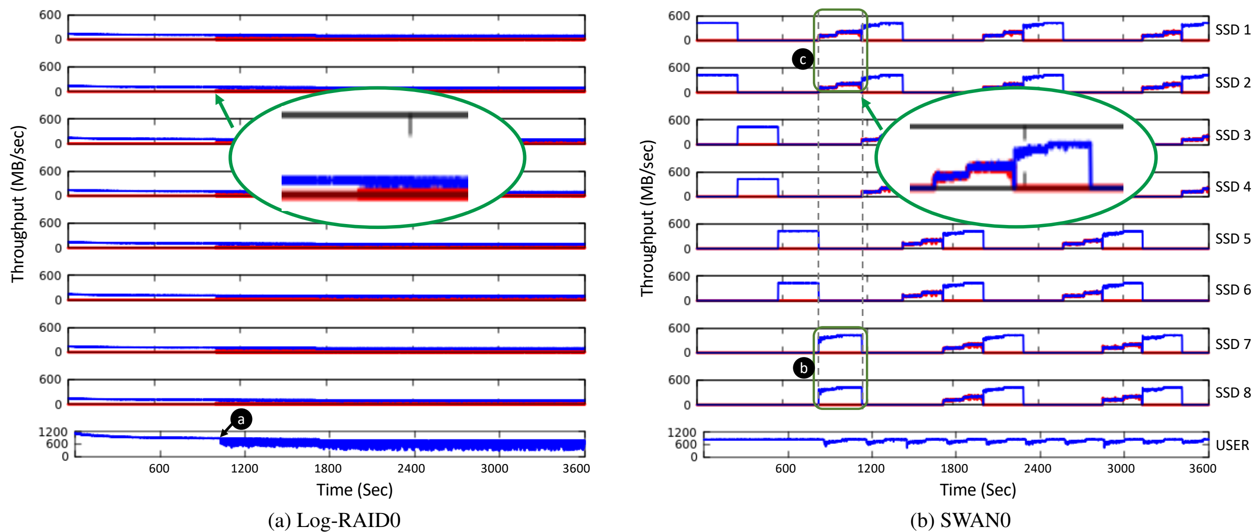
5.3 Real-world Workload

To see how effective SWAN is in a real-world setting, we experiment with the YCSB benchmark [11] on RocksDB [5]. For these experiments, we use RAID4 and 5 configurations, which is different from previous sections, to test SWAN in a more realistic setting. In particular, we use 9 SSDs with RAID4, RAID5, Log-RAID4, and SWAN4, which is configured as 3R-3SSD with 2 data SSDs and 1 parity SSD per R-group.

Table 3: I/O characteristics of YCSB benchmark

YCSB	Load	Run			
		A	B	C	D
Read	-	32GB	60GB	64GB	60GB
Update	-	32GB	3GB	-	-
Insert	64GB	-	-	-	3GB
R:W ratio	0:100	50:50	95:5	100:0	95:5

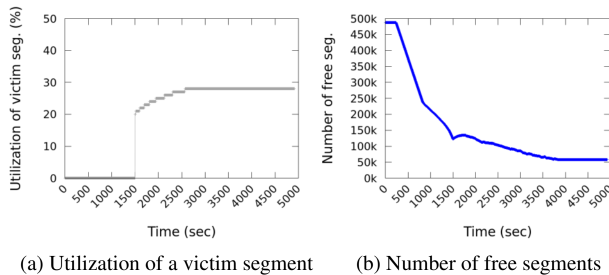
The workload characteristics of YCSB is summarized in Table 3, which includes the amount of data accessed by three different operations, Read, Update, and Insert, as well as the read/write ratios. Note that all the YCSB benchmarks consist of two phases: load and run phases. The load phase is responsible for creating the entire data set in the database, thus involves a large number of Insert operations. The run phase



(a) Log-RAID0

(b) SWAN0

Figure 6: Throughput of Log-RAID0 and SWAN0 for random write workload used in Figure 5. Top eight rows are the write throughput for each SSD and they include not only user requests but also GC incurred by each scheme. The bottom row shows the aggregate throughput of each scheme. The blue (upper) line denotes write throughput and the red (lower) line denotes the read incurred by GC. The SWAN configuration here is the same as that of Figure 5.



(a) Utilization of a victim segment (b) Number of free segments

Figure 7: Utilization of a victim segment and the number of free segments for SWAN0 with 8KB size random write workload for 80 minutes

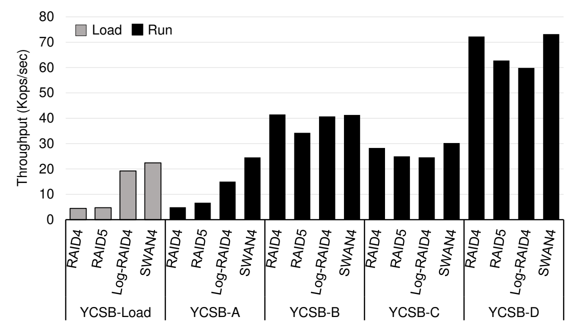


Figure 8: Throughput comparison for RAID4, RAID5, Log-RAID4, and SWAN4 for YCSB benchmark.

executes a specific workload (YCSB-A through YCSB-D) with different I/O patterns on the created data set.

Overall Performance: Figure 8 shows the overall throughput results. The results show that SWAN4 outperforms RAID4, RAID5, and Log-RAID for all the workloads. In the Load phase where almost all of the requests are writes, SWAN exhibits over 4× higher throughput compared to RAID-4/5 and even performs 17% better than Log-RAID. This is due to the fact that SWAN4 maintains sufficient free space to serve incoming writes immediately without interference by GC. In particular, for the YCSB-A workload where the workload is composed of reads and updates, SWAN4 performs significantly better than the other schemes, including Log-RAID4. Even in the other workloads, which are read dominant, SWAN4 performs slightly better or similar compared to the other schemes. As read is more latency-sensitive, we now further analyze read latency.

Read Latency: We now consider the effect of SWAN on read latency. As shown in Figure 9, the average read latency of SWAN is similar to or better than the other schemes. Moreover, as illustrated in Figure 10, SWAN exhibits much shorter tail latency compared to others across all of the YCSB benchmarks. This is because, in RAID4/5 and Log-RAID4, read requests are often blocked by AFA-level or SSD-level GC. In particular, we find that even under read-dominant workloads (YCSB-C and YCSB-D), SWAN4 exhibits shorter read latency. The reason for this is due to background GC. More specifically, recall that in all our experiments we include a systematic cleaning and aging process for the array of SSDs. We find that AFA-level GC (for Log-RAID4 and SWAN4) continues for a considerable length of time (roughly 15 minutes), while SSD-level GC [55] contin-

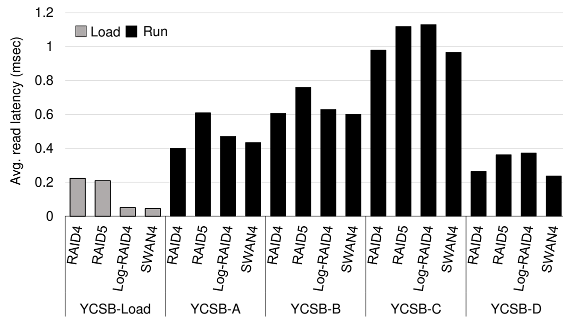

Figure 9: Average read latency comparison for RAID4, RAID5, Log-RAID4 and SWAN4 for YCSB benchmark

Table 4: Read requests in SWAN for YCSB-A workload

	# of requests (million)	Avg. latency (usec)
Front-end	20.3	98
Back-end (Idle)	25.9	88
Back-end (GC)	3.93	103

ues even further, which interfere with read requests. Fortunately, SWAN spatially separates GC so that it occurs only in one R-group, which enables us to effectively hide interference by GC. This argument is supported by Figure 11, which depicts the latency distribution of read requests for YCSB-C. Unlike the other schemes where we observe high latency spikes, SWAN shows fairly stable and consistent read latency.

To further understand SWAN's impact on read latency in more detail, we measure the latency of reads served by three different types of R-groups in SWAN: the frond-end, the idle back-end (that does not perform GC), and the busy back-end (that is performing GC), as shown in Table 4. As expected, the idle back-end provides the shortest read latency. The frond-end, on the other hand, is responsible for handling user writes, and thus it provides longer read latency than the idle back-end. Finally, the read latency on the busy back-end shows worst performance as it is more likely to be delayed by the erase and the write operations incurred by GC.

Table 4 also shows the number of reads handled by the three R-groups with the YCSB-A workload. We observe that 92% of the read requests are serviced by the idle back-end (52%) and the front-end (40%). Only 8% of the reads are destined for the busy back-end group that is performing GC. This skewed data access is due to YCSB's I/O pattern model that is based on the Zipf distribution, which is typically observed in many data-center applications [8, 14]. We find that, under the Zipf distribution with temporal locality, the front-end and the idle back-end R-groups are likely to receive more reads because they hold recently written data as we delay GC of R-groups as much as possible (as depicted in Figure 6). The frond-end receives a relatively smaller number of read requests than the idle back-end because many read requests are hit and served by the OS page cache holding data that were recently written but have not yet been evicted to the front-end R-group. The busy back-end contains old data, so only few read requests are directed to that R-group.

5.4 Analysis with an open-channel SSD

In AFA systems with RAID, I/O requests can be unexpectedly delayed if SSD-level GC is triggered. In particular, GC-blocked read I/Os are considered to be the root cause of long tail latency [60]. Unlike existing AFA systems, SWAN suffers less from SSD-level GC because it writes all the data in an append-only manner, thereby avoiding valid page copies for GC inside an SSD.
