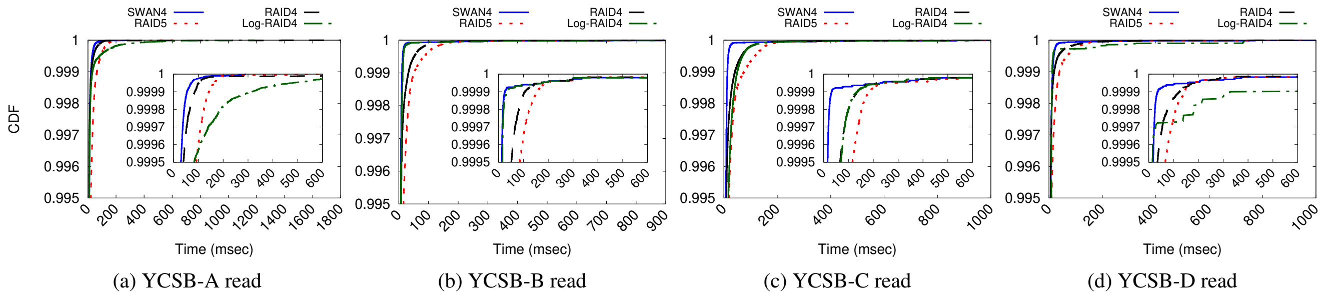
In this section, we quantitatively analyze the benefits of SWAN on individual SSDs, in terms of tail latency. Since we cannot modify and analyze the internals of off-the-shelf SSDs, we implement a custom page-level FTL scheme on an open-channel SSD [34]. From two different settings, SWAN0 and RAID0 with six SSDs, we collect block I/O traces of FIO random read/write workloads, and then replay the traces atop our open-channel SSD. We integrate a performance profiler with the custom FTL and monitor and collect detailed FTL activity statistics including page reads/writes, block erasures, as well as elapsed times for serving host reads and writes.

Figure 12 depicts the latency CDF measured in the open-channel SSD. The read and write latencies of NAND chips in the open-channel SSD is around 100*u*s and 500*u*s, respectively. SWAN0 shows shorter latency and shorter tail compared to RAID0 throughout its execution. This indicates that I/O performance of RAID0 is deteriorated by the extra page copies for internal GC. Consequently, the results confirms that SWAN is effective in reducing SSD-level GC overhead.

6 Discussion

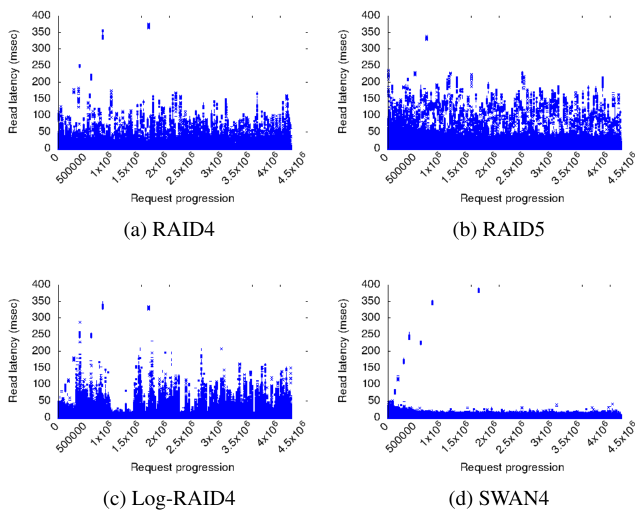
Benefits with simpler SSDs: The main design principle of SWAN is minimizing the performance interference caused by SSD-level GC and AFA-level GC. We think this opens opportunities to save cost and power consumption without compromising performance by adopting SSDs with simpler design. We expect that the main benefits of the simpler SSD will come from 1) smaller DRAM size, 2) FTL implemented on a low-power ARM core or hardware, and 3) smaller over-provisioning space (OPS).

A high-end modern SSD today requires an FTL (SSD firmware), a large amount of DRAM (e.g., 0.5-16 GB for mapping tables [45, 49]), high-end processors to run its space management and garbage collection algorithm (e.g., multi-core ARM processor [19]) along with additional over-provisioning space (OPS) (e.g., extra 6.7% to 28% of flash capacity just for OPS [46, 47]) to reduce garbage collection overhead. However, SWAN does not rely on such a sophisticated, powerful FTL. SWAN sequentially writes data to segments and TRIMs a large chunk of data in the same segment at once. This implies that an SSD receives sequential write



(a) YCSB-A read (b) YCSB-B read (c) YCSB-C read (d) YCSB-D read

Figure 10: CDF of read latency for YCSB benchmark. The tail latency of SWAN is shortest in all workloads. In particular, at 99.9th or higher latency, SWAN shows much shorter latency than others.

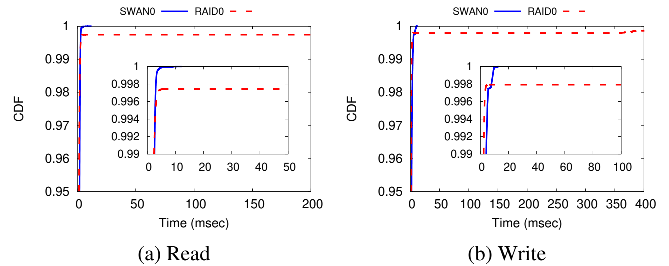


(a) RAID4 (b) RAID5

(c) Log-RAID4 (d) SWAN4

Figure 11: Read latency distribution of YCSB-C

streams all the time from the host, which will be obsolete together later. Under such workloads, it is only necessary for an SSD to carry out block erasures to reclaim fully invalidated flash blocks, and thus complicated media management algorithms like address remapping and garbage collection are not needed. On the SSD side, actually, a simple block-level FTL is sufficient to support SWAN's workloads. By making the design of FTL simpler, we can reduce cost for DRAM and the processor inside the SSD and save power consumption as well. For example, a page-level FTL scheme requires roughly 1 GB of memory for a 1 TB SSD to manage the mapping information [45]. However, in our experience of implementing the block-level FTL for SWAN, only 8 MB of DRAM is required for address mapping. Also, for SSDs deployed with SWAN, they do not require a powerful processor to run sophisticated FTL algorithms such as hot-cold separation and multi-streamed I/O management [27] that are designed to reduce GC overhead. We expect a single low-power ARM core or even hardware logic to be enough to manage NAND flash with SWAN. Finally, SSDs used in SWAN do not need to reserve large OPS, which is critical to reduce



(a) Read (b) Write

Figure 12: Latency CDF of FIO random read/write workloads measured in open-channel SSD for RAID0 and SWAN0

GC overhead. This has the benefit of improving the effective storage capacity provided to users.

Effect of NVRAM: As a remedy for GC overhead, one might argue that NVRAM could be used as a write buffer to accommodate incoming writes while the underlying SSDs are busy doing GC. Using NVRAM, however, is costly because it requires expensive battery-backed DRAM. Thus, even high-end AFA controllers have only few GBs of NVRAM (e.g., 8-64 GB [3]) and use it to improve data persistence and consistency, for example, by keeping user data for a few seconds before a new consistency point starts [56]. However, considering various factors such as cost of NVRAM, the high bandwidth of the AFA network, the ever-increasing working-set size, as well as the limited DIMM slots, we think using NVRAM to buffer large amounts of user data for an extended period of time to maintain high throughput and hide SSD-level GC is not an easily acceptable solution.

7 Related Work

Reducing GC overhead: Considerable effort have been made at various layers in the storage stack to reduce GC overhead in flash storage, including at the file system [32, 39, 41], the I/O scheduler [24, 29], buffer replacement [26], and the SSD itself [17, 27, 28]. These efforts, likewise, alleviate GC overhead through reduced write amplification, but

do not completely remove or hide GC overhead.

The recently proposed TTFlash almost eliminates GC overhead by exploiting a combination of current SSD technologies including a powerful flash controller, the Redundant Array of Independent NAND (RAIN) scheme, and the large RAM buffer in SSD internals [60]. By making use of the timely technologies in SSD, Tiny-tail handles I/O requests with almost no-GC scenario, with the caveat that the copy-back operation must be supported. While Tiny-tail is an SSD internal approach, it is different from what we propose as, first, we target an array of SSDs and second, we can make use of any commodity SSD, though a SWAN optimized, simpler SSDs would be most efficient.

GC preemption: Preemption is another way to decouple GC impact from user requests. GC preemption is a means of virtually postponing GC to avoid conflicts between GC and user requests. A number of studies, including an industry standard, have been conducted in this direction [33, 57, 59]. However, GC preemption is prone to failure for various reasons such as excessive write requests or ill-chosen GC policies [60].

Array of Flash/SSDs: There have been studies to address GC impact in arrays of SSDs. Flash on Rails [51] and Harmonia [30] are SSD-based array schemes suggested to resolve the GC problem. Flash on Rails separates read and write requests on different physical disks to separate the read request handling SSD from the GC handling SSD. This is a similar approach as our work, with the difference being that we consider a large scale, network connected storage system while Flash on Rails maintain at least one replica SSD for servicing read requests. It basically differs from SWAN in physical data placement and redundancy level. In large capacity storage devices such as an AFA system, this doubling of space is subject to deployment constraints. In contrast, in Harmonia, the host OS synchronizes the GC of all SSDs to prevent request blocking from unaligned GC for an array of SSDs. This approach does not remove or hide GC, but synchronizes GC to reduce its negative effect.

Gecko: The work most similar to ours is Gecko, which was designed for an array of HDDs [50]. Gecko is similar to SWAN in that it views the chain of HDDs as a log with new writes being made to the tail of the log to reduce disk contention by GC. SWAN advances this idea especially in the context of AFA, which is SSD-based. The key differences between Gecko and SWAN in terms of storage media can be summarized are as follows. 1) SWAN provides a guide to organizing of an array of SSDs based on the analytical model that reflects the characteristics of commercial SSD devices. 2) SWAN introduce the most efficient way to use SSDs in AFA through writing large amount of data sequentially and trimming, which is an SSD-only feature. 3) GC preemption is employed for serving read requests. 4) SWAN provides implications for a cost effective SSD design for AFA.

In terms of system organization, unlike Gecko, which uses a one-dimensional array of HDDs, SWAN manages SSDs in two dimensions to spatially separate GC writes from first-class writes and to achieve higher aggregated storage throughput than the network throughput. Also, Gecko has to prevent interference by read operations because it targets HDDs, where a read operation can also move the disk head.

Exposing flash to host: LightNVM [7] and Application-managed Flash [34] attempt to eliminate GC overhead by letting the host software manage the exposed flash channel. These approaches are similar to our method in that GC is being managed by the host, but they are different in that they do not decouple the I/Os for GC and those requested by user applications. Hence, even though these approaches reduce GC impact by directly controlling the flash devices from the host, GC is required in managing the flash device. SWAN, on the other hand, hides GC overhead through host controlled GC in an array of SSDs.

8 Conclusion

We presented a novel all flash array management scheme, named SWAN (Spatial separation Within an Array of SSDs on a Network). Our work was motivated by key observations that aggregating a number of SSDs is sufficient to surpass the network bandwidth. However, burdensome garbage collection together with all flash array software prevented us from realizing optimal performance by making it difficult to fully saturate the peak network bandwidth. In an attempt to overcome this problem, SWAN decoupled GC I/Os from normal ones by partitioning the SSD array into two mutually exclusive groups and by using them for different purposes in a serial manner: 1) serving incoming writes or 2) performing GC in the background. This spatial separation of SSDs enabled us to hide costly GC overheads, providing GC free performance to the applications. Moreover, using an analytical model, we confirmed that SWAN guaranteed no GC interference I/Os at all times if two mutually exclusive groups were properly partitioned. Our evaluation results showed that SWAN offered consistent I/O throughput at close to the maximum network bandwidth and that read latency also improved.

Abstract

As NAND flash technology continues to scale, flash-based SSDs have become key components in data-center servers. One of the main design goals for data-center SSDs is low read tail latency, which is crucial for interactive online services as a single query can generate thousands of disk accesses. Towards this goal, many prior works have focused on minimizing the effect of garbage collection on read tail latency. Such advances have made the other, less explored source of long read tails, *block erase operation*, more important. Prior work on erase suspension addresses this problem by allowing a read operation to interrupt an ongoing erase operation, to minimize its effect on read latency. Unfortunately, the erase suspension technique attempts to suspend/resume an erase pulse at an arbitrary point, which incurs additional hardware cost for NAND peripherals and reduces the lifetime of the device. Furthermore, we demonstrate this technique suffers a write starvation problem, using a real, production-grade SSD. To overcome these limitations, we propose alternative *practical* erase suspension mechanisms, leveraging the iterative erase mechanism used in modern SSDs, to suspend/resume erase operation at well-aligned safe points. The resulting design achieves a sub-200μs 99.999th percentile read tail latency for 4KB random I/O workload at queue depth 16 (70% reads and 30% writes). Furthermore, it reduces the read tail latency by about 5× over the baseline for the two data-center workloads that we evaluated with.

1 Introduction

NAND flash-based SSDs offer superior throughput and average latency compared to those of hard disks and thus have become the de-facto standard for storage devices. However, SSDs have much greater performance variability than that of hard disks [11]. While SSDs can achieve very low average read latency (e.g., under 15μs [5]), their tail latency (e.g., 99.999th percentile) can be very long (e.g., over 10ms). Figure 1 demonstrates this issue with a real low-latency SSD.

One can mistakenly think that long tail read latency is a rare event that affects very few requests. However, such tail latency can play a considerable role in data-center computing because a single query (e.g., web search) may require thousands of disk reads across the data-center [2,7]. In such a case, a single long-latency disk access can lead to an increase in the overall query response time. Also, the chance of a query experiencing

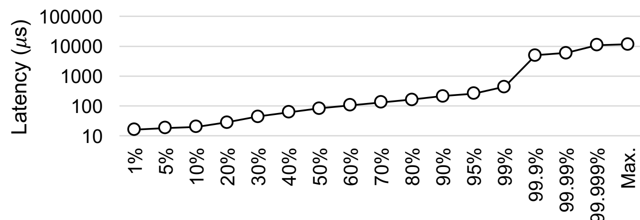

Figure 1: Read latency distribution of a PCIe 3×4 NVMe low-latency SSD [5] running 4KB random reads (70%) and writes (30%) workload with a queue depth of 16.

long disk tail latency is continuously increasing with the trend of ever-increasing data size.

To avoid such performance degradation in a data-center induced by SSD tail latency, minimizing the tail latency of a read operation is very important. Naturally, this requires tackling two significant sources of long read tails: garbage collection (GC) and erase operations. Recent prior works have already explored ways to minimize the effect of GC on read tail latency [6, 14, 37]. Furthermore, production-level low-latency SSDs — such as Samsung Z-SSD [38], which we base our work on — have already minimized the effect of GC on read operation [38] by allowing the user-initiated read to be processed between operations in a GC (i.e., read and program to copy valid pages from one block to another) [4, 20]. In contrast, much less attention has been paid to the effect of erase operation on read tail latency, primarily because erase latency is relatively small (e.g., 5ms) compared to the effect of GC on tail latency (e.g., can exceed 100ms without any optimization). However, with techniques minimizing this effect, erase latency is now becoming the most dominant component of read tail latency.

To control the effect of erase on tail latency, Wu et al. [35] proposed an erase suspension technique, which suspends an ongoing erase (and verify) pulse when a read request is issued to the same flash die. After processing the read request, the erase pulse resumes from the exact point at which it was suspended. However, the commodity NAND flash business is known to be extremely cost-sensitive, and this technique may increase the cost of NAND peripherals to generate an erase pulse of an arbitrary length and track the exact state of every erase. Furthermore, it can cause a serious NAND reliability problem and write starvation.

To address these limitations, we present *practical* erase suspension schemes for modern low-latency SSDs. Instead

of suspending/resuming an erase pulse at an arbitrary point, our work focuses on suspending/resuming the erase operation at well-aligned safe points by either i) aborting an ongoing erase operation immediately and resuming from the last safe point or ii) deferring the suspension of erase operation until the next safe point. Exploiting their trade-offs, we also introduce a timeout-based switching mechanism between the two mechanisms, to adapt to workload changes dynamically. This scheme enables modern low-latency SSDs to offer extremely low read tail latency on a wide range of workloads without causing any NAND reliability problem or write starvation.

Our contributions are summarized as follows:

- We are the first to identify the problems of NAND reliability and write starvation in the existing erase suspension scheme and demonstrate the latter on a real, production-grade SSD.
- We propose two practical erase suspension mechanisms, *immediate* erase suspension and *deferred* erase suspension. We also analyze the trade-offs between the two mechanisms and introduce a timeout-based switching policy between the two, to take the best of both as the workload changes.
- We demonstrate a significant reduction in read tail latency with the proposed erase suspension mechanisms on various workloads including Aerospike Certification Tool (ACT) [1] and TPC-C benchmark workloads [31].

2 Practical Erase Suspension

2.1 Motivation

To perform a NAND block erase, the incremental step pulse erasing scheme is a standard feature in modern SSDs [18]. Instead of utilizing a single, very high voltage pulse (e.g., 14V) for an erase, which has negative impact on NAND lifetime [12, 25, 29], this scheme performs an erase operation with several, discrete pulses (typically 5 or fewer), and each pulse has a higher nominal voltage than the previous one. Figure 2 illustrates this scheme. By verifying the set of erased cells between erase pulses and by applying higher voltage pulses to cells that are not erased yet, this scheme minimizes damage on NAND cells [12]. A single erase pulse consists of the following 3 stages: ① *voltage ramping* stage in which the erase pulse reaches the desired voltage, ② *erase execution* stage during which the voltage is stabilized and maintained, and ③ *voltage recovery* stage in which the erase voltage is reset for the erase-verify operation.

The erase suspension mechanism has been proposed to provide tight read tail latency by suspending an ongoing erase pulse at the arrival of a read request to be resumed later [35]. While effective in reducing read tail latency, this mechanism poses several implementation challenges in terms of NAND

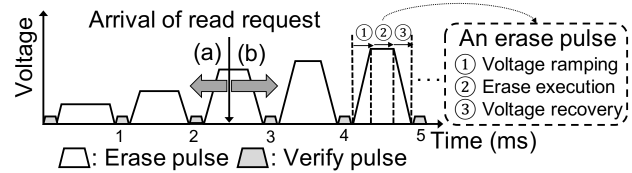

Figure 2: Incremental step pulse erase and practical erase suspension mechanisms: (a) Immediate erase suspension (I-ES) and (b) Deferred erase suspension (D-ES).

reliability and cost. First, an erase suspension adds to the cost of an erase an extra pair of voltage recovery (③) and ramping (①) stages for suspending and resuming the erase pulse. These additional stresses caused by ramping up and down the voltage degrade the endurance of NAND [12, 25, 29]. For example, a recent case study using sub-20nm TLC NAND shows that the *raw bit error rate (RBER)* is increased by 14.4% with only 1000 erase suspensions [26]. The increased RBER leads to an increase in *uncorrectable bit error rate (UBER)* even with error correction, to eventually reduce the lifetime of SSD [3].

Another limitation of the existing erase suspension scheme is that it requires the capability to suspend and resume an erase pulse at an arbitrary point. This increases the cost for NAND peripherals to generate a pulse of an arbitrary length, track the exact state of each suspended erase, and recover the peripheral state to resume. As NAND cells continue to scale with the introduction of 3D NAND, NAND peripherals are becoming a scalability bottleneck to a greater extent [19, 24, 27]. Considering the extreme cost sensitivity of the commodity NAND business, this is a significant drawback.

Instead, our erase suspension scheme allows erase suspension only at the beginning or the end of each erase step. When a read request arrives while an erase pulse is still asserted, our scheme asserts an erase suspension command that either i) aborts the ongoing erase pulse and forfeits the current erase step progress to serve the read request immediately (named *immediate erase suspension*) or ii) finishes the ongoing erase step and serves the read request (named *deferred erase suspension*). The next subsections discuss each option in detail and also present an adaptive switching scheme between our two proposed mechanisms.

2.2 Immediate Erase Suspension (I-ES)

One way to serve an incoming read request during the erase pulse is to immediately terminate the ongoing erase step and to forfeit the progress (Figure 2(a)). Then, after serving the read request(s), the erase operation can resume from the beginning point of the current erase step. We call this scheme *Immediate Erase Suspension (I-ES)* since it immediately cancels the ongoing erase step.

In effect, I-ES is a practical variant of the original erase suspension [35] with the following two changes. To improve NAND reliability, a verify pulse is applied before resuming a suspended erase pulse, exploiting the incremental step

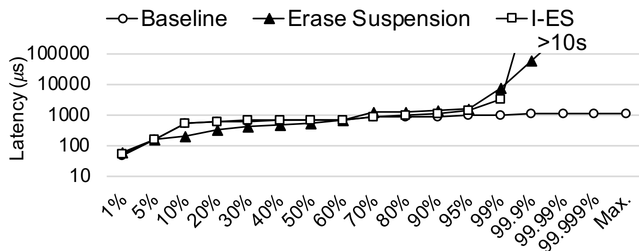

Figure 3: Write starvation experiment results. This workload consists of two threads where one thread continuously generates 128KB read requests, while another thread continuously generates 128KB write requests (QD 1 for both). Baseline and I-ES use real low-latency SSD [5], and Erase Suspension [35] uses an SSD simulator [33].

pulse erasing scheme in Section 2.1. As each NAND cell in a NAND block has different erase timing, some NAND cells get erased more quickly than others [12,25,26,29]. Therefore, applying the same pulse to all NAND cells when resuming the erase pulse results in over-erasure of some cells, which puts unnecessary stress on already erased cells and harms the reliability of NAND. A verify pulse, before resuming the erase pulse, detects already erased cells to not inflict unnecessary stress on these cells in a NAND block. Furthermore, to keep the cost of NAND peripherals low, a whole step pulse is asserted at every resumption, instead of the remaining step pulse time. To generate an erase pulse of an arbitrary length, a variable-length pulse generator with fine-grained control must be placed on a NAND device. However, today's commodity NAND does not provide such a mechanism. In contrast, I-ES does not require such changes keeping the cost of NAND low.
Advantages and Disadvantages. Since the erase step is canceled immediately, the read command can always be guaranteed the highest priority. The read command does not experience any other delay caused by an erase operation except for a fixed latency (e.g., $\sim$100μs) that tries to cancel the ongoing erase pulse (③ in Figure 2).

However, this scheme is problematic. With the continuous incoming read requests, an erase step may be repeatedly canceled, preventing write requests (which are dependent on the erase requests) from completion. To confirm this behavior, we modified the firmware of the real, production-grade low-latency SSD [5] to implement this scheme. Figure 3 shows the outcome of this experiment. As expected, a few write operations cannot finish for a long time because the preceding erase operation is continuously canceled by incoming read requests. As a result, its tail latency keeps increasing until the end of the workload.

The erase (and write) starvation problem occurs because the latency of erase suspension/resuming operation is longer than the incoming rate of read requests on the NAND chip. For example, if the throughput of PCIe Gen 3$\times$4 NVMe interface is 3.2GB/s (i.e., the incoming read rate is 1.19μs/4KB) and the erase suspension/resuming overhead is 100μs, it is possible for a read request to arrive while the erase suspension/resumption is happening. In such cases, the erase will immediately suspend again without making any forward progress, and thus the erase (and write) operation will starve. Note that the same problem manifests with the original erase suspension scheme [35], which differs from I-ES only for the duration of the asserted pulse at resumption, as shown in Figure 3. NVMe and PCIe specifications require the host to reset both hardware and software at write starvation (i.e., user's write requests timeout) [23, 28], which adversely affects system performance [22] and may eventually lead to a fatal system failure if repeated.

2.3 Deferred Erase Suspension (D-ES)

Another way to serve an incoming read request during the erase pulse is to let the read request wait until the current erase step finishes (Figure 2(b)). After that, in lieu of proceeding to the next erase step, the read request(s) is (are) served. Then, the erase operation resumes and continues to the next erase step. We call this *Deferred Erase Suspension (D-ES)* as it defers erase suspension until the end of the current erase step.
Advantages and Disadvantages. This mechanism lets the erase operation finish without incurring the write starvation problem. By guaranteeing a single erase step to be performed once the erase step is initiated, this mechanism guarantees forward progress for the erase operation.

Although this mechanism does not incur erase (and write) starvation, it can harm read tail latency by making read requests wait until the end of the current erase step (i.e., 1ms in our low-latency NAND). This scheme can also show worse read latency for bursty reads as D-ES adds extra latency to reads. However, such situations could be avoided by batching backlogged erases after serving the bursty reads first. This issue is addressed by T-ES, which switches adaptively between I-ES and D-ES.

2.4 Timeout-based Erase Suspension (T-ES)

Timeout-based Erase Suspension Policy. If it is possible to know the request pattern of an application *a priori*, one should use I-ES when the application is expected to have a phase with sparse read requests as in this case erase (and write) starvation does not occur as an erase is likely to make progress during the upcoming sparse read period. On the other hand, if an application is expected to have a steady stream of incoming read requests, the user should use D-ES as in this case, employing I-ES leads to an exponential increase in write tail latency (i.e., write starvation).

Unfortunately, in reality, it is not easy to predict future I/O access patterns without profiling runs. Thus, we propose a *Timeout-based Erase Suspension (T-ES)* scheme, which performs I-ES until the erase operation is delayed for Nms. If the erase operation is delayed for Nms (i.e., timeout happens), this scheme switches to D-ES mode to avoid potential erase (and write) starvation. Hopefully, this scheme finds a period to perform an erase operation without being interrupted by a

Table 1: Parameters used to model our low-latency SSD [5].

PCIe Gen 3×4 Lane, 240GB, NVMe SSD Device	
NAND Configurations	4 channels, 4 chips/channel, 1 die/chip
DRAM, Flash Speed Rate	1600MT/s, 1200MT/s (MT/s: Mega Transfers per Second [9])
FTL Schemes	Page Mapping, Preemptible GC [20]
Over-provisioning Ratio	7%
NAND Structure	
128Gb die capacity, 8 planes per die, 683 blocks per plane, 768 pages per block, 4KB page	
NAND Latency	
Read: 3μs, Program: 100μs, Block Erase: 1ms per step (5 steps), Erase Suspension Penalty: 100μs	

Table 2: Throughput and average latency of low-latency SSD prototype and MQSim running various I/O pattern workloads.

	Low-Latency SSD / MQSim	
Seq. read (256KB)	3300 / 3250 MiB/s	
Seq. write (256KB)	2700 / 3100 MiB/s	
	Kilo I/O per seconds	Average latency
Rnd. read (4KB, QD 1)	59 / 65 KIOPS	16.9 / 15.3μs
Rnd. write (4KB, QD 1)	61 / 66 KIOPS	16.4 / 15.2μs
Rnd. read (4KB, QD 32)	790 / 790 KIOPS	40.5 / 40.5μs
Rnd. write (4KB, QD 32)	61 / 66 KIOPS	524 / 484μs

read operation.

Choice of Erase Timeout Delay. T-ES covers a spectrum of policies between I-ES and D-ES, controlled by the value of N. If we set it to 0, this is equivalent to the base D-ES scheme. In contrast, if we set it to infinite, this is equivalent to I-ES scheme prone to erase (and write) starvation problem. In general, choosing a higher value offers more chance to provide better read tail latency by delaying an erase operation, but this choice leads to an increase in maximum write tail latency. On the other hand, choosing a smaller N makes it behave more like a D-ES, which provides smaller maximum write tail latency at the expense of an increased number of reads experiencing erase latency. T-ES provides a knob for the user to choose N based on her willingness to trade-off the maximum write tail latency for potential improvement in read tail latency. For example, if the user wants to achieve sub-100ms write tail latency and the maximum write delay occurring from a GC scheme (e.g., GC policy [6, 13–15, 17, 37], over-provisioning ratio [30]) is 35ms, the user should set N to be 64ms so that the total maximum write latency remains under 100ms. By default, we set N to 64ms for our experiments.

3 Evaluation

3.1 Methodology

Evaluation Framework. Although we utilized a real, prototype low-latency SSD [5] with modified firmware to perform some experiments (Figure 1 and Figure 3), it is not possible to utilize the real device to evaluate our presented schemes such as D-ES and T-ES since implementations of such policy require an extension to the interface between the SSD controller and NAND flash chips (e.g., new commands). For this

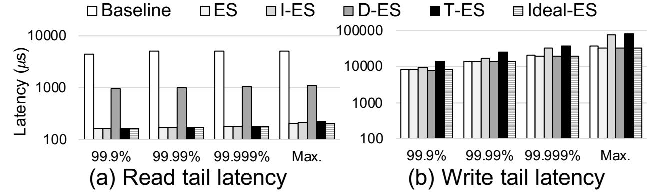

Figure 4: Read/write tail latency on 4KB random reads (70%) and writes (30%) workload.

reason, we use MQSim [33] for our experiments, which we extend so that it can accurately model low-latency NAND flash chips. In particular, we i) allow data cache manager and FTL to use strict 8 plane program so that it can achieve higher write throughput, ii) enable I/O scheduler to process the user read request as the highest priority, and iii) modify NAND flash controller and memory logic to model our practical erase suspension mechanisms. Table 1 summarizes the parameters used for our MQSim, while Table 2 compares the simulation results against those of a real low-latency SSD [5] for various I/O patterns as validation of the simulator. The average read/write latency and throughput from the simulator demonstrate only a 6% error on average (with 13% in the worst case) compared to measurements from the real device.

Evaluated Configurations. Throughout this section, we present evaluation results for the following configurations across different benchmarks (i.e., random 4KB access, ACT [1], and TPC-C [34]). Also, we use for all experiments the steady state pre-condition [32] in which the space of an SSD including the over-provisioning (OP) [30] area is full; this pre-condition helps evaluate the latency behaviors that can happen under the worst-case condition of read and write requests. Section 2 discusses three practical erase suspension mechanisms: I-ES, D-ES, and T-ES. We add the following three configurations to our evaluation for comparison:

- Baseline: Erase operations do not get preempted by an incoming read request.
- Erase Suspension (*ES*): The scheme can suspend and resume an erase pulse from an arbitrary point as proposed by Wu et al. [35].
- Ideal Erase Suspension (*Ideal-ES*): This scheme can suspend and resume an erase operation from any arbitrary point with *zero* erase suspension penalty.

3.2 Random Access Benchmark

Workload. We first evaluate our erase suspension policies using a microbenchmark that generates a mixture of 4KB random reads (70%) and writes (30%) at queue depth 16. We utilize Flexible I/O Tester (FIO) [8] to generate such disk access patterns. This workload is widely used to evaluate an SSD's latency performance [10, 38]. Figure 4 shows the results of this experiment.

Read Tail Latency. In the baseline, when an erase happens,

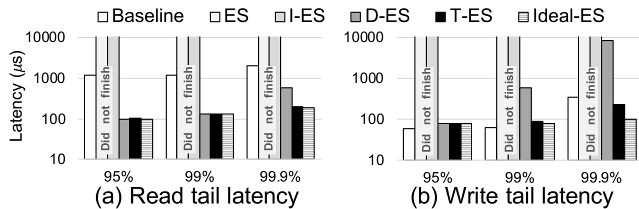

Figure 5: Read/Write tail latency on ACT workload (30× workload multiplier).

Table 3: Performance and stress test results using ACT.

	Baseline	ES	I-ES	D-ES	T-ES	Ideal-ES
Stress	32×	22×	22×	30×	30×	32×
Performance	14×	22×	22×	30×	30×	32×

the subsequent read requests are simply delayed for the duration of the remaining erase time (up to 5ms). As a result, baseline policy shows around 5ms read tail latency. With ES and I-ES such an erase operation is repeatedly aborted by the incoming read requests. As a result, incoming read requests do not experience an extra delay caused by the ongoing erase operation except for the 100μs latency required for erase suspension/resumption. For this reason, both ES and I-ES policies have very low read tail latency. Note that they are prone to experience erase (and write) starvation as pointed out in Section 2.2. However, it does not happen here because this workload has a period when read requests are not sent out for some time (i.e., all 16 outstanding requests in the queue are write requests waiting for an erase to proceed). During this period, erase operation successfully finishes. The read tail latency of D-ES is around 1ms because it always lets the ongoing erase step (not the whole erase) finish, making a read request wait. T-ES behaves similarly to I-ES in this workload as the timeout is rarely triggered.

Write Tail Latency. Baseline, ES, D-ES, and Ideal-ES have a lower write tail latency because their erase operation is finished in a relatively short period of time without canceling an existing erase pulse. Notably, the write tail latency of the baseline policy is the maximum GC latency (35ms) of our model without erase suspension. On the other hand, both I-ES and T-ES abort the erase multiple times, and thus delays write operations significantly. As a result, they tend to have a longer write tail latency.

3.3 Database Benchmark

Workload. ACT models the Aerospike database servers' real-time I/O access patterns. In essence, ACT consists of three threads: one issuing 2K small (1.5KB) read requests per second, another issuing 24 large (128KB) read requests per second, and the third one issuing 24 large (128KB) write requests per second. ACT gradually increases this rate in integer multiples (e.g., ACT 4× workload means 8K small read requests/s, 96 large read requests/s, 96 large write requests/s) and considers that the device has passed the *performance test* if it meets the following conditions for a long time (e.g., 24hrs): i) 95% of transactions finish in 1ms, ii) 99% of transactions finish in

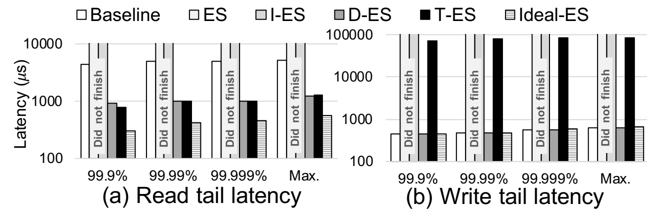

Figure 6: Read/Write tail latency on TPC-C.

8ms, iii) 99.9% of transactions finish in 64ms, and iv) average transaction time for each type of requests is smaller than ACT workload's I/O request period. If a device satisfies only the fourth condition but fails to satisfy one of the first three conditions, that device is said to pass the *stress test* but not the *performance test*. The maximum ACT multiplier that an SSD can satisfy is that particular SSD's performance rating.

ACT Results. Table 3 shows the maximum multiplier in which each configuration passed the performance and stress tests. Figure 5 shows the tail latency of 95%, 99%, and 99.9% accesses at 30× workload multiplier. As shown in Table 3, the baseline has a good average response time and thus can successfully run ACT with 32× multiplier. On the other hand, it has the worst read tail latency since the part of erase latency (up to 5ms) is exposed to read requests. This leads to a relatively poor performance test result for the baseline. ES and I-ES have good read tail latency behavior. However, continuous read requests cause erase (and write) starvation, which leads to a failure in the stress test (fourth condition) at the workload multiplier whose value is above 22×. On the other hand, both D-ES and T-ES demonstrate strong results for both stress and performance tests. Both D-ES and T-ES can maintain low read tail latency while avoiding erase (and write) starvation.

3.4 Transaction Processing Benchmark

Workload. TPC-C [34] is a popular benchmark for online transaction processing frameworks. We utilize a published disk trace of the system running TPC-C from SNIA [31], to evaluate our erase suspension mechanisms.

TPC-C Results. Figure 6 shows the results from this experiment. The baseline policy generally observes a noticeably higher read tail latency than the other schemes since latency is exposed to many read requests queued behind the erase operation. Neither ES or I-ES runs to completion as they suffer from a severe erase (and write) starvation and cause the simulator to exit prematurely after failing to serve many write requests for a long time. As in the ACT workload, this is because continuous read requests prevent the completion of an erase operation. Both T-ES and D-ES achieve much lower tail latency than the baseline. In particular, both achieve around 1ms max tail latency, which indicates that a read request only experiences about a single erase step delay at most.

The write tail latency of the baseline, D-ES, and Ideal-ES is similar to each other. In contrast, ES and I-ES suffer write starvation, and T-ES records the longest write tail latency. The

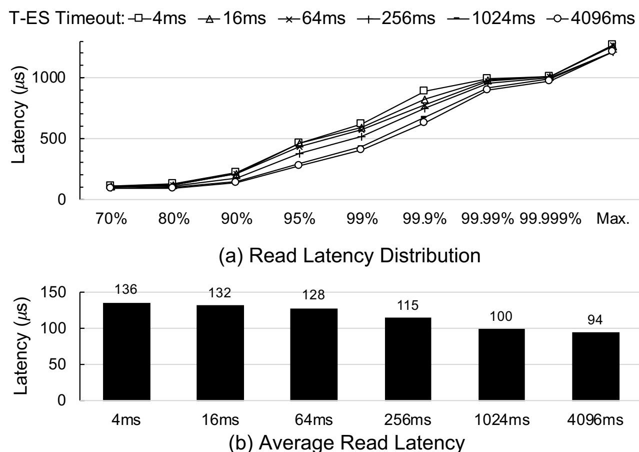

Figure 7: (a) Read latency distribution and (b) average read latency with varying T-ES timeout values for TPC-C.

Table 4: Maximum write latency for TPC-C.

T-ES Timeout	4ms	16ms	64ms	256ms	1.02s	4.09s
Write Latency (Maximum)	27ms	40ms	86ms	280ms	1.04s	4.1s

T-ES scheme delays erase (and following writes) for up to the timeout value hoping to find a period in which it can perform an erase without blocking reads. In this case, T-ES does not find such a period and hence ends up triggering the D-ES mechanism after delaying the write requests; as expected, the maximum write latency converges within 90ms (i.e., the sum of GC latency (24ms) and the T-ES timeout value (64ms)).

3.5 Sensitivity to T-ES Timeout Threshold (N)

If an erase operation is delayed for Nms, T-ES switches from I-ES to D-ES to avoid erase (and hence write) starvation. We perform a sensitivity study, using TPC-C with varying N to provide an insight into the tradeoff with selection of this parameter.

Figure 7(a) shows the read latency distribution with different values of N from 4ms to 4096ms. At around the 80th percentile we start to observe a gradual transition of read latency from more of I-ES (about 200μs) to D-ES (about 1ms). Increasing N generally i) lowers frequency of both high-latency read (i.e., over-200μs) and ii) average read latency, but iii) increases the maximum write latency. As N increases, T-ES has a greater chance of running in I-ES mode to lower the chance for a read request to experience a 1ms delay for finishing an ongoing erase pulse. Fewer long-latency reads lead to a lower average read latency as shown in Figure 7(b).

However, increasing N negatively affects the maximum write latency. Table 4 summarizes the maximum write latency with varying N. As discussed in Section 2.4, the maximum write latency of T-ES is the sum of GC latency and the T-ES timeout value. This is because GC operations, which need an erase operation to produce a free block for user data write, may be interfered while running in I-ES mode. Once T-ES timeout is triggered, it switches to D-ES to allow GC operations to produce the free blocks to write user's data. The maximum GC latency of the TPC-C workload (with steady state pre-condition) is 24ms. Thus, the measured maximum write latency is not far off from the estimated value (i.e., GC latency plus N).

4 Related Work

Garbage Collection Optimization. There are several prior works on alleviating the effect of GC on tail latency [6, 13–15, 17, 37]. While these optimizations can effectively reduce the effect of coarse-grained GCs on read tail latency, they do not address the effect of long erase operation on read tail latency, which becomes more important with optimized GC. Thus, these techniques are orthogonal or complementary to our presented erase suspension schemes.

I/O Scheduling Optimization. Another way to optimize tail latency is to schedule a read/write request in an intelligent way [16, 20, 21, 36, 39, 40]. These proposals are effective when there are multiple devices available. On the other hand, our work focuses on tail latency reduction without requiring multiple devices. Still, if multiple devices are available, our technique can be applied jointly with these optimizations.

5 Conclusion

This paper introduces practical erase suspension mechanisms to limit the impact of erase operation on long read tail latency. Leveraging the iterative erase mechanism commonly employed by today's flash devices, the proposed mechanisms minimize the impact of erase operation on read tail latency, while requiring only minor extensions to the flash interface. With the proposed erase suspension mechanisms, our proposal enables flash-based SSDs to achieve very low read tail latency, while avoiding erase (and write) starvation and endurance degradation of NAND. For example, our results demonstrate the feasibility of a sub-200μs 99.999th percentile read tail latency for 4KB random access workloads, which is competitive with an emerging non-flash NVM-based SSD [10]. This will harness the full potential of flash-based SSDs as the primary storage platform for future data-centers that will be required to run a variety of latency-sensitive online services.

Track-based Translation Layers for Interlaced Magnetic Recording

Mohammad Hossein Hajkazemi⋆, Ajay Narayan Kulkarni†, Peter Desnoyers⋆, Timothy R Feldman†
Northeastern University⋆, Seagate Technology†

Abstract

Interlaced magnetic recording (IMR) is a state-of-the-art recording technology for hard drives that makes use of heat-assisted magnetic recording (HAMR) and track overlap to offer higher capacity than conventional and shingled magnetic recording (CMR and SMR). It carries a set of write constraints that differ from those in SMR: "bottom" (e.g. even-numbered) tracks cannot be written without data loss on the adjoining "top" (e.g. odd-numbered) ones. Previously described algorithms for writing arbitrary (i.e. bottom) sectors on IMR are in some cases poorly characterized, and are either slow or require more memory than is available within the constrained disk controller environment.

We provide the first accurate performance analysis of the simple *read-modify-write (RMW)* approach to IMR bottom track writes, noting several inaccuracies in earlier descriptions of its performance, and evaluate it for latency, throughput and I/O amplification on real-world traces. In addition we propose three novel memory-efficient, track-based translation layers for IMR—*track flipping*, *selective track caching* and *dynamic track mapping*, which reduce bottom track writes by moving hot data to top tracks and cold data to bottom ones in different ways. We again provide a detailed performance analysis using simulations based on real-world traces.

We find that RMW performance is poor on most traces and worse on others. The proposed approaches perform much better, especially dynamic track mapping, with low write amplification and latency comparable to CMR for many traces.

1 Introduction

Magnetic recording technology has made enormous strides over the last several decades, reaching densities of about a terabit per square inch, higher than that of any but the most modern and densest solid-state storage technologies. Yet in recent years density improvements have run up against the *superparamagnetic limit* [17]—as bits get smaller, the magnetic media coercivity (resistance to being magnetized) must go up, to avoid bit flips from thermal noise, while as heads get smaller their magnetic field becomes weaker, requiring lower coercivity media. In other words, smaller bits require smaller track sizes, requiring smaller write heads, requiring lower-coercivity media, resulting in larger minimum bit sizes. When the minimum bit size becomes as large as the write head, further density improvements require new approaches. We are currently at or near this limit; increases in disk capacity in the past 5 years or more have relied more on increasing the number of platters per drive rather than increases in areal density.

New strategies allow further increases in areal density by sidestepping one or both sides of this trade-off, i.e. either breaking the link between bit size and write head size / magnetic field strength, or between bit reliability and media coercivity. Shingled Magnetic Recording (SMR) [1] overlaps adjacent tracks, reducing the effective track width without reducing the write head size. Yet, this increase in density comes at a cost: random writes are not allowed, as overwriting a sector will also overwrite the corresponding sector in the adjacent "downstream" track, and therefore the data could be lost. Heat-Assisted Magnetic Recording [12] takes advantage of the fact that the coercivity of a material goes down with temperature, and uses a laser to heat the media to near the Curie point[1] before writing. This allows use of a medium with much higher room-temperature coercivity and smaller grain size (and thus minimum bit size), and also allows an effective track width narrower than the write head by narrowing the width of the heated domain, by controlling the laser current.

Interlaced Magnetic Recording (IMR) [9] uses both heat-assisted recording and track overlap. This is in contrast to SMR, which uses track overlap but conventional room-temperature recording. As shown in Figure 1, tracks are written in an "interlaced" fashion, with a "bottom" layer of tracks written first, after which a "top" layer is written between (and partly overlapping) these bottom tracks. To avoid total overwrite of the bottom tracks, top tracks are written with a narrower width and thus slightly lower capacity, roughly 90% that of the

[1]The temperature above which the material will no longer retain its magnetic properties.

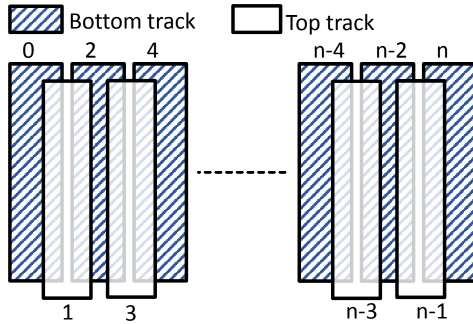

Figure 1: IMR technology: tracks are written in an interlaced fashion; top tracks are written between and over bottom tracks. Top track *i* partially overlaps bottom track *i-1* and *i+1*.

bottom tracks. The result is a drive with write constraints, but ones that are far less strict (and thus less performance-limiting) than those for SMR. Where SMR writes must be limited to a single track per zone (a group of a few hundred of tracks) to avoid data loss, in IMR nearly half of the sectors (i.e. those on the top tracks) can be re-written safely. Moreover whereas moving valid data in SMR requires reading and/or writing an entire (typically 256 MB) zone, for IMR in the worst case only two tracks (less than 5 MB) must be moved.

IMR is a very new technology, with the first descriptions of its physical feasibility dating to 2016 [4,9]; with one exception, Wu et al. [20] that is discussed in Section 5 the publications to date have focused on the magnetic and physical aspects of IMR, rather than system implications and algorithms. We provide the first thorough performance analysis of the naive *read-modify-write (RMW)* strategy described in the first IMR proposals [4], correcting several mistaken assumptions, and quantifying the performance degradation of IMR with RMW for real workloads. We offer three algorithms for improved management of IMR writes, *track flipping*, *selective track caching* and *dynamic track mapping*, all of which (unlike the approach of Wu et al.) may be readily implemented in disk firmware with limited memory and compute resources. We provide detailed performance models of these algorithms, and evaluate them in simulation on real workloads, showing substantial improvement over RMW in all cases and near-conventional-drive performance for some workloads.

In particular, the contributions of this paper are:

1. a thorough performance analysis of naive read-modify-write for IMR disk—i.e. as proposed in Hwang et al. [9]—showing a performance overhead of more than 2x that assumed by prior work,

2. three novel track-based translation layers—track flipping, selective track caching and dynamic track mapping—which mitigate most of the IMR performance penalty at a sufficiently modest cost in memory that they may be implemented within today's on-board disk controllers,

3. evaluation of conventional ("CMR") disk, RMW and the three proposed algorithms on real-world traces, demonstrating (a) significant costs to RMW vs. CMR, and (b) substantial improvements for all proposed algorithms particularly dynamic track mapping.

2 Algorithms for IMR

As with SMR, IMR write limitations maybe addressed from the host or within the device; however the complexity of the IMR track-to-track write restrictions makes it preferable to employ a device-based block translation layer rather than expose restrictions to the host.

We describe in detail four algorithms: naive read-modify-write [9], track flipping, selective track caching and dynamic track mapping. For each algorithm we estimate memory usage, describe the data copies and logging of mapping changes needed to prevent data loss in the case of a crash, and analyze the performance of the algorithm's operations.

2.1 Read-modify-write

The simplest IMR translation layer is what we term naive read-modify-write (RMW). Sectors on disk are assigned fixed logical addresses, as in conventional drives, and before performing any write to some sector S on a bottom track T, the drive (1) reads the adjacent top track sectors (S_{T-1} on $T-1$ and S_{T+1} on $T+1$) and (2) copies them to a "backup region", then (3) performs the bottom-track write, and finally (4) re-writes the adjacent top track sectors.

When numbering tracks $T-1$, T, $T+1$ we are referring to physical position, which may not directly correspond to logical block numbering. In particular IMR is expected to use a *serpentine* or *zig-zag* layout [10], where LBAs are numbered sequentially across N adjacent bottom tracks, and then across the corresponding N top tracks. The result is that sectors in physically adjacent top and bottom tracks will be separated by a distance of N track sizes either in all cases (zig-zag) or on average (serpentine).

Memory usage: Other than buffers for copying, no additional memory is required beyond that needed for standard LBA to physical location translation in a conventional drive.

Safety and crash consistency: We first note that to avoid data loss, host writes to the affected top tracks must be blocked during the RMW operation, as they would be overwritten when data is copied back to the tracks. The duration of this locking determines a phase, which is atomic with respect to user I/O, and mapping updates need only be persisted once per phase.

Copying sectors S_{T-1} and S_{T+1} to the backup region forms a single phase, and the temporary location of the sectors is logged to the backup region just before the phase completes. If a crash occurs before restoring the top tracks, a startup scan of the log will locate the saved data, which may be copied back to its proper location. The length of the log is determined by the number of simultaneous RMW operations allowed; if this

is 1, then no log trimming is needed as it will just be replaced by the log from the next operation.

When logging data to the backup region, we can write additional metadata with negligible overhead, much like journal entries in a file system. Efficiently persisting the fact that S_{T-1} and S_{T+1} have been restored is more difficult, however; if this is not done, then future writes to these locations may be lost if stale backup data is copied back on restart. A straightforward way to do this is to clear the backup region; however this requires an additional seek and possibly lost rotation. Instead we clear the backup region *lazily*, if we detect a write to S_{T-1} or S_{T+1}. Since *any* RMW operation will clear the previous contents of the backup region, in most cases this lazy cleaning may be omitted, as until S_{T-1} or S_{T+1} are modified, the backup data is not stale and may be copied back safely on startup.

Timing: The performance of this approach may be analyzed by examining the steps above. We assume a random single-sector write to sector S on bottom track T, and assume as well that sectors S_{T-1} and S_{T+1} on tracks $T-1$ and $T+1$ respectively must be moved to avoid data loss. The time taken is thus at least:

1. $0.5t_{rot} + t_{seek}$ to reach and read sector S_{T-1}, where t_{rot} is the rotation time, assuming an average 0.5-rotation delay for random access.
2. A missed rotation, t_{rot}, to reach and read sector S_{T+1}.
3. $t_{seek} + 0.5t_{rot}$ to reach the backup region, plus negligible transfer time to write sector S_{T-1} and S_{T+1}.
4. $t_{seek} + 0.5t_{rot}$ (see below) to reach and write sector S on track T.
5. a missed rotation (t_{rot}) plus negligible transfer time to reach and write S_{T-1} on track $T-1$.
6. a missed rotation (t_{rot}) plus negligible transfer time to reach and write S_{T+1} on track $T+1$.

Steps 3 and 4 together will take an integral number of rotations, either 1 or 2, depending on whether the disk is able to seek to the safe track, wait until the write location passes under the head, and seek back within a single rotation (t_{rot}). Based on discussions with disk vendors we assume the two steps will take $2t_{rot}$ to complete, for a random write latency of $t_{seek} + 5.5t_{rot}$. The same operation would take $t_{seek} + 0.5t_{rot}$ on a CMR drive, for a RMW overhead of 5 rotations

Performance is even worse for sequential write, as the previous write finishes just after writing sector S, so that step 1 will require an entire missed rotation, for a total latency of $6t_{rot}$. Note that multiple writes to the same track may be coalesced into a single RMW operation, whether via command queuing or the use of write caching on the drive; however it will still take 5 or 6 rotations longer than writing a full track on a conventional drive.

We note that in our analysis, the actual performance of RMW will be significantly worse than that implied by Hwang et al. [9], where they state that writes to bottom tracks will require two rewrites, for a mean of one extra rewrite per host write request. We attribute the inaccuracy of their analysis[2] to several factors: (1) the significance of missed rotations in the rewrite process, each of which is far more costly than all but the largest write requests; (2) the need to read top-track data so that it can be re-written, and (3) the need to persist top-track data in a secondary location, to avoid data loss from failure in the middle of a RMW operation.

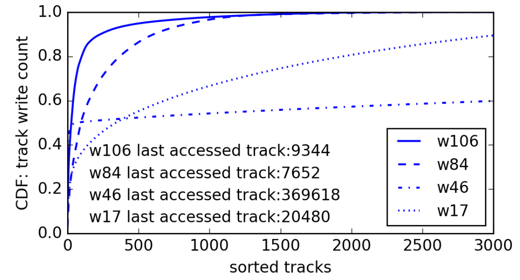

Figure 2: Track write count CDF (the first 3000 hottest tracks) for traces w17, w46, w84, w106 (See Section 3 for trace description); tracks are sorted from the hottest (i.e. track 0) to the coldest (i.e. track 3000).

2.2 Track flipping

Real workloads show high locality, with typically a small number of *hot* sectors being overwritten frequently, and the remaining sectors receiving few if any writes; the same phenomena is found at the track level, as shown in Figure 2 (an illustration of the first 3000 hottest tracks in a few workloads). For instance, a significant portion of writes (80%) are received by a small number (100) of tracks in w106. We can take advantage of this locality by moving data between tracks to maximize the amount of hot data stored on re-writable top tracks. Our first algorithm, *track flipping*, locates bottom tracks containing hot sectors (i.e. *hot tracks*) and swaps them with adjacent top tracks, moving the hot data to the top, where additional writes can be performed directly, and (hopefully) moving cold data to the bottom track. In particular, we track the number of writes to each track, periodically identify candidates for flipping—i.e. hot bottom tracks which are adjacent to cold top tracks—and swap them. The actual swap of tracks T (bottom) and $T+1$ (top) is straightforward:

1. read tracks $T-1$, T, and $T+1$
2. write $T-1$ and T contents to a backup region[3]
3. write $T+1$ contents to T
4. write T contents to $T+1$
5. rewrite $T-1$

Implementation of this algorithm must take into account several real-world factors. Top and bottom tracks hold

[2] To be fair, their analysis is a minor paragraph in the middle of a magnetics paper.

[3] The backup region must accommodate at least two tracks.

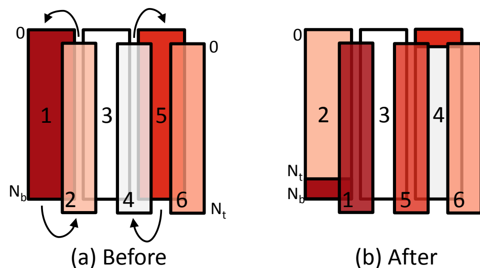

Figure 3: Track flipping: hot bottom tracks 1 and 5 (red) are swapped with cold top tracks 2 and 4. Since top tracks (N_t sectors) are smaller than bottom tracks (N_b sectors), only the first or last N_t sectors of hot bottom tracks are moved.

differing amounts of data, with top tracks estimated to have 90% the capacity of bottom tracks. In addition, neighboring top tracks or bottom tracks may vary slightly in capacity, due to the presence of bad sectors hidden by *slip sparing* [10]—i.e. the LBA numbering skips a bad sector, resulting in a track containing fewer sectors than if it were perfect. We note that there are other variations in track capacity due to the use of zone bit recording [10] and adaptive formatting [11]; however in all but a negligible number of cases these will not result in differing capacities for adjacent tracks.

Our solution to differing track capacities is to swap *most* of the bottom track with the top track contents, as shown in Figure 3. If a bottom and adjacent top track hold N_b and N_t sectors respectively, then we can swap the first N_t sectors of the bottom track with the entire contents of the top track (tracks 4 and 5 in Figure 3). In the case where hot sectors are located at the "end" of the bottom track, we instead swap the last N_t sectors of the bottom track with the contents of the top track (tracks 1 and 2 Figure 3). Given the original location of a sector (i.e. sector position S on track T) the sector can be located precisely in the flipped configuration given knowledge of which flip (low LBA or high LBA) has been performed and the exact track sizes N_t and N_b, which are already known by the firmware as part of the LBA translation process. Note that once two tracks have been flipped, data cannot migrate any further; if tracks T and $T+1$ have been flipped, then flipping $T-1$ and T, or $T+1$ and $T+2$, is not allowed until T and $T+1$ have been flipped back.

Memory usage: The track mapping may be represented in a very concise fashion, as each bottom track T is in one of five states: (1) unmoved, (2) its low LBAs flipped with track $T-1$, (3) its high LBAs flipped with $T-1$, or (4) and (5), its high or low LBAs flipped with $T+1$. The resulting track map requires 3 bits per bottom track, or 1.5 bits per track; assuming a mean track size of 1.5 MB, this would require a map of about 2.5 MB for a 20 TB drive.

Memory requirements for hot track detection can be modest, as well. The total number of tracks is large, 1.3×10^7 for our 20 TB drive; however the number of tracks written in the period between iterations of the track flipping algorithm is much smaller (e.g. 20K in our experiments). Logging these track numbers in memory (using data structures such as an array or a list) will take less than 0.25 MB, and they may then be sorted and counted to determine track write frequency during that interval.

Safety and crash consistency: For track flipping we need to persist not only the state of the flipping process, but also updates to the track mapping. The flip process involves one more copy than RMW, but may be handled in the same way, by keeping an update log in the backup region, and marking sectors when they are copied back to their home (or flipped) locations. Backup region metadata can include a small log of map updates which can be appended to the track map in batches. To persist changes to the track map we keep a copy of the map on disk, and a log of updates to the map in the "checkpoint location". The checkpoint can be rewritten periodically and the log recycled, resulting in a negligible amortized cost for persisting map changes.

Timing: Assuming the head starts in an arbitrary location, the time required to flip bottom track T and top track T+1 will be:

1. t_{seek} to reach track T
2. $3t_{rot}$ to read tracks $T-1$, T and $T+1$[4]
3. t_{seek} to reach a backup region
4. $2t_{rot}$ to write backup copies of track $T-1$ and T
5. t_{seek} to return to track T
6. t_{rot} to write the contents of $T+1$ into track T
7. t_{rot} to write the contents of track T into $T+1$
8. t_{rot} to rewrite the contents of track T-1

for a total cost of $3t_{seek} + 8t_{rot}$. Since all accesses are to entire tracks, we assume that existing disk scheduling and buffering mechanisms allow reading or writing to begin immediately after reaching a track, rather than incurring additional rotational delay. Note, however, that track flipping is a background operation, and can be interrupted at any point in time—resuming an interrupted flip is very similar to the crash recovery scenario, except that in-memory state is still available. The primary performance impacts of track flipping are thus a reduction in overall throughput, from the background flipping process, in combination with RMW latency for those bottom-track writes to tracks which have not been flipped.

For track flipping to be effective, hot bottom tracks must be paired with neighboring cold top tracks, as there would be no advantage to flipping the two tracks of the same "temperature". Although one can easily construct synthetic workloads (e.g. uniform random) which lack neighboring hot/cold track pairs, we wish to determine whether they are found in real-world workloads. To address this question we analyze one of our experimental workloads (w17, described in the Section 3 below), assuming a constant track size of 2 MB. In Figure 4 we see write counts for the 20 hottest tracks and their neighbors.

[4] Seeks due to track switches as well as short seeks from track $T-1$ to track $T+1$ and vice versa are not included in our calculations.

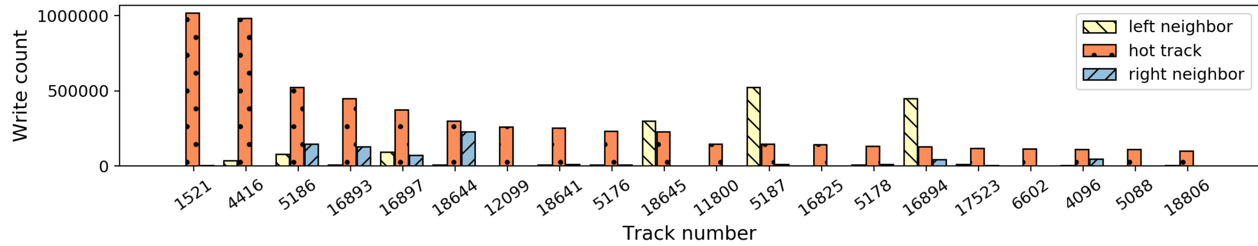

Figure 4: Write count of 20 hottest tracks and their neighbors, trace w17. This workload is seen to be “track flipping-friendly”.

In only a few cases (e.g. track 5187) do hot tracks have a hot neighbor; however even in those cases the other neighbor is cold. Similar results are seen in many—but not all—other workload traces. However we note that results may vary with file systems other than the ones found in our traces, i.e. ext4 and NTFS, and will certainly vary with differing track sizes.

Real-world workloads are time-varying, with the identity of hot locations changing over time. We see this in Figure 5, which shows the write frequency over time for a range of 4 tracks. Not only does write frequency to a given track vary, but relative write frequency between tracks changes as well: e.g. track 3854 is much hotter than 3857 for a significant period, while later in the trace track 3857 is hotter. By using time-limited write counts, which are periodically reset after each search for hot tracks to flip, we are able to adapt to these changes in access frequency. In Algorithm 1 we see the full track-flipping algorithm: every N writes (e.g. 20,000) we select the hottest *k* bottom tracks over the last interval and, if possible, switch them with cold neighbors.

Algorithm 1: track flipping

```
   parameter : updateFrequency, flipThreshold, maxFlips
   variable  : ioDirection (read/write), trackPosition
               (bottom/top), trackNumber, writeCount,
               flipCount, trackIdLog [], trackCounts []
 1 ioDirection, trackPosition, trackNumber ← ReceiveIO()
 2 if ioDirection == write then
 3   writeCount ++
 4   trackIdLog.append(trackNumber)
 5   if writeCount mod updateFrequency == 0 then
 6     trackCounts [] ← Count (trackIdLog)
 7     for every track in Hottest (trackCounts) do
 8       flipCount ++
 9       middleCounter = trackCounts [track ]
10       leftCounter = trackCounts [track-1]
11       rightCounter = trackCounts [track +1]
12       selected = Min (leftCounter, rightCounter)
13       temperatureDiff = middleCounter- selected
14       if temperatureDiff > flipThreshold then
15         TrackFlip (track, selected) maxFlips ++
16       end
17       if flipCount >= maxFlips then
18         Break ()
19       end
20     end
21   end
22 end
```

2.3 Selective track caching

With track flipping—as with RMW—every track on the disk except for the two “backup region” tracks is filled with user data, requiring significant “data shuffling” to move data. If we instead reserve a small number of tracks for translation layer use, we can achieve additional gains in performance. *Selective track caching* does precisely this, reserving a small range of non-interlaced bottom-only tracks as a persistent cache for holding data from hot bottom tracks. Whereas track flipping is not able to move a hot bottom track if both of its neighbors are also hot or if both of its neighbors are already flipped with another bottom track, selective track caching is able to move any hot bottom track, at any time.

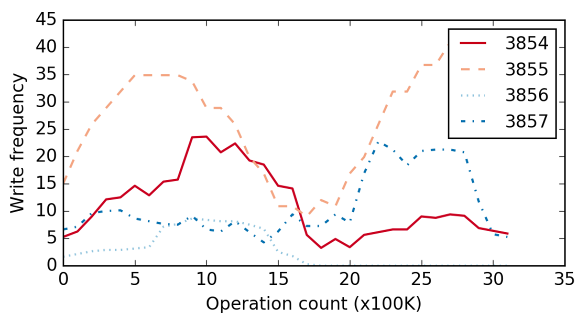

Figure 5: Track write frequency for tracks 3054-3057, trace w106. Y axis is the number of writes to a track out of 100,000 total writes.

More specifically, we reserve *k* bottom tracks as a random-write region (much like an SMR persistent cache), either at the outer diameter to maximize track size and transfer rate, or distributed in smaller groups across the disk to minimize seek time to the nearest cache. We note that tracks in the persistent cache will not be precisely the size of tracks that are cached there; instead we allocate “logical tracks” within the cache, where each logical track is a range of LBAs long enough to

hold a full track and a metadata header. As seen in Algorithm 2, we again monitor track write counts, and periodically select the hottest bottom tracks to be moved to persistent cache, while moving the coldest cached tracks back to their home location.

Memory usage: For this algorithm, memory is needed for monitoring track write counts and for keeping a map of the cached tracks. The requirements for track write monitoring are the same as they are for track flipping, and thus the same approaches may be used with identical memory usage: hundreds of KB for logging the track numbers written in the period between iterations, or negligible usage if write tracking already performed by the drive is adequate. If the cache map is structured as a look-aside list of exceptions to the standard map, then its memory usage is proportional to the size of the persistent cache, not the drive itself. In our experiments a cache of 100 tracks was used, requiring a trivial amount of memory; however for a cache of several tens of thousands of tracks, memory usage should still remain in the range of a few MB.

Safety and crash consistency: The same approach may be used for maintaining a consistent copy of the map as for track flipping: updates are logged, and a full checkpoint written periodically. Alternately if the cache size is sufficiently small we can exhaustively scan the cache and rebuild the map on startup; however this requires t_{rot} per track, and starts to become impractical at cache sizes of less than 100 tracks.

Timing: The actual data movement portion of this algorithm is straightforward. Promotion of a bottom track to the cache merely requires seeking to it (t_{seek}), reading it (t_{rot}), seeking to the cache (t_{seek}), and writing it (t_{rot}), for a total of $2t_{seek} + 2t_{rot}$. However track eviction takes longer as it requires a full-track RMW operation; the time taken will be:

1. t_{seek} to reach track C in the cache
2. t_{rot} to read track C
3. t_{seek} to reach track $T-1$
4. $2t_{rot}$ to read track $T-1$ and $T+1$
5. t_{seek} to reach to the backup region
6. $2t_{rot}$ to write backup copies of track $T-1$ and $T+1$
7. t_{seek} to seek back to track T
8. t_{rot} to write the contents of track C into T
9. $2t_{rot}$ to re-write track $T-1$ and $T+1$

Algorithm 2: selective track caching

```
   parameter : updateFrequency, cacheSize
   variable  : ioDirection, trackPosition,
               trackNumber, writeCount, trackIdLog
               [], cachedTracks [], trackCounts [], victim
1  ioDirection, trackPosition, trackNumber ← ReceiveIO()
2  if ioDirection == write then
3  |  writeCount ++
4  |  trackIdLog.append(trackNumber)
5  |  if writeCount mod updateFrequency == 0 then
6  |  |  trackCounts [] ← Count (trackIdLog)
7  |  |  for every track in Hottest (trackCounts) do
8  |  |  |  if track not in cache then
9  |  |  |  |  victim ← Coldest (cachedTracks)
10 |  |  |  |  TrackSwap (track, victim)
11 |  |  |  end
12 |  |  end
13 |  end
14 end
```

for a total cost of $4t_{seek}$+$8t_{rot}$. In steady state one track will be evicted for every track promoted, for a total cost of $7t_{seek} + 8t_{rot}$ per track promoted. Batching of promotions and evictions may remove several seek times from this total, but will not make great improvements due to the scattered locations of tracks being promoted or evicted. Again we note that promotions and evictions are interruptible background operations; the impact on host I/O will be a loss of throughput due to these operations, plus RMW latency for writes to non-promoted tracks.

2.4 Dynamic track mapping

Dynamic track mapping is another strategy for addressing the track flipping key limitations: (1) only neighboring tracks could be switched and (2) a small portion of bottom track must remain unflipped. It achieves this by allowing arbitrary permutations of tracks within *zones* (groups of small numbers of tracks).

To address unequal track sizes, in dynamic mapping we concatenate all bottom-track LBAs and group them in fixed-sized pseudo-tracks of approximately one physical track in size (except for the last pseudo-track). We similarly group all top-track LBAs into pseudo-tracks of the same size. These equal-sized pseudo-tracks may then be arbitrarily switched with each other. Algorithm 3 describes dynamic track mapping in more detail; as seen, we periodically check for hot bottom pseudo-tracks and swap the hottest bottom with the coldest top tracks.

Memory usage: If zones are sized to hold 256 pseudo-tracks, only 8 bits are needed for each map entry; for our 20 TB drive with almost 13M tracks this would require about 12.5 MB of memory: more than that needed for track flipping, but still modest.

Safety and crash consistency: Similar to track flipping and track caching, to persist the changes, dynamic track mapping logs the updates to the map and also writes a full checkpoint periodically.

Timing: The time required to swap a hot bottom track T with a cold top track T' in dynamic track mapping is very similar to that of track flipping. However, since pseudo-track size is not equal to physical track size, it is possible that a track cannot be read immediately after the head is placed resulting in a half rotation on average. The time required for a single swap will be:

1. $t_{seek} + 0.5t_{rot}$ to reach track T
2. $3t_{rot}$ to read tracks $T-1$, T, and $T+1$
3. t_{seek} to reach a backup region

4. $3t_{rot}$ to write backup copies of track $T-1$, T and $T+1$
5. $t_{seek}+0.5t_{rot}$ to reach track T'
6. t_{rot} to read track T'
7. $t_{seek}+0.5t_{rot}$ to return to track T
8. $3t_{rot}$ to write the contents of T' into track T and write back the contents of $T-1$ and $T+1$
9. $t_{seek}+0.5t_{rot}$ to return to track T'
10. t_{rot} to write the contents of T into track T'

Thus, the expected total cost is $5t_{seek}$+$13t_{rot}$.

3 Methodology

We evaluate the four IMR translation algorithms—naive read-modify-write (RMW), track flipping, selective track caching and dynamic track mapping— in addition to conventional disk (CMR) via trace-driven simulation. We use the CloudPhysics traces [18], a recent set of block traces from virtual machines running Linux and Windows with modern file systems and large storage volumes. The LBA ranges covered in the traces varied from tens of gigabytes to 1.5TB.

Prior work [6] has shown that older traces (e.g. the widely-used MSR Cambridge traces [13] from c. 2007) display fine-grained behavior which is very different from that exhibited by modern file systems; although this difference in behavior may not be significant in block-level systems (e.g. FTLs) that ignore spatial locality, it has been demonstrated

Algorithm 3: dynamic track mapping

```
parameter :updateFrequency, swapThreshod
variable  :ioDirection (read/write), trackPosition,
           trackNumber, writeCount, trackIdLog
           [], trackCounts [], cldstTrk, hotstTrk
1  ioDirection, trackPosition, trackNumber ← ReceiveIO()
2  Function RemapTracks() is
3  |  trackCounts [] ← Count (trackIdLog)
4  |  for every cldstTrk in Coldest (trackCounts)
   |    and hotstTrk in Hottest (trackCounts) do
5  |  |  temperatureGap = hotstTrkCntr- cldstTrkCntr
6  |  |  if temperatureGap > swapThreshod then
7  |  |  |  TrackSwap (cldstTrk, hotstTrk)
8  |  |  end
9  |  end
10 end
11 if ioDirection == write then
12 |  writeCount ++
13 |  trackIdLog.append(trackNumber)
14 |  if writeCount mod updateFrequency == 0 then
15 |  |  for every zone do
16 |  |  |  RemapTracks()
17 |  |  end
18 |  end
19 end
```

to result in significant differences in the performance of disk-based systems. The CloudPhysics corpus comprises 106 different traces; we sampled this set and selected a collection that represents different levels of read/write intensity and spatial locality. A summary of the selected workloads is shown in Table 1. The workloads range in size from about 3 to 44 million I/Os, and range from read-heavy (w08, 09% writes) to very write-heavy (w39, 95% writes).

Disk model: Our simulation assumes a 6000 RPM disk ($T_{rot} = 10$ms) with equal-sized 2 MB tracks; although crude, we argue that this model is fairly accurate in the absence of real IMR disks for comparison. Based on current trends, 2 MB is a reasonable estimate of the mean track size for a next-generation drive; however real disks have decreasing track sizes towards the inner radius of the platter, with roughly a factor of two difference between the largest and smallest tracks. Since the majority of sectors lie in the larger outer tracks, the actual variance from the mean is less than this factor of two would imply, and as modern file systems (ext4 and NTFS) do not consider track location (as opposed to locality) in placement, errors in either direction are expected to cancel out.

The primary inaccuracy introduced by this model is in track flipping: the model assumes that top and bottom tracks are of equal size, so that no remainder of the bottom track is left behind after flipping. If top tracks in a real drive have 90% the capacity of bottom tracks, this would result in up to 10% of writes to this track being classified by the simulator as top-track writes, rather than bottom-track RMW writes. Since the colder end of the track is left behind, we expect that the misclassification rate be less than 10%. However, if both track ends are equally hot, the misclassification rate will be higher. Our observation of hot-track LBA access patterns suggests that either one end is extremely hot or all LBAs are accessed evenly. At present we neither know the actual ratio of top to bottom track size in a specific real IMR drive, nor the practical range of this parameter for feasible drives; therefore this 90% figure is highly speculative. Given this uncertainty, the choice of a uniform track size is simple and not unreasonable.

Trace playback: The traces used were collected in a virtualized environment, with a high-performance multi-disk (or SSD) back-end storage system. The resulting I/O rates may be seen in the inter-arrival time CDFs in Figure 6, where half of inter-arrival times for one trace (w84) are in the 100 μS range (up to 10,000 IOPS), while 80% of writes for another trace (w35) are below 500 μS (2000 IOPS). Several approaches may be taken in adapting such a trace to a single-disk simulation. One method is to run the simulation "flat-out", ignoring inter-arrival times and launching (or queuing) each I/O as soon as possible. However since our IMR translation algorithms include background work, the resulting behavior would not be representative of system behavior for real applications.

Our goal instead is to simulate what system behavior would be if the application that produced the original trace were run against the simulated (and much slower) I/O device.

Table 1: Statistical summary of selected workloads.

workload	w08	w09	w17	w24	w26	w28	w31	w34	w39	w43	w46	w48	w56	w61	w84	w87	w106
I/O count (M)	44.3	49.6	31.3	27.1	26.5	19.7	21.1	19.5	17.9	15.6	11.5	14	10.8	9.8	4.8	3.7	3.2
write ratio	0.09	0.55	0.78	0.11	0.58	0.33	0.16	0.23	0.97	0.51	0.62	0.42	0.95	0.50	0.86	0.79	0.82

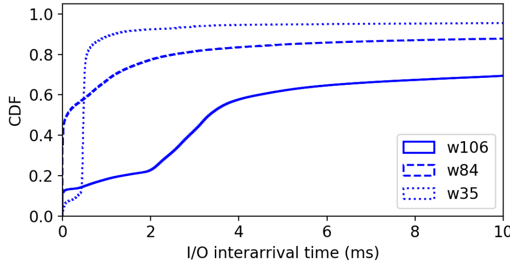

Figure 6: CDF of I/O inter-interval times in a few workloads.

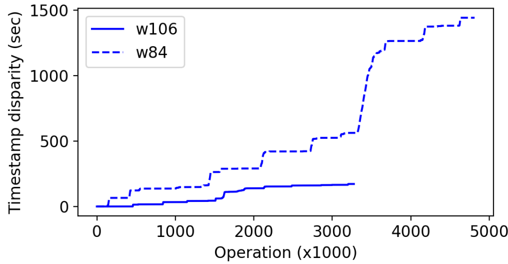

Figure 7: "Stretching" of original trace timestamps for IMR simulation.

Accurate simulation of such behavior requires information on application CPU usage and I/O dependencies which are not available in the original traces. Although recent work [5] provides mechanisms for inferring I/O dependencies given a trace containing both initiation and completion times for I/Os, very few of the traces we used contained this information.

Instead we consider a fixed-queue model, with a queue size of 64; based on inspection of the traces we believe this is an intermediate point between the lower effective queue depths seen with many application-initiated I/Os, and the very high degree of parallelism with which I/Os are initiated by the virtual memory system. I/O inter-arrival times are preserved when inserting items into the queue until it is filled, and then further I/Os are blocked until a position in the queue opens; in other words, the inter-arrival time between I/Os N and N+1 is the maximum of the original trace inter-arrival time and the time for the queue to drain by 1. The resulting I/O performance reflects a combination of individual I/Os and queuing delays due to device throughput limitations. As an example, in Figure 7 we see this "time dilation" for two workloads with naive RMW—in one case trace completion is delayed by about 150s, and in the other by over 1440s.

3.1 Disk model details

I/O latency: In our simulation, I/O latency includes host and device queuing, seek time, rotational delay and transfer time. Seek time (T_{seek}) is calculated from the source and destination track locations using the following equation proposed by Shafaei [16], assuming minimum and maximum seek times of 2 and 20 ms and calculating α accordingly:

$$t_{seek}(trk_{src}, trk_{des}) = \alpha * \sqrt{|trk_{src} - trk_{des}|} + t_{seek_{min}} \tag{1}$$

Rotational delay for I/Os on different tracks is assumed to be uniformly distributed between 0 and 1 rotation ($T_{rotation}$); for deterministic simulation we assume a constant value of a half rotation, giving a total I/O latency of:

$$t_{I/O} = t_{seek} + \frac{1}{2} t_{rotation} + t_{transfer} \tag{2}$$

We note that IOs are split at boundaries in case they touch more than a track. The full list of drive specifications and experiment configurations is shown in Table 2.

4 Evaluation

In this section we evaluate five alternatives—conventional disk (CMR), IMR with naive read-modify-write (RMW), IMR with track flipping, IMR with selective track caching and IMR with dynamic track mapping—by measuring I/O latencies and write amplification factor (WAF). Summary results for all traces and algorithms are shown in Figure 8 (write amplification) and Figure 9 (latency).

All track flipping, selective track caching and dynamic track mapping are seen to give substantial improvements in write

Table 2: Experimental parameters and drive specification.

drive specification		
track size	drive cache size	rotation delay
2MB	100MB	10 ms
dynamic track mapping and flipping configuration		
update frequency	hot/cold threshold	max flips
20K write ops	50	50
selective track caching configuration		
update frequency	track cache size	cache location
20K write ops	100 tracks	OD

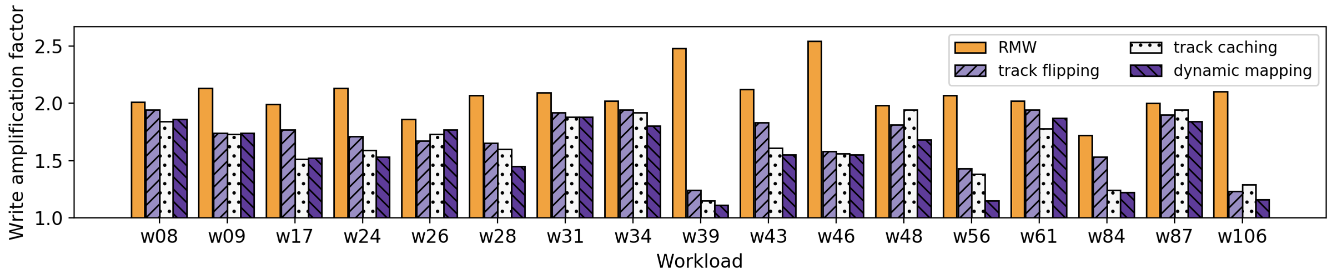

Figure 8: IMR write amplification by workload and translation layer.

(b) 90th percentile latency

Figure 9: Mean and tail latency for 17 workloads: CMR, RMW, track flipping, track caching and dynamic track mapping.

amplification when compared to naive read-modify-write, by a factor of 2 or more in over half of the cases; in no case is performance degraded. As expected, dynamic track mapping shows the best performance in most cases as it has the minimum limitations among the proposed approaches. For several workloads it reduces the write amplification by a factor of 2 or more; in some cases (e.g., w56, w39 and w106) write amplification is nearly eliminated.

Results for mean latency are more mixed. In several cases (e.g., w09, w17, w39, w46, w56, w61 and w87) IMR read-modify-write latencies were noticeably higher than for the conventional drive. For w56 this excess latency was virtually eliminated by track flipping, track caching or dynamic track mapping. For some others (e.g., w17, w39, w46) at least one of the approaches gave a significant reduction (more than 2x) in IMR latency, while still remaining about twice that of conventional. For w09 and w87, however, latency improvements from dynamic track mapping were modest, with performance still significantly worse than CMR.

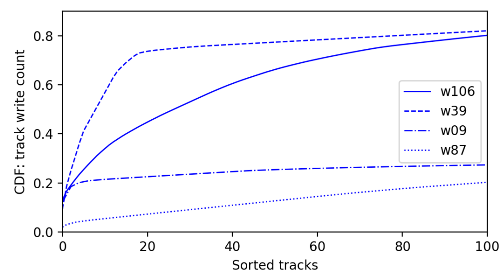

Figure 10: CDF of track write counts for workloads with highest (w106 and w39) and lowest (w87 and w87) WAF improvement with track flipping and/or selective track caching.

In Figure 10 we explore one possible reason for lower improvement for traces w09 and w87: the overall number of hot tracks. We compare these traces with w106 and w39, the traces that show the greatest improvements in write amplification when track flipping or track caching is used (see

Figure 8). We see that a high fraction of writes in w106 are to the hottest 100 tracks, and that half of the writes in w39 are to a handful of tracks. In contrast the "working set" of hot tracks for w09 and w87 appears to be very large, with only around 20% and 15% of writes going to the hottest 100 tracks, respectively. The track cache used in our experiments (100 tracks) would do almost nothing to help in this case, and if many writes are to tracks which are written only a few times at most, then the gain from flipping them will not outweigh the cost.

As with mean latency, results for tail latency (Figure 9b) are also mixed, although worse. In a few cases (e.g., w39 and w56) RMW increases tail latency by a factor of tens of thousands. That is because with CMR most writes in these cases appear to complete in the write cache which results in a mean latency of about 0.1ms, and there is just enough idle time for them to be flushed to disk; however with RMW the disk cannot keep up during idle time, so the queue fills and stays that way causing mean latency of about 2.4s. Overall tail latency is increased by more than 4x across majority of the workloads. In the worst cases (w39, w56) the proposed algorithms limit the relative increase in tail latency to double digits, but is still very high. In about half the cases tail latency with dynamic track mapping is similar to that of CMR; however in the remainder it is significantly worse.

For both mean and tail latency, there are a few workloads (w08, w24, w31 and w43) that are not affected by IMR and accordingly no improvement is observed when the proposed algorithms are applied. Besides w43 with almost 51% of write operations, the rest of the workloads are read-heavy traces and therefore are less prone to significant performance penalty due to IMR.

To examine further, in Figure 12 we see CDFs of I/O latencies for traces w46 and w28. In each case IMR read-modify-write results in high-latency I/Os due to a combination of operation latency and queuing delays due to reduced throughput; roughly 2/3 of writes were slowed in both cases. We note that there are some other cases e.g., w56 with fewer writes (roughly 10%) being affected. Track flipping, track caching and dynamic track mapping are all able to improve the w28 and w46 performance considerably, but a significant fraction of writes (roughly 25%) still suffer excessive latency. Our observations show that for the case w56 the three improved algorithms are all able to eliminate the excess latencies, resulting in performance comparable to a conventional drive.

The impact of IMR overhead on throughput can be approximated by looking at the issue time expansion during the simulation run; this indicates the periods at which the device was unable to keep up with the I/O trace, and by how much. In Figure 13 we see issue time disparity vs. I/O count for traces w46 and w28. We note that for w46 all dynamic track mapping, and to a slightly lesser extent track caching and track flipping, result in significantly improved throughput. For w28, dynamic track mapping shows a considerable throughput improvement; track caching and track flipping show a smaller improvement. We also note that throughput of the simulated algorithms would increase with larger I/Os, as read-modify-writes would be amortized over larger I/O sizes.

Track flipping only works if hot tracks are adjacent to cold tracks; if hot regions on the disk are substantially larger than a track, this might not be the case. In Figure 4 of Section 2.2 we saw that this was the case for trace 17; however in Figure 11 we see the same analysis for w87; although the hottest few tracks stand alone, many tracks with very high write counts are surrounded by tracks of similar hotness.

5 Related work

Interlaced Magnetic Recording [9] is a new storage technology using HAMR (Heat assisted magnetic recording) [4, 12] and track overlap (the technique on which SMR [19] is based) to achieve higher areal density than possible with either approach alone [3]. Numerous works have characterized [1] and modeled [15, 16] SMR performance; however due to fundamental differences in track layout and write constraints such work is not directly applicable to IMR.

While only a limited number of translation layers and data management techniques have been proposed for IMR in the two years since the original work became public [20], a wide range of file systems and translation layers have been proposed for SMR, such as Cassuto's indirection system [2], SMaRT [8] from He and Du, Shafaei's Virtual Guard [14], and FSTL [7]. Cassuto et al. propose a set associative persistent cache to hold updated sectors. SMaRT [8] proposes using a track-based dynamic mapping. Shafaei et al. propose a track-based static mapping translation layer which caches tracks containing at-risk data, rather than the track targeted by the I/O. Hajkazemi et al. [7] propose an LBA-based translation layer based on dynamic mapping. Since the write restrictions in SMR are a strict superset of IMR restrictions, SMR translation layers could in fact be applied to IMR; however this would ignore the performance improvements possible due to lessened write restrictions.

To the best of our knowledge, the data management design introduced by Wu et al. [20] is the only published work on IMR translation layers to date. The authors propose *Top-Buffer*, a technique utilizing unallocated top tracks of each track-group (a small set of tracks interlaced with top tracks) as a buffer to store LBA updates corresponding to bottom tracks. Moreover they suggest *Block Swapping*, a technique to swap bottom hot LBAs with cold ones within a track-group. Our work differs in that it is targeted for in-disk implementation, in a restricted-memory environment, while the memory requirements for Wu et al.'s algorithm are beyond the capabilities of a drive controller.

6 Conclusion

Interlaced magnetic recording is still a new—or even speculative—technology, and we cannot be sure of its precise characteristics until real prototypes are available. However, when such prototypes arrive, algorithms will be needed to cope with the IMR write restrictions, and due to the track-based nature of the restrictions, those algorithms will need to run in the memory-limited environment of the drive controller.

We quantify the performance of the naive read-modify-write algorithm for IMR bottom track writes, showing that it is significantly more costly than assumed in prior work, and show via trace-driven simulations that for some workloads its performance is comparable to that of a conventional disk, but that it is worse, sometimes catastrophically so, for others. We present three algorithms to reduce the frequency of IMR bottom-track writes: *track flipping*, *selective track caching* and *dynamic track mapping*, with sufficiently modest memory requirements to be readily implemented in drive controllers. These algorithms are shown to improve I/O amplification significantly for almost all workloads examined, and to improve latency for some—but not all—of the workloads which performed poorly with IMR read-modify-write. Further research is needed to determine whether extensions of this work (e.g. track flipping+caching) will yield conventional drive-level performance for IMR with acceptable memory cost.

Acknowledgment

We would like to thank Irfan Ahmad and CloudPhysics for the use of their traces, our shepherd William Jannen, and the anonymous reviewers for their valuable suggestions.

Your Coflow Has Many Flows: Sampling Them for Fun and Speed

Abstract

Coflow scheduling improves data-intensive application performance by improving their networking performance. State-of-the-art online coflow schedulers in essence approximate the classic Shortest-Job-First (SJF) scheduling by learning the coflow *size* online. In particular, they use multiple priority queues to simultaneously accomplish two goals: to sieve long coflows from short coflows, and to schedule short coflows with high priorities. Such a mechanism pays high overhead in learning the coflow size: moving a large coflow across the queues delays small and other large coflows, and moving similar-sized coflows across the queues results in inadvertent round-robin scheduling.

We propose PHILAE, a new online coflow scheduler that exploits the spatial dimension of coflows, *i.e.,* a coflow has many flows, to drastically reduce the overhead of coflow size *learning*. PHILAE pre-schedules sampled flows of each coflow and uses their sizes to estimate the average flow size of the coflow. It then resorts to Shortest Coflow First, where the notion of shortest is determined using the learned coflow sizes and coflow contention. We show that the sampling-based learning is robust to flow size skew and has the added benefit of much improved scalability from reduced coordinator-local agent interactions. Our evaluation using an Azure testbed, a publicly available production cluster trace from Facebook shows that compared to the prior art Aalo, PHILAE reduces the coflow completion time (CCT) in average (P90) cases by 1.50× (8.00×) on a 150-node testbed and 2.72× (9.78×) on a 900-node testbed. Evaluation using additional traces further demonstrates PHILAE's robustness to flow size skew.

1 Introduction

1.1 Motivation

In big data analytics jobs, speeding up the communication stage where the data is transferred between compute nodes is important to speed up the jobs. However, improving network level metrics such as flow completion time may not translate into improvements at the application level metrics such as job completion time. The coflow abstraction [18] was proposed to bridge such a gap. The abstraction captures the collective network requirements of applications, as reduced coflow completion time (CCT) can directly lead to faster job completion time [20, 24].

There have been a number of efforts on network designs for coflows [7, 21, 27] that assume complete prior knowledge of coflow sizes (The coflow size is defined as the total size of its constituent flows.). However, in many practical settings, coflow characteristics are not known a priori. For example, multi-stage jobs pipeline data from one stage to the next as soon as the data is generated, which makes it difficult to know the size of each flow [22, 40]. A recent study [40] shows various other reasons why it is not very plausible to learn flow sizes from applications, for example, learning flow sizes from applications requires changing either the network stack or the applications.

Scheduling coflows in such *non-clairvoyant* settings, however, is challenging. The major challenge in developing an effective non-clairvoyant coflow scheduling scheme has centered around how to learn the coflow sizes online quickly and accurately, as once the coflow sizes (bytes to be transferred) can be estimated, one can apply variations of the classic Shortest-Job-First (SJF) algorithm such as Shortest Coflow First [21] or apply an LP solver (*e.g.,* [7]).

State-of-the-art online non-clairvoyant schedulers such as Saath [30], Gravtion [29] and Aalo [19] in essence learn coflow sizes and approximate SJF using discrete priority queues, where all newly arriving coflows start from the highest priority queue, and move to lower priority queue as they send more data (without finishing), *i.e.,* cross the per-queue thresholds. In this way, the smaller coflows finish in high priority queues, while the larger coflows gradually move to the lower priority queues where they finish after smaller coflows.

To realize the above idea in scheduling coflows which have flows at many network ports, *i.e.,* in a distributed setting, Aalo uses a global coordinator to assign coflows to logical priority queues, and uses the total bytes sent by all flows of a coflow as its logical "length" in moving coflows across the queues. The logical priority queues are mapped to local priority queues at each port, and the individual local ports then schedule the flows in its local priority queues, *e.g.,* by enumerating flows from the highest to lowest priority queues and using FIFO to order the flows within each queue.

In essence, Aalo learns coflow sizes by actually scheduling the coflow, a "try and miss" approach to approximate SJF. As coflow sizes are not known, in each queue, Aalo schedules each coflow for a fixed amount of data (try). If the coflow does not finish (miss), it is demoted to a lower priority queue.

Afterwards, such a coflow will no longer block coflows in higher priority queues.

Using multiple priority queues to learn the relative coflow sizes of coflows this way, however, negatively affects the average CCT and the scalability of the coordinator:

(1) Intrinsic queue-transit overhead: Every coflow that Aalo transits through the queues before reaching its final queue worsens the average CCT because during transitions, such a coflow effectively *blocks other shorter* coflows in the earlier queues it went through, which would have been scheduled before this coflow starts in a perfect SJF.

(2) Overhead due to inadvertent round-robin: Although Aalo attempts to approximate SJF, it inadvertently ends up doing *round-robin* for coflows of similar sizes as it moves them across queues. Aalo assigns a *fixed threshold of data transfer* for each coflow in each queue. Assume there are "N" coflows in a queue that do not finish in that queue. Aalo schedules one coflow (chosen using FIFO) and demotes it to a lower priority queue when the coflow reaches the data threshold. At that point, the next coflow from the same queue is scheduled, which joins the previous coflow at a lower priority queue after exhausting its quantum, and this cycle continues as coflows of similar sizes move through the queues. Effectively, these coflows experience the round-robin scheduling which is known to have the worst average CCT [39], when jobs are of similar sizes.

(3) Limited scalability from frequent updates from local ports: To support the try-and-error style learning, the coordinator requires frequent updates from all local ports of the bytes sent for each coflow in order to move coflows across multiple queues timely. This results in high load on the central coordinator from receiving frequent updates and calculating and sending new rate allocations, which limits the scalability of the overall approach.

Empirical measurement We quantify the coflow size *learning overhead* of Aalo, defined as the portion of the bytes of a coflow that has been transferred (or the fraction of its CCT spent in doing so) before reaching its correct queue, using a trace from Facebook clusters [4] (see detailed methodology in §8). Figure 1 shows that 40% of the coflows that moved beyond the initial queue reached the correct priority queue after spending more than 20% of their CCT moving across early queues.

1.2 Our Contribution

We propose Philae, a new non-clairvoyant coflow scheduler with a dramatically different approach to learning coflow sizes to enable online SJF. To leverage optimal scheduling SJF in coflow scheduling, it is vital to learn the coflow sizes quickly and accurately. Philae achieves this objective by exploiting the *spatial dimension* of coflows, *i.e.,* a coflow typically consists of many flows, via *sampling*, a highly effective technique used in large-scale surveys [34]. In particular, Philae pre-schedules sampled flows, called *pilot flows*, of each coflow and uses their measured size to estimate the coflow size. It then resorts to SCF using the estimated job size.

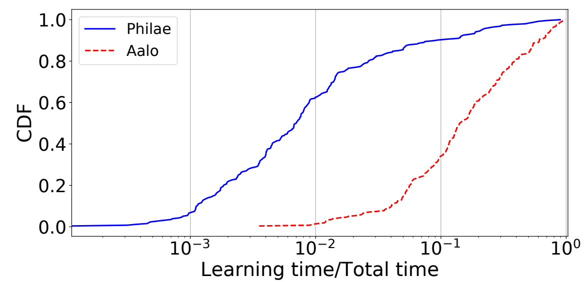

Figure 1: CDF of learning overhead per coflow, *i.e.,* the time to reach the correct priority queue as a fraction of CCT, excluding coflows directly scheduled by Philae or finish in Aalo's first queue.

Intuitively, such a sampling scheme avoids all three sources of overhead in Aalo – Once the coflow sizes are learned, the coflows are assigned to the correct queues, which avoids the intrinsic queue-transit and round-robin effects. Further, a sampling-based design has an important benefit – it offers much higher scalability than priority-queue-based learning in Aalo. This is because unlike Aalo, after estimating the coflow size, Philae clients do not need to send periodic updates of bytes sent-so-far to the centralized coordinator.

Developing a complete non-clairvoyant coflow scheduler based on the simple sampling idea raises three questions: (1) Why is sampling more efficient than the priority-queue-based coflow size learning? (2) Will sampling be effective in the presence of skew of flow sizes? (3) How to design the complete scheduler architecture? We systematically address these questions with design rational, theoretical analysis, system design, prototyping, and extensive evaluation.

In summary, this paper makes the following contributions:

(1) Using a production datacenter trace from Facebook, we show that the prior art scheduler Aalo spends substantial amount of time and network bandwidth in learning coflow sizes, which negatively affects the CCT of coflows.
(2) We propose the novel idea of applying sampling in the spatial dimension of coflow to significantly reduce the overhead of online learning coflow sizes.
(3) We present theoretical underpinning explaining why sampling remains effective in the presence of flow size skew.
(4) We present the design and implementation of Philae.
(5) We extensively evaluate Philae via simulations and testbed experiments, and show that compared to the prior art, the new design reduces the average CCT by 1.51× for the Facebook coflow trace and by 1.36× for a trace with properties similar to a Microsoft production cluster.
(6) The CCT improvement mainly stems from reduced coflow size learning overhead. Philae reduces the median latency and data sent in finding the right queue for coflows in Aalo by 19.0× and 20.0×, respectively (§8.2).

2 Background and Problem Statement

We start with a brief review of the coflow abstraction and the need for non-clairvoyant coflow scheduling. We then state the network model and problem formulation.

Coflow abstraction In data-parallel applications such as Hadoop [1] and Spark [2], the job completion time heavily depends on the completion time of the communication stage [12, 20]. The coflow abstraction [18] was proposed to speed up the communication stage to improve application performance. A coflow is defined as a set of flows between several nodes that accomplish a common task. For example, in map-reduce jobs, the set of all flows from all map to all reduce tasks in a single job forms a typical coflow. The coflow completion time (CCT) is defined as the time duration between when the first flow arrives and the last flow completes. In such applications, improving CCT is more important than improving individual flows' completion time (FCT) for improving the application performance [19, 21, 24, 29, 30].

Non-clairvoyant coflows Data-parallel directed acyclic graphs (DAGs) typically have multiple stages which are represented as multiple coflows with dependencies between them. Recent systems (*e.g.,* [3, 22, 28, 36]) employ optimizations that pipeline the consecutive computation stages which removes the barrier at the end of each coflow, making knowing flow sizes of each coflow beforehand difficult. Thus in this paper, we focus on *non-clairvoyant* coflow scheduling which do not assume knowledge about coflow characteristics such as flow sizes upon coflow arrival.

Non-blocking network fabric We assume the same non-blocking network fabric model in recent network designs for coflows [7, 19, 21, 29, 30], where the datacenter network fabric is abstracted as a single non-blocking switch that interconnects all the servers, and each server (computing node) is abstracted as a network port that sends and receives flows. In such a model, the ports, *i.e.,* server uplinks and downlinks, are the only source of contention as the network core is assumed to be able to sustain all traffic injected into the network. We note that the abstraction is to simplify our description and analysis, and is not required or enforced in our evaluation.

Problem statement Our goal is to *develop an efficient non-clairvoyant coflow scheduler that optimizes the communication performance, in particular the average CCT, of data-intensive applications without prior knowledge, while guaranteeing starvation freedom and work conservation and being resilient to the network dynamics.* The problem of non-clairvoyant coflow scheduling is NP-hard because coflow scheduling even assuming all coflows arrive at time 0 and their size are known in advance is already NP-hard [21]. Thus practical non-clairvoyant coflow schedulers are approximation algorithms. Our approach is to dynamically prioritize coflows by efficiently learning their flow sizes online.

3 Key Idea

Our new non-clairvoyant coflow scheduler design, Philae, is based on a key observation about coflows that a coflow has a *spatial dimension, i.e.,* it typically consists of many flows. We thus propose to explicitly learn coflow sizes online by using *sampling*, a highly effective technique used in large-scale surveys [34]. In particular, Philae preschedules sampled flows, called *pilot flows*, of each coflow and uses their measured sizes to estimate the coflow size. It then resorts to SJF or variations using the estimated coflow sizes.

Developing a complete non-clairvoyant coflow scheduler based on the simple sampling idea raises three questions:

(1) Why is sampling more efficient than the priority-queue-based coflow size learning? Would scheduling the remaining flows after sampled pilot flows are completed adversely affect the coflow completion time?

(2) Will sampling be effective in the presence of skew of flow sizes?

(3) How to design the complete scheduler architecture?

We answer the first two questions below, and present the complete architecture design in §4.

3.1 Why is sampling more efficient?

Scheduling pilot flows first before the rest of the flows can potentially incur two sources of overhead. First, scheduling pilot flows of a newly arriving coflow consumes port bandwidth which can delay other coflows (with already estimated sizes). However, compared to the multi-queue based approach, the overhead is much smaller for two reasons: (1) Philae schedules only a small subset of the flows (*e.g.,* fewer than 1% for coflows with many flows). (2) Since the CCT of a coflow depends on the completion of its last flow, some of its earlier finishing flows could be delayed without affecting the CCT. Philae exploits this observation and schedules pilot flows on the least-busy ports to increase the odds that it only affects earlier finishing flows of other coflows.

Second, scheduling pilot flows first may elongate the CCT of the newly arriving coflow itself whose other flows cannot start until the pilot flows finish. This is again typically insignificant for two reasons: (1) A coflow (*e.g.,* from a MapReduce job) typically consists of flows from all sending ports to all receiving ports. Conceptually, pre-scheduling one out of multiple flows from each sender may not delay the coflow progress at that port, because all flows at that port have to be sent anyway. (2) Coflow scheduling is of high relevance in a busy cluster (when there is a backlog of coflows in the network), in which case the CCT of coflow is expected to be much higher than if it were the only coflow in the network, and hence the piloting overhead is further dwarfed by a coflow's actual CCT.

3.2 Why is sampling effective in the presence of skew?

The flow sizes within a coflow may vary (*skew*). Intuitively, if the skew across flow sizes is small, sampling even a small number of pilot flows will be sufficient to yield an accurate estimate. Interestingly, even if the skew across flow sizes is large, our experiment indicates that sampling is still highly effective. In the following, we give both the intuition and theoretical underpinning for why sampling is effective.

Consider, for example, two coflows and the simple setting where both coflows share the same set of ports. In order to improve the average CCT, we wish to schedule the shorter coflow ahead of the longer coflow. If the total sizes of the two coflows are very different, then even a moderate amount of estimation error of the coflow sizes will not alter their ordering. On the other hand, if the total sizes of the two coflows are close to each other, then indeed the estimation errors will likely alter their ordering. However, in this case since their sizes are not very different anyway, switching the order of these two coflows will not significantly affect the average CCT.

Analytic results. To illustrate the above effect, we show that the gap between the CCT based on sampling and assuming perfect knowledge is small, even under general flow size distributions. Specifically, coflows C_1 and C_2 have cn_1 and cn_2 flows, respectively. Here, we assume that n_1 and n_2 are fixed constants. Thus, by taking c to be larger, we will be able to consider wider coflows. Assume that each flow of C_1 (correspondingly, C_2) has a size that is distributed within a bounded interval $[a_1, b_1]$ ($[a_2, b_2]$) with mean μ_1 (μ_2), *i.i.d.* across flows. However, the exact distributions can be arbitrary. Let T^c be the total completion time when the exact flow sizes are known in advance. Let $\tilde{T}^c$ be the average CCT by sampling m_1 and m_2 flows from C_1 and C_2, respectively. Without loss of generality, we assume that $n_2\mu_2 \geq n_1\mu_1$. Then, using Hoeffding's Inequality, we can show that,

$$\lim_{c\to\infty} \frac{\tilde{T}^c - T^c}{T^c} \leq 4\exp\left[-\frac{2(n_2\mu_2 - n_1\mu_1)^2}{\left(\frac{n_2(b_2-a_2)}{\sqrt{m_2}} + \frac{n_1(b_1-a_1)}{\sqrt{m_1}}\right)^2}\right] \frac{n_2\mu_2 - n_1\mu_1}{n_2\mu_2 + 2n_1\mu_1} \tag{1}$$

(Note that here we have used the fact that, since both coflows share the same set of ports and c is large, the CCT is asymptotically proportional to the coflow size.)

Equation (1) can be interpreted as follows. First, due to the first exponential term, the relative gap between $\tilde{T}^c$ and T^c decreases as $b_1 - a_1$ and $b_2 - a_2$ decrease. In other words, as the skew of each coflow decreases, sampling becomes more effective. Second, when $b_1 - a_1$ and $b_2 - a_2$ are fixed, if $n_2\mu_2 - n_1\mu_1$ is large (i.e., the two coflow sizes are very different), the value of the exponential function will be small. On the other hand, if $n_2\mu_2 - n_1\mu_1$ is close to zero (i.e., the two coflow sizes are close to each other), the numerator on the second term on the right hand side will be small. In both cases, the relative gap between $\tilde{T}^c$ and T^c will also be small, which is consistent with the intuition explained earlier. The largest gap occurs when $n_2\mu_2 - n_1\mu_1$ is on the same order as $\frac{n_2(b_2-a_2)}{\sqrt{m_2}} + \frac{n_1(b_1-a_1)}{\sqrt{m_1}}$. Finally, although these analytical results assume that both coflows share the same set of ports, similar conclusions on the impact of estimation errors due to sampling also apply under more general settings.

The above analytical results suggest that, when c is large, the relative performance gap for CCT is a function of the number of pilot flows sampled for each coflow, but is independent of the total number of flows in each coflow. In practice, large coflows will dominate the total CCT in the system. Thus, these results partly explain that, while in our experiments the number of pilot flows is never larger than 1% of the total number of flows, the performance of our proposed approach is already very good.

Finally, the above analytical results do not directly tell us how to choose the number of pilot flows, which likely depends on the probability distribution of the flow size. In practice, we do not know such distribution ahead of time. Further, while choosing a larger number of pilot flows reduces the estimation errors, it also incurs higher overhead and delay. Therefore, our design (§4) needs to have practical solutions that carefully address these issues.

4 Philae Design

In this section, we present the detailed design of Philae, which addresses three design challenges: (1) *Coflow size estimation:* How to choose and schedule the pilot flows for each newly arriving coflow? (2) *Starvation avoidance:* How to schedule coflows after size estimation using variations of SJF that avoid starvation? (3) *Coflow scheduling:* How to schedule among all the coflows with estimated sizes?

4.1 Philae architecture

Fig. 2 shows the Philae architecture. Philae models the entire datacenter as a single big-switch with each computing node as an individual port. The scheduling task in Philae is divided among (1) a central coordinator, and (2) local agents that run on individual ports. A computing framework such as Spark [42] first registers (removes) a coflow when a job arrives (finishes). Upon a new coflow arrival, old coflow completion, or pilot flow completion, the coordinator calculates a new coflow schedule, which includes (1) coflows that are to be scheduled in the next time slot, and (2) flow rates for the individual flows of a coflow, and pushes this information to the local agents which use this information to allocate their bandwidth. The local agents will follow the current schedule until they receive a new schedule.

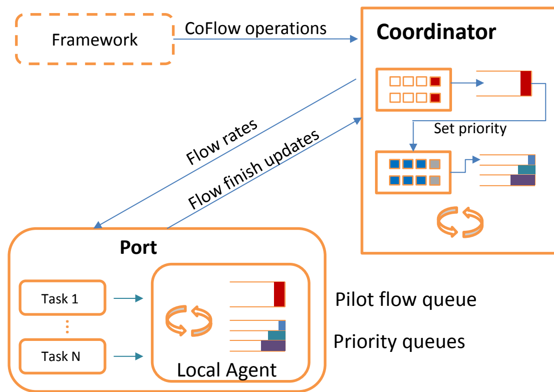

Figure 2: PHILAE architecture.

4.2 Sampling pilot flows

As discussed in §3, PHILAE estimates the size of a coflow online by actually scheduling a subset of its flows (*pilot flows*) at their ports. We do not schedule the flows of a coflow other than the pilot flows until the completion of the pilot flows in order to avoid unnecessary extra blocking of other potentially shorter coflows.

How many pilot flows? When a new coflow arrives, PHILAE first needs to determine the number of pilot flows. As discussed at the end of §3, the number of pilot flows affects the trade-off between the coflow size estimation accuracy and scheduling overhead. For coflows with skewed flow sizes, accurately estimating the total coflow size potentially requires sampling the sizes of many pilot flows. However, scheduling pilot flows has associated overhead, *i.e.,* if the coflow turns out to be a large coflow and should have been scheduled to run later under SJF.

We explore several design options for choosing the number of pilot flow. Two natural design choices are using a constant number of pilot flows or a fixed fraction of the total number of flows of a coflow. In addition, we observe that typical coflows consist of flows between a set of senders (*e.g.,* mappers) and a set of receivers (*e.g.,* reducers) [23]. We thus include a third design choice of a fixed fraction of sending ports. This design also spreads the pilot flows to avoid having multiple pilot flows contending for the same sending ports. We empirically found that (§8.2) limiting the pilot flows to 5% to 10% of the number of its sending ports (*e.g.,* mappers in a MapReduce coflow) strikes a good balance between estimation accuracy and overhead. We note the total number of flows sampled in this case is still under 1%.

Finally, we *estimate the total coflow size as* $S = f_i \cdot N$, where N is the number of flows in a coflow, and f_i is the average size of the sampled pilot flows.

Which flows to probe? Second, PHILAE needs to decide which ports to schedule the chosen number of probe flows for a coflow. For this, we use a simple heuristic where, upon the arrival of a new coflow, we select the ports for its pilot flows that are least busy, *i.e.,* having pilot flows from the least number of other coflows. PHILAE starts with the least busy sending port and iterates over receiving ports starting with the least busy receiving port and assigns the flow if it exists. It then updates the statistics for the number of pilot flows scheduled at each port and repeats the above process. Such a choice will likely delay fewer coflows when the pilot flows are scheduled and hence reduce the elongation on their CCT. We note that such an online heuristic may not be optimal; more sophisticated algorithms can be derived by picking ports for multiple coflows together. However, we make this design choice for its simplicity and low time complexity to ensure that the coordinator makes fast decisions.

How to schedule pilot flows? In PHILAE, we prioritize the pilot flows of a new coflow over existing flows to accelerate learning the size of the new coflow. In particular, at each port, pilot flows have high priority over non-pilot flows. If there are multiple outstanding pilot flows (of different coflows) at a port, PHILAE schedules them in the FIFO order.

4.3 Coflow scheduling with starvation avoidance

Once the sizes of coflows are learned, we can apply variations of the SJF policy to schedule them. However, it is well known that such policies can lead to starvation.

There are many ways to mitigate the starvation issue. However, a subtlety arises where *even slight difference in how starvation is addressed can result in different performance.* For example, the multiple priority queues in Aalo has the benefit of ensuring progress of all coflows, but assigning different time-quanta to different priority queues can result in different average CCT for the same workload. To ensure the fairness of performance comparison with Aalo, we need to ensure that both PHILAE and Aalo provide the same level of starvation freedom (or progress measure).

For this reason, in this paper, we inherit the multiple priority queue structure from Aalo for coflow scheduling. As in Aalo, PHILAE sorts the coflows among multiple priority queues. In particular, PHILAE uses N queues, Q_0 to Q_{N-1}, with each queue having lower queue threshold Q_q^{lo} and higher threshold Q_q^{hi}, where $Q_0^{lo} = 0$, $Q_{N-1}^{hi} = \infty$, $Q_{q+1}^{lo} = Q_q^{hi}$, and the queue thresholds grow exponentially, *i.e.,* $Q_{q+1}^{hi} = E \cdot Q_q^{hi}$.

The overall coflow scheduling in PHILAE works as follows. After the coflow size is estimated using pilot flows, PHILAE assigns the coflow to the priority queue using inter-coflow policies discussed in §4.4. Within a queue, we use FIFO to schedule coflows. Lastly, we use weighted sharing of network bandwidth among the queues, where a priority queue receives a network bandwidth based on its priority. As in Aalo, the weights decrease exponentially with decrease in the priority of the queues.

Using FIFO within the priority queue and weighted fair sharing among the queues together ensure the same starva-

tion freedom and thus meaningful performance comparison between PHILAE and Aalo [19].

4.4 Inter-coflow scheduling policies

In PHILAE, we explore four different scheduling policies based on different combinations of coflow size and contention, two size-based policies (*A, B*) as in Aalo, a contention-based, similar to the intra-queue policy used in Saath [30] (*C*), and a new contention-and-length-based policy (*D*):

(A) Smallest job first: Coflows are sorted based on coflow size ($l \cdot n$).

(B) Smallest remaining data first: Coflows are sorted based on remaining data ($l \cdot n - d$).

(C) Least contention first: Coflows are sorted based on their contention (c).

(D) Least length-weighted total-port contention first: Coflows are sorted based on the sum of port-wise contention times estimated flow length $\sum_p c^p \cdot l$.

We use the following parameters of a coflow to define the metrics in scheduling algorithms: (1) average flow length (l) from piloting, (2) number of flows (n), (3) number of sender and receiver ports (s,r), (4) total amount of data sent so far (d), (5) contention (c), defined as the number of other coflows sharing any ports with the given coflow, and (6) port-wise contention (c^p), defined as the number of other coflows blocked at a given port p.

PHILAE uses Policy D by default, as it results in the least average CCT (§8). For all policies, we continue to use the priority-queue based scheduling, and the algorithms only differ in what metric they use in assigning coflows to the priority queues. In contrast, Aalo does not handle inter-coflow contention, and uses the total bytes sent so far (d) to move coflows across multiple priority queues.

4.5 Rate allocation

Once the scheduling order of the coflows is determined, we need to determine the rates for the individual flows at each port. First, since we want to quickly finish the pilot flow, at any port that has pilot flows, PHILAE assigns the *entire* port bandwidth to the pilot flows. For the remaining ports, as discussed in §4.3, across multiple queues, PHILAE assigns weighted shares of the port bandwidth, by assigning them varying numbers of scheduling intervals according to the weights assigned to each priority queues.

Second, at each scheduling interval, PHILAE assigns rates for the flows of the coflow in the head of the FIFO queue as follows. It assigns equal rates at all the ports containing its flows as there is no benefit in speeding-up its flows at certain ports when its CCT depends on the slowest flow. At each port, we could use max-min fairness to schedule the individual flows of the coflow (to different receivers), and then assign the rate of the slowest flow to all the flows in the coflow. Afterwards, the port-allocated bandwidths are incremented accordingly at the coordinator, which then allocates rates for the next coflow in the same FIFO queue, and so on.

Though the above max-min approach has the advantage of minimizing bandwidth wastage, it slows down the coordinator which has to iterate over many flows. In our experiments, we used a simple scheme where we assign the *entire* bandwidth at the sender and receiver ports to one flow of the coflow at the head of the FIFO queue at a time. We found that this simple scheme has very marginal effect on CCTs but makes the rate assignment process considerably faster.

4.6 Additional design issues

Thin coflow bypass Recall that, in PHILAE, when a new coflow arrives, PHILAE only schedules its pilot flows. All other flows of that coflow are delayed until the pilot flows finish and coflow size is known. However, such a design choice can inadvertently lead to higher CCTs for coflows, particularly for thin coflows, *e.g.,* a two-flow coflow would end up serializing scheduling its two flows, one for the piloting purpose.

To avoid CCT degradations for thin coflows, we schedule all flows of a coflow if its width is under a threshold (set to 7 in PHILAE; §8.6 provides sensitivity analysis for thresholds).

Failure tolerance and recovery Cluster dynamics such as stragglers or node failure can delay some of the flows of a coflow or start new flows, increasing their CCT. The PHILAE design automatically self-adjusts to speed up coflows that are affected by cluster dynamics using the following mechanisms: (1) It adjusts the coflow size as the amount of data left by the coflow, which is essentially the difference between the size calculated using pilot flows and amount of data already sent. (2) It calculates contention only on the ports that have unfinished flows.

Work Conservation By default, PHILAE schedules non-pilot flows of a coflow only after all its pilot flows are over. This can lead to some ports being idle where the non-pilot flows are waiting for the pilot flows to finish. In such cases, PHILAE schedules non-pilot flows of coflows which are still in the sampling phase at those ports. In work conservation, the coflows are scheduled in the FIFO order of arrival of coflows.

5 Scalability Analysis

Compared to learning coflow sizes using priority queues (PQ-based) [19, 30], learning coflow sizes by sampling PHILAE not only reduces the learning overhead as discussed in §3.1 and shown in §8.2, but also significantly reduces the amount of interactions between the coordinator and local agents and thus makes the coordinator highly scalable, as summarized in Table 1.

First, *PQ-based learning requires much more frequent update from local agents.* PQ-based learning estimates coflow sizes by incrementally moving coflows across priority queues

Table 1: Comparison of frequency of interactions between the coordinator and local agents.

	Update of data sent	Update of flow completion	Rate calculation
Philae	No	Yes	Event triggered
Aalo	Periodic (δ)	Yes	Periodic (δ)

according to the data sent by them so far. As such, the scheduler needs frequent updates (every δ ms) of data sent per coflow from the local agents. In contrast, Philae directly estimates a coflow's size upon the completion of all its pilot flows. The only updates Philae needs from the local agents are about the flow completion which is needed for updating contentions and removing flows from active consideration..

Second, *PQ-based learning results in much more frequent rate allocation.* In sampling-based approach, since coflow sizes are estimated only once, coflows are re-ordered only upon coflow completion or arrival events or in the case of contention based policies only when contention changes, which is triggered by completion of all the flows of a coflow at a port. In contrast, in PQ-based learning, at every δ interval, coflow data sent are updated and coflow priority may get updated, which will trigger new rate assignment.

Our scalability experiments in §9.3 confirms that Philae achieves much higher scalability than Aalo.

6 Implementation

We implemented both Philae and Aalo scheduling policies in the same framework consisting of the global coordinator and local agents (Fig. 2), in 5.2 KLoC in C++.

Coordinator: The coordinator schedules the coflows based on the operations received from the registering framework. The key implementation challenge for the coordinator is that it needs to be fast in computing and updating the schedules. The Philae coordinator is optimized for speed using a variety of techniques including pipelining, process affinity, and concurrency whenever possible.

Local agents: The local agents update the global coordinator only upon completion of a flow, along with its length if it is a pilot flow. Local agents schedule the coflows based on the last schedule received from the coordinator. They comply to the last schedule until a new schedule is received. To intercept the packets from the flows, local agents require the compute framework to replace `datasend()`, `datarecv()` APIs with the corresponding Philae APIs, which incurs very small overhead.

Coflow operations: The global coordinator runs independently from, and is not coupled to, any compute framework, which makes it general enough to be used with any framework. It provides RESTful APIs to the frameworks for coflow operations: (a) `register()` for registering a new coflow when it enters, (b) `deregister()` for removing a coflow when it exits, and (c) `update()` for updating coflow status whenever there is a change in the coflow structure, *e.g.*, during task migration and restarts after node failures.

7 Evaluation Highlights

We evaluated Philae using a 150-node and a 900-node testbed cluster in Azure and using large scale simulations by utilizing a publicly available Hive/MapReduce trace collected from a 3000-machine, 150-rack Facebook production cluster [4] and multiple derived traces with varying degrees of flow size skew to measure Philae's robustness to skew.

- **Facebook (FB) trace**: The trace contains 150 ports and 526 ($> 7 \times 10^5$ flows) coflows, that are extracted from Hive/MapReduce jobs from a Facebook production cluster. Each coflow consists of pair-wise flows between a set of senders and a set of receivers.

Due to the lack of other publicly available coflow trace[1], we derived three additional traces using the original Facebook trace in order to more thoroughly evaluate Philae under varying coflow size skew:

- **Low-skew-filtered**: Starting with the FB trace, we filtered out coflows that have skew (*max flow length*/*min flow length*) less than a constant k. We generated five traces in this class with $k = 1,2,3,4,5$. The filtered traces have 142, 100, 65, 51 and 43 coflows, respectively.

- **Mantri-like**: Starting with the FB trace, we adjusted the sizes of the flows sent by the mappers, keeping the total reducer data the same as given in the original trace, to match the skew of a large Microsoft production cluster trace as described in Mantri [12]. In particular, the sizes are adjusted so that the coefficients of variation across mapper data are about 0.34 in the 50th percentile case and 3.1 in the 90th percentile case. This trace has the same numbers of coflows and ports as the FB trace.

- **Wide-coflows-only**: We filtered out all the coflows in the FB trace with the total number of flows ≤ 7, the default thin coflow bypass threshold (thinLimit) in Philae. The filtered trace has 269 coflows spreading over 150 ports.

The primary performance metrics used in the evaluation are CCT or CCT speedup, defined as the ratio of a CCT under other baseline algorithms and under Philae, piloting overhead, and coflow size estimation accuracy.

The highlights of our evaluation results are:

(1) Philae significantly improves the CCTs. In simulation using the FB trace, the average CCT is improved by 1.51× over the prior art, Aalo. Individual CCT speedups are 1.78× in the median case (P90 = 9.58×). For the Mantri-like trace,

[1] A challenge that has also been faced by previous work on coflow scheduling such as [19, 27, 29, 44].

Table 2: Performance improvement over Aalo for varying pilot flow selection schemes.

	Constant	Proportional to number of senders					Proportional to number of flows	
	2	5%	10%	20%	50%	100%	1%	10%
Avg. error	13.21%	6.14%	5.42%	4.94%	5.53%	4.25%	4.15%	2.90%
Avg. CCT	1.27x	1.51x	1.45x	1.50x	1.50x	1.50x	1.43x	0.49x
P50 speedup	1.75x	1.78x	1.76x	1.71x	1.52x	1.40x	1.33x	0.69x
P90 speedup	9.00x	9.58x	9.00x	9.15x	8.33x	8.45x	8.23x	8.23x

the average CCT is improved by 1.36× and individual CCT speedups are 1.75× in the median case (P90 = 12.0×).

(2) The CCT improvement mainly stems from the reduction in the learning overhead (in terms of latency and amount of data sent) in determining the right queue for the coflows. Compared to Aalo, median reduction in the absolute latency in finding the right queue for coflows in PHILAE is 19.0×, and in absolute amount of data sent is 20.0× (§8.2).

(3) PHILAE improvements are consistent when varying the skew among the flow sizes in a coflow (§8.5).

(4) PHILAE improvements are consistent when varying its parameters (§8.6).

(5) The PHILAE coordinator is much more scalable than that of Aalo (§9.3).

8 Simulation

We present detailed simulation results in this section, and the testbed evaluation of our prototype in §9.

Experimental setup: Our simulated cluster uses the same number of nodes (sending and receiving network ports) as in the trace. As in [19], we assume full bisection bandwidth is available, and congestion can happen only at network ports.

The *default parameters* for Aalo and PHILAE in the experiments are: starting queue threshold (Q_0^{hi}) is 10MB, exponential threshold growth factor (E) is 10, number of queues (K) is set to 10, the weights assigned to individual priority queues decrease exponentially by a factor of 10, and the new schedule calculation interval δ is set to 8ms for the 150-node cluster [2], the default suggested in its publicly available simulator [19]. In PHILAE, a new schedule is calculated on demand, upon arrival of a new coflow, completion of a coflow, or completion of all pilot flows of a coflow. Finally, in PHILAE the threshold for thinLimit (T) is set to 7, the number of pilot flows assigned to wide coflows are $max(1, 0.05 \cdot S)$, where S is the number of senders, and the default inter-coflow scheduling policy in PHILAE is Least length-weighted total-port contention.

8.1 Pilot flow selection policies

We start by evaluating the impact of different policies in choosing the pilot flows for a coflow in PHILAE. Table 2 summarizes the improvement in average CCT of PHILAE over Aalo and average error in size estimation normalized to the actual coflow size, when varying the pilot flow selection policy while keeping other parameters as the default in PHILAE, using the FB trace.

Unsurprisingly, the estimation accuracy increases when increasing the number of pilot flows across the three selection schemes: constant, fraction of senders, and fraction of total flows. However, as the number of pilot flows increases (over the range of parameter choices), the CCT speedup (P50 and P90 of individual coflow CCT speedups) decreases. This is because the benefit from size estimation accuracy improvement from using additional pilot flows does not offset the added overhead from completing the additional pilot flows and the delay they incur to other coflows.

We find sampling 5% of the number of senders per coflow strikes a good trade-off between piloting overhead and size estimation accuracy leading to the best CCT reduction. We thus set it ($0.05 \cdot S$) as the default pilot flow selection policy.

8.2 Piloting overhead and accuracy

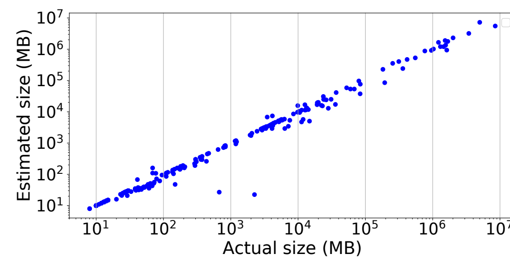

Figure 3: PHILAE coflow size learning accuracy. Coflows that did not go through the piloting phase (48%) are not shown.

Next, using the default pilot selection policy, we evaluate PHILAE's effectiveness in estimating coflow sizes by sampling pilot flows. Fig. 3 shows a scatter plot of the actual coflow size vs. estimated size from running PHILAE under the default settings. We observe that PHILAE coflow's size estimation is highly accurate except for a few outliers. Overall, the average and standard deviation of relative estimation error are 0.06 and 0.15, respectively, and for the top 99% and 95% coflows (in terms of estimation accuracy), the average (standard deviation) of relative error are only 0.05 (0.12) and 0.03 (0.07) respectively. Interestingly, a few coflows experience large estimation errors, and we found they all have very high skew

[2]8ms is the time to send 1MB of data.

in their flow lengths; the mean standard deviation in flow lengths, normalized by the average length, of the bottom 1% (in terms of accuracy) ranges between 4.6 and 6.8.

Fig. 1 shows the cost of estimating the correct queue for each coflow in Philae and Aalo, measured as the time in learning the coflow size as a fraction of the coflow's CCT in Philae and Aalo. We see that under Philae, about 63% of the coflows spent less than 1% of their CCT in the learning phase, while under Aalo, 63% coflows reached the correct priority queue after spending up to 22% of their CCT moving across other queues. Compared to Aalo, Philae in the median case sends 20× less data in determining the right queue and reduces the latency in determining the right queue by 19×.

8.3 Inter-coflow scheduling policies

Philae differs from Aalo in two ways: online size estimation and inter-flow scheduling policy. Here, we evaluate the effectiveness of the four inter-coflow scheduling policies of Philae discussed in §4.4, keeping the remaining parameters as the default. Such evaluation allows us to decouple the contribution of sampling-based learning from the effect of scheduling policy difference.

Table 3 shows the CCT improvement of Philae under the four inter-flow scheduling policies over Aalo. We make the following observations.

First, Philae with the purely sized-based policy, **Smallest job first (A)**, which uses the same inter-queue and intra-queue scheduling policy as Aalo and only differs from Aalo in coflow size estimation, reduces the average CCT (P50) of Aalo by 1.40x (1.48x).

In contrast, the default Philae uses **Least length-weighted total-port contention (D)**, which uses the sum of size-weighted port contention to assign coflows to priority queues, and slightly outperforms the size-based policy A; it reduces the average CCT (P50) of Aalo by 1.51x (1.78x). This is because it captures the diversity of contention at different ports, which happens often in real distributed settings, and at the same time accounts for the coflow size by using length-weighted sum of the port-wise contention. The above results for policy A and policy D indicate that the primary improvement in Philae comes from its sampling-based coflow size estimation scheme.

Shortest remaining time first (B) performs similarly as smallest job first. This is because the preemptive nature of SRTF will kick in only on arrival of new coflows. Also, although SRTF is advantageous for small coflows, since Philae already schedules thin coflows at high priority, many thin and thus small coflows are anyways being scheduled at high priority under both policies A and B, and as a result they perform similarly.

Finally, **Least contention first (C)** performs poorly. This is because contention for a coflow is defined as the unique number of other coflows that share ports, and as a result such a policy completely ignores the size (length) of the coflows.

Table 3: CCT speedup in Philae under different inter-coflow scheduling policies (§4.4) over Aalo.

Priority estimation metric	P50	P90	Avg. CCT
Estimated size (A)	1.48x	8.27x	1.40x
Remaining size (B)	1.54x	8.34x	1.37x
Global Contention (C)	0.75x	8.26x	0.13x
Length-weighted total-port contention (D) (Philae)	1.78x	9.58x	1.51x

8.4 Average CCT improvement

We now compare the CCT speedups of Philae against 5 well-known coflow scheduling policies: (1) Aalo, (2) Aalo-Oracle, which is an oracle version of Aalo where the scheduler knows the final queue of a coflow upon its arrival time and directly starts the coflow from that queue, (3) SEBF in Varys [21] which assumes the knowledge of coflow sizes apriori and uses the Shortest Effective Bottleneck First policy, where the coflow whose slowest flow will finish first is scheduled first. (4) FIFO, which is a single queue FIFO based coflow scheduler, and (5) FAIR, which uses per-flow fair sharing. We do not include Saath [30] in the comparison as it does not provide the same liveliness guarantees as Philae which as discussed in §4.3 can obscure the comparison result. All experiments use the default parameters discussed in the setup, including K, E, S, unless otherwise stated. The results are shown in Fig. 4(a). We make the following observations.

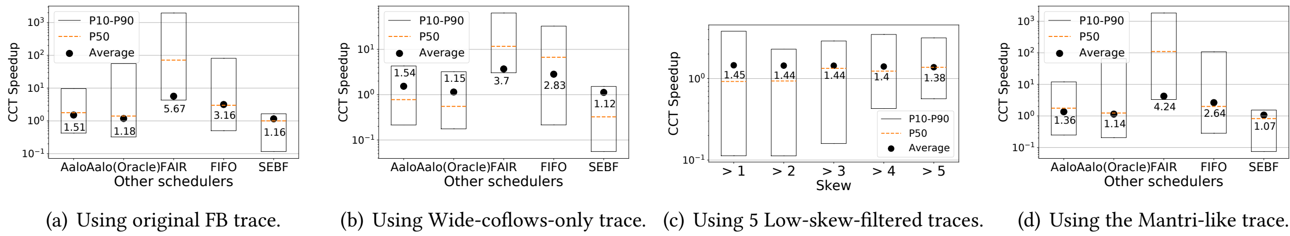
First, we compare CCT under Philae against under Aalo-Oracle, where Aalo-Oracle starts all coflows at the correct priority queues (*i.e.,* no learning overhead). Philae improves the average CCT by 1.18× and P50 CCT by 1.40×, respectively. Since Aalo-Oracle pays no overhead for coflow size estimation, its worse performance suggests that using length-weighted total-port contention in assigning coflows to the priority queues in Philae outperforms Aalo's size-based, contention-oblivious policy in assigning coflows to the queues.

Second, Philae improves the average CCT over Aalo by 1.51× (median) and P50 by 1.78. The significant *additional* improvement on top of the gain over Aalo-Oracle comes from fast and accurate estimation of the right queues for the coflows (Fig. 1).

Third, Philae, which requires no coflow size knowledge a priori, achieves comparable performance as SEBF [21]; it reduces the average CCT by 1.16×. Again this is because its total-port contention policy outperforms the contention-oblivious SEBF.

Finally, Philae significantly outperforms the single-queue FIFO-based coflow scheduler, with a median (P90) CCT speedup of 3.00 (77.96)× and average CCT speedup of 3.16×, and the un-coordinated flow-level fair-share scheduler, with a median (P90) CCT speedup of 70.82× (1947×) and average CCT speedup of 5.66×.

To gain insight into how different coflows are affected by Philae over Aalo, we group the coflows in the trace into



(a) Using original FB trace. (b) Using Wide-coflows-only trace. (c) Using 5 Low-skew-filtered traces. (d) Using the Mantri-like trace.

Figure 4: CCT speedup using Philae compared to using other coflow schedulers on different traces. In Fig. 4(c), the x-axis denotes the minimum skew in the 5 Low-skew-filtered traces.

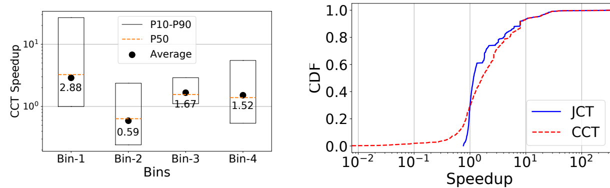


Figure 5: Performance breakdown into bins shown in Table 4.

Figure 6: [Testbed] Distribution of speedup in CCT and JCT in Philae using the FB trace.

Table 4: Bins based on total coflow size and width (number of flows). The numbers in brackets denote the fraction of coflows in that bin.

	width $\leq$ 7(thin)	width $>$ 7(wide)
size $\leq$ 100MB (small)	bin-1 (44.3%)	bin-2 (24.1%)
size $>$ 100MB (large)	bin-3 (4.5%)	bin-4 (27.1%)

four bins defined in Table 4, and show in Fig. 5 the CCT speedups for each bin. We see that Philae improves CCT for all coflows in bin 1 and 3 and for large fraction in bin-4. Most of the underperforming coflows fall in bin-2. Coflows in bin-2 have width $>$ 7 and size $<$ 100MB, *i.e.,* the flows are short but wide. Because the width exceeds the thinLimit, Philae schedules the pilot flows to estimate the coflow size first (§4). Thus, although the remaining flows are short, they get delayed until the completion of the pilot flows, which results in CCT increase.

Finally, since thin coflows benefit from Philae's scheme of bypassing probing for thin coflows, we also compare Philae with other schemes using the Wide-coflows-only trace which consists of all coflows wider than the default thinLimit (7) in Philae. Fig. 4(b) shows that Philae continues to perform well, reducing the average CCT by 1.54×, 1.15×, and 1.12× over Aalo, Aalo-Oracle, and SEBF, respectively.

8.5 Robustness to coflow data skew

Next, we evaluate Philae's robustness to flow size skew by comparing it against Aalo using traces with varying degrees of skew. First, we evaluate Philae using the Mantri-like trace. Fig. 4(d) shows that Philae consistently outperforms prior-art coflow schedulers. In particular, Philae reduces the average CCT by 1.36x compared to Aalo. Second, we evaluate Philae using the Low-skew-filtered traces which have low skew coflows filtered out. Fig. 4(c) shows that Philae performs better than Aalo even with highly skewed traces and reduces the average CCT by 1.45×, 1.44×, 1.44×, 1.40× and 1.38× for the five Low-skew-filtered traces containing coflows with skew of at least 1, 2, 3, 4 and 5, respectively.

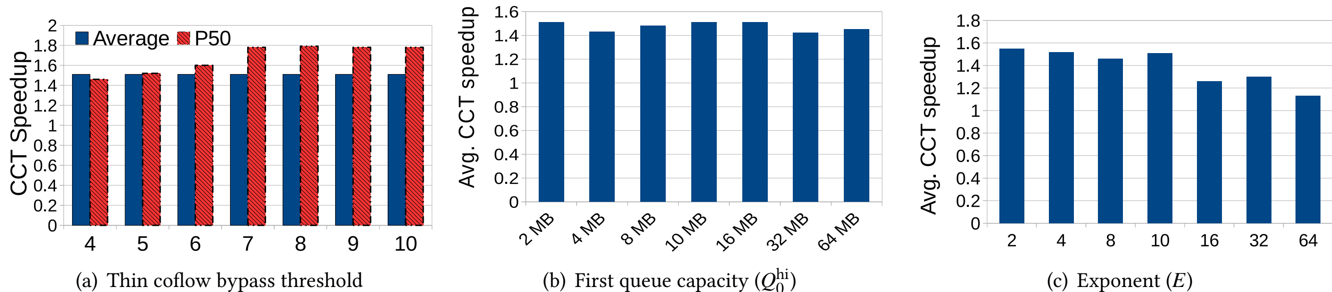
8.6 Sensitivity analysis

Compared to Aalo, Philae has only two additional paramaters: thinLimit and flow sampling rate. We already discussed the choice of sampling rate in §8.1. Below, we evaluate the sensitivity of Philae to thinLimit and other design parameters common to Aalo by varying one parameter at a time while keeping the rest as the default.

Thin coflow bypassing limit (T) In this experiment, we vary thinLimit (T) in Philae for bypassing coflows from the probing phase. The result in Fig. 7(a) shows that the average CCT remains almost the same as T increases. This is because the average CCT is dominated by wide and large coflows, which are not affected by thinLimit. However, the P50 speedup increases till $T = 7$ and tapers off after $T = 7$. The reason for the CCT improvement until $T = 7$ is that all flows of thin coflows (with width ≤ 7) are scheduled immediately upon arrival which improves their CCT, and the number of thin coflows is significant.

Start queue threshold (Q_0^{hi}) We next vary the threshold for the first priority queue from 2 MB to 64 MB. Fig. 7(b) shows the average CCT of Philae over Aalo. Overall, Philae is not very sensitive to the threshold of first priority queue and the CCT speedup over Aalo is within 8% of the default Philae (10 MB). The speedup appears to oscillate with a periodicity of 5x to 10x. For example, the speedups for 2 MB and 64 MB are close to that of the default (10 MB), while for 4 MB and 32 MB are lower. This can be explained by the impact of the first queue threshold on job segregation; with the default queue threshold growth factor of 10, every time the first queue threshold changes by close to 10x, the distribution of jobs across the queues become similar.

Multiplication factor (E) In this experiment, we vary the queue threshold growth factor from 2 to 64. Recall that the queue thresholds are computed as $Q_q^{hi} = Q_{q-1}^{hi} \cdot E$. Thus, as E grows, the number of queues decreases. As shown in Fig. 7(c),



(a) Thin coflow bypass threshold (b) First queue capacity (Q_0^{hi}) (c) Exponent (E)

Figure 7: [Simulation] PHILAE sensitivity analysis. We vary one parameter of PHILAE keeping rest same as default and compare it with Aalo.

smaller queue threshold multiplication factor which leads to more queues performs better because of fine-grained priority segregation.

9 Testbed Evaluation

Next, we deployed PHILAE in a 150-machine Azure cluster and a 900-machine cluster to evaluate its performance and scalability.

Testbed setup: We rerun the FB trace on a Spark-like framework on a 150-node cluster in Microsoft Azure [5]. The coordinator runs on a Standard DS15 v2 server with 20-core 2.4 GHz Intel Xeon E5-2673 v3 (Haswell) processor and 140GB memory. The local agents run on D2v2 with the same processor as the coordinator with 2-core and 7GB memory. The machines on which local agents run have 1 Gbps network bandwidth. Similarly as in simulations, our testbed evaluation keeps the same flow lengths and flow ports in trace replay. All the experiments use default parameters K, E, S and the default pilot flow selection policy.

9.1 CCT Improvement

In this experiment, we measure CCT improvements of PHILAE compared to Aalo. Fig. 6 shows the CDF of the CCT speedup of individual coflows under PHILAE compared to under Aalo. The average CCT improvement is 1.50× which is similar to the results in the simulation experiments. We also observe 1.63× P50 speedup and 8.00× P90 speedup.

We also evaluated PHILAE using the Wide-coflow-only trace. Table 5 shows that PHILAE achieves 1.52× improvement in average CCT over Aalo, similar to that using the full FB trace. This is because the improvement in average CCT is dominated by large coflows, PHILAE is speeding up large coflows, and the Wide-coflow-only trace consists of mostly large coflows.

9.2 Job Completion Time

Next, we evaluate how the improvement in CCT affects the job completion time (JCT). In data clusters, different jobs spend different fractions of their total job time in data shuffle. In this experiment, we used 526 jobs, each corresponding to one coflow in the FB trace. The fraction of time that the jobs spent in the shuffle phase follows the same distribution used in Aalo [19], *i.e.,* 61% jobs spent less than 25% of their total time in shuffle, 13% jobs spent 25-49%, another 14% jobs spent 50-74%, and the remaining spent over 75% of their total time in shuffle. Fig. 6 shows the CDF of individual speedups in JCT. Across all jobs, PHILAE reduces the job completion time by 1.16× in the median case and 7.87× in the 90th percentile. This shows that improved CCT translates into better job completion time. As expected, the improvement in job completion time is smaller than the improvement in CCT because job completion time depends on the time spent in both compute and shuffle (communication) stages, and PHILAE improves only the communication stage.

Table 5: [Testbed] CCT improvement in PHILAE as compared to Aalo.

	P50	P90	Avg. CCT
FB Trace	1.63×	8.00×	1.50×
Wide-coflow-only	1.05×	2.14×	1.49×

Table 6: [Testbed] Average (standard deviation) coordinator CPU time (ms) per scheduling interval in 900-port runs. PHILAE did not have to calculate and send new rates in 66% of intervals, which contributes to its low average.

	Rate Calc.	New Rate Send	Update Recv.	Total
PHILAE	2.99 (5.35)	4.90 (11.25)	6.89 (17.78)	14.80 (28.84)
Aalo	4.28 (4.14)	17.65 (20.9)	10.97 (19.98)	32.90 (34.09)

9.3 Scalability

Finally, we evaluate the scalability of PHILAE by comparing its performance with Aalo on a 900-node cluster. To drive the evaluation, we derive a 900-port trace by replicating the FB trace 6 times across ports, *i.e.,* we replicated each job 6 times, keeping the arrival time for each copy the same but assigning sending and receiving ports in increments of 150 (the cluster size for the original trace). We also increased the

Table 7: [Testbed] Percentage of scheduling intervals where synchronization and rate calculation took more than δ for 150-port and $\delta'(= 6 \times \delta)$ for 900-port runs.

	150 ports	900 ports
PHILAE	1%	10%
Aalo	16%	37%

scheduling interval δ by 6 times to $\delta' = 6\times\delta$.

PHILAE achieved 2.72× (9.78×) speedup in average (P90) CCT over Aalo. The higher speedup compared to the 150-node runs (1.50×) comes from higher scalability of PHILAE. In 900-node runs, Aalo was not able to finish receiving updates, calculating new rates and updating local agents of new rates within δ' in 37% of the intervals, whereas PHILAE only missed the deadline in 10% of the intervals. For 150-node runs these values are 16% for Aalo and 1% for PHILAE. The 21% increase in missed scheduling intervals in 900-node runs in Aalo resulted in local agents executing more frequently with outdated rates. As a result, PHILAE achieved even higher speedup in 900-node runs.

As discussed in§5, Aalo's poorer coordinator scalability comes from more frequent updates from local agents and more frequent rate allocation, which result in longer coordinator CPU time in each scheduling interval. Table 6 shows the average coordinator CPU usage per interval and its breakdown. We see that (1) on average PHILAE spends much less time than Aalo in receiving updates from local agents, because PHILAE does not need updates from local agents at every interval – on average in every scheduling interval PHILAE receives updates from 49 local agents whereas Aalo receives from 429 local agents, and (2) on average PHILAE spends much less time calculating new rates and send new rates. This is because rate calculation in PHILAE is triggered by events and PHILAE did not have to flush rates in 66% of the intervals.

10 Related Work

Coflow scheduling: In this paper, we have shown PHILAE outperforms prior-art non-clairvoyant coflow scheduler Aalo from more efficient learning of coflow sizes online. Saath [30] and Graviton [29] also learn coflow sizes online using priority queues and hence suffers the same inefficiency as Aalo. Graviton [29] uses the number of ports a coflow is present at, as an additional indicator of its size. In [19], Aalo was shown to outperform previous non-clairvoyant coflow schedulers Baraat [24] by using global coordination, and Orchestra [20] by avoiding head-of-line blocking.

Clairvoyant coflow schedulers such as Varys [21] and Sincronia [7] assume prior knowledge of coflows upon arrival. Varys runs a shortest-effective-bottleneck-first heuristic for inter-coflow scheduling and performs per-flow rate allocation at the coordinator. Sincronia improves the scalability of the centralized coordinator of Varys by only calculating the coflow ordering at the coordinator (by solving an LP) and offloading flow rate allocation to individual local agents. Sincronia is orthogonal to PHILAE; once coflow sizes are learned through sampling, ideas from Sincronia can be adopted in PHILAE to order coflows and offload rate allocation to local ports. CODA [44] tackles an orthogonal problem of identifying flows of individual coflows online.

However, recent studies [19, 40] have shown various reasons why it is not very plausible to learn flow sizes from applications beforehand. For example, many applications stream data as soon as data are generated and thus the application does not know the flow sizes until flow completion, and learning flow sizes from applications requires changing either the network stack or the applications.

Flow scheduling: There exist a rich body of prior work on flow scheduling. Efforts to minimize flow completion time (FCT), both with prior information (*e.g.,* PDQ [26], pFabric [9]) and without prior information (*e.g.,* Fastpass [35], PIAS [13], [14]), fall short in minimizing CCTs which depend on the completion of the last flow [21]. Similarly, Hedera [8] and MicroTE [15] schedule the flows with the goal of reducing the overall FCT, which again is different from reducing the overall CCT of coflows.

Speculative scheduling Recent works [16, 33] use the idea of online requirement estimation for scheduling in datacenter. In [31], recurring big data analytics jobs are scheduled using their history.

Job scheduling: There have been much work on scheduling in analytic systems and storage at scale by improving speculative tasks [11, 12, 43], improving locality [10, 41], and end-point flexibility [17, 38]. The coflow abstraction is complimentary to these work, and can benefit from them. Combining coflow with these approaches remains a future work.

Scheduling in parallel processors: Coflow scheduling by exploiting the spatial dimension bears similarity to scheduling processes on parallel processors and multi-cores, where many variations of FIFO [37], FIFO with backfilling [32] and gang scheduling [25] have been proposed.

11 Conclusion

State-of-the-art online coflow schedulers approximate the classic SJF by implicitly learning coflow sizes and pay a high penalty for large coflows. We propose the novel idea of sampling in the spatial dimension of coflows to explicitly and efficiently learn coflow sizes online to enable efficient online SJF scheduling. Our extensive simulation and testbed experiments show the new design offers significant performance improvement over prior art. Further, the sampling-in-spatial-dimension technique can be generalized to other distributed scheduling problems such as cluster job scheduling. We have made our simulator publicly available at https://github.com/coflowPhilae/simulator [6].

Abstract

Unexpected bursty traffic due to certain sudden events, such as news in the spotlight on a social network or discounted items on sale, can cause severe load imbalance in backend services. Migrating hot data—the standard approach to achieve load balance—meets a challenge when handling such unexpected load imbalance, because migrating data will slow down the server that is already under heavy pressure.

This paper proposes PostMan, an alternative approach to rapidly mitigate load imbalance for services processing small requests. Motivated by the observation that processing large packets incurs far less CPU overhead than processing small ones, PostMan deploys a number of middleboxes called helpers to assemble small packets into large ones for the heavily-loaded server. This approach essentially offloads the overhead of packet processing from the heavily-loaded server to others. To minimize the overhead, PostMan activates helpers on demand, only when bursty traffic is detected. To tolerate helper failures, PostMan can migrate connections across helpers and can ensure packet ordering despite such migration. Our evaluation shows that, with the help of PostMan, a Memcached server can mitigate bursty traffic within hundreds of milliseconds, while migrating data takes tens of seconds and increases the latency during migration.

1 Introduction

Modern distributed systems usually scale by partitioning data and assigning these partitions to different servers [4, 10, 11, 14, 15, 17, 33, 37, 41, 50]. In such an architecture, some servers may experience a higher load than others, creating a classic load imbalance problem [11, 16].

Many works have studied how to mitigate load imbalance by better data partitioning and placement strategies [4, 10, 11, 14, 16, 17, 41], which work well for long-term and stable load imbalance. For load imbalance caused by unexpected bursty traffic, however, these approaches meet an additional challenge: to adapt to such unexpected load imbalance, we need to adjust the data partitioning or placement strategies online by migrating hot data to less busy servers, but migrating hot data will inevitably slow down the server hosting hot data—this is the server we want to accelerate. This means to alleviate load imbalance, these approaches will first exacerbate load imbalance for a while, which is a risk that production systems are often unwilling to afford. For example, Amazon Dynamo runs data migration at the lowest priority, and finds that during a busy shopping season, data migration can take almost a day to complete [16]. Unfortunately, unexpected bursty traffic is frequently reported in practice, for various reasons such as a sudden event drawing public attention on a social network [9] or a hot item on sale [18, 34, 39, 40].

This paper proposes PostMan, an alternative approach to mitigate load imbalance for services that are processing small packets, which usually incur a high overhead for packet processing. Typical examples of such services include key-value stores and metadata servers. For example, Facebook reported that in its caching layer, most key sizes are under 40 bytes and median value size is 135 bytes [5, 38]; metadata servers, such as NameNode in HDFS [50], are usually processing packets with a size of tens to a few hundred bytes.

The key idea of PostMan is motivated by the observation that there is a significant gap between the overhead of processing small and large packets, because the networking stack has to pay a constant overhead for each packet, such as interrupt handling and system call. For example, when processing 64B packets on 10Gb Ethernet, Linux can achieve a throughput of 2.4 Gbps with a CPU utilization of 800%. On the contrary, when processing 64KB packets, Linux can achieve a throughput of 9.1Gbps with a CPU utilization of only 220%. Newer networking stacks, such as mTCP [24] and IX [7], have mitigated this problem, but first, the gap still exists, though smaller, and second, a wide deployment of a new networking stack requires a big effort, because the networking stack is a critical component of the whole system, which may affect all

*The corresponding author is Fangming Liu (fmliu@hust.edu.cn).

other components.

Motivated by this observation, PostMan incorporates a number of middleboxes called helpers, which batch small packets for the server experiencing bursty traffic (called "helpee" in the rest of the paper), so that the helpee can enjoy the low overhead of processing large packets. This approach essentially offloads the constant overhead associated with each small packet from the helpee to the helpers.

This approach brings several benefits: first, PostMan does not require the time-consuming data migration. Instead, it only requires the clients to re-connect to the helpers, which can be completed within hundreds of milliseconds as shown in our evaluation. Second, PostMan can incrementally deploy new networking stacks on helpers and allow other servers to still use traditional stacks. Third, PostMan can use multiple helpers to accelerate one helpee, which means its capability is not limited by the power of a single machine. Finally, offloading batching opens up new opportunities for further optimization: we observe that packets to the same destination have significant redundancy in their packet headers (e.g., same destination IP and port). By removing such redundancy, PostMan is able to achieve a considerable reduction in bandwidth consumption at the helpee.

Of course, PostMan has its own limitation: if load imbalance lasts long, PostMan will be more expensive than data migration because incorporating helpers incurs additional data transfer and extra server resource. Therefore, we expect PostMan and data migration to be complementary to mitigate load imbalance: for unexpected bursty traffic, we can activate PostMan to accelerate the heavily-loaded server first; if such burst continues to happen regularly, we can migrate data when the machine is less busy; after data migration is completed, we can disable PostMan to minimize cost. As a result, the helpers would not be active for a long time. Moreover, since PostMan only targets the servers experiencing bursty traffic, we can use a few helpers for a large cluster to further reduce cost.

The idea of batching small requests to improve performance is certainly not novel. The key novelty of PostMan lies in its observation that, *for the purpose of mitigating unexpected load imbalance, batching should be performed remotely and on demand*: remote batching allows PostMan to accelerate a heavily-loaded server with the help of resource from other servers; on-demand batching allows PostMan to minimize the overhead by only helping those servers experiencing bursty traffic. To realize these ideas, PostMan includes three main components:

- We provide an efficient implementation of the helpers. By utilizing state-of-the-art techniques like DPDK and efficiently parallelizing work among multiple cores, a single helper node can assemble and disassemble around 9.6 million small packets per second. By removing redundancy in headers, PostMan can reduce packet header size from 46 bytes to 7 bytes: for 64-byte packets, this means about 50% higher bandwidth utilization at the helpee.
- To ensure packet ordering despite migrating connections across helpee and helpers and despite helper failures, PostMan keeps helpers *stateless* by maintaining sufficient information at the clients and servers to detect out-of-order packets and retransmit packets when necessary. While we find many applications already implement similar functionalities, we provide a library to those which do not.
- We present an adaptive batching mechanism to decide how many packets to assemble. It can increase batch size for higher throughput under heavy traffic and decrease batch size for lower latency under light traffic.

Our evaluation on Memcached and Paxos shows that, with the help of PostMan, the service can mitigate bursty traffic within hundreds of milliseconds, while migrating data can take tens of seconds. Further investigation shows that this is because PostMan can improve the goodputs of Memcached and Paxos by 3.3× and 2.8×, respectively.

2 Related work

Load balancing. Load balancing is a classic topic of distributed systems. Most existing systems use an adaptive approach to achieve load balancing: they can monitor the load of each machine and place new data on less busy machines [4, 10, 11, 14, 16, 17, 20, 41]; some of them can split, merge, and migrate existing data partitions online (e.g., Bigtable [11], RAMCloud [41] and ElMem [20]).

Despite the support from such mechanisms, how to mitigate load balancing caused by unexpected bursty traffic is still a challenge: since these mechanisms will put more pressure on the machine that is already heavily loaded, the administrator is facing a painful trade-off between the short-term loss and the long-term gain of migrating hot data.

Batching small packets. A classic method to improve the performance of processing small packets is to batch them to amortize the constant overhead across multiple packets. For example, TCP has the Nagle's algorithm to batch small packets. Modern NICs often use Generic Receive Offload (GRO) to re-segment the received packets. However, the power of such per-connection batching mechanisms is limited by the number of outstanding packets per client. In many cases, a client may have to wait for replies before it can issue new ones and thus the number of packets that can be batched is limited.

Comet [21] batches the received data before batched stream processing at the server side. KV-direct [29] first batches multiple KV operations at the client side to increase bandwidth utilization, and then at the server side, it batches memory accesses by clustering computation together.

A few systems incorporate a number of nodes to batch packets for other nodes. For example, Facebook has built mcrouter to batch packets for its Memcached service [38]. NetAgg aggregates traffic along network traffics for applications following a partition/aggregation pattern [35]. MPI has a collective I/O mode to batch I/Os from multiple processes before writing them to disks [36].

Compared to these systems, PostMan uses batching for a different goal—mitigating unexpected load imbalance. To achieve this goal, PostMan offloads the overhead of batching from the heavily-loaded server to others and only performs such offloading when a server is under heavy pressure. These techniques allow PostMan to use extra resource to accelerate a server experiencing bursty traffic and minimize the overhead when there is no such bursty traffic.

Efficient network stack. There is a continuous effort to develop more efficient network stacks for high-speed networks: mTCP [24] moves the TCP stack to the user space to reduce system call overhead and further improves performance by batching I/Os; DPDK [1] asks a network card to transfer data to the user space directly and applies a series of optimizations like CPU affinity, huge page, and polling to get close to bare-metal speed; IX [8] and Arrakis [43] design new operating systems to separate data transfer and access control to achieve both high speed and good protection; Netmap [46] improves networking performance by reducing memory allocation, system call, and data copy overhead; many works [12, 22, 25, 26, 30–32, 44, 48, 49, 51] exploit the RDMA technique and FPGA to improve networking performance.

Although these works have significantly improved the network performance, the performance gap between small and large packets persists (Table 1). Taking IX [8] as an example, it can achieve almost 10Gbps bandwidth even with 64-byte packets, which is significantly better than Linux. However, first, it needs to consume a considerable amount of CPU resource (see Section 6.2); second, there is still a gap between goodput (bandwidth used for payload) and throughput, because packet headers consume a large portion of bandwidth. Such per-packet overhead exists in RDMA systems as well [27].

Furthermore, the deployment of new networking stacks is usually a slow procedure, because networking service is critical and production systems are unwilling to pay any risk. On the other hand, PostMan allows administrators to incrementally deploy such new techniques on a few servers to accelerate a large number of legacy servers.

Others. The architecture of PostMan is similar to existing proxies (e.g., NGINX [45] and mcrouter [38]), which are also deployed between clients and servers. The key difference is that PostMan dynamically enables and disables helpers according to the load of servers.

The design of PostMan may seem to be similar to that of the split TCP approach [19, 42, 47], which also deploys helper nodes in the network. However, their goals and internal mechanisms are totally different: split TCP is designed to reduce latency in a network with large round-trip delays, by letting helper nodes send *ack*s to the sender directly; PostMan, on the other hand, is designed to improve the throughput of transferring small packets by letting helper nodes batch small packets. For the purpose of tolerating helper failures, PostMan's helpers actually delay sending *ack*s to the sender, until the helpers receive *ack*s from the helpee (see Section 4.2).

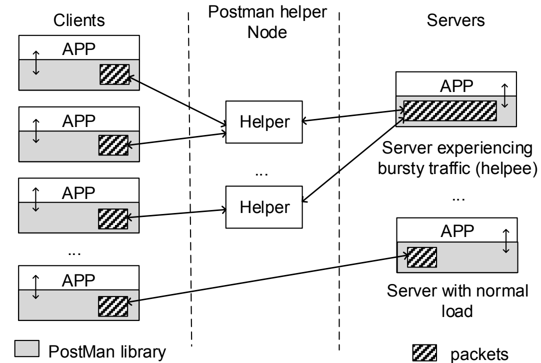

Figure 1: Overview of PostMan.

3 Overview of PostMan

In this paper, we propose PostMan, a distributed service to offload the overhead of packet processing from a heavily-loaded server (called helpee in the rest of this paper). Motivated by the observation that processing large packets incurs far less overhead than processing small packets, PostMan deploys a number of helper nodes in the network to assemble small packets for the helpee. By doing so, PostMan essentially offloads the constant overhead associated with each packet from a helpee to the helpers. With the help of PostMan, a helpee node only needs to process large packets.

Figure 1 shows the organization of PostMan. The core of PostMan consists of: 1) a number of helper nodes that assemble small packets for the helpees, and 2) a PostMan library that provides the applications with the functionalities of packet re-direction, assembly, and disassembly. Furthermore, PostMan library provides functions to detect out-of-order packets and re-transmit packets when necessary. These functions allow PostMan to achieve fault tolerance and load balance by migrating connections across helpers.

As shown in Figure 1, in a large scale distributed system,

PostMan will only activate helpers to accelerate servers experiencing unexpectedly high load, which causes their latency to be higher than their service level agreement (SLA). For servers with normal load, their clients should communicate with the servers directly. Accelerating these normal servers with PostMan, though possible, is not cost effective. Essentially PostMan *offloads* overhead instead of *reducing* overhead: in fact, PostMan increases overall overhead because it needs to perform additional work to assemble and disassemble packets. Therefore, PostMan tries to keep such overhead low by only helping nodes with trouble.

4 PostMan Design

PostMan is designed for the scenario that, suddenly, a large number of clients are sending small requests to a few servers (i.e., helpees). PostMan deploys helper nodes to assemble the clients' small packets to the helpee and disassemble the helpee's small packets to the clients, so that the helpee only needs to process large packets. To differentiate these two directions, we use "request" to refer to a packet from a client to a server and "reply" to refer to a packet from a server to a client.

In the rest of this section, we discuss how to assemble and disassemble packets efficiently at helper nodes, what APIs PostMan provides and how to apply them, and how to adaptively balance throughput and latency.

4.1 Assembling and disassembling packets

Format of assembled packet: For small packets, the size of their headers (at least 20 bytes for IP and TCP header respectively, 6 bytes for MAC header) is comparable to the size of their payloads, and that is one major reason why network throughput cannot reach bare-metal bandwidth, even with new techniques like DPDK. However, when considering packets to the same destination, their headers contain a significant amount of redundancy: packet assembly at the helper nodes can remove such redundancy and further improve throughput at the helpee. For example, since packets to be assembled have the same destination, PostMan only needs to maintain one copy of destination IP and port in the assembled packet. PostMan can shrink source IP as well for small to medium clusters by maintaining a mapping from IP to a shorter identification number at each node (e.g., 2 bytes for clusters with less than 64K machines). Moreover, since the connections from the clients to the helper and the connections from the helper to the helpee are separate, they perform congestion control independently, which means the helper can simply discard related information in the original packets.

As shown in Figure 2, a helper node can assemble packets from multiple connections, and when doing so, the helper discards their TCP/IP/MAC headers and only sends their payloads, together with one TCP/IP/MAC header for all payloads,

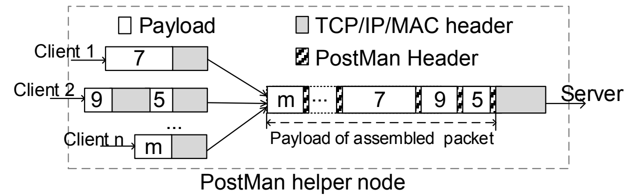

Figure 2: PostMan assembles packets from different clients by using a short header for each payload.

Type	Length (bytes)	Description
ID code	1	Message type
Len	2	Message length
Sender	2* + 2	Src IP/port

Table 2: The format of PostMan header. (*: for a cluster with less than 64K machines, the helper extracts the lower 16 bits from a source IP and then hashes them into a 2-byte identifier)

so that the helpee does not need to pay the header overhead for each packet. However, to ensure that the helpee can correctly disassemble packets, the helper node must encapsulate necessary information for each payload, which is called a "PostMan header".

A PostMan header is a 3-tuple structure (Table 2): 1) an identification code to identify the packet type, 2) a length field to record the length of one payload, and 3) the source IP and port of the payload to locate the sender. A packet can have one of the following three types: 1) *request*, i.e., a packet sent by a client, 2) *reply*, i.e., a packet sent by a server, and 3) *connect*, i.e., a command to create a connection (see Section 4.2). As a result, compared to a TCP/IP/MAC header that takes at least 46 bytes, a PostMan header only takes 7 bytes: this is a significant saving when processing small packets.

Workflow of assembling and disassembling packets: When assembling packets from the clients to the helpee, a helper node fetches all pending packets in its network stack, replaces their TCP/IP/MAC headers with corresponding PostMan headers, concatenates all of them, and adds its own TCP/IP/MAC header. By doing so, both the PostMan headers and the payloads of the original small packets become the payload of the assembled packet.

On the opposite direction, when a helpee sends replies to clients, it will first send the assembled reply to the helper node, which will disassemble the replies and dispatch them to the clients. The format of the assembled reply is similar to that in Figure 2.

Each helper node can create multiple connections to the helpee, so that one helpee can utilize multiple cores and threads to receive packets concurrently.

4.2 PostMan library

A traditional networking library provides a number of APIs, such as *bind*, *connect*, *send*, and *recv* to the application. PostMan library provides a few additional ones: *pm_connect* allows a client to create a connection to a helper node; *compose* and *decompose* assemble and disassemble packets as described in Section 4.1; *get_info* allows the application to retrieve connection information. A developer should use these additional APIs together with traditional APIs to build the application. Next, we show how these functions work and how to modify an application to utilize these functions.

Establish connections. A server should bind to a port and wait for new connections, like using a traditional network library. Of course here a server may accept new connections from the helper nodes. A client can use the traditional network library when the latency is low and switch to PostMan when the latency is high by calling *pm_connect*. *pm_connect* will choose a helper (see Section 5.1) and connect to the helper. Then it sends a special "connect" packet to the helper node. This packet contains the destination IP and port of the helpee and the source IP and port of the client. The helper node will connect to the corresponding helpee, if there is no connection yet, and forward this packet. At the same time the helper creates a mapping from the client's socket to the server's socket. When the server application reads data from a helper connection, it should call *decompose*, which will identify the special "connect" packet and notify the server application that a new client tries to connect. Finally, the server library will return a "success" packet to the client through the helper node, telling the application *pm_connect* succeeds.

Transfer data. When PostMan is activated, a client should send packets through the connection to the helper. The helper node assembles multiple small packets and sends the assembled packet to the server. When the server application reads a packet, it calls *decompose* to disassemble the packet into small packets and process them. On the opposite direction, when a server sends replies, it should buffer multiple replies and assemble them by calling *compose*. Then it can send the assembled reply to the connection to the helper. The helper node disassembles the replies and sends them to the corresponding clients based on the PostMan headers. The clients can read packets using a *recv* or *read* system call.

Ensure packet ordering. Applications often need to ensure packets are not lost, duplicated, or re-ordered. Since PostMan uses TCP connections between the clients and the helper nodes, and between the helper nodes and the helpees, one can easily verify that these properties hold when there is no migration of connections. However, PostMan may migrate connections for several reasons: if a client is connecting directly to a server and finds the latency is high, it will call *pm_connect* to migrate its connection to a helper; when a helper is heavily loaded, PostMan will instruct its clients to migrate to other helpers; finally if a helper fails, its clients must migrate to other helpers as well. As a result, PostMan needs additional mechanisms to ensure packet ordering despite such connection migration. For the first two cases, where migration is executed gracefully, a simple solution is to ask a client to wait for replies of all its pending requests before migrating its connection. For the helper failure case, however, this problem becomes challenging, because a client is uncertain about which packets are delivered.

In distributed systems, two approaches are widely used to achieve fault tolerance: one is to replicate the nodes that can be faulty, and the other is to re-direct requests to another node. Replication can fully hide faults from upper layers, at the cost of increased overhead. The re-direction approach has lower overhead, but it requires the faulty node to be *stateless*, i.e., it does not have any important state that will affect execution.

We use the re-direction approach because of its low overhead. To ensure packet ordering even if the system loses all information on the faulty helper node, PostMan needs to maintain sufficient information at the senders and receivers. Its basic idea is similar to that of TCP: a sender should buffer a packet until it gets acknowledged and re-send a packet if it does not get acknowledgement in a given amount of time; a receiver should check the sequence numbers in the packets to ensure they are in order. Unlike TCP that implements this mechanism in one connection, PostMan needs to implement this mechanism across different connections because when a helper fails, the client needs to re-connect to a new helper.

On one hand, we observe that many applications have already implemented such mechanism. The fundamental reason they choose to do so instead of relying on TCP is that they are designed to tolerate machine failures: in this case, a node needs to connect to other nodes and face the same problem as PostMan. For these systems, PostMan can utilize the application's mechanism directly.

On the other hand, for applications that do not have this mechanism, PostMan provides a general solution. To ensure packets will not be lost, PostMan library at senders[1] will buffer packets until it receives *acks* from receivers, like the TCP protocol does. Since the underlying layer maintains separate TCP connections between the senders and the helper nodes, and between the helper nodes and the receivers, the key to avoid data loss is to coordinate the underlying *ack* mechanisms: after receiving a packet from a sender, the helper node should not send the *ack* to the sender until it has got *ack* from the receiver. We modify the TCP implementation at the helper nodes to realize this mechanism. Since Postman targets small packets, delaying acks and sending them in burst should have little impact on congestion control.

When a helper fails, a sender may not receive *acks* for its outgoing packets, so it may decide to reconnect to another helper and retransmit those packets through the new helper.

[1] Note that senders and receivers are different concepts compared to clients and servers: when a server is receiving packets from a client, it is the receiver; when a server is sending a reply to a client, it is the sender.

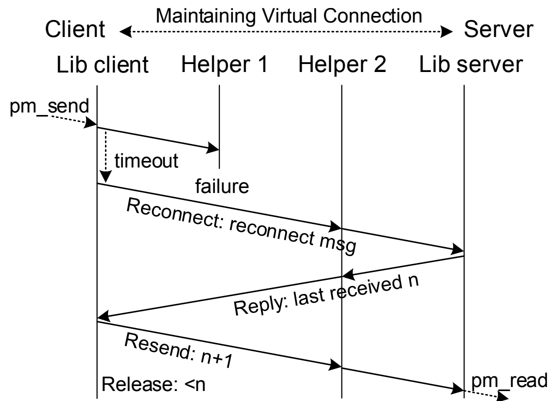

Figure 3: Maintaining a virtual connection by redirecting and re-sending requests when a helper node fails.

In this case, since the receiver may have already received these packets (*acks* may be lost due to helper failure), these packets may be duplicated or re-ordered. To prevent such abnormality, PostMan libraries at the sender and the receiver maintain additional information to detect duplicate or out-of-order packets.

To be specific, the library will keep track of how many bytes are already sent and received on each connection; for each buffered outgoing packet, the library will record its offset in the stream. As shown in Figure 3, when a helper node fails, the client library, which is the sender in this example, will connect to another helper node and sends a "reconnect" message to the server through the new helper node, which contains the number of sent and received bytes at the client side. When the server library receives this command, it will first stop receiving packets from the old connection and then respond with the number of sent and received bytes at the server side. By exchanging the number of sent and received bytes and comparing them to the offsets of buffered packets, both sides can determine which packets should be re-transferred.

Further optimization. So far we assume an application server needs to disassemble packets before processing them. However, this may not be necessary for some applications. A typical example is a server that needs to forward or broadcast packets (e.g., proxy server, leader replica in replication protocols, etc). For such servers, since they do not care about the content of payload, they can forward or broadcast the assembled packets directly, instead of disassembling them first. Note that when sending assembled packets, the application should not use PostMan, since these packets are large.

Using PostMan library. To apply PostMan to existing applications, the developer needs to modify its code: at the client side, the client should call *pm_connect* to switch to PostMan when it observes a high latency and switch back to traditional sockets when the latency drops back to normal; at the server side, the server should call *decompose* when it receives a packet from a helper (*get_info* can tell whether a connection is from a client or from a helper) and should assemble a number of replies by calling *compose* when it sends packets through helpers. If the application needs PostMan's help to ensure packet ordering, it should notify PostMan when a packet is sent or received, so that PostMan can buffer and release packets and update corresponding metadata.

It is possible to hide all the mechanisms mentioned above in the library and provide the applications with an illusion that they are using direct connections between clients and servers. We have implemented a library to achieve such transparency. However, we find it can incur up to 50% overhead for additional operations like memory copy, synchronization, context switch, etc. Considering the main goal of this work is to improve the performance of the heavily-loaded server, we decide to give up transparency for better performance.

4.3 Adaptive batching

Batching can affect system latency in two opposite ways: on one hand, to assemble packets, a helper node must wait for a certain amount of time to accumulate enough small packets, which will increase the latency of the system. On the other hand, according to queuing theory, when the load is close to or higher than the system's capacity, queuing delay will become a dominant factor for latency. Since batching can improve a system's capacity, it can reduce queuing delay and thus can reduce latency.

PostMan partially avoids such trade-off by only activating helpers for heavily-loaded servers. In addition, PostMan incorporates an adaptive batching algorithm to balance latency and throughput when helpers are enabled. Like many systems using batching, PostMan defines a maximum batch interval (T) and a preferred batch size (S): if the helper has waited for T (condition 1) or if its assembled packet has reached size S (condition 2), the helper will send the assembled packet to the helpee. Then the question turns to how to set T and S: large T and S lead to unnecessary waiting when traffic load is light; small T and S reduce the chance of assembling packets when traffic load is heavy.

To address this problem, PostMan uses an adaptive batch size and interval to increase throughput under heavy loads and decrease latency under light loads, as shown in Algorithm 1. PostMan records the batch size (s) and waiting time (t) of the last batch: if s is significantly different from S or t is significantly different from t, PostMan updates S and T accordingly. Furthermore, it sets a lower bound of S and T to ensure efficiency. Note that although T is the maximum batch interval, the actual interval t can be much larger than T when the helper does not receive any packets for a long time; s can be much larger than S as well when the helper receives many packets at the same time.

This algorithm has a few parameters: we set the lower bound of S to be 1500 because that is the MTU size; the lower

Algorithm 1 Adaptive batching algorithm

Input: the size (s) and waiting time (t) of last batch

```
 1: procedure Update S and T
 2:     S_l ← 0.75S
 3:     S_u ← 1.25S
 4:     if (s < S_l ∨ s > S_u) ∧ (s ≥ 1500) then
 5:         S ← s
 6:     end if
 7:     T_l ← 0.5T
 8:     T_u ← 1.5T
 9:     if (t < T_l ∨ t > T_u) ∧ (t ≥ 10µs) then
10:         T ← t
11:     end if
12: end procedure
```

bound of T should be set according to the SLA requirement; we set other parameters based on empirical experiments.

5 Implementation

In this section, we present how to achieve efficiency and scalability for PostMan.

5.1 Efficient helper

Fast I/O and user-level stack: Each helper node needs to assemble requests from the clients, and disassemble the replies from the servers. To efficiently process the small packets on the helper nodes, we implement PostMan upon DPDK [1], which is a set of libraries and drivers for fast packet processing. DPDK minimizes the overhead of packet processing by transferring packets from NICs directly to user space programs and thus can achieve a throughput of hundreds of millions packets per second. Upon DPDK, we use mTCP [23] to handle TCP protocol and connections. DPDK provides a poll mode I/O model, which can transfer a batch of packets in one I/O operation. This I/O model not only avoids the overhead caused by frequent interrupts in per-packet based processing in Linux, but also naturally fits the assembling requirements of our helper nodes: a helper can simply add all the payload data from these packets to the assembling buffer, instead of performing the read operation several times.

In-stack processing: Since the assembling logic only involves simple operations for request/response headers, PostMan implements these operations in the network layer to accelerate the identification and pre-processing of the original packets. PostMan uses direct data exchange between the server and the client streams so as to avoid redundant memory copy and improve the performance of fragmented data operation. By implementing everything in the network stack, PostMan eliminates the interaction and context switching between the applications and the stack to further improve assembling efficiency. All necessary assembling and disassembling operations are queued in the stack, so that PostMan can perform them after finishing processing the incoming packet in the TCP protocol. Furthermore, PostMan only keeps the necessary procedures for receiving and sending packets in a TCP stream. Other operations, like the ICMP protocol, are abandoned, either because they have nothing to do with packet assembly, or they should be performed in the helpee's stack.

Independent per-core context: PostMan leverages per-core thread (affiliated to a hardware thread) and independent per-core context to avoid synchronization among different assembling threads. On each helper node, we enable the Receive Side Scaling (RSS) [3] function of NIC—this is widely supported by today's NICs—to hash flows into different physical queues in hardware, where each queue is assigned to a dedicated CPU thread. PostMan does not share any global information, hence the connection can be locally processed on each core. PostMan sets up at least one queue for each thread, such that the flows in each RSS group can be processed independently without exchanging any information between CPU cores. Consequently, PostMan can scale well on today's multi-core system. Note that RSS will reduce a helper's chance to batch packets, but since PostMan is enabled only when the server is under high load, there are still plenty of chances for a helper to batch packets as shown in our evaluation. For each thread, PostMan uses hugepages to store raw packet data, similar as many DPDK based applications, so as to reduce the number of TLB misses; PostMan uses hardware-based CRC instruction for flow hashing to accelerate the assembling process.

5.2 Scalability and load balancing

As presented in the previous section, PostMan is designed for hardware thread and RSS built-in NIC. Hence, PostMan scales well with the number of cores.

For helper nodes, their stateless nature, which allows connections to be migrated freely across helpers, significantly simplifies scaling and load balancing: when a client connects to helpers, it picks up one with a low load; whenever some helper nodes are overloaded, they can simply disconnect some clients and those clients will automatically re-connect to other helper nodes. To achieve this, PostMan uses a standard load-balancing technique: each helper monitors its own CPU and network utilization; when a client establishes a connection, either for a new connection or for re-connecting, it randomly chooses a number of helpers; each helper will reply with its resource utilization, so that the client can choose the helper with the lowest utilization; when a helper finds its resource utilization is too high, it disconnects existing connections, so that the corresponding clients can connect to other helpers.

PostMan has no inherent scalability bottleneck: since a client can connect to any helper, PostMan does not need a centralized master node to map clients to helpers.

5.3 When to enable and disable helpers?

PostMan provides a mechanism to enable and disable helpers on demand, but in practice, we still need to answer the policy question about when to enable and disable helpers. In principle, both the clients and the servers can make the decision and we observe the following trade-offs:

A client can monitor its perceived latency to the server and make decisions accordingly: this approach brings minimal overhead to the server side, but since a client cannot gain the overall load statistics of the server, it may not be able to make the best decisions in certain cases. On the other hand, a server certainly has more information to make a better decision, but to execute the decision, the server must pay the overhead of notifying corresponding clients and helpers, which could be problematic if the server is already under heavy load.

Therefore, the current implementation of PostMan uses a hybrid approach: a client will decide to enable helpers (i.e., the client disconnects from the server and connects to a helper) if it detects its perceived latency is higher than SLA—this could minimize the overhead at the server side when the server is busy; a server will decide to disable helpers when its throughput becomes low—the overhead is fine in this case since the server is not too busy.

6 Evaluation

The goal of PostMan is to quickly mitigate the bursty traffic directed to one or a few servers. To assess whether PostMan achieves this goal, we evaluate the performance of PostMan using various applications and workloads. In particular, our evaluation answers the following questions:

- How well can PostMan help a service reduce the load caused by bursty traffic?
- How is PostMan's capability affected by packet size?
- How much resource does PostMan need to achieve such benefit?
- How does the system perform when there are helper failures?

To answer the first question, we run benchmarks on Memcached and Paxos, and emulate the case of bursty traffic by drastically increasing the load during the middle of the experiment; we enable PostMan after such burst to measure 1) whether it can reduce the latency of the target service and 2) how long it takes to enable PostMan. We compare the results of PostMan to those of the data migration approach.

To answer the following three questions, we use a ping-pong microbenchmark to measure the performance of PostMan under different parameters.

Memcached. Memcached is a key-value based memory object caching system [2]. It is used widely in the data centers to cache data to speed up the lookups of frequently accessed data. As reported in [5], Memcached is often used to store small but hot data. We have modified 454 lines of code in Memcached 1.4.32 to apply PostMan. The benchmark generates GET/SET commands with a fixed key size (32 bytes) and different value sizes.

Paxos. Paxos is an asynchronous replication protocol to achieve consensus in a network of unreliable processors [28]. Paxos needs $2f+1$ replicas to tolerate f machine crashes and asynchronous events (e.g inaccurate timeout caused by network partitions). A number of systems, such as Megastore [6], Windows Azure [10] and Spanner [14], are using Paxos for fault tolerance and since they use many Paxos groups, one for each data partition, it is possible that a few of them experience bursty traffic.

In Paxos, one replica is elected as leader, and it needs to broadcast the received requests to other non-leader replicas. It is a typical example of applications that do not care about the contents of packets. Therefore, the leader can read the assembled packets from PostMan and broadcast the assembled packets directly. After the non-leader replicas receive the assembled packets, they will disassemble them. Such mechanism can avoid the redundant disassembling and assembling operations at the leader replica, which is the bottleneck in the system. To exploit such opportunities, we implement our own version of Paxos using PostMan and compare it to a vanilla version that reads individual packets from the clients, assembles them, and then broadcasts the assembled packets. For simplicity, we only implement the Paxos protocol in the failure-free case, which is enough to evaluate the performance benefit of PostMan.

Ping-pong benchmark. This benchmark [8] can test network performance with configurable packet sizes. To avoid the inaccuracy caused by TCP merging packets, this benchmark asks each client to perform a ping-pong like communication with the server: the client sends a packet to the server and then waits for the server to send the packet back. By doing so, since a client has only one outstanding packet, TCP has no chance to merge packets.

Experiment Setup. We run all experiments on CloudLab [13] with 15 machines. Each machine is equipped with an Intel Xeon E5-2660 v3 @ 2.60GHz CPU, with 10 physical cores and hyper-threading, and an Intel 82599ES 10-Gigabit NIC. These severs run Ubuntu 16.0.2 LTS with Linux 4.8.0 kernel, and use DPDK 16.07.2 for the helper nodes. For DPDK Poll Mode Driver, we set the batch size to 64, which is the maximum number of packets received/transmitted in each iteration. For Paxos and Ping-pong experiments, we use IX [8], a state-of-the-art network stack built upon DPDK, at the client side, so that we can stress-test the server with a limited number of client nodes. We also add 17 LoC to count

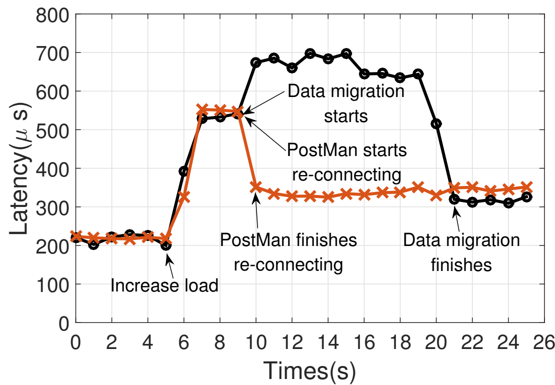

Figure 4: Mitigating bursty traffic in Memcached (PostMan enables two helpers).

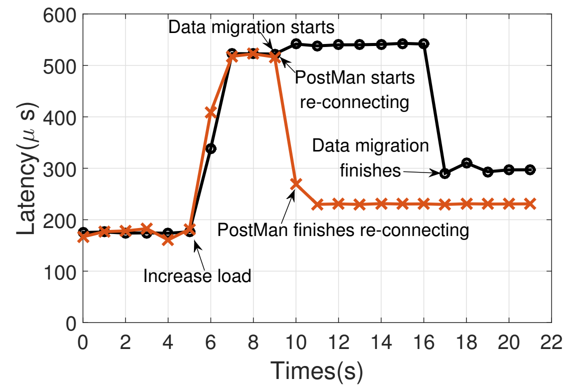

Figure 5: Mitigating bursty traffic in Paxos (PostMan enables two helpers).

the RX/TX bytes and packets in the data plane of IX, whose impact on the performance is negligible in our experiments. For Memcached experiments, since the Linux stack is sufficient to saturate the server, we do not switch to IX. By default, the application server of our benchmarks runs on 16 cores (8 real cores with hyperthreading). Note that in all experiments, when enabling PostMan, our reported goodput does not include the PostMan header and the TCP/IP/MAC header added by the helper nodes, which allows a fair comparison with the goodput without PostMan. When using PostMan, a client enables helpers if its observed 99 percentile latency (p99) is higher than 500 µs [7].

6.1 Effectiveness of PostMan

To measure the effectiveness of PostMan, we emulate the case of bursty traffic on both Memcached and Paxos.

Memcached. We measure p99 latency of Memcached using a read workload with 32B keys and 64B values. As shown in Figure 4, we first use a light load, which incurs a latency of 200 µs, till time 5. Then we increase the load drastically, which increases the latency to more than 500 µs. At about time 9, we enable PostMan, which asks clients to re-connect to helpers. Such re-connection involves 660 client connections and finishes within 550 ms. Afterwards, the latency is reduced to around 300 µs.

As a comparison, we emulate the data migration approach by assuming 50% of the clients are accessing 10% of the data (i.e., 6.4GB) in the Memcached server. Therefore, we start a thread in the Memcached server to copy the data to another server at time 9. Normally such a thread needs to access the internal data structure of Memcached, which may incur additional CPU overhead and may contend with the client's requests. Our emulation avoids such overhead by letting the migration thread copy dummy data to another server, which is in favor of the data migration approach. After data copy is complete, we remove half of the clients since they should be re-directed to another server. As one can see, the data migration takes about 13 seconds and during this procedure, the latency of the service further increases, because the migration traffic and the client's traffic compete for resource. One can of course limit the rate of migrating data to reduce such interference, but that will further increase the length of data migration.

Paxos. We run a similar set of experiments on Paxos. We measure the p99 latency of Paxos using a workload with 64B requests (Paxos does not execute the request, so the content of the request does not matter). As shown in Figure 5, we first use a light load, which incurs a latency of 200 µs, till time 5. Then we increase the load, which increases the latency to about 500 µs. At about time 9, we enable PostMan, which asks clients to re-connect to helpers. Such re-connection involves 960 client connections and finishes within 750 ms. Afterwards, the latency is reduced to around 220 µs.

Similarly, we emulate the data migration approach by assuming 50% of the clients are accessing 10% of the data. Therefore, we start a thread in the non-leader server to copy the data to another server at time 9. Since the leader has the highest overhead in Paxos, copying data from a non-leader server should incur less interference on the clients' requests. After data copy is complete, we remove half of the clients since they should be re-directed to another server. As one can see, the data migration takes about 8 seconds. During this procedure, unlike the Memcached experiments, data migration has little impact on the clients' requests, because it is performed from a non-leader server. Note that after mitigating bursty traffic, the performance of the two systems is different because they have different workloads: with PostMan, the server is processing full load with big packets; after data migration, the server is processing half load with small packets. Which one has better performance depends on the actual workload: in Figure 5 the system with PostMan has lower latency while in Figure 4 the system with PostMan has slightly higher latency.

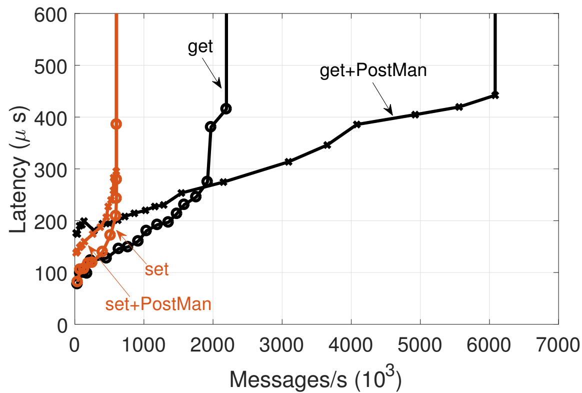

Figure 6: The latency with different load for Memcached and Memcached + PostMan (64-byte payloads; PostMan enables up to five helper nodes).

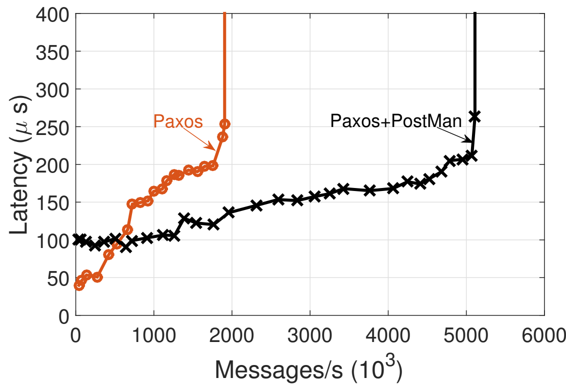

Figure 7: The latency with different load for Paxos and Paxos + PostMan (64-byte payloads; PostMan enables up to six helper nodes).

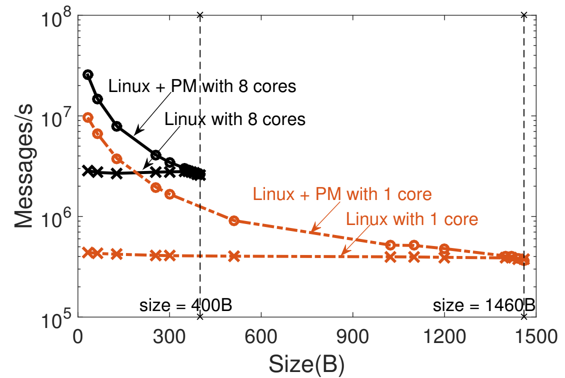

Figure 8: The throughput with different payload sizes for Linux and Linux + PostMan (PostMan enables up to six helper nodes).

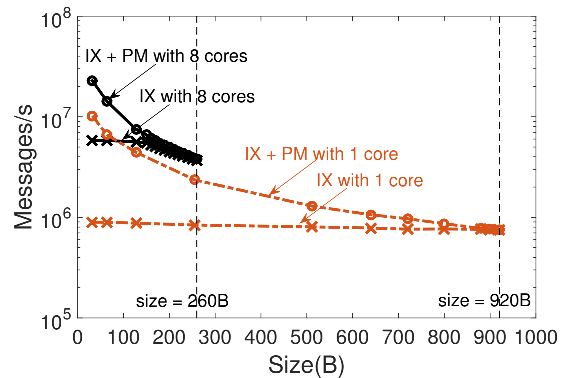

Figure 9: The throughput with different payload sizes for IX and IX + PostMan (PostMan enables up to six helper nodes).

Both the Memcached and the Paxos experiments have confirmed the effectiveness of PostMan: for services processing small packets, PostMan can quickly mitigate the long latency caused by unexpected bursty traffic, because it can offload the overhead of packet processing to helpers; data migration, on the other hand, takes much longer to achieve the same goal, and may further increase the latency during data migration when data migration competes for resource with processing clients' requests.

Capabilities of PostMan. To understand in what circumstances can PostMan help to mitigate bursty traffic, we measure how Memcached's and Paxos' tail latency grow with the load and how PostMan changes such trend.

As shown in Figure 6 and Figure 7, both Memcached get experiment and Paxos experiment show the same trend: when the load is low (i.e., lower than 2000K messages/s in Memcached and 500K messages/s in Paxos), using PostMan will actually introduce extra latency, because of the additional processing at the helper; when the load grows, the latency of the original systems will grow as well due to queuing delay and when these systems are close to saturation, their latency jumps, which is what happens when the service experiences bursty traffic. PostMan can offload their overhead of packet processing to helpers and thus can improve their maximum throughput, which reduces their queuing delay in a range of loads: for Memcached get experiments, PostMan can reduce the latency if the load is between 2000K and 6000K messages/s; for Paxos, PostMan can reduce its latency if the load is between 500K and 5000K messages/s. Memcached set experiments do not benefit from PostMan, because as shown in our profiling, its bottleneck is lock contention, which has nothing to do with packet processing. This set of experiments show that PostMan is effective for a wide range of loads, but it does have its limits: that's why it is complementary to data migration, which does not have such limits but requires a longer time to be effective.

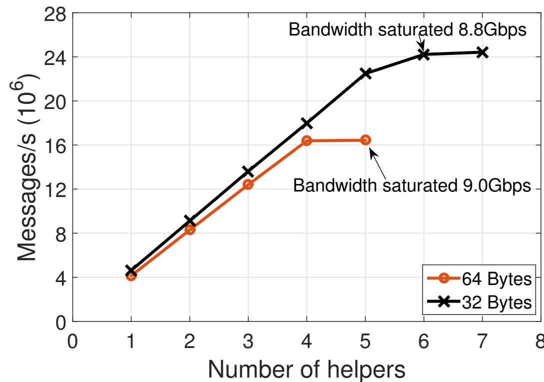

Figure 10: The performance scale linearly when increasing the number of helpers nodes.

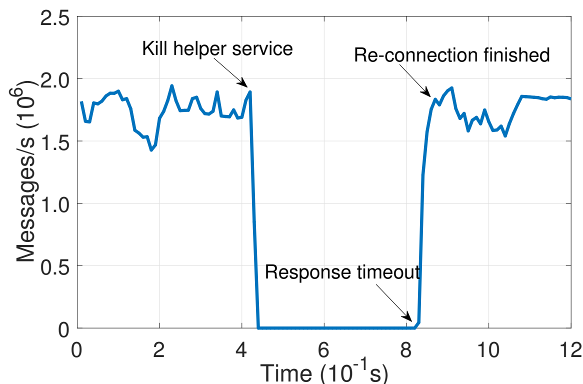

Figure 11: The performance when PostMan recovers the connections by mapping them to another active helper.

6.2 Effects of packet size

The capability of PostMan is affected by the packet size because PostMan's key idea of assembling packets naturally works well with smaller packets. To quantitatively understand how PostMan's capability is affected by this factor, we use the ping-pong microbenchmark to measure the throughput of PostMan, since as shown in Section 6.1, the maximal throughput of PostMan determines the range of loads in which PostMan might be helpful. We compare the throughput of PostMan to those of Linux and IX [7]. Since we fail to run an IX server with more than nine cores, we reduce the number of cores to eight in this set of experiments. Since IX shows it can outperform mTCP [24], another popular network stack, we do not further compare PostMan with mTCP.

Figure 8 shows the throughput of Linux under different packet sizes, with and without PostMan. As shown in this figure, when the server can utilize 8 cores for packet processing, PostMan can improve throughput when the payload size is less than 400 bytes. However, for CPU-intensive applications, this may not be a fair comparison because PostMan can reduce CPU utilization as well as improving throughput. Therefore, we also show the comparison when the server can utilize only one core for packet processing. In this case, PostMan can improve throughput when payload size is smaller than 1460 bytes.

Figure 9 shows the throughput of IX under different packet sizes, with and without PostMan. It shows a similar trend as the Linux experiment, though the turning points are smaller, 260B and 920B respectively. The benefit of PostMan still exists although becomes smaller than that in the Linux experiment. This is because IX, with an optimized networking stack, pays less overhead per packet compared to Linux.

Comparing Figure 8 and Figure 9, one can see that Linux+Postman can even outperform IX when the packet size is small, despite the fact that the former approach does not require installing a new OS on all servers.

6.3 Performance of helper nodes

So far we have measured the performance gain at the server side. A natural question is how much resource we need to pay at the helper side to achieve such performance gain. To answer this question, we measure how much throughput a single helper can provide and whether PostMan scales with the number of helpers.

In this set of experiment, we use IX as the server side to ensure the server will not become the bottleneck. As Figure 10 shows, a single helper node can process about 9.6 million small messages (assembling 4.8 million requests and disassembling 4.8 million responses) per second. When increasing the number of helper nodes, the overall throughput of PostMan scales almost linearly, till the helpee's bandwidth is saturated.

Such results have demonstrated that PostMan does need a number of helper nodes to improve the throughput at the server side: this is as expected because PostMan offloads overhead instead of reducing overhead. Therefore, we expect a small-scale deployment of PostMan to help a few heavily loaded servers.

6.4 Fault tolerance

To test whether PostMan can tolerate failures of helper nodes, we set up a simple scenario, in which two active helper nodes are connected to the server. A Linux client running on PostMan client library is performing request-reply communication to the server, with 10 threads and 1000 connections in total. To examine the failure recovery of helper nodes, we first let all clients connect to one helper, record the throughput (measured every 100ms) of the clients and manually kill the connected helper node. As shown in Figure 11, the library waits until a timeout on receiving the reply message, and then reconnects to the other helper node. The re-connection takes about

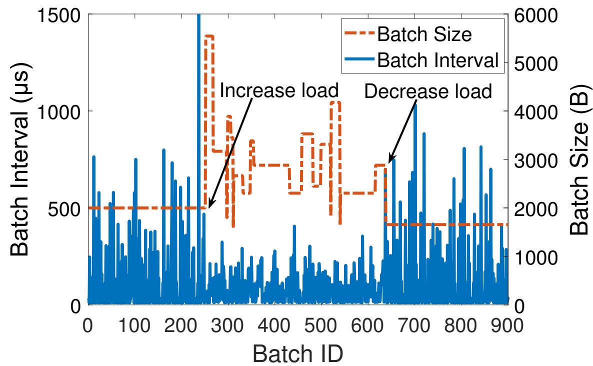

Figure 12: Adaptively changing batch size and interval.

0.4s to recover all 1000 connections. After that, the message exchange reaches the previous rate.

Note that PostMan's correctness does not rely on the correctness of timeout: even if the timeout is inaccurate (i.e., a timeout is triggered when the previous helper node is still alive), PostMan can still guarantee all its properties because clients and servers will close the old connection and exchange necessary information when establishing a new connection (Section 4.2). This means in practice, the developers can use a shorter timeout to improve availability. In this experiment, we simply use an arbitrary 1-second timeout to show that PostMan can function correctly despite failures.

6.5 Adaptive batching

To test the effectiveness of our adaptive batching algorithm, we change the load of our system and see how PostMan reacts. As shown in Figure 12, with the load increasing, the batch interval decreases, implying that the helper nodes batch packets more frequently. Although the size variation seems noisy, the batch sizes are mostly larger than those with low load. When the load decreases, the helper nodes can reduce the batch size and increase the batch interval. As a result, we can conclude that the batch size and batch interval are well adapted to fluctuating load.

7 Conclusion

In this paper, we present PostMan, a distributed service to mitigate load imbalance caused by bursty traffic, by offloading the overhead of packet processing from heavily-loaded servers and reducing data redundancy in packet headers. By batching small packets remotely and on demand, PostMan can utilize multiple nodes to help a heavily-loaded server when bursty traffic occurs and can minimize the overhead when there is no such bursty traffic. Experiments with Memcached and Paxos show that, compared to data migration, PostMan can quickly mitigate the extra latency caused by bursty traffic.

R2P2: Making RPCs first-class datacenter citizens

Marios Kogias George Prekas Adrien Ghosn Jonas Fietz Edouard Bugnion

EPFL, Switzerland

Abstract

Remote Procedure Calls are widely used to connect datacenter applications with strict tail-latency service level objectives in the scale of µs. Existing solutions utilize streaming or datagram-based transport protocols for RPCs that impose overheads and limit the design flexibility. Our work exposes the RPC abstraction to the endpoints and the network, making RPCs first-class datacenter citizens and allowing for in-network RPC scheduling.

We propose R2P2, a UDP-based transport protocol specifically designed for RPCs inside a datacenter. R2P2 exposes pairs of requests and responses and allows efficient and scalable RPC routing by separating the RPC target selection from request and reply streaming. Leveraging R2P2, we implement a novel *join-bounded-shortest-queue (JBSQ)* RPC load balancing policy, which lowers tail latency by centralizing pending RPCs in the router and ensures that requests are only routed to servers with a bounded number of outstanding requests. The R2P2 router logic can be implemented either in a software middlebox or within a P4 switch ASIC pipeline.

Our evaluation, using a range of microbenchmarks, shows that the protocol is suitable for µs-scale RPCs and that its tail latency outperforms both random selection and classic `HTTP` reverse proxies. The P4-based implementation of R2P2 on a Tofino ASIC adds less than 1µs of latency whereas the software middlebox implementation adds 5µs latency and requires only two CPU cores to route RPCs at 10 Gbps line-rate. R2P2 improves the tail latency of web index searching on a cluster of 16 workers operating at 50% of capacity by 5.7× over NGINX. R2P2 improves the throughput of the Redis key-value store on a 4-node cluster with master/slave replication for a tail-latency service-level objective of 200µs by more than 4.8× vs. vanilla Redis.

1 Introduction

Web-scale online data-intensive applications such as search, e-commerce, and social applications rely on the scale-out architectures of modern, warehouse-scale datacenters to meet service-level objectives (SLO) [7, 17]. In such deployments, a single application can comprise hundreds of software components, deployed on thousands of servers organized in multiple tiers and connected by commodity Ethernet switches. The typical pattern for web-scale applications distributes the critical data (*e.g.,* the social graph) in the memory of hundreds of data services, such as memory-resident transactional databases [26, 85, 87–89], NoSQL databases [62, 78], key-value stores [22,54,59,67,93], or specialized graph stores [14]. Consequently, online data-intensive (OLDI) applications are deployed as 2-tier applications with root servers handling end-user queries and leaf servers holding replicated, sharded data [8, 58]. This leads to a high fan-in, high fan-out connection graph between the tiers of an application that internally communicates using RPCs [11]. Each client must (a) fan-out an RPC to the different shards and (b) within each shard, choose a server from among the replica set. Moreover, each individual task can require from only few microseconds (µs) of user-level execution time for simple key-value requests [54] to a handful of milliseconds for search applications [35].

To communicate between the tiers, applications most commonly layer RPCs on top of TCP, either through RPC frameworks (*e.g.,* gRPC [31] and Thrift [86]) or through application-specific protocols (*e.g.,* Memcached [59]). This leads to a mismatch between TCP, which is a byte-oriented, streaming transport protocol, and message-oriented RPCs. This mismatch introduces several challenges, one of which is RPC load distribution. In one approach, root nodes randomly select leaves via direct connections or L4-load balancing. This approach leads to high fan-in, high fan-out communication patterns, load-imbalance and head-of-line blocking. The second approach uses a L7 load balancer or reverse proxy [1, 16, 25] to select among replicas on a per request basis, *e.g.,* using a Round-Robin or Join-Shortest-Queue (JSQ) algorithm. While such load balancing policies improve upon random selection, they do not eliminate head-of-line blocking. Furthermore, the load balancer can become a scalability bottleneck.

This work proposes a new communication abstraction for datacenter applications that exposes RPCs as first-class citi-

zens of the datacenter not only at the client and server endpoints, but also in the network. Endpoints have direct control over RPC semantics, do not suffer from head-of-line blocking because of connection multiplexing, and can limit buffering at the endpoints. The design also enables RPC-level processing capabilities for in-network software or hardware middleboxes, including scheduling, load-balancing, straggler-mitigation, consensus and in-network aggregation.

As a first use case, we show how to use our network protocol to implement efficient, scalable, tail-tolerant, high-throughput routing of RPCs. Our design includes an RPC router that can be implemented efficiently either in software or within a programmable switch ASIC such as P4 [12]. In addition to classic load balancing policies, we support *Join-Bounded-Shortest-Queue* (`JBSQ(n)`), a new RPC scheduling policy that splits queues between the router and the servers, allowing only a bounded number of outstanding requests per server, which significantly improves tail-latency.

We make the following contributions :

- The design of *Request-Response Pair Protocol (R2P2)*, a transport protocol designed for datacenter µs-RPCs that exposes the RPC abstraction to the network and the endpoints, breaks the point-to-point RPC communication assumptions, and separates request selection from message streaming, nearly eliminating head-of-line blocking.
- The implementation of the R2P2 router on a software middlebox that adds only 5µs to end-to-end unloaded latency and is capable of load balancing incoming RPCs at line rate using only 2 cores.
- The implementation of the R2P2 router within a P4-programmable Tofino dataplane ASIC, which eliminates the I/O bottlenecks of a software middlebox and reduces latency overhead to 1µs.
- The implementation of `JBSQ(n)`, a split-queue scheduling policy that utilizes a single in-network queue and bounded server queues and improves tail-latency even for µs-scale tasks.

Our evaluation with microbenchmarks shows that our R2P2 deployment with a `JBSQ(3)` router achieves close to the theoretical optimal throughput for 10µs tasks across different service time distributions for a tail-latency SLO of 150µs and 64 independent workers. Running Lucene++ [56], an open-source websearch library over R2P2, shows that R2P2 outperforms conventional load balancers even for coarser-grain, millisecond-scale tasks. Specifically, R2P2 lowers the 99th percentile latency by 5.7× at 50% system load over NGINX with 16 workers. Finally, running Redis [78], a popular key-value store with built-in master-slave replication, over R2P2 demonstrates an increase of 4.8×– 5.6× in throughput vs. vanilla Redis (over TCP) at a 200µs tail-latency SLO for different `read:write` ratios. The Redis improvements are due to the cumulative benefits of a leaner protocol, kernel bypass, and scheduling improvements.

The paper is organized as follows: §2 provides the necessary background. §3 describes the R2P2 protocol and §4 its implementation. §5 is the experimental evaluation of R2P2. We discuss related work in §6 and conclude in §7. The R2P2 source code is available at `https://github.com/epfl-dcsl/r2p2`.

2 Background

2.1 Datacenter RPCs

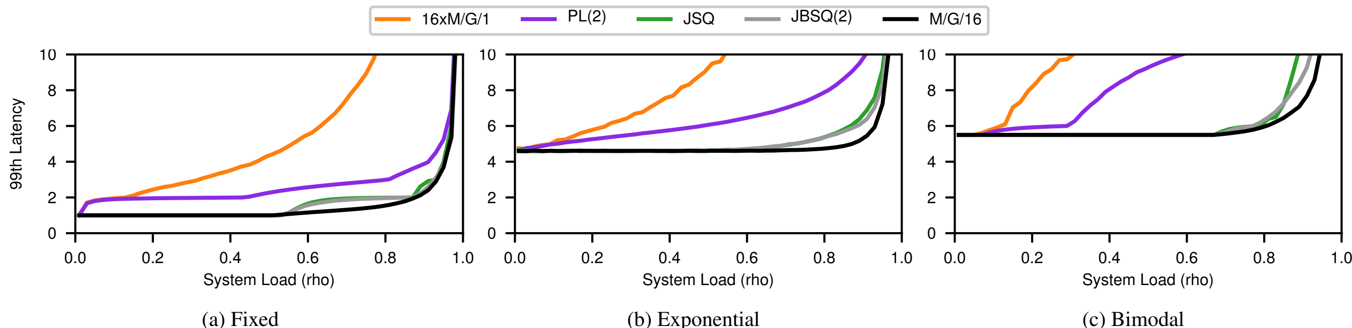
TCP has emerged as the main transport protocol for latency-sensitive, intra-datacenter RPCs running on commodity hardware, as its reliable stream semantics provide a convenient abstraction to build upon. Such use is quite a deviation from the original design of a wide-area, connection-oriented protocol for both interactive (*e.g.,* `telnet`) and file transfer applications. TCP's generality comes with a certain cost as RPC workloads usually consist of short flows in each direction. In many cases, the requests and replies are small and can fit in a single packet [5,63]. Although RDMA is an alternative, it has specific hardware requirements and can be cumbersome to program, leading to application-specific solutions [22,42,43].

Overall, the requirements of RPCs differ from the assumptions made by TCP in terms of failure semantics, connection multiplexing, API scalability, and end-point buffering:

RPC semantics: Some datacenter applications choose weak consistency models [18] to lower tail latency. These applications typically decompose the problem into a series of independent, often idempotent, RPCs with no specific ordering guarantees. Requests and responses always come in pairs that are semantically independent from other pairs. Thus, the reliable, in-order stream provided by TCP far stronger than the applications needs and comes with additional network and system overheads.

Connection multiplexing: To amortize the setup cost of TCP flows, RPCs are typically layered on top of persistent connections, and most higher-level protocols support multiple outstanding RPCs on a flow, *e.g.,* `HTTP/2`, memcache, *etc.* Multiplexing different RPCs on the same flow implies ordering the requests that share a socket, even though the individual RPCs are semantically independent. This ordering limits scheduling choices and can lead to Head-of-Line-Blocking (HOL). HOL appears when fast requests are stuck behind a slower request and when a single packet drop affects multiple pending requests.

Connection scalability: The high fan-in, high fan-out patterns of datacenter applications lead to large number of connections and push commodity operating systems beyond their



(a) Fixed (b) Exponential (c) Bimodal

Figure 1: Simulation results for the 99th percentile latency across 3 service time distributions with $\bar{S} = 1$

efficiency point. Recent work has addressed the issue either by deviating from the POSIX socket interface while maintaining TCP as the transport [9] or by developing custom protocols, *e.g.,* to deploy memcached on a combination of connection-less UDP for RPC `get` and router proxy for RPC `set` [67].

Endpoint bufferbloat: Prior work has addressed network-specific issues of congestion management and reliability within the network [2, 3]. Unfortunately, the use of TCP via the POSIX socket API leads to buffering in both endpoints over which applications have little control or visibility [45]. Applications willing to trade-off harvest vs. yield [29] would ideally never issue RPCs with no chance of returning by the deadline due to buffering in the network stack.

2.2 Load balancing

The problem of spreading out load extends to load balancing across servers within a distributed, scale-out environment. Load balancers encapsulate a set of servers behind a single virtual IP address and improve the availability and capacity of applications. Load balancing decisions, however, can severely affect throughput and tail-latency; thus, a significant amount of infrastructure is dedicated to load balancing [23, 60]. Load balancers can be implemented either in software [23, 64, 69] or in hardware [1, 16, 25, 60] and fall into two broad categories: (1) Layer-4 ("network") load balancers that use the 5-tuple information of the TCP or UDP flow to select a destination server. The assignment is static and independent of the load; (2) Layer-7 ("application") load balancers come in the form of `HTTP` reverse proxies as well as protocol-specific routers implemented in software middleboxes [67] or SDN switches [13, 15]. These load balancers terminate the client TCP connections, use dynamic policies to select a target, and reissue the request to the server on a different connection.

Layer-7 load balancers support many policies to decide the eventual RPC target, including random, power-of-two [61], round-robin, Join-Shortest-Queue (JSQ), and Join-Idle-Queue (JIQ) [55]. Layer-7 load balancers are ubiquitous at the web tier and can theoretically mitigate tail-latency better, due to their dynamic policies. However, they are less commonly deployed within tiers of applications to support µs-scale RPCs. The reasons for this are (i) the increased latency due to the extra hop (ii) the scalability issues introduced when all requests and responses flow through a proxy.

2.3 As a queuing theory problem

In this section, we approach the problem of RPC load balancing from a theoretical point of view by abstracting away system aspects using basic queuing theory. We show the benefits of request-level load balancing over random-selection among distributed queues (which is equivalent to L4 load balancing) in improving tail-latency, and we evaluate different request-level load balancing policies.

Fortunately, the theoretical answers are clear: single-queue, multi-worker models (*i.e.,* `M/G/k` according to Kendall's notation) perform better than distributed multi-queue models (*i.e.,* `k×M/G/1`, with one queue per worker) because they are work-conserving and guarantee that requests are processed in order [49, 90].

Between those two extremes, there are other models that improve upon random selection and are practically implementable through L7 load balancing. Power-of-two [61] (`PL(2)`), or similar schemes, are still in the realm of randomized load balancing, but perform better than a blind random selection. `JSQ` performs close to a single queue model for low-variability service times [55].

We define Join-Bounded-Shortest-Queue `JBSQ(n)` as a policy that splits queues between a centralized component with an unbounded queue and distributed bounded queues of maximum depth `n` for each worker (including the task currently processed). The single-queue model is equivalent to `JBSQ(1)` whereas `JSQ` is equivalent to `JBSQ(∞)`.

Figure 1 quantifies the tail-latency benefit, at the 99th percentile, for these queuing models observed in a discrete event simulation. We evaluate a configuration with a Poisson arrival process, $k = 16$ workers, and three well-known distributions with the same service time $\bar{S} = 1$. These distributions are: deterministic, exponential and bimodal-1 (where 90% of re-

quests execute in .5 and 10% in 5.5 units) [55].

From the simulation results, we conclude that: (1) there is a dramatic gap in performance between the random, multi-queue model and the single-queue approach, which is optimal among FCFS queuing systems. (There is no universally optimal scheduling strategy for tail-latency [90].) (2) `PL(2)` improves upon random selection, but these benefits diminish as service time variability increases. `JSQ` performs close to the optimal for low service time variability. (3) `JBSQ(2)`, while it deviates from the single queue model, outperforms `JSQ` under high load as the service time variability increases.

These results are purely theoretical and in particular assume perfect global knowledge by the scheduler or load balancer. This global view would be the result of communication between the workers and the load balancer in a real deployment. Any practical system must consider I/O bottlenecks and additional scheduling delays because of this communication. In this paper, we make the claim that `JBSQ(n)` can be implemented in a practical system and can deliver maximal throughput with small values of n even for µs-scale tasks, thus minimizing tail latency and head-of-line blocking.

3 R2P2: A transport protocol for RPCs

We propose R2P2 (*Request-Response Pair Protocol*), a UDP-based transport protocol specifically targeting latency-critical RPCs within a distributed infrastructure, *i.e.,* a datacenter. R2P2 exposes the RPC abstraction to the network, thus allowing for efficient in-network request-level load balancing.

R2P2 is a connectionless transport protocol capable of supporting higher-level protocols such as `HTTP` without protocol-level modifications. Unlike traditional multiplexing of the RPC onto a reliable byte-oriented connection, R2P2 is an inherently request/reply-oriented protocol that maintains no state across requests. The R2P2 request-response pair is initiated by the client and is uniquely identified by a triplet of $< src_IP, src_port, req_id >$. This design choice decouples the request destination (set by the client) from the actual server that will reply, thus breaking the point-to-point RPC communication semantics and enabling the implementation of any request-level load balancing policy.

Figure 2 describes the interactions and the packets exchanged in sending and receiving an RPC within a distributed infrastructure that uses a request router to load balance requests across the servers. We illustrate the general case of a multi-packet request and a multi-packet response.

1. A `REQ0` message opens the RPC interaction, uniquely defined by the combination of source IP, UDP port, and an RPC sequence number. The datagram may contain the beginning of the RPC request itself.

2. The router identifies a suitable target server and directs the message to it. If there is no available server, requests can temporarily queue up in the router.

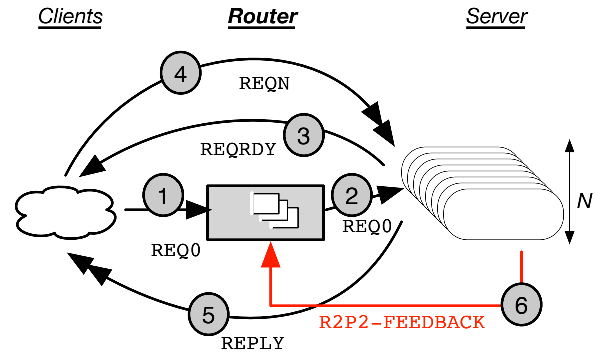


Figure 2: The R2P2 protocol for a request-reply exchange. Each message is carried within a UDP packet. Single arrows represent a single packet whereas double arrows represent a stream of datagrams.

3. If the RPC request exceeds the size of data in the `REQ0` payload, then the server uses a `REQready` message to inform the client that it has been selected and that it will process the request.

4. Following (3), the client directly sends the remainder of the request as `REQn` messages.

5. The server replies directly to the client with a stream of `REPLY` messages.

6. The servers send `R2P2-FEEDBACK` messages to the router to signal idleness, availability, or health, depending on the load balancing policies.

We note a few obvious consequences and benefits of the design: (i) Given that an RPC is identified by the triplet, responses can arrive from a different machine than the original destination. Responses are sent directly to the client, bypassing the router; (ii) there is no head-of-line blocking resulting from multiplexing RPCs on a socket, since there are no sockets and each request-response pair is treated independently; (iii) there are no ordering guarantees across RPCs; (iv) the protocol is suited for both short and long RPCs. By avoiding the router for `REQn` message and replies, the router capacity is only limited by its hardware packet processing rate, not by the overall amount of size of the messages.

Unlike protocols that blindly provide reliable message delivery, R2P2 exposes failures and delays to the application. R2P2 follows the end-to-end argument in systems design [80]. A client application initiates a request-response pair and determines the failure policy of each RPC according to its specific needs and SLOs. By propagating failures to the application, the developer is free to choose between *at-least-once* and *at-most-once* semantics by re-issuing the same request that failed. Unlike TCP, failures affect only the RPC in question, not other requests. This is useful in cases with fan-out replicated

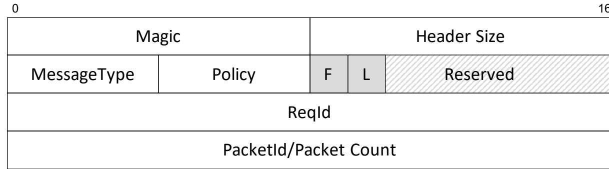

Figure 3: R2P2 Header Format

Message	Description
REQUEST	A message carrying an RPC request
REPLY	A message carrying an RPC reply
REQRDY	Sent by the server to the client to ack the REQ0 of a multi-packet request
R2P2-FEEDBACK	Sent by the server to the router
DROP	Sent by the router or the server to a client to explicitly drop a request
SACK	Sent by the client or the server to ask for missing packets in a request or reply

Table 1: The R2P2 message types

requests, where R2P2 can provide system support for the implementation of tail-mitigation techniques, such as hedged requests [17].

While novel in the context of µs-scale, in-memory computing, the connection "pair" is similar in spirit to the "exchange" that is the core of the SCSI/Fibre Channel protocol (FCP [27]). For example, a single-packet-request-multi-packet-response RPC over R2P2 would be similar to SCSI `read` within a single fibre channel exchange. Equivalently, an R2P2 multi-packet-request-single-packet-response would be similar to a SCSI `write`.

3.1 Transport considerations

Figure 3 describes a proposed R2P2 header, while Table 1 includes the different R2P2 messages. All R2P2 messages are UDP datagrams. R2P2 supports a 16-bit request id whose scope is local to the `(src_ip, src_port)` pair. As such, each client (`(src_ip, src_port)` pair) can have up to 65536 outstanding RPCs, well beyond any practical limitations. The R2P2 header also includes a 16-bit packet id meaning that each R2P2 message can consist of up to 65536 MTU-sized packets. The above two fields can be extended, if necessary, without changing the protocol semantics. Currently R2P2 uses two flags (`F, L`) to denote the first and last packet of a request.

Finally, the R2P2 header contains a `Policy` field, which allows client applications to directly specify certain policies to the router, or any other intermediate middlebox, for this specific RPC. Currently, the only implemented policies are `unrestricted`, which allows the router to direct `REQ0` packet to any worker in the set, and `sticky`, which forces the router to direct the message to the master worker among the set. This mechanism is central to our implementation of a tail-tolerant Redis, based on a master/slave architecture. It is used to direct writes to the master, but balances reads according to the load balancing policy. Additional policies, *e.g.,* session-stickiness, or policies implementing different consistency models, can be implemented in R2P2 middleboxes and will be identified by this header field, thus showcasing the benefits of R2P2's in-network RPC awareness.

Deployment assumptions: We assume that R2P2 is deployed within a datacenter, *i.e.,* the clients, router and servers are connected by a high-bandwidth, low-latency Ethernet fabric. We make no assumptions about the core network that can depend either on ECMP flow hashing or packet spraying [30, 32, 63]. R2P2 tolerates packet reordering within the same message and reconstructs the message at the end-point. By design, though, there is no ordering guarantee across RPCs, even if they are sent by the same client.

Timer management: Given that the assumed deployment model allows for packet reordering, packet loss detection depends on timers. There is one retransmission timeout `RTO` timer used for multi-packet requests or responses. It is in the order of milliseconds and triggers the transmission of a `SACK` message request for the missing packets. Servers garbage collect RPCs with failed multi-packet requests or multi-packet replies after a few `RTO`s. On the client side there is a timer set by the client application when sending the request. This timer is disarmed when the whole reply is received, and can be as aggressive as the application SLO. Based on this timer applications can implement tail-mitigation techniques [17] or early drop requests based on their importance.

Congestion management: R2P2 focuses on reducing queuing on the server side; we do not make any explicit contribution in congestion control. Instead, R2P2 can utilize existing solutions for congestion control, including (1) Homa [63], whose message semantics easily map to R2P2's request-response semantics and (2) ECN-based schemes such as DCTCP [2] and DCQCN [94]. Congestion control will be necessary only for multi-packet requests and replies (`REQN` and `REPLY`), and is independent of the interactions described in Fig 2.

Flow Control: R2P2 implements two levels of flow control, one between the client and the middlebox and one between the middlebox and the servers. R2P2 middleboxes can drop individual requests, either randomly or based on certain priority policies, if they become congested, without affecting other requests, thus implementing the first level of flow control. Based on the functionality and the policy, the middlebox is in charge of implementing the second level of flow control to the servers. In the `JBSQ` case, `JBSQ` limits the number of

outstanding requests on each server, thus servers can not be overwhelmed.

3.2 API

R2P2 exposes a non-POSIX API specifically designed for RPC workloads. Making RPCs first class citizens and exposing the request-response abstraction through the networking stack significantly simplifies writing client-server applications. Application code that traditionally implements the RPC logic on top of a byte stream abstraction is now part of the R2P2 layer of the networking stack.

Table 2 summarizes the corresponding application calls and callbacks for the client and server application. The API has an asynchronous design that allows applications to easily send and receive independent RPCs. When calling `r2p2_send_req` the client application sets the timer timeout and callback functions independently for each RPC request. The client and server applications are notified only when the entire response or request messages have arrived through the `req_success` and `req_recv` callbacks, equivalently.

3.3 `JBSQ` router design considerations

R2P2 exposes the request-response abstraction to the network as a first-class citizen. It is expected that a software or hardware middlebox will manipulate client requests to implement a certain policy, *e.g.,* scheduling, load balancing, admission control, or even application logic, *e.g.,* routing requests to the right server in a distributed hash table. In this section, we discuss the design choices regarding an R2P2 request router implementing the `JBSQ` scheduling policy. Similar ideas can be applied to other middleboxes with alternative functionality.

The choice of `JBSQ`: As seen in § 2.3 `JSQ` and `JBSQ` perform closer to the optimal single queue model. `JBSQ` though offers several practical benefits over `JSQ`. It implements router-servers flow control and can be implemented within a Tofino ASIC. JSQ requires finding the minimum among a number of values, which is hard to implement in a hardware dataplane. Also, JBSQ achieves better latency under high load and service time dispersion. That is because JSQ uses the queue size as a proxy for queuing time, which can be misleading in the presence of service-time dispersion.

Application Calls	
Type	**Description**
r2p2_poll	Poll for incoming req/resp
r2p2_send_req	Send a request
r2p2_send_response	Send a response
r2p2_message_done	Deallocate a request or response

Callbacks	
Type	**Description**
req_recv	Received a new request
req_success	Request was successful
req_timeout	Timer expired
req_error	Error condition

Table 2: The `r2p2-lib` API

R2P2-FEEDBACK messages: To implement the `JBSQ(n)` policy we leverage the `R2P2-FEEDBACK` messages provided by the R2P2 specification. These messages, sent by the servers back to the router after completing the service of a request, specify: (i) The maximum number of outstanding RPCs the server is willing to serve (the "`n`" in `JBSQ(n)`). By sending the current "`n`" in every `R2P2-FEEDBACK` message, servers can dynamically change the number of outstanding requests based on the application SLOs. (ii) The number of requests this server has served including the last request. The router uses this information to track the current number of outstanding requests in the server's bounded queue. This field makes the message itself idempotent and the protocol robust to `R2P2-FEEDBACK` drops.

We note that this approach puts each server in charge of controlling its own lifecycle by sending unsolicited `R2P2-FEEDBACK` messages, *e.g.,* to join a load balancing group, leave it, adjust its bounded queue size based on its idle time, or to periodically signal its idleness.

Direct client request - direct server return: R2P2 implements direct server return (DSR) [34, 65] since the replies do not go through the router. This is a widely-used technique in L4 load balancers with static policies [65]. R2P2 uses DSR while implementing request-level load balancing. In addition, R2P2 implements direct client request, where the router handles only the first packet of a multi-packet request, while the rest is streamed directly to the corresponding server, thus avoiding router IO bottlenecks.

Deployment: A software R2P2 router is deployed as a middlebox and traffic is directed to its IP address. The hardware R2P2 router is also deployed as an IP-addressed middlebox. The same hardware can also be a Top-of-Rack switch serving traffic to servers within the rack, following a "rack-scale" deployment pattern. In such a pattern, the router has full visibility on the RPC traffic to the rack and all packets go through the ToR switch. This could enable simplifications to the packet exchange, *e.g.,* using `R2P2-FEEDBACK` messages only for changing the depth of the bounded queues; the ToR can estimate their current size by tracking the traffic.

Router high availability: The router itself is nearly stateless and a highly-available implementation of the router is relatively trivial. Upon a router failure, only soft state regarding the routing policy is lost, including the current size of the per-worker bounded queue and the queue of pending RPCs. Clients simply failover to the backup router using a virtual IP address and reissue RPCs upon timeout, using the

exact same mechanism used to handle a REQ0 packet loss. Servers reconstruct the relationship with the router with their R2P2-FEEDBACK message to the new router.

Server membership: Servers behind the R2P2 router can fail and new servers can join the load balancing group. R2P2-FEEDBACK messages implicitly confirm to the router that a server is alive. In case of a failure, the lack of R2P2-FEEDBACK messages will prevent the router from sending requests to the failed server, and the bounded nature of JBSQ(n) limits the number of affected RPCs. Similarly, newly-added servers can send R2P2-FEEDBACK messages to the router informing about their availability to serve requests.

The choice of JBSQ(n): The choice of n in JBSQ is crucial. A small n will behave closer to a single-queue model, but will restrict throughput. The rationale behind the choice of n is similar to the Bandwidth Delay Product. On each queue there should be enough outstanding requests so that the server does not stay idle during the server-router communication. For example, for a communication delay of around 15 µs and a fixed service time of 10 µs, n=3 is enough to achieve full throughput. Shorter service times will require higher n values. High service time dispersion and batching on the server will also require higher values than what predicted by the heuristic. Servers can even dynamically adjust the value of n based on their processing rate and minimal idle time between requests.

4 Implementation

We implement (1) r2p2-lib as userspace Linux library on top of either UDP sockets or DPDK [21] (§4.1); (2) the software R2P2 router on top of DPDK (§4.2) and (3) the hardware solution in the $P4_{14}$ programming language [72] to run within a Barefoot Tofino ASIC [6] (§4.3).

4.1 r2p2-lib

The library links into both client and server application code. It exposes the previously described API and abstracts the differences between the Linux socket and the DPDK-based implementations. The current implementation is non-blocking and rpc_poll is typically called in a spin loop. To do so, we depend on epoll for Linux, while for DPDK we implemented a thin ARP, IP, and UDP layer on top of DPDK's polling mode driver, and exposed that to r2p2-lib. Our C implementation of r2p2-lib consists of 1300 SLOC.

R2P2 does not impose any threading model. Given the callback-based design, threads in charge of sending or receiving RPCs operate in a polling loop mode. The library supports symmetric models, where threads are in charge of both network and application processing, by having each thread manage and expose a distinct worker queue through a specific UDP destination port. The DPDK implementation further manages a distinct Tx and Rx queue per thread, and uses Flow Director [36] to steer traffic based on the UDP destination port. In an asymmetric model, a single dispatcher thread links with r2p2-lib, and the other worker threads are in charge of application processing only. This model exposes one worker queue via one UDP destination port.

4.2 Router - software implementation

We implemented a Random, a Round-Robin, a JSQ and a JBSQ(n) policy on the software router. The main implementation requirements for the router are (1) it should add the minimum possible latency overhead, and (2) it should be able to process short REQ0 and R2P2-FEEDBACK messages at line rate. While the router processes only those two types of packets, the order in which it processes them matters. Specifically for JBSQ, the ideal design separates REQ0 from R2P2-FEEDBACK messages into two distinct ingress queues and processes R2P2-FEEDBACKs with higher priority to ensure that the server state information is up-to-date and minimize queuing delays.

Our DPDK implementation uses two different UDP ports, one for each message type, using Flow Director for queue separation. Given the strict priority of control messages and the focus on scalability, we chose a multi-threaded router implementation with split roles for REQ0 threads and R2P2-FEEDBACK threads, with each thread having its own Rx and Tx queues.

JBSQ(n) requires a counter per worker queue that counts the outstanding requests. To minimize cache-coherency traffic, the router maintains two single-writer arrays, one updated on every REQ0 and the other on every R2P2-FEEDBACK, with one entry per worker.

The implementation of the R2P2-FEEDBACK thread is computationally very cheap and embarrassingly scalable. Processing REQ0 messages requires further optimizations to reduce cache-coherency traffic, *e.g.,* maintain the list of known idle workers, cache the current queue sizes, *etc.* Our implementation relies on adaptive bounded batching [9] to amortize the cost of PCIe I/O operations, as well as that of the cache-coherency traffic (the counters are read once per iteration). We limit the batch size to 64 packets.

Finally, we implement a tweak to the JBSQ(n) policy with $n \geq 2$: when no idle workers are present, up to 32 packets are held back for a bounded amount of time on the optimistic view that an R2P2-ACK message may announce the next idle worker. This optimization helps absorb instantaneous congestion and approximate the single-queue semantics in medium load situations.

4.3 P4/Tofino implementation

We built a proof-of-concept P4 implementations of R2P2 router for Tofino [6] using $P4_{14}$ [72]. Similar to the software implementation, the switch only processes REQ0 and

R2P2-FEEDBACK messages and leverages P4 registers to keep soft state. P4 registers are locations in the ASIC SRAM, which can be read and updated from both the control and dataplane.

We focus our description on the implementation of JBSQ(n) for the Tofino dataplane, as the others are trivial in comparison. It consists of 480 lines of P4 source, including header descriptions. Unlike the software implementation that can easily buffer the outstanding REQ0 messages if there is no available server queue, high-performance pipelined architectures, such as Tofino, do not allow buffering in the dataplane. Thus, our P4 logic executes as part of the ingress pipeline of the switch and relies heavily on the ability to recirculate packets through the dataplane via a virtual port. The implementation leverages an additional header that is added to the packet to carry metadata through the various recirculation rounds and is removed before forwarding the packet to the target server.

The logic for REQ0 tries to find a server with $\leq i$ outstanding packets in round i. There is one register instance corresponding to each server, holding the number of outstanding requests. If a suitable server is found, the register value is increased by one, the packet destination is changed to the address of the equivalent server, and the packet is directed to the egress port. We start with $i = 0$ and we increase till $i = n$ from JBSQ(n). When i reaches n and there is still no available server, we keep recirculating the packet without increasing i further. As an optimization to reduce the number of recirculations, the dataplane keeps the i for the last forwarded request and starts from that.

To overcome the Tofino limitation of only being able to compare a limited number of registers in one pass, we also leverage recirculation to inspect the outstanding requests of each bounded queue in each round. Register instances that correspond to different queues are organized in groups that can be checked in one pass. If no available queue is found in the first group, the packet is recirculated (without increasing i) and the second group of queues is checked, *etc.* When a REQ0 arrives, it is initially assigned to a group in a round-robin fashion to further reduce the amount of recirculations.

The logic for R2P2-FEEDBACK decrements the outstanding count for the specific server based on the packet source and consumes the packet without forwarding it.

The use of recirculation has two side-effects: (1) the order of RPCs cannot be guaranteed as one packet may be recirculated while another one is not; (2) the atomicity of the full set of comparisons is not guaranteed as R2P2-FEEDACK packet may be processed while an REQ0 packet is being recirculated. Non-optimal decisions may occur as the result of this race condition.

5 Evaluation

To evaluate the performance and the efficacy of the R2P2 protocol, the two implementations of the router, as well as the trade-offs in using JBSQ(n) over other routing policies, we run a series of synthetic microbenchmarks and two real applications in a distributed setup with multiple servers. The microbenchmarks depend on an RPC service with configurable service time and response size. All our experiments are open-loop [83] and clients generate requests with a Poisson inter-arrival time. We use two baselines and compare them against different configurations for R2P2 with and without the router: (1) vanilla NGINX [66] serving as reverse proxy for HTTP requests; and (2) ZygOS [76], a state-of-the-art work-conserving multicore scheduler. As a load generator we use an early version of Lancet [46].

Our experimental setup consists of cluster of 17 machines connected by a Quanta/Cumulus 48x10GbE switch with a Broadcom Trident+ ASIC. The machines are a mix of Xeon E5-2637 @ 3.5 GHz with 8 cores (16 hyperthreads), and Xeon E5-2650 @ 2.6 GHz with 16 cores (32 hyperthreads). All machines are configured with Intel x520 10GbE NICs (82599EB chipset). To reduce latency and jitter, we configured the machine that measures latency to direct all UDP packets to the same NIC queue via Flow Director. The Barefoot Tofino ASIC runs within a Edgecore Wedge100BF-32X. The Edgecore is directly connected to the Quanta switch via a 40Gbps link and therefore operates as a 1-port router.

5.1 Router characterization

We use the synthetic RPC service to evaluate the latency overhead of the router, the maximal throughput and the optimal request load balancing policy. We configure a setup of 4 servers with 16 threads (64 independent workers), running the synthetic RPC service over DPDK.

Throughput: We first evaluate the sustainable throughput of the software router. We run a synthetic RPC service with 8-byte requests and we configure the size of the response.

Figure 4 shows the achieved goodput as a function of the response size, and compares a configuration with R2P2 messages handled by a JBSQ load balancing policy, with a NGINX configured as reverse proxy for HTTP messages. For small response sizes, the router is bottlenecked by the router's NIC's packets per second (PPS), or the number of outstanding requests in each queue, n in $JBSQ(n)$. JBSQ(3) was enough to achieve maximum throughput. As the response size increases though, the application goodput converges to $4 \times$ 10GbE, the NIC bottleneck of the 4 servers with payloads as small as 2048. Obviously, this is made possible by the protocol itself, which bypasses the router for all REPLY messages. Note that because R2P2 leverages both Direct Server Return and Direct Client Request, even in cases of large requests the router would not be the bottleneck, unlike traditional L4 DSR-enabled load balancing. In contrast, the NGINX I/O bottleneck limits goodput to the load balancer's 10Gbps NIC.

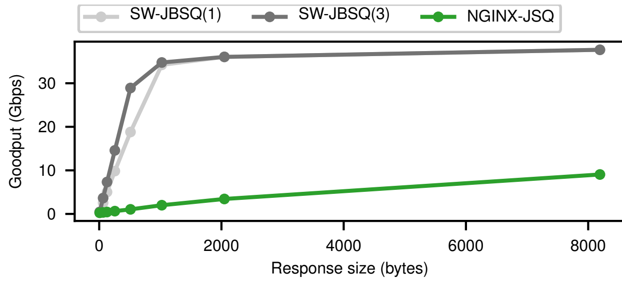

Figure 4: Achieved Goodput as a function of the response size for the JBSQ policy on the software router managing 4 servers connected with 10GbE NICs compared to NGINX configured as HTTP reverse proxy loadbalancing the same 4 servers using a JSQ policy.

Latency overheads and saturation: Figure 5 uses a zero-cost ("echo") RPC service with 8-byte requests and responses, to measure the 99th percentile tail latency as a function of the load for the software middlebox and the Tofino router with the JBSQ policy. As a baseline, we use a DIRECT configuration where clients bypass the router and send requests directly to the servers after a random choice. The figure shows that the latency added by the router is 5µs for the software middlebox and 1µs for the Tofino solution. The software latency is consistent with the characteristics of one-way forwarding performance of the Intel x520 chipset using DPDK. The hardware latency is consistent with the behavior of an ASIC solution that processes and rewrites packet headers in the dataplane. Figure 5 also shows the point of saturation, which corresponds to 7 MRPS for the software middlebox. Given that for every request forwarded the router receives one R2P2-FEEDBACK message, the router handles more than 14M PPS, which is the hardware limit. We were unable to characterize the maximal per-port capability of the Tofino ASIC running the R2P2 logic beyond >8 MRPPS with tiny requests and replies, simply for lack of available client machines. We also observe that the hardware implementation, as expected, requires a smaller n for JBSQ(n). In the figure we show the smallest value of n that achieved maximum throughput.

Comparison of scheduling policies: Figure 6 uses a synthetic $\bar{S} = 25\mu s$ workload to evaluate the different request load balancing policies, implemented on the software router. We evaluate the following policies: DIRECT, where clients bypass the router by making a random server selection, RANDOM where clients talk to the router and the router makes a random selection among the servers, RR where the router selects a target server in a round-robin manner, SW-JBSQ(n) which is the software implementation for the bounded shortest queue with n outstanding requests, and JSQ which is the R2P2 router's implementation of the join-shortest-queue policy. We also compare R2P2 with using NGINX as an HTTP reverse proxy implementing a JSQ policy, which is a vanilla, widely-used

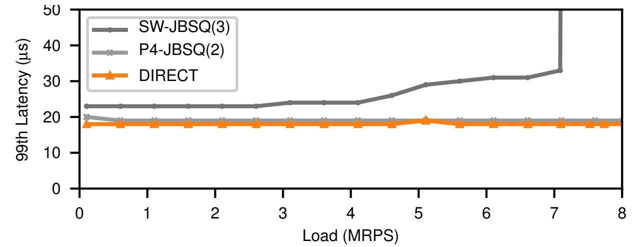

Figure 5: Tail-latency as a function of throughput for a zero service time synthetic RPC service for the software (SW-JBSQ) and the Tofino (P4-JBSQ) implementation of JBSQ compared to DIRECT. In DIRECT clients bypass the router and talk directly to servers by making a random server choice.

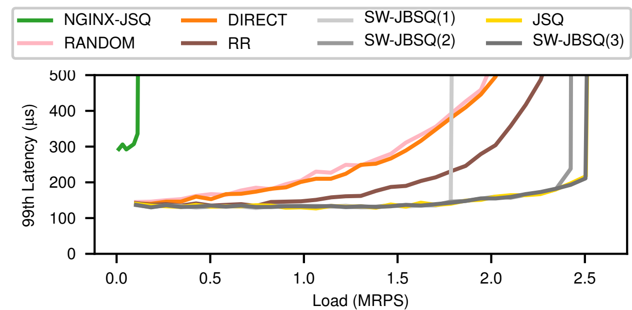

Figure 6: Evaluation of different load balancing policies for an exponential service time workload with $\bar{S} = 25\mu s$.

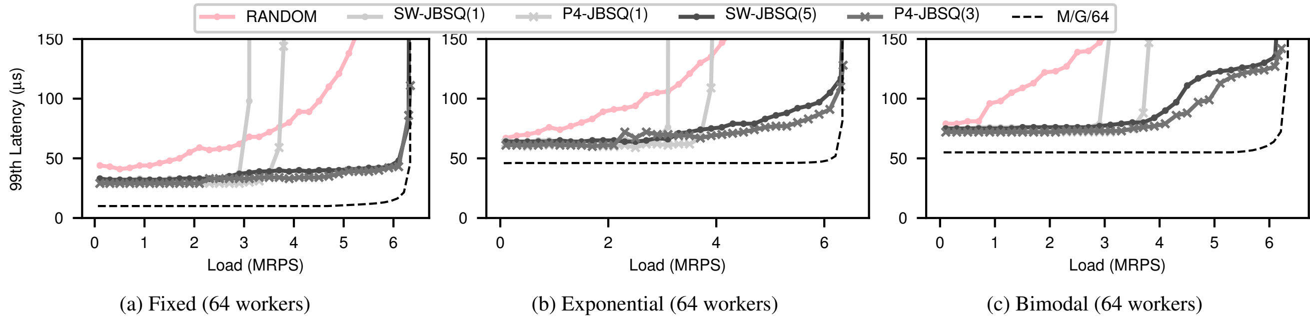
deployment for request-level load balancing.

We make the following observations: (i) NGINX overheads prevent throughput scalability; (ii) DIRECT and RAND configurations perform similarly for R2P2, which is the result of a random choice (in the client or the router equivalently); (iii) RR performs better than random choice, but worse than JBSQ, given the service time dispersion; (iv) JBSQ($n \geq 3$) achieves maximum throughput. Given that the communication time between the server and the router is $\sim 15\mu s$ and the exponential service time dispersion, this is on par with our analysis in § 3.3. (v) JSQ performs similarly to JBSQ(3) for this service time.

5.2 Synthetic Time Microbenchmarks

Figure 7 evaluates JBSQ(n) performance with an aggressive $\bar{S} = 10\mu s$ mean service time and three different service time distributions: Fixed, Exponential and Bimodal where 10% of the request are 10x slower than the rest [55]. We present results for both the software and Tofino implementation, for JBSQ(1) and the optimal n choice for each configuration. Requests and the responses are 8 bytes. We observe:

- For all experiments, all JBSQ(n) variants approximate the optimal single-queue approach ($M/G/64$) until the saturation point for JBSQ(1).



(a) Fixed (64 workers) (b) Exponential (64 workers) (c) Bimodal (64 workers)

Figure 7: Synthetic Service Time Microbenchmarks. Service time $\bar{S} = 10\mu s$.

- Beyond the saturation point of `JBSQ(1)`, an increase in the tail latency as the system configuration trades off higher throughput (*i.e.,* `JBSQ(`$n > 1$`)`) against the use of a theoretically-optimal approach.

- A comparison between the software and hardware implementation shows that more outstanding requests are required for the software implementation; this is because the communication latency between the server and the hardware router is $\sim 5\mu s$ faster.

- `JBSQ` achieves the optimal performance, as predicted by the `M/G/64` model, both for the software and the hardware implementation within the 150µs SLO.

- Reducing `n` can have a considerable impact on tail-latency especially in cases with high service time dispersion, as it can be seen in Figure 7c (`SW-JBSQ(5)` vs. `P4-JBSQ(3)`)

5.3 Multi-packet Requests Microbenchmark

R2P2 implements the following logic in splitting requests to packets. If the request fits in a single packet, the whole request payload is transferred with `REQ0`. In the case of a multi-packet request, `REQ0` is a 64-byte packet, carrying only the first part of the request and the rest of the payload is transferred with the `REQN` packets directly to the server. This way the router does not become a throughput bottleneck in the case of large requests, while the extra round-trip is avoided in the case of small requests.

To evaluate the extra round-trip that R2P2 introduces in the case of multi-packet requests with the distinction between `REQ0` and `REQN`, we ran a synthetic microbenchmark with larger requests. Based on the above logic, a 1464-byte request is the biggest request that fits in a single packet given the size of protocol headers. Equivalently, a 1465-byte request is the smallest request that requires 2 packets, and consequently an extra round-trip. We run the synthetic service time RPC server with the bimodal service time distribution of $\bar{S} = 10$ and the 2 different request sizes. We compare the `DIRECT` deployment with one using the router with the `JBSQ` policy.

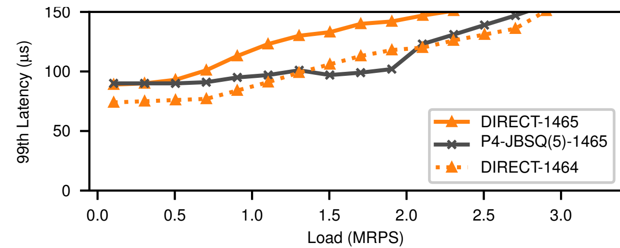


Figure 8: Bimodal service time with $\bar{S} = 10\mu s$ and 64 workers with single and multi-packet requests. `DIRECT-1464` corresponds to an 1-packet request, while `DIRECT-1465` and `P4-JBSQ(5)` correspond to 2-packet requests.

Figure 8 summarizes the result of the experiment. We observe that there is a fixed gap of around 15µs between `DIRECT-1464` and `DIRECT-1465` curves that corresponds to the extra round-trip between the client and the server. We, also, run the multi-packet request scenario while using the P4 router with the `JBSQ` policy. We show that despite the extra round-trip, the intermediate hop, and the increased number of packets to process, the 99th percentile latency is close to the single-packet scenario in the `DIRECT` case, which justifies our design decision to pay an extra round-trip to achieve better scheduling.

5.4 Using R2P2 for server work conservation

We now demonstrate how the use of network-based load balancing, *e.g.,* using R2P2, can increase the efficiency of a *single* server scheduling tasks. For this, we compare R2P2 with `JBSQ` with the performance of ZygOS [76], a state-of-the-art system optimized for µs-scale, multicore computing that includes a work-conserving scheduler within a specialized operating system. ZygOS relies on work-stealing across idle cores and makes heavy use of inter-processor interrupts. Both ZygOS and `JBSQ(n)` offer a work-conserving solution to dispatch requests across the multiple cores of a server: Zy-

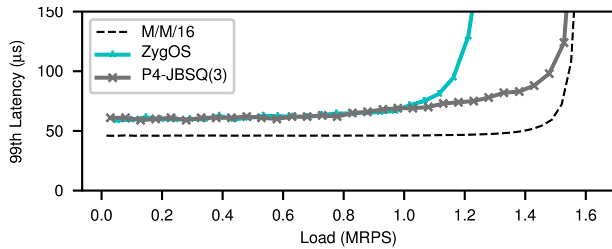

Figure 9: Comparison of R2P2 with the ZygOS [76] work-conserving scheduler: Exponential workload with $\bar{S} = 10\mu s$.

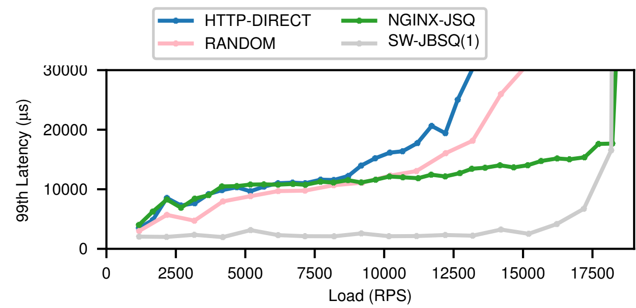

Figure 10: Lucene++ running on 16 16-threaded workers

gOS does it within the server in a protocol-agnostic manner, whereas R2P2 implements the policy in the network.

Figure 9 compares ZygOS with the Tofino implementation of `JBSQ(3)` for the 10µs exponentially-distributed service time workload using a single Xeon server. As in the previous configurations, for the R2P2 implementation each of the 16 Xeon cores, is exposed as a worker with a distinct queue to the router, listening to a different UDP port. In this experiment, the theoretical lower bound is therefore determined by $M/M/16$. We observe that `JBSQ(3)` exceeds the throughput performance of ZygOS, with no visible impact on tail latency despite the additional hop and that `JBSQ(3)` is sufficient to achieves the maximum throughput. For a service-level objective set at 150µs, R2P2 with `JBSQ(3)` outperforms ZygOS by 1.26×. The explanation is that the R2P2 server operates on a set of cores in parallel without synchronization or cache misses, whereas ZygOS has higher overheads due to protocol processing, boundary crossings, task stealing, and inter-processor interrupts.

5.5 Lucene++

Web search is a replicated, read-only workload with variability in the service time coming from the different query types, thus it is an ideal use-case for `R2P2-JBSQ`. For our experiments we used Lucene++ [56], which is a search library ported to serve queries via either HTTP or R2P2. A single I/O thread dispatches one request at a time to 16 Lucene++ worker threads, each of them searching part of the dataset. The experimental setup relies on 16 disjoint indices created from the English Wikipedia page articles dump [91], yielding an aggregated index size of 3.5MB. All indices are loaded in memory at the beginning of the execution to avoid disk accesses. The experimental workload is a subset of the Lucene nightly regression query list, with 10K queries that comprise of simple term, Boolean combinations of terms, proximity, and wildcard queries [57]. The median query service time is 750µs, with short requests taking less than 450µs and long ones over 10ms.

Figure 10 summarizes the experiment results for running Lucene++ on a 16-server cluster, each using 16 threads. The `NGINX-JSQ` and `HTTP-DIRECT` experiments rely on 1568 persistent TCP client connections. First, we observe that `HTTP-DIRECT` over TCP and `RANDOM` over R2P2 which are multi-queue models, have higher tail-latency. Then, we see that `NGINX-JSQ` and `SW-JBSQ(1)` on R2P2 deliver the same throughput; system and network protocol overheads are irrelevant for such coarse-grain workload. Also, $n = 1$ is enough to get maximum throughput, given the longer average service time. `SW-JBSQ(1)` delivers that throughput via the optimal single-queue implementation, with a significant impact on tail latency. As a result, R2P2 lowers the 99th percentile latency by 5.7× at 50% system load over `nginx`.

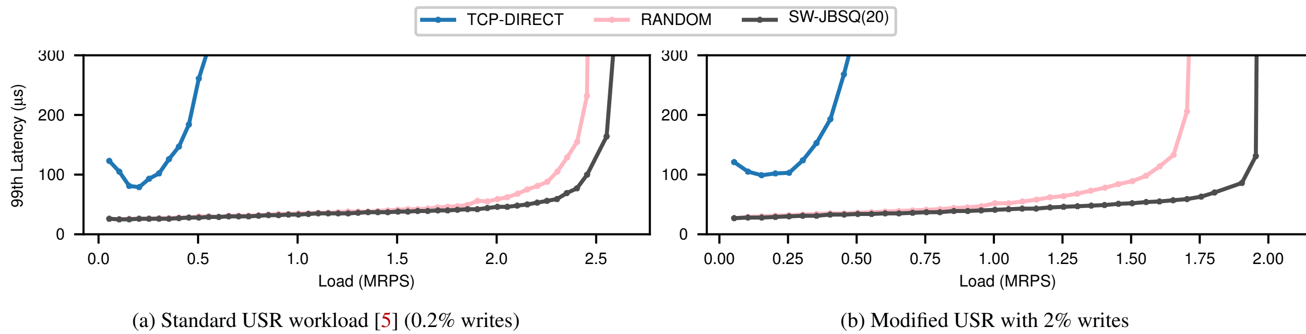
5.6 Redis

Redis [78] supports a master/slave replication scheme with read-only slaves. We ported Redis on R2P2 and ran it on DPDK for the Facebook USR workload [5]. We used the `sticky` R2P2 policy (see §3) to direct writes to the master node and we load balance reads across the master and slave nodes, based on the `RANDOM` and the `JBSQ` policy. Redis has sub-µs service times. Thus, to achieve maximum throughput we had to increase the number of tokens to 20 per worker (`SW-JBSQ(20)`), for the software router. For the vanilla Redis over TCP clients randomly select one of the servers for read requests, while they only send write requests to the master.

Figure 11a shows that R2P2, for an SLO of 200µs at the 99th percentile, achieves 5.30× better throughput for the USR workload over vanilla Redis over TCP (`TCP-DIRECT`) because of reduced protocol and system overheads, while `SW-JBSQ(20)` achieves slightly better throughput than `RANDOM` for the same SLO. Figure 11b increases the write percentage of the workload from 0.2% to 2%, which increases service time variability: R2P2 `RANDOM` has 4.09× better throughput than `TCP-DIRECT`. `SW-JBSQ(20)` further improves throughput by 18%, for a total speedup of 4.8×, as a result of better load balancing decisions.

6 Related work

RPCs can be transported by different IP-based protocols including HTTP2 [10], QUIC [48], SCTP [84], DCCP [47],



(a) Standard USR workload [5] (0.2% writes)

(b) Modified USR with 2% writes

Figure 11: 99th percentile latency vs. throughput for Redis in a 4-node master/slave configuration.

or similar research approaches [4, 28, 30, 32, 63] that identify the TCP limitations and optimize for flow-completion time. Libraries such as gRPC [31] and Thrift [86] abstract away the underlying transport stream into request-reply pairs. Approaches such as eRPC [41] aim at end-host system optimizations and are orthogonal to R2P2. Load balancers proxy RPC protocols such as HTTP in software [23, 66, 69] or in hardware [1, 16, 25, 60]. R2P2 exposes the RPC abstraction to the network to achieve better RPC scheduling, and to the application to hide the complexity of the underlying transport.

Load dispatching, direct or through load balancers, typically *pushes* requests to workers, requiring tail-mitigation techniques [17, 33]. In Join-Idle-Queue [55], workers *pull* requests whenever they are idle. R2P2 additionally supports `JBSQ(n)`, which exposes the tradeoff between maximal throughput and minimal tail latency explicitly.

Task scheduling in distributed big data systems is largely aimed at taming tail-latency and sometimes depends on split-queue designs [19, 20, 44, 71, 75, 77, 92], typically operating with millisecond-scale or larger tasks. R2P2 provides the foundation for scheduling of µs-scale tasks.

Multi-core servers are themselves distributed systems with scheduling and load balancing requirements. This is done by distributing flows using NIC mechanisms [79] in combination with operating systems [24, 73] or dataplane [9, 37, 74] support. Zygos [76] and Shinjuku [40] are an intra-server, work-conserving schedulers for short tasks that rely on task stealing and inter-processor interrupts. R2P2 eliminates the need for complex task stealing strategies by centralizing the logic in the router.

Recent work has focused on key-value stores [54,59,70,78]. MICA provide concurrent-read/exclusive-access (CREW) within a server [54] by offloading the routing decisions to the client, while hardware and software middleboxes [39, 53, 67] or SDN switches [13, 15] enhance the performance and functionality of key-value stores in-network. RackOut extended the notion of CREW to rack-scale systems [68]. R2P2 supports general-purpose RPCs not limited to key-value stores, together with a mechanisms for steering policies which can be used to implement CREW both within a single server and across the datacenter.

Finally, R2P2 adheres and encourages the in-network compute research path by increasing the network visibility to application logic and implementing in-network scheduling. Approaches leveraging in-network compute include caching [39, 53], replicated storage [38], network sequencing [51, 52], DNN training [81, 82], and database acceleration [50].

7 Conclusion

We revisit the requirements to support µs-scale RPCs across tiers of web-scale applications and propose to solve the problem in the network by making RPCs true first-class citizens of the datacenter. We design, implement and evaluate a proof-of-concept transport protocol developed specifically for µs-scale RPCs that exposes the RPC abstraction to the network and at the endpoints. We showcase the benefits of the new design by implementing efficient, tail-tolerant µs-scale RPC load-balancing based on a software router or a programmable P4 ASIC. Our approach outperforms standard load balancing proxies by an order of magnitude in throughput and latency, achieves close to the theoretical optimal behavior for 10µs tasks, reduces the tail latency of websearch by 5.7× at 50% load, and increases the scalability of Redis in a master-slave configuration by more than 4.8×.

Lancet: A self-correcting Latency Measuring Tool

Marios Kogias[1] Stephen Mallon[2] Edouard Bugnion[1]

[1]*EPFL, Switzerland* [2]*University of Sydney*

Abstract

We present LANCET, a self-correcting tool designed to measure the open-loop tail latency of µs-scale datacenter applications with high fan-in connection patterns. LANCET is self-correcting as it relies on online statistical tests to determine situations in which tail latency cannot be accurately measured from a statistical perspective. The workload configuration, the client infrastructure, or the application itself could, under circumstances, prevent accurate measurement. Because of its design, LANCET is also extremely easy to use. In fact, the user is only responsible for (i) configuring the workload parameters, *i.e.,* the mix of requests and the size of the client connection pool, and (ii) setting the desired confidence interval for a particular tail latency percentile. All other parameters, including the length of the warmup phase, the measurement duration, and the sampling rate, are dynamically determined by the LANCET experiment coordinator.

When available, LANCET leverages NIC-based hardware timestamping to measure RPC end-to-end latency. Otherwise, it uses an asymmetric setup with a latency-agent that leverages busy-polling system calls to reduce the client bias.

Our evaluation shows that LANCET automatically identifies situations in which tail latency cannot be determined and accurately reports the latency distribution of workloads with single-digit µs service time. For the workloads studied, LANCET can successfully report, with 95% confidence, the 99th percentile tail latency within an interval of $\leq$ 10µs. In comparison with state-of-the-art tools such as Mutilate and Treadmill, LANCET reports a latency cumulative distribution that is ~20µs lower when the NIC timestamping capability is available and ~10µs lower when it is not.

1 Introduction

Today's webscale datacenter applications such as search, social networking, and e-commerce all rely extensively on the decomposition of online, data-intensive queries into smaller subqueries that process data directly from the memory of hundreds or thousands of tightly-interconnected servers to ensure service-level objectives, scalability and availability [4,11,12,33,34]. The combined advancements in hardware technology (*e.g.,* 10-100Gbps NICs, cut-through switches, NVMe), system software (*e.g.,* dataplanes [6,49]), and data management systems (*e.g.,* in-memory databases and key-value stores [17,47,48,55]) now allow µs-scale interactions between application components [5]. The increased number of components involved in a single query and the extensive use of high fan-in, high fan-out patterns have shifted the performance focus to tail-latency considerations [11].

This emerging µs-scale computing era is characterized by new key performance metrics such as the tail-latency service-level objective (SLO), *e.g.,* 99th *percentile* $\leq$ 500µs [6,29]. To put this into perspective, 500µs is one order of magnitude longer than an in-memory relational database processing TPC-C [55] and two-to-three orders of magnitude longer than basic operations on a key-value store [17,35,48]. Yet, it is shorter than an operating system quantum, a TCP retransmission timeout, or the DVFS governor's reaction time [36]. This requires complete rethinking of traditional assumptions about systems, stacks, protocols, and applications [5,17,48,53]. A large body of research focuses on the systematic characterization and reduction of tail latency effects [6,13,14,23,27–29,34,36,50].

While throughput can easily be measured, tail latency is harder to capture and characterize in a statistically meaningful manner, as it depends on a number of factors beyond the workload itself. These factors include the choice of a tool with overheads and biases, its precise configuration, and the experimental methodology. The literature describes many pitfalls specific to latency, *e.g.,* Treadmill [58] discusses situations in which: (i) the inter-arrival request distribution does not match the production environment; (ii) the measuring methodology silently masks some tail behaviors; (iii) the measuring tool affects the measured end-to-end latency because the measuring granularity is too coarse-grained or because the clients are overloaded.

This matches our own experience in building and evaluating multiple research systems for µs-scale computing [6,30,

50, 51], which used either modified versions of Mutilate [33] or home-grown latency-measurement and load-generation tools. While these tools measured the tail latency of our systems as a function of the load, we were required to unscientifically tweak a large number of workload and system parameters in an ad-hoc manner by: (i) repeatedly increasing the number of load-generating clients until stability; (ii) repeatedly increasing the number of outstanding requests (*e.g.,* number of connections) until the tail-latency diverges at saturation, as expected in an open-loop process; (iii) and last, but not least, running each experiment "longer" with the hope of reducing result jitter.

This paper introduces LANCET, a self-correcting latency measurement tool designed to measure, in a statistically sound manner, the end-to-end tail latency of remote procedure calls in a testing environment. LANCET is self-correcting as it relies on on-line statistical tests to determine situations in which tail latency cannot be accurately measured. This includes situations when (i) the workload configuration, and in particular the number of client connections, leads to closed-loop behavior; (ii) the infrastructure (*e.g.,* number of machines) cannot generate the desired load without introducing client bias; (iii) the service time of the workload itself is heavy-tailed distributed.

Because it relies on statistical methods within its control system, LANCET is also easier to use than existing tools. While the scientist specifies the infrastructure used for an experiment (*e.g.,* number of client machines), and the workload itself (*e.g.,* mix reads and writes, distribution of keys and values, number of client connections, maximum number of outstanding requests per connection *etc.*), LANCET then automatically determines, using statistical tests, what can be measured and at which confidence interval. LANCET's control system internally sets additional experimental parameters such as the duration of the experiment and its warmup phase.

Finally, LANCET relies on state-of-the-art, hardware-based measurement techniques that combine NIC timestamping in hardware and userlevel matching of packets to RPCs. This approach noticeably eliminates the client bias, and increases the accuracy of individual measurements without creating a long-term dependency on immature kernel-bypass protocols stacks and libraries.

This paper contributes the methodology, design, and implementation of LANCET, with the following novel features:

- LANCET measures the open-loop tail latency of a workload using only two user-provided parameters: the target load level and the desired confidence interval at the target tail percentile. For this, it relies on proven statistical methods such as hypothesis testing to configure the experiment methodology parameters.
- LANCET is self-correcting and reports "N/A" when no statistically-sound tail latency can be measured. This can be due to limitations in workload specification, client infrastructure, or because the service time distribution has high variability.
- LANCET clearly separates (i) the methodological considerations, implemented by the LANCET controller, (ii) the measurement tool, implemented by a combination of agents, and (iii) the workloads and application-level protocol support, implemented in an extensible manner by the LANCET agent's internal API.
- LANCET is designed with stability and production deployment in mind, with a focus on Ethernet-based protocols. It therefore uses exclusively the standard Linux kernel-based implementations of networking protocols. For applicable NICs, LANCET supports hardware-based timestamping to measure TCP-based RPC latencies for improved measurement accuracy. Our work demonstrates that kernel-bypass is not necessary to achieve precise µs-scale client-side measurements.

Our evaluation of LANCET with workloads with synthetic service times demonstrates that it (i) automatically identifies the right number of samples necessary for the target experiment accuracy and result convergence; (ii) accurately reports the latency distributions for workloads with service time as short as $\bar{S} = 1\mu s$; and (iii) provides substantially more accurate results than Treadmill [58] and Mutilate [33], state-of-the-art tail latency measurement tools.

LANCET is open-source and can be found at `https://github.com/epfl-dcsl/lancet-tool`. The rest of the paper is structured as follows. We discuss the necessary background (§2), analyze a latency experiment (§3), and discuss the design (§4) and implementation of LANCET (§5). We then evaluate LANCET (§6) and compare our methodology to existing tools (§7), and conclude (§8).

2 Background

The accurate measurement of the latency of any software application serving RPCs requires the appropriate combination of metrics, tools, workloads and experimental methodology: (i) the metrics determine which type of latency is being measured for a certain load, whether mean, median, tail (*e.g.,* 99th percentile), or the empirical cumulative distribution function (ECDF); (ii) the choice of tool determines the precision of the benchmark; (iii) the choice of workload determines the degree of realism, generality, and relevance of the experiment; (iv) the choice of methodology determines the overall soundness of the results, their accuracy, and reproducibility.

The high-level process is straightforward: the tool acts as an RPC client which generates requests for the system(s) under test. The tool timestamps requests and corresponding replies to determine the end-to-end latency. The requests themselves are determined in a workload-specific manner (*e.g.,* a mix of

get and set with a specific distribution of keys). The individual request inter-arrival time typically follows a Poisson process for a given rate λ. For a fixed rate λ, scientists typically report the full ECDF or the complementary cumulative distribution or tail distribution (CCDF), often on a log scale, to highlight the tail latency levels (99th, 999th, *etc.*). To study the impact of load on latency, scientists repeat the fixed-rate experiment for different λ and report the tail latency as a function of the load [6, 14, 22, 29, 29, 33, 37, 50, 58]. Finally, for dynamic experiments that mimic daily datacenter patterns, the tool dynamically adjusts λ according to a diurnal (or accelerated) time pattern [4, 6, 51, 56].

2.1 Taxonomy of tools

We attempt to make a taxonomy of the existing tools for generating load and measuring latency, the techniques used and the main design decision.

Packet vs. RPC generators: At the highest level, latency measuring tools can be easily classified into packet generators, which measure a network device or a network function, and application RPC generators, which measure a server.

Packet generators use stateless network packets to measure the throughput and the latency of datacenter network equipment such as switches and routers as defined in RFCs [7, 39]. These tools can be implemented to achieve different levels of precision in software. For example, MoonGen [19], TRex [8], and netperf [46], rely on hardware timestamping facilities in modern NICs (*e.g.,* MoonGen) or use custom hardware appliances such as Spirent [54] or IXIA [24].

Application RPC generators measure the latency of client-server interactions using protocols such as http or memcached's binary protocol, typically implemented on top of TCP or RDMA connections. These tools provide advanced workload-generation capabilities. For example, Mutilate [33, 45] can model Facebook's various uses of key-value stores [4], YCSB [10, 57] can generate a Zipfian distribution of keys, and CloudSuite [9, 20] offers a mix of applications. For the rest of the paper, we will focus on RPC generators.

Open-loop vs. Closed loop: There are two main ways to control the flow of requests to the target. An open-loop system models $n = \infty$ clients that send requests to the target according to a rate λ and an inter-arrival distribution, *e.g.,* Poisson. A closed-loop system bounds the maximum number of possible outstanding requests at any given time. The distinction between an open and a closed loop system is a property of a specific deployment and the same system can be deployed under different scenarios, *e.g.,* a key-value store may serve only a few blocking clients (*i.e.,* closed-loop) or thousands of application servers, which is best modelled as open-loop. Testing for the right scenario is crucial because open-loop systems can lead to large queuing, and thus longer tail latencies, whereas closed-loop tail latencies are typically bounded by the number of possible outstanding requests. Tools such as Treadmill and Mutilate are open-loop systems, while others such as YCSB are closed-loop systems.

Generating the necessary load: Precise tools are typically used to evaluate the benefit of innovations in new hardware, protocol designs, kernel bypass architectures, networking stacks, operating system configurations, or applications. Leading research systems today can deliver high-throughput solutions that easily scale to millions of requests per second, even on commodity hardware. As a consequence, the load-generation and latency-measuring tools, which typically run on reference vanilla Linux infrastructure, must be distributed on multiple client machines to saturate a single server [6, 33, 50].

Multi-machine setups follow two basic design patterns. First, in symmetric generators, all client machines generate load and measure latency. Then, an external agent accumulates and processes the collected results to report the aggregated verdict. This category includes YCSB [10], Treadmill [58], CloudSuite [20], memaslap [43], *etc.* Unfortunately the open-source versions of these tools provide no coordinator or aggregator script to run them in a distributed fashion.

Second, the asymmetric design splits the client machines between load-generating and latency-measuring. The bulk of the load is generated by client machines that generate requests according to a specific inter-arrival distribution, *e.g.,* Poisson, in an open-loop manner without measuring latency, while a separate, dedicated client machine makes closed-loop requests to the same server and measures its latency. By reducing the system load on the latency-generating thread, such tools reduce client bias in the measurement. Mutilate [33] is the most well-known tool in that category.

Point of measurement: Latency can be measured at different points in the system resulting in different levels of accuracy. This includes the actual wire, the NIC, the Ethernet driver, the in-kernel socket layer, or the application itself. The point of measurement has a large impact on precision. According to Primorac *et al.* [52], (i) the packet generators using hardware-based NIC timestamping such as MoonGen can accurately measure the latency of stateless network functions up to the 99.99^{th} percentile whereas (ii) the best software solution relying on kernel bypass can only measure up to the 99th percentile, and (iii) the solutions relying on the traditional networking stack should not be used at all for µs-scale latency measurements.

NIC-based timestamping is available on mainstream NICs. Intel NICs, such as 10Gbe 82599 and x54, or 40Gbe x710, implement hardware timestamping only to support IEEE 1588 Precision Time Protocol [18]. This restricts the type and amount of packets that can be hardware-timestamped. The MoonGen packet generator takes advantage of this precise, yet

restrictive mechanism. The Mellanox NICs, *e.g.,* ConnectX-4 [42] or newer, offer general-purpose hardware timestamping support to all incoming and outgoing packets. The Linux kernel provides support for hardware timestamping via the Linux socket interface, yet deriving RPC timestamps from packet timestamps is challenging, as later described.

Another way to increase precision and reduce jitter is to leverage kernel bypass and NIC polling at the client. Tools such as MoonGen and T-Rex use the DPDK [16] toolkit for better performance and precision. Unfortunately, kernel bypass limits application and protocol support, and requires using less-proven protocol stacks as part of the experiment.

Reporting results: From a methodology perspective, most tools depend on histograms to compute latency percentiles, thus avoiding keeping all the recorded latency samples. Histograms with fixed bucket sizes, as used by Mutilate, can affect the reported results by masking tail phenomena, if not configured properly. Some tools such as Treadmill [58] propose a user-defined calibration phase to determine the bucket allocation. Other tools, such as TailBench [29], use dynamic histograms, whose bucket sizes change over the execution of the experiment. Finally, few tools, *e.g.,* Mutilate, allow collecting all latency samples and save them in a file to be used for plotting the ECDF.

2.2 Configuration burden

Load generators put the methodological burden on the scientist who configures it. For example, a scientist using Mutilate must first determine the time for each load experiments (default=5s), which must be long enough to be statistically sound; then specify the number of machines, threads and overall number connections for the load-generating agents, and the maximum number of outstanding requests per connection; and finally specify the configuration of the latency-measurement agent, which operates as a closed-loop with one outstanding request a time.

This configuration setup has subtle implications as (i) increasing the number of machines reduces client bias [58]; (ii) increasing the number of open sockets reduces the throughput of the server because of operating system overheads [6]; (iii) increasing the maximum number of outstanding requests per socket allows for batching and increases throughput; (iv) the product of the number of connections $\times$ the number of outstanding requests must be larger than the bandwidth-delay product of the workload if the scientist wishes to measure the open-loop tail latency of the service.

Figure 1 illustrates the challenge via the study of an out-of-the-box memcached/Linux deployment with Mutilate configured with 320 and 144 connections with one outstanding request each. We report the 99th tail latency as a function of the load. The orange curve (144 Connections) operates as a closed-loop, with the clients unable to generate the target rate,

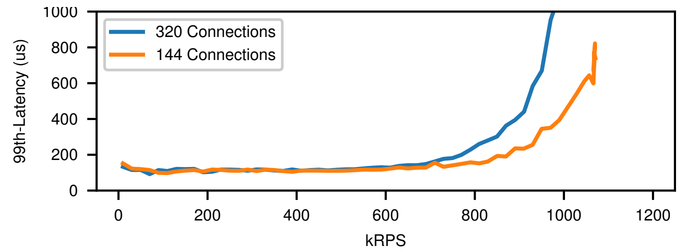

Figure 1: 99th percentile latency for memcached USR measure with Mutilate with 144 and 320 connections with 1 outstanding request per connection.

and without ever saturating the server. The lower reported tail latency is merely a reflection of the limited number of outstanding requests. This experiment can lead to false conclusions, *e.g.,* on the maximum throughput that meets a SLO (*e.g.,* $\leq 300\mu$s).

2.3 Statistics Background

This section provides the sufficient background to understand our use of statistical methods in LANCET.

Hypothesis testing: Statistical testing follows a specific thought process. Initially, the statistician formulates a null hypothesis implying that there is no relation between two populations and the observations are the results of pure chance. She then identifies a test statistic that can assess the truth of the null hypothesis and computes the p-value. p-value gives the probability of the given test statistic resulting in the observed value if the null hypothesis is true. The smaller the p-value, the stronger the evidence against the null hypothesis. Finally, she compares the p-value to the α value, which corresponds to the level of confidence. If the p-value is less than α, she rejects the hypothesis and therefore conclude that the effect she observed was not due to random chance.

LANCET uses the following tests. First, the **Anderson-Darling** test checks whether a group of samples comes from a certain probability distribution and was chosen because it is less sensitive to outliers compared to similar tests, *e.g.,* the Kolmogorov-Smirnov test [31]. We use that to validate the inter-arrival request distribution. Second, the **Augmented Dickey Fuller** test [15] checks a series of samples for stationarity. We use the ADF test to determine the duration of the warm-up phase and whether the experiment results change over time. Finally, we use the **Spearman** rank correlation coefficient and the associated p-value to check if a series of samples is autocorrelated when checking for *iid*-data.

IID-data: Most types of hypothesis testing or general statistical processing, such as the calculation of confidence intervals, require samples that are *independent and identically distributed (iid)*. When running a latency experiment, latency

Latency Experiment Concerns			
Workload		**Methodology**	**Measuring Tool**
transport protocol	connection balance	system stability	workload-compliant
application protocol	open/closed queueing	unbiased result processing	methodology-compliant
request types and ratio	outstanding requests/connection	result convergence	measuring bias free
connection count	inter-arrival distribution	distribution coverage	

Table 1: Classification of concerns related to running a latency experiment into workload, methodology, and measuring tool-specific components. We advocate that the Workload column has to be user defined, while Methodology and Measuring Tool columns have to be handled systematically by the measuring framework.

samples are naturally identically distributed since they come from the same target server. Sample independence, though, is challenging to meet because of queuing effects. The end-to-end latencies of two requests that are queued back-to-back are dependent because the latency of the latter request includes the service time of the prior. While independence cannot be taken for granted, it can be tested, with autocorrelation being the standard way to check independence for a series of samples.

Confidence Intervals: We focus here on the confidence intervals for tail latency of a *single* execution, assuming that the system environment remains identical and stable during the entire experiment. The confidence intervals for a distribution's percentiles can be computed in closed form when the data are *iid*. The formula identifies, with a certain level of confidence, two threshold values that belong to the collected samples, between which the value for the specific percentile is expected to be found. Formulas 1, 2 give the indices of those two threshold values in the sorted of collection of samples [31] for a certain confidence level γ.

$$j \approx \lfloor np - \eta\sqrt{np(1-p)} \rfloor \quad (1)$$

$$k \approx \lceil np + \eta\sqrt{np(1-p)} \rceil + 1 \quad (2)$$

where n is the number of samples, p is the percentile, and η is defined as $N_{0,1} = \frac{1+\gamma}{2}$. For example, for 10,000 *iid* samples ($n = 10000$), the confidence interval for the 99-th percentile with 95% confidence ($\gamma = 0.95$, so $\eta = 1.96$) will be between the values with indices $j = 9880$ and $k = 9921$.

Note that determining confidence across different executions of the same experiment is challenging as the system's boot-time and application initialization can have a persistent effect on performance, leading to the hysteresis problem described in Treadmill [58].

3 Experiment Decomposition

Our goal is to build a latency-measuring tool that is precise and simplifies the configuration burden discussed in §2.2, with the explicit objective to identify situations in which the configuration cannot lead to a statistically meaningful result.

Table 1 classifies concerns related to a latency experiment into three main categories: workload, methodology, and measuring tool. These concerns often correspond to user-defined parameters in most of the existing tools and can be easily misconfigured. This decomposition will guide the design of modular, self-correcting latency-measuring tools. We claim that the workload-specific parameters have to be user defined, otherwise the experiment is insufficiently described. The methodology and measuring tool concerns have to be systematically managed by the measuring framework to reduce the pitfalls induced by the user misconfiguration.

Workload: The first aspect of a latency experiment is the actual workload and a large set of the configuration parameters refer to the workload specification. The experiment workload is both application- and deployment-specific, meaning that the same application should be tested differently if the deployment environment is also different. The workload includes the application specific parameters (*e.g.,* `get:set` ratio, request size distributions, TPC-C request mix, *etc.*), the application-level protocol (*e.g.,* `HTTP`, binary memcached, *etc.*) and the network-level protocol (*e.g.,* UDP vs. TCP). The definition of the workload also includes the client assumptions, *i.e.,* the number of expected client connections, the maximum number of outstanding requests per connection, and whether clients operate in an open- or a closed-loop system.

Critically, the specification of the workload is independent of the measuring tool , but affects the results, which could lead to unrealistic or wrong conclusions. For example, one cannot meaningfully report the open-loop tail latency of a workload with an insufficient number of connections, or insufficient outstanding requests per connection.

Measuring methodology: The second aspect of a latency experiment is the methodology, which describes how the latency samples are collected and processed. Examples of configuration parameters that are relevant to the methodology are the experiment duration, the number of collected samples, and the number and size of the histogram buckets. Reducing the number of configuration parameters related to methodology is a major goal of our design.

Regarding the latency sample collection, a good method-

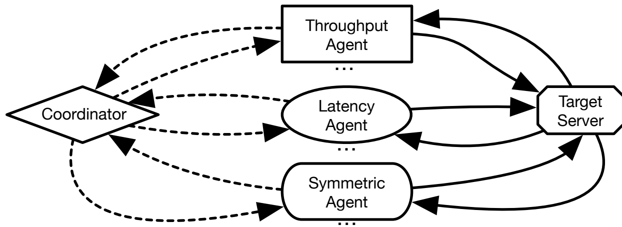

Figure 2: Lancet's architecture depicting a coordinator (C), throughput agents (TA), latency agents (LA), symmetric agents (SA), and the target server under test. The dashed arrows correspond to the LANCET API while the solid ones are application RPCs

ology should first ensure that the system under test is in a steady state to avoid measuring transient phenomena. Then it should ensure that the collected results converge and that all desired tail behaviors are covered. Finally, during the result processing, it should avoid adding statistical bias, *e.g.,* by the misconfiguration of histograms.

Measuring tool: Finally, the last part of a latency experiment is the actual client software used to collect the latency samples. Examples of parameters related to the tool are the number of client machines or threads used in the experiment, and whether hardware or software timestamping is used. The tool should be able to implement the specific methodology, generate the target workload accurately, and measure latency without adding too much client bias.

4 Design

4.1 LANCET infrastructure

Figure 2 shows the basic LANCET overview, which splits the methodology from the actual measuring tool and workload generator according to §3. LANCET is a by-design distributed tool that consists of a coordinator (C) and various measuring agents. The coordinator is in charge of the experiment methodology (see §4.3) and communicates with the agents over the LANCET API (Table 2). The measuring agents drive the workload via application RPCs generated based on application-specific random distributions. The agents also measure latency precisely, identify cases of workload violations, and run statistical tests.

Figure 3 describes a typical agent state transitions triggered by the coordinator via the API for a fixed-load experiment. From an idle state (*Idle*), the agent transitions into the loading phase (*Load*), where it attempts to issue *l* requests per second to the server. During that period the agent does not record latency. The agent eventually transitions into the measurement phase (*Measure*) specified by a sampling rate (*sr*) and a number of latency samples to collect (*s*). The agent can

Request Type	Request Params	Reply
start_load	load (rps)	ACK
start_measure	#samples sampling rate(sr)	ACK
get_throughput	None	Throughput (rps) Correct IA (T/F)
get_latency	None	Latency CI Stationary (T/F) IID (T/F, sr)
exit	None	ACK

Table 2: The LANCET coordinator API with the information returned by the agents on each call. For the `get_throughput` and `get_latency` requests, the agents also reply information related to the Inter-Arrival distribution (IA), the latency Confidence Intervals (CI), and whether the collected samples are stationary and *iid*. If they are not *iid*, the reply contains the target sampling rate necessary to get *iid* data.

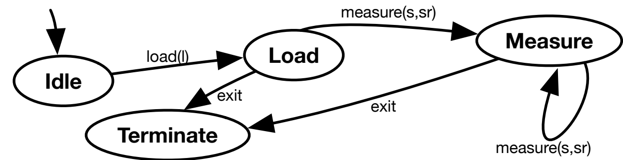

Figure 3: Lancet agent's state transition. Arrows represent messages from the coordinator.

stay in that state while the *sr* and *s* parameters can change. Finally, the coordinator decides to terminate the experiment (*Terminate*) via an `exit` message. At any point in time, while the agent is in the *Load* or *Measure* phase the coordinator can ask for the current throughput and latency.

4.2 Measurement options

Figure 2 shows that LANCET implements three agent types, selected to match the capabilities of the available hardware, the measuring methodology and the target experiment granularity. This way LANCET can support both symmetrical and asymmetrical deployments described in § 2.1.

LANCET uses the asymmetrical model when the latencies are captured in software. This model reduces jitter by dedicating cores and even machines to only measure latency. The drawback is that the experiment collects fewer samples per time period. Furthermore, special care must be taken to ensure that the collected samples are representatives of the workload. For example, a latency agent should open multiple connections (*i.e.,* emulate multiple clients) to ensure that a server configured with an RSS NIC will use all cores.

LANCET uses the symmetrical model when the NIC offers the capability to timestamp all incoming and outgoing Ethernet frames and the Linux operating system exposes the infor-

mation to userspace (v4.14+ kernels). LANCET associates the hardware timestamping of packets to the end-to-end latency of RPCs. This is not straightforward because of the inherent mismatch between the stream-oriented TCP protocol and the message-oriented RPCs. Implementation details follow in §5.

4.3 LANCET's self-correcting methodology

LANCET's primary contribution is its novel, self-correcting methodology which follows the experiment decomposition and split of concerns described in Table 1, and tries to systematically and based on statistics, identify: (i) when the server is in a stable state to start measuring latency (managed by the user-defined warm-up time in other tools); (ii) if the collected latency samples converge and whether tail phenomena are fully covered (controlled by the user-defined experiment duration in other tools); (iii) how to process the collected samples and report latency without introducing statistical bias (histograms are mainly used for that purpose in other tools); (iv) the confidence intervals of the latency results (unlike most tools which simply report latency percentiles).

Figure 4 illustrates the state machine transitions of the coordinator when measuring the open-loop tail-latency of a server under a certain load. To run such an experiment, the scientist needs to provide, apart from the necessary workload specification (first column in Table 1), the following:

- the target load (`l`).
- the target confidence interval for a specific latency percentile, *e.g.,* 10µs interval for the 99th percentile with 95% confidence.

The output of such an experiment will be either the tail-latency percentiles with the corresponding confidence intervals or an indication that the specific experiment cannot be executed because some of the assumptions are violated, *e.g.,* the target load cannot be reached, the service time has high variability and the computed latency confidence interval is wider than the target, the client does not respect the workload specifications, *etc.*

System Stability: Initially, the methodology ensures that the target load can actually be reached before starting measuring latency, thus eliminating transient phenomena. Then, the methodology ensures that agents load the server while respecting the workload's specified inter-arrival distribution. This second confirmation is essential to avoid reporting misleading latencies. For this, every agent records the inter-transmission intervals of requests by recording request transmissions, ideally in hardware, but if necessary at the socket interface. Every agent runs an Anderson-Darling test to check whether the inter-transmission intervals follow the target inter-arrival distribution, *e.g.,* exponential in the case of Poisson inter-arrival. The controller exits the system stability step only when the load is reached according to the correct inter-arrival distribution.

Unbiased Result Processing: Each agent collects, according to the parameters (s, sr) set by the controller, s samples, each randomly sampled among the RPCs at rate of sr, *e.g.,* collecting 10,000 samples with a 1:20 sampling rate would require $\sim$200K RPCs. Sampling is necessary because the collected samples need to be *iid* to compute the confidence interval correctly. Computing confidence intervals on non-*iid* data will underestimate their size.

The *iid*-ness is confirmed or rejected by computing the autocorrelation of the collected latency samples sorted by their transmission time. To do so, latency-measuring agents compute the Spearman correlation of the collected latency samples shifted over time. We leverage the associated p-value to determine whether the correlation is significant or not. This correlation being significant implies that data that are close in time depend on each other, which is the result of them being queued back to back in the servers queue.

A way to reduce the autocorrelation is to decrease the sampling rate. The LANCET built-in parameters initialize the measuring phase with 10,000 collected samples with a first sampling rate of 1:5. If the autocorrelation is non-significant, the latency measuring agents report that the samples are *iid*. Otherwise, they report how much to reduce the sampling rate to achieve non-significant correlation. The latency measuring agents report the Pearson correlation co-efficient back to the coordinator as part of their latency results. To do so, the agents compute the autocorrelation for different lags and report the one that leads to a non-significant correlation. Based on the agents' replies, the coordinator decides whether to proceed to the next state or reduce the sampling rate accordingly if it fails to confirm *iid*-ness.

Result Stationarity: The methodology needs to identify whether the number of samples collected is sufficient for the results to converge to a stable distribution of latencies that does not change over time. To ensure stationarity, the methodology leverages an Augmented Dickey Fuller test [15]. Each latency-measuring agent sorts the collected latency results based on their transmission timestamp and runs the test. Again, the latency measuring agents report the result of the test to the coordinator. In cases where lack of stationarity is detected, the coordinator decides to increase the number of samples by 10,000 and retry. Otherwise it proceeds with the next check.

Determine the confidence interval: Finally, the methodology has to check if the results converge within the target confidence interval size. For that, we use the Formulas 1 and 2. Each latency measuring agent reports the confidence intervals for the latency percentiles to the coordinator. The coordinator ensures that the intervals from different agents

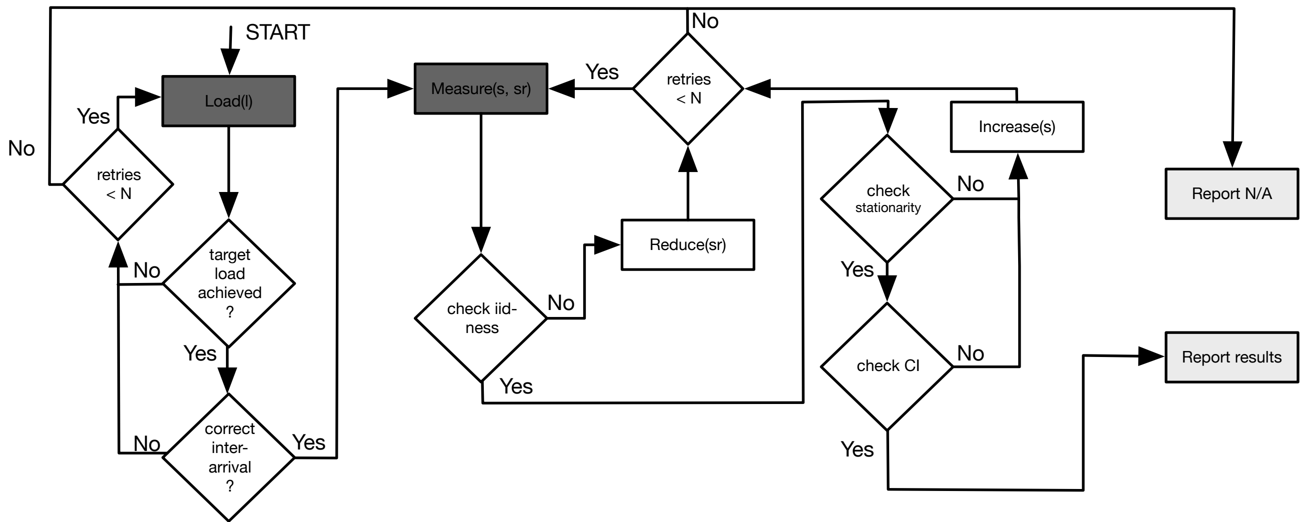

Figure 4: LANCET's experiment methodology implemented by the coordinator. Dark grey boxes correspond to messages from the coordinator to the agents. Light grey boxes show the experiment end.

are overlapping and computes their average. If the final confidence interval is wider than the user-selected target, the coordinator increases the number of samples by 10,000 and continues the experiment.

Termination: If the target confidence is reached, the coordinator finishes the experiment and reports the final latency percentiles with the equivalent confidence intervals. If the coordinator cannot reach the target confidence after a fixed number of failed retries, or if the experiment duration is above a certain threshold, it terminates the experiment, and reports that the specific experiment is not conclusive, the reasons why, along with the collected results so far.

5 Implementation

In addition to the design goals of §4, LANCET was implemented with robustness and long-term relevance in mind. LANCET is therefore built purely on functionality provided by the Linux kernel, using built-in drivers and protocol stacks. During development we identified some inconsistencies regarding hardware timestamping in the Linux kernel; our patch was merged in Linux kernel 4.19.4 [38].

The LANCET coordinator (Figure 2) is in charge of deploying the agents, communicating with them over sockets, driving their state machine according to Figure 3, and implementing the methodology of Figure 4. The coordinator is implemented in Golang. It relies on *goroutines* for easy distributed coordination and failure management, and consists of ∼1000 lines of code. From those lines, ∼300 of them implement the methodology described in § 4.3 and the rest implemented the LANCET API to communicate with the agents, manage collected results, *etc.* Thus, implementing a new coordinator logic for different experiment methodologies is relatively easy.

We implemented three different agents that can be used according to the available hardware, the measuring methodology, and the necessary experiment granularity. Our agents can achieve better measuring granularity compared to previous tools and can be used in both a symmetrical and asymmetrical deployment, independently of the available hardware. The agents are implemented in a combination of C and Python, and can be easily extended with new transport and application protocols.

Figure 5 depicts the structure of a multi-threaded LANCET agent. Each agent is split between a Python control plane and a C data plane communicating over shared memory. The Python control plane is in charge of communicating with the coordinator and performing the statistical computations. The choice of Python allowed us to take advantage of the rich Python ecosystem using libraries such as NumPy and SciPy. The choice of C for dataplane gave us direct access to low level socket APIs and reduced the client overhead. LANCET lancet currently supports TCP, UDP, and R2P2 [30] as transports, and Memcached, Redis, and HTTP as application protocols.

Throughput Agent: This agent leverages `epoll_wait` to manage connections and is in charge of loading the server without measuring latencies. It is used only in asymmetrical deployments in cooperation with one of the two following agents that can measure RPC latency.

Latency SW-timestamping Agent: This agent depends on software timestamping and does not have any hardware dependencies. It improves the measuring precision over

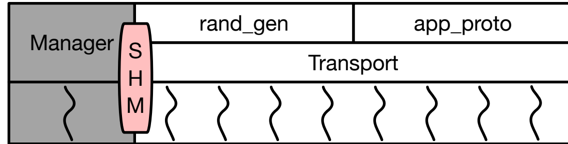

Figure 5: The structure of a LANCET agent. The grey part corresponds to the Python control plane, while the white part corresponds to the C dataplane communicating over shared memory (SHM).

other software-based tools, though, by leveraging the busy polling functionality introduced in Linux 3.11. Specifically, the `SO_BUSY_POLL` socket option allows blocking system calls to poll the NIC instead of depending on interrupts. While still dependent on userspace timestamping, this agent reduces client bias and measures latency with similar accuracy to kernel-bypass approaches. The blocking nature of this agent limits the load and the inter-arrival distribution of requests the agent can achieve. Consequently, this agent can only be used in asymmetric setups in conjunction with throughput agents that generate the necessary target system load according to the expected inter-arrival distribution.

Symmetric HW-timestamping Agent: Finally, we implemented a symmetric agent that leverages hardware timestamping to measure RPC end-to-end latency. This agent depends on the Linux kernel functionality for hardware timestamping added in kernel 4.14 for TCP. It also requires a NIC that timestamps all the incoming and outgoing packets, *e.g.*, the Mellanox ConnectX-4 [42]. The preferred deployment is based on symmetric HW-timestamping agents, as they improve on the latency agent in terms of precision and they can scale throughput while the coordinator can symmetrically collect results from all client machines, thus increasing the experiment accuracy.

The most challenging part of the implementation was the attribution of RPC latencies when requests and replies are layered on top of the stream-based TCP protocol, as used in the popular protocols, such as Memcached.

For TX timestamps, the Linux kernel provides an asynchronous API to collect timestamps, returning asynchronously one timestamp for each `sendmsg` system call. The notification is propagated to the userspace through an `EPOLERR` for the equivalent socket that is handled by `epoll_wait`. Along with the timestamp, the kernel also returns the number of the last transmitted byte this timestamp corresponds to. For example, if the first request has a size of 20 bytes, the notification will mention that this timestamp is associated with byte 20. For the second request of the same size, the notification will mention byte 40, *etc.* The same information is maintained by LANCET in userspace for validation purposes, and to deal with cases of coalescing or resubmissions.

The kernel provides a synchronous API to retrieve the RX timestamp: the RX timestamp is part of the metadata to the `recvmsg` system call, and corresponds to the receive timestamp of the frame that carried the last byte returned by the system call. The LANCET application-parsing logic leverages this information to associate timestamps to replies of variable sizes: if the content returned by `recvmsg` consists of an incomplete reply, that timestamp is ignored; if the content contains the replies to multiple requests (which is possible because of TCP's streaming nature and coalescing in the socket layer), LANCET only considers the timestamp for the last reply returned in that call. The Linux kernel coalesces `sk_buffs` internally and keeps a single timestamp per `sk_buff` corresponding to the last arrival. Consequently, earlier received responses might appear to have later receive timestamps.

Our contribution to the kernel 4.19.4 [38] guarantees that each `recvmsg` system call will return the hardware timestamp that corresponds to the last byte read. Previously, this was only the case for software in-kernel timestamping.

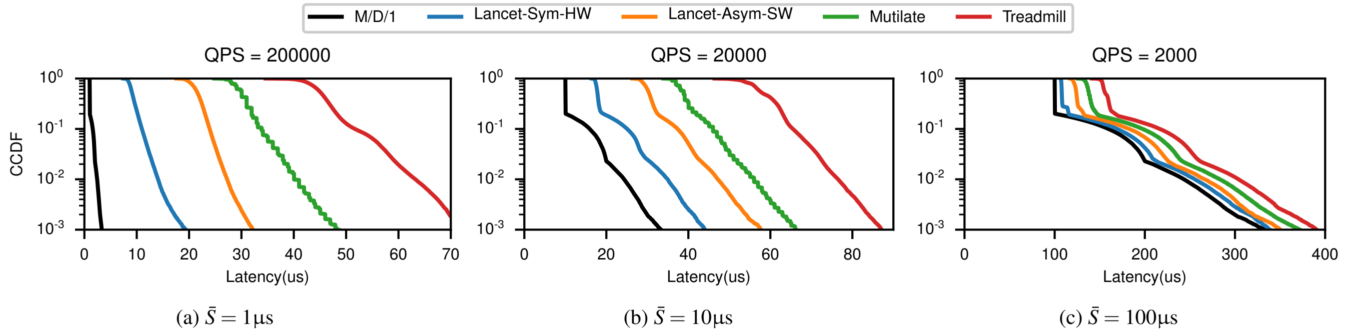
6 Evaluation

Our evaluation aims to answer three fundamental questions: (i) how does LANCET compare with existing RPC load-generating tools such as Mutilate and Treadmill (ii) how does LANCET's self-correcting methodology work in practice (iii) how LANCET performs in characterizing a server's behavior across different loads.

We answer these questions using a methodology in which the server's execution time is explicitly controlled. Doing so enables comparing the client-side measurements made by the tools to an idealized queueing theoretic model. We leverage an RPC server with synthetic service times following well-known distributions. Specifically, we tried a fixed, an exponential, and a bimodal distribution where 10% of the requests take $\sim 10\times$ longer to execute. To further reduce server-side overheads, our server uses the open-source IX operating system [6] configured with 1 CPU and adaptive batching disabled. The operating system overhead is $\sim 1\,\mu s$ of CPU execution time per request, which includes driver and network processing overheads. As baselines we use the opensource versions of Mutilate [1] and Treadmill [3]. For Treadmill, we had to make changes in order to build it for our setup.

To be able to compare with other tools, our synthetic server uses the `ascii-memcached` protocol. Clients submit `get` requests with for a 19-byte key (similarly to Facebook's USR [4]), the server spins for a configurable amount of time, and replies that that key was not found. We chose `ascii-memcached` because it is the only protocol supported by both Treadmill and Mutilate.

The idealized models correspond to the expected latency distribution, as determined by a discrete event simulation, assuming zero operating system overheads, zero network propagation delays, and zero client-side measurement overheads.



(a) $\bar{S} = 1\mu s$ (b) $\bar{S} = 10\mu s$ (c) $\bar{S} = 100\mu s$

Figure 6: Latency ECDF for an M/D/1 model and three deterministic workloads at 20% load.

For all of our experiments, we configure each client machine with 15 threads and 4 connections per thread with 1 outstanding request per connection. Also, we consider a Poisson inter-arrival distribution of requests.

6.1 Experimental setup

Our experimental setup uses 5 clients and one server machine connected by a Quanta/Cumulus 48x10GbE switch with a Broadcom Trident+ ASIC. The client machines are equipped with a Xeon E5-2637 @ 3.5 GHz and a Mellanox Connect-X4 NIC. The machines run an Ubuntu LTS 16.04 distribution running Linux kernel version 4.19.4. The systems are tuned to reduce jitter: all power management features, including CPU frequency governors and TurboBoost, and support for transparent huge pages, are disabled. The server is a Xeon E5-2665 @ 2.4 GHz with an Intel x520 NIC running the IX operating system.

6.2 Benefits of hardware timestamping

First, we compare the measuring granularity of LANCET with the measuring granularity achieved by Mutilate and Treadmill. For LANCET we consider both the hardware timestamping, symmetrical setup and the asymmetrical one based on the busy-polling agent. LANCET and Mutilate provide a way to run an experiment based on multiple machines, but for Treadmill there is no opensource coordinator script. Thus, we run one Treadmill instance on each client that contributes 1/5 of the load. Also, we modified Treadmill to save the collected latencies at the end of the experiment.

From a methodology perspective, we plot the latency CCDF for a deterministic service time distribution with different average service times. The load is set at 20% of the theoretical saturation, we range the average service time from $\bar{S} = 1\mu s$ to $\bar{S} = 100\mu s$. We collected 1M samples for each tool.

Figure 6 summarizes the experiment results. We observe that LANCET, for both configurations and in all three experiments, achieves lower measuring granularities when compared to the other tools because it reduces the client measuring overheads. Specifically, for $\bar{S} = 1\mu s$ hardware timestamping measures a 99th percentile tail of 14.1µs and the LANCET polling agent one of 27.3µs. Mutilate measures 40µs and Treadmill reports 63µs. Figure 6a also shows that Mutilate's line is not smooth because of the µs reported granularity, as opposed to nanoseconds reported by the other tools. Also, we see that LANCET aligns better with the theoretic results. For example, with $\bar{S} = 10\mu s$, the blue line nicely tracks the model; the offset between the two (∼10µs) is essentially due to the operating system overhead and the propagation delay. Finally, Figure 6c shows that the tools make a difference even for coarser grain tasks ($\bar{S} = 100$), where the operating system and propagation delay overheads are comparatively small.

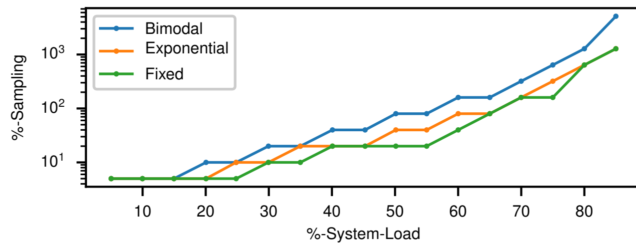
For the rest of our evaluation we will focus on the symmetric hardware-timestamping agent as it reports the most accurate results.

6.3 LANCET self-controlling dynamics

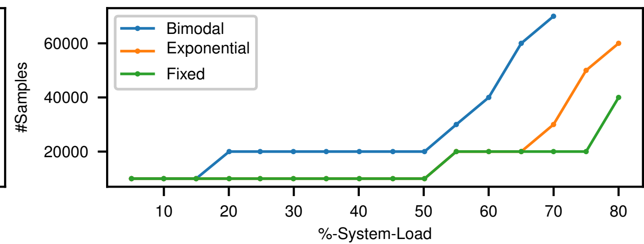
In the next series of benchmarks, we want to identify the impact of the self-correcting methodology and how the coordinator controls the experiment parameters based on the different service time distributions and the system load. To do so, we run the three different service time distributions across a variety of loads and we collect the necessary level of sampling to achieve *iid*-ness, and the number of samples necessary for a target confidence interval size of 10µs.

Figure 7a shows the sampling rate that is necessary to the unbiased processing of the results caused by queuing effects. We observe that high-dispersion workloads (*e.g.,* bimodal) and higher load levels require lower sampling rates. This is expected as increasing either service time dispersion or load level leads to more queuing, thus more dependent samples.

In Figure 7b, we set the size of the target confidence interval for the 99th percentile latency to be 10µs with 95% confidence. The figure shows the number of collected samples, as decided by the coordinator, that are required to satisfy the result target. We observe that more samples are necessary to fulfill the constraint as the load increases, since higher



(a) Required level of sampling to guarantee *iid*-ness



(b) Required number of samples to achieve the target CI of 10µs

Figure 7: Dynamics of LANCET's self-correcting methodology based on load for three service time distributions with $\bar{S} = 10\mu s$

system load leads to higher latency variability.

The bimodal distribution shows an interesting behavior of the tool: With load $> 70\%$, execution stops after the maximum number iterations ($N = 10$) but the target CI expectations can not be met. Our experiment logs showed that the collected 99th percentile latency at 75% load is 411.333µs [-5.87µs, 7.56µs] at 95% confidence; this interval is $> 10\mu s$.

We also tested LANCET's self-correcting behavior with the lognormal distribution, which is a heavy tailed distribution. LANCET terminates without ever being able to confirm results convergence(CI < 10µs for the 99-th percentile latency), even at a low load of 20%. Thus, LANCET is effective in detecting heavy-tailed service time distributions.

6.4 Inter-Arrival distribution Impact

In the following experiment we try to showcase the impact of the inter-arrival distribution on the latency results and how LANCET identifies cases of inter-arrival distribution violations. We use the fixed synthetic time distribution with $\bar{S} = 10\mu s$ and we run a latency experiment across a variety of loads with different number of connections. We disable LANCET's checks for inter-arrival distribution and we only report whether there is a workload violation. To eliminate any system interference we configure LANCET with one connection per thread, and add connections by adding client machines.

Figure 8 shows the 99-th percentile latency as a function of throughput for the different connection count configurations. The vertical lines correspond to the load level that the equivalent configuration started violating the inter-arrival distribution. We observe that once LANCET reports a violation the curves start deviating. This experiment shows that cases as the one described in Figure 1 can be avoided by LANCET's self-correcting methodology.

6.5 Server characterization

Figure 9 shows the 99th-percentile tail latency as a function of the load for three workloads. We compare LANCET with Mutilate as well as the idealized, zero-overhead theoretical model. Both tools use 5 machines – necessary to achieve the high loads required. For LANCET, we additionally report the confidence interval of each measurement. This experiment does not include Treadmill as Treadmill's open-source distribution does not support multi-machine deployments. Note that because of system overheads, the IX server cannot get close to the expected maximum load for Figure 9a which would be 1M RPS, thus we do not plot the theoretic curve.

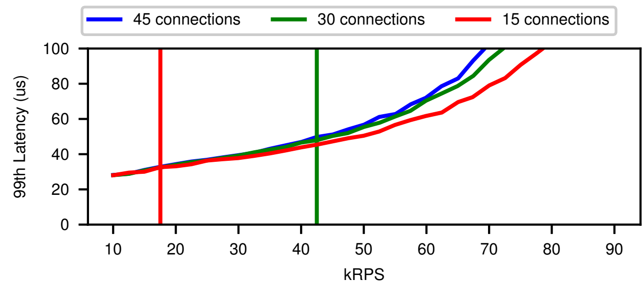


Figure 8: Impact of the inter-arrival distribution to tail-latency for a fixed with $\bar{S} = 10\mu s$. Vertical lines correspond to the load levels where Lancet reports inter-arrival distribution violations

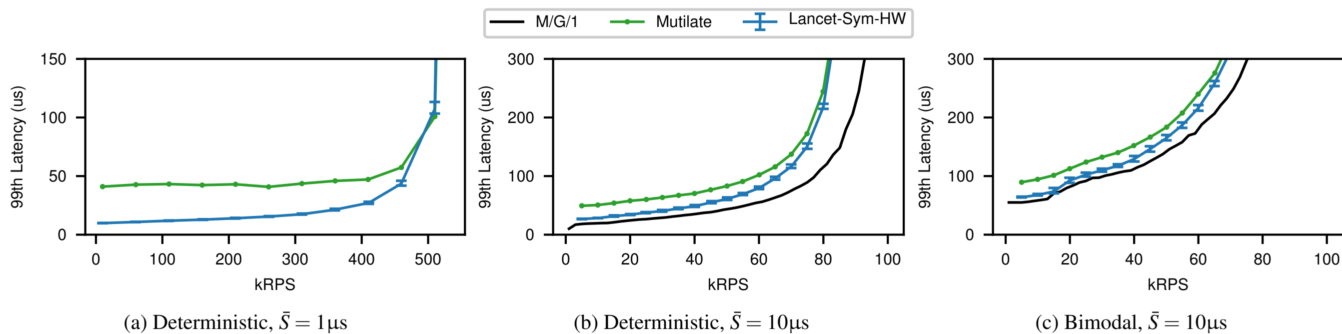
We observe that LANCET reports latencies that closely match the idealized model across the entire load spectrum, to the point that it accurately reflects the two inflection points of the binomial distribution. We also observe how the size of the confidence intervals change across different distributions and system loads. For low loads and low service time dispersion, the interval is shorter than the maximum configured (10µs). For the bimodal distribution, the reported confidence interval is at its maximum configuration even for low loads.

7 Related Work

LANCET is one of the many contributions towards enabling reproducibility and accurate experimentation in systems research [25, 40].

µs-scale computing: Recent research focuses on µs-scale



(a) Deterministic, $\bar{S} = 1\mu s$ (b) Deterministic, $\bar{S} = 10\mu s$ (c) Bimodal, $\bar{S} = 10\mu s$

Figure 9: Latency vs throughput graphs for a 5-client experiment with average service time of $\bar{S} = 1$ and $\bar{S} = 10$

computing [5] both in operating systems and networking and either aim to optimize [6,26,35,49,50], or attribute the sources of tail-latency [29, 33, 34, 52, 58]. LANCET does not attempt to attribute the sources of the jitter. Instead, it provides a tool to measure µs tail latency precisely on an end-to-end basis to be used in similar research efforts.

Precise measurements: RPC generators [10, 20, 33, 43, 58] use software timestamping. However, researchers need more accurate tools to evaluate system's latency, *e.g.,* ZygOS used a modified version of Mutilate based on DPDK [16], and MICA [35] used a custom version of YCSB on DPDK. Software-based packet generators [8, 19, 46] also used DPDK for increased precision [52]. Hardware-based packet generators [24, 54] provide sub µs-scale precision with little jitter [52]. Some tools repurposed the IEEE PTP feature of standard NICs to measure packet latencies [19,32,44]. LANCET is the first tool that leverages hardware-based NIC timestamping for capturing latency for RPCs over TCP with even higher precision. In addition, LANCET uses the standard Linux networking stack for all experiments, proving a more realistic simulation environment. While we used Mellanox ConnectX-4 NICs in our experiments, hardware timestamping of all packets is also available on Solarflare NICs [2].

Methodology: Although tail-latency is a widely used system metric, there is no widely accepted experiment methodology for measuring it, and usually tools are bounded to specific methodologies. LANCET attempts to split the methodology from the actual tool and reason about them separately. Measurement bias from non-determinism can be avoided via setup randomization [21, 41, 58]. Repeated runs eliminate hysteresis effects in systems [58]. Distributed benchmarking tools seek to minimize client side queuing bias by reducing the client load, in asymmetric *e.g.,* Mutilate [33], or symmetric setups [58]. LANCET's use of hardware timestamping eliminates client bias in the point of measurement. Treadmill [58] avoids issues of imbalance by leveraging a symmetric measurement model, and bias from outliers by computing interested metrics on individual instances and combining them using aggregation functions. LANCET also supports the symmetric setup to detect imbalance across client machines. Most tools use histograms to capture latencies. Treadmill determines bucket ranges during a calibration phase. YCBS [10] and Tailbench [29] have dynamic range histograms. LANCET relies on on-line sampling but keeps all sampled results to determine both the CCDF and the confidence intervals. Confidence intervals can also be used to determine statistical convergence of results [21,41]. LANCET's self-correcting controller relies on statistical tests to ensure stability and results convergence similarly to [40].

8 Conclusion

LANCET is a new latency-measuring tool designed with the explicit goal to accurately measure µs-scale tail-latencies while reducing methodological pitfalls in a principled manner. Its self-correcting methodology uses proven statistical methods to detect situations where application tail latency cannot be reliably measured. LANCET's agents uniquely leverage NIC-based timestamping to measure the end-to-end latency of TCP-based applications, completely eliminating client bias. LANCET measures latency distributions with more accuracy than popular tools such as Mutilate and Treadmill. Our evaluation with µs-scale workloads shows that it robustly self-corrects as a function of the load for workloads with challenging service time distributions.

Pangolin: A Fault-Tolerant Persistent Memory Programming Library

Lu Zhang

Steven Swanson
University of California, San Diego
swanson@cs.ucsd.edu

Abstract

Non-volatile main memory (NVMM) allows programmers to build complex, persistent, pointer-based data structures that can offer substantial performance gains over conventional approaches to managing persistent state. This programming model removes the file system from the critical path which improves performance, but it also places these data structures out of reach of file system-based fault tolerance mechanisms (e.g., block-based checksums or erasure coding). Without fault-tolerance, using NVMM to hold critical data will be much less attractive.

This paper presents Pangolin, a fault-tolerant persistent object library designed for NVMM. Pangolin uses a combination of checksums, parity, and micro-buffering to protect an application's objects from both media errors and corruption due to software bugs. It provides these protections for objects of any size and supports automatic, online detection of data corruption and recovery. The required storage overhead is small (1% for gigabyte-sized pools of NVMM). Pangolin provides stronger protection, requires orders of magnitude less storage overhead, and achieves comparable performance relative to the current state-of-the-art fault-tolerant persistent object library.

1 Introduction

Emerging non-volatile memory (NVM) technologies (e.g., battery-backed NVDIMMs [31] and 3D XPoint [30]) provide persistence with performance comparable to DRAM. Non-volatile main memory (NVMM), is byte-addressable, cache-coherent NVM that resides on the system's main memory bus. The combination of NVMM and DRAM enables hybrid memory systems that offer the promise of dramatic increases in storage performance and a more flexible programming model.

A key feature of NVMM is support for direct access, or DAX, that lets applications perform loads and stores directly to a file that resides in NVMM. DAX offers the lowest-possible storage access latency and enables programmers to craft complex, customized data structures for specific applications. To support this model, researchers and industry have proposed various persistent object systems [3, 5, 12, 20, 25, 28, 39, 47].

Building persistent data structures presents a host of challenges, particularly in the area of crash consistency and fault tolerance. Systems that use NVMM must preserve crash-consistency in the presence of volatile caches, out-of-order execution, software bugs, and system failures. To address these challenges, many groups have proposed crash-consistency solutions based on hardware [33, 34, 37, 40], file systems [4, 10, 48, 49], user-space data structures and libraries [3, 5, 12, 39, 43, 47, 50], and languages [9, 38].

Fault tolerance has received less attention but is equally important: To be viable as an enterprise-ready storage medium, persistent data structures must include protection from data corruption. Intel processors report uncorrectable memory media errors via a machine-check exception and the kernel forwards it to user-space as a `SIGBUS` signal. To our knowledge, Xu *et al.* [49] were the first to design an NVMM file system that detects and attempts to recover from these errors. Among programming libraries, only `libpmemobj` provides any support for fault tolerance, but it incurs 100% space overhead, only protects against media errors (not software "scribbles"), and cannot recover corrupted data without taking the object store offline.

Xu *et al.* also highlighted a fundamental conflict between DAX-`mmap()` and file system-based fault tolerance: By design, DAX-`mmap()` leaves the file system unaware of updates made to the file, making it impossible for the file system to update the redundancy data for the file. Their solution is to disable file data protection while the file is mapped and restore it afterward. This provides well-defined protection guarantees but leaves file data unprotected when it is in use.

Moving fault-tolerance to user-space NVMM libraries solves this problem, but presents challenges since it requires integrating fault tolerance into persistent object libraries that manage potentially millions of small, heterogeneous objects.

To satisfy the competing requirements placed on NVMM-based, DAX-mapped object store, a fault-tolerant persistent object library should provide at least the following characteristics:

1. **Crash-consistency**. The library should provide the means to ensure consistency in the face of both system failures and data corruption.
2. **Protection against media and software errors**. Both types of errors are real threats to data stored to NVMM, so the library should provide protection against both.
3. **Low storage overhead**. NVMM is expensive, so minimizing storage overhead of fault tolerance is important.
4. **Online recovery**. For good availability, detection and recovery must proceed without taking the persistent object store offline.
5. **High performance**. Speed is a key benefit of NVMM. If fault-tolerance incurs a large performance penalty, NVMM will be much less attractive.
6. **Support for diverse objects**. A persistent object system must support objects of size ranging from a few cache lines to many megabytes.

This paper describes *Pangolin*, the first persistent object library to satisfy all these criteria. Pangolin uses a combination of parity, replication, and object-level checksums to provide space-efficient, high-performance fault tolerance for complex NVMM data structures. Pangolin also introduces a new technique for accessing NVMM called *micro-buffering* that simplifies transactions and protects NVMM data structures from programming errors.

We evaluate Pangolin using a suite of benchmarks and compare it to `libpmemobj`, a persistent object library that offers a simple replication mode for fault tolerance. Compared to `libpmemobj`, performance is similar, and Pangolin provides stronger protection, online recovery, and greatly reduced storage overhead (1% instead of 100%).

The rest of the paper is organized as follows: Section 2 provides a primer on NVMM programming and NVMM error handling in Linux. Section 3 describes how Pangolin organizes data, manages transactions, and detects and repairs errors. Section 4 presents our evaluations. Section 5 discusses related work. Finally, Section 6 concludes.

2 Background

Pangolin lets programmers build fault-tolerant, crash-consistent data structures in NVMM. This section first introduces NVMM and the DAX mechanism applications use to gain direct access to persistent data. Then, we describe the NVMM error handling mechanisms that Intel processors and Linux provide. Finally, we provide a brief primer on NVMM programming using `libpmemobj` [39], the library on which Pangolin is based.

2.1 Non-volatile Main Memory and DAX

Several technologies are poised to make NVMM common in computer systems. 3D XPoint [30] is the closest to wide deployment. Phase change memory (PCM), resistive RAM (ReRAM), and spin-torque transfer RAM (STT-RAM) are also under active development by memory manufacturers. Flash-backed DRAM is already available and in wide use. Linux and Windows both have support for accessing NVMM and using it as storage media.

The performance and cost parameters of NVMM lie between DRAM and SSD. Its write latency is longer than DRAM, but it will cost less per bit. From the storage perspective, NVMM is faster but more expensive than SSD.

The most efficient way to access NVMM is via direct access (DAX) [15] memory mapping (i.e., DAX-`mmap()`). To use DAX-`mmap()`, applications map pages of a file in an NVMM-aware file system into their address space, so the application can access persistent data from the user-space using load and store instructions, without the file system intervening.

2.2 Handling NVMM Media Errors

To recover from data corruption, Pangolin relies on error detection and media management facilities that the processor and operating system provide together. Below, we describe these facilities available on Intel and Linux platforms. Windows provides similar mechanisms.

Hardware Error Correction Memory controllers for commercially available NVMMs (i.e., battery-backed DRAM and 3D XPoint) implement error-correction code (ECC) in hardware to detect and correct media errors when they can, and they report uncorrectable (but detectable) errors with a machine check exception (MCE) [14] that the operating system can catch and attempt to handle.

Pangolin provides a layer of protection in addition to the ECC hardware provides, but it does not require hardware ECC. Pangolin uses checksums to detect errors that hardware cannot detect. This mechanism also catches software bugs (which are invisible to hardware ECC). ECC does, however, improve performance by transparently handling many media errors.

Regardless of the ECC algorithm hardware provides, field studies of DRAM and SSDs [13, 29, 35, 41, 42, 45] have shown that detectable but uncorrectable media errors occur frequently enough to warrant additional software protection. Furthermore, file systems [23, 49, 51] apply checksums to

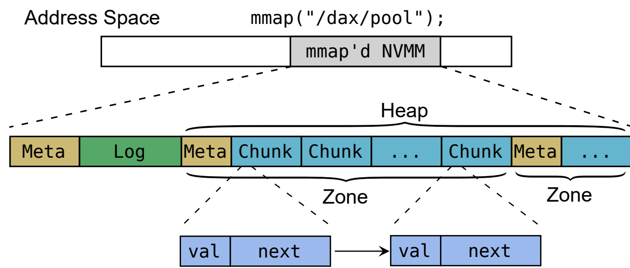

Figure 1: DAX-mapped NVMM as an object store – `Libpmemobj` divides the mapped space into zones and chunks for memory management. The `val` field is a 64-bit integer and the `next` field is a persistent pointer (`PMEMoid`) pointing to the next node object in the pool.

```
1  PMEMobjpool *pool = pmemobj_open("/dax/pool");
2  ...
3  struct node *n = pmemobj_direct(node_oid);
4  n->val = value;
5  pmemobj_persist(pool, &n->val, 8);
6  ...
7  TX_BEGIN(pool) {
8    n = pmemobj_direct(node_oid);
9    pmemobj_tx_add_range(node_oid, 0, sizeof(*n));
10   n->next = pmemobj_tx_alloc(...);
11 } TX_ONABORT {
12   /* handling transaction aborts */
13 } TX_END
14 ...
15 pmemobj_close(pool);
```

Listing 1: A `libpmemobj` program - First modify a node value in a linked list, and later allocate and link a new node from the pool.

their data structures to protect against scribbles.

Repairing Errors When the hardware detects an uncorrectable error, the Linux kernel marks the region surrounding the failed load as "poisoned," and future loads from the region will fail with a bus error. Pangolin assumes an error poisons a 4 KB page since Linux currently manages memory failures at page granularity.

If a running application causes an MCE (by loading from a poisoned page), the kernel sends it a `SIGBUS` and the application can extract the affected address from the data structure describing the signal.

The software can repair the poisoned page by writing new data to the region. In response, the operating system and NVDIMM firmware work together to remap the poisoned addresses to functioning memory cells. The details of this process are part of the Advanced Configuration and Power Interface (ACPI) [46] for NVDIMMs.

Recent kernel patches [6–8, 26] and NVMM library [39] provide utilities for user-space applications to restore lost data by re-writing affected pages with recovered contents (if available).

2.3 NVMM Programming

In this section, we describe `libpmemobj`'s programming model. `Libpmemobj` is a well-supported, open-source C library for programming with DAX-mapped NVMM. It provides facilities for memory management and software transactions that let applications build a persistent object store. Pangolin's interface and implementation are based on `libpmemobj` from PMDK v1.5.

Linux exposes NVMM to the user-space as memory-mapped files (Figure 1). `Libpmemobj` (and Pangolin) refer to the mapped file as a *pool* of persistent objects. Each pool spans a continuous range of virtual addresses.

Within a pool, `libpmemobj` reserves a metadata region that contains information such as the pool's identification (64-bit UUID) and the offset to a "root object" from which all other live objects are reachable. Next, is an area reserved for transaction logs. `Libpmemobj` uses redo logging for its metadata updates and undo logging for application object updates. Transaction logs reside in one of two locations depending on their sizes. Small log entries live in the provisioned "Log" region, as shown in Figure 1. Large ones overflow into the "Heap" storage area.

The rest of the pool is the persistent heap. `Libpmemobj`'s NVMM allocator (a persistent variant of `malloc`/`free`) manages it. The allocator divides the heap's space into several "zones" as shown in Figure 1. A zone contains metadata and a sequence of "chunks." The allocator divides up a chunk for small objects and coalesces adjacent chunks for large objects. By default, a zone is 16 GB, and a chunk is 256 KB.

Listing 1 presents an example to highlight the key concepts of NVMM programming. The code performs two independent operations on a persistent linked list: one is to modify a node's value, and another is to allocate and link a new node.

This example demonstrates two styles of crash-consistent NVMM programming: *atomic*-style (lines 3-5) for a simple modification that is 8 bytes or smaller, and *transactional*-style (lines 7-13) for arbitrary-sized NVMM updates.

Building data structures in NVMM using `libpmemobj` (or any other persistent object library) differs from conventional DRAM programming in several ways:

Memory Allocation `Libpmemobj` provides crash-consistent NVMM allocation and deallocation functions: `pmemobj_tx_alloc`/`pmemobj_tx_free`. They let the programmer specify object type and size to allocate and prevent orphaned regions in the case of poorly-time crashes.

Addressing Scheme Persistent pointers within a pool must remain valid regardless of at what virtual address the pool resides. `Libpmemobj` uses a `PMEMoid` data structure to address an object within a pool. It consists of a 64-bit file ID

and a 64-bit byte offset relative to the start of the file. The `pmemobj_direct()` function translates a `PMEMoid` into a native pointer for use in load or store instructions.

Failure-atomic Updates Modern x86 CPUs only guarantee that 8-byte, aligned stores atomically update NVMM [16]. If applications need larger atomic updates, they must manually construct software transactions. `Libpmemobj` provides undo log-based transactions. The application executes stores to NVMM between the `TX_BEGIN` and `TX_END` macros, and snapshots (`pmemobj_tx_add_range`) a range of object data before modifying it in-place.

Persistence Ordering Intel CPUs provide cache flush/write-back (e.g., `CLFLUSH(OPT)` and `CLWB`) and memory ordering (e.g., `SFENCE`) instructions to make guarantees about when stores become persistent. In Listing 1, the `pmemobj_persist` function and `TX` macros integrate these instructions to flush modified object ranges.

`Libpmemobj` supports a replicated mode that requires a replica pool, doubling the storage the object store requires. `Libpmemobj` applies updates to both pools to keep them synchronized.

Replicated `libpmemobj` can detect and recover from media errors only when the object store is offline, and it cannot detect or recover from data corruption caused by errant stores to NVMM – so-called "scribbles," that might result from a buffer overrun or dereferencing a wild pointer.

3 Pangolin Design

Pangolin allows programmers to build complex, crash-consistent persistent data structures that are also robust in the face of media errors and software "scribbles" that corrupt data. Pangolin satisfies all of the criteria listed in Section 1. This section describes its architecture and highlights the key challenges that Pangolin addresses to meet those requirements. In particular, Pangolin provides the following features unseen in prior works.

- It provides fast, space-efficient recovery from media errors and scribbles.
- It uses checksums to protect object integrity and supports incremental checksum updates.
- It integrates parity and checksum updates into an NVMM transaction system.
- It periodically scrubs data to identify corruption.
- It detects and recovers from media errors and scribbles online.

Pangolin guarantees that it can recover from the loss of any single 4 KB page of data in a pool. In many cases, it can recover from the concurrent loss of multiple pages.

We begin by describing how Pangolin organizes data to protect user objects, library metadata, and transaction logs using a combination of parity, replication, and checksums. Next, we describe micro-buffers and explain how they allow Pangolin to preserve a simple programming interface and protect against software scribbles. Then, we explain how Pangolin detects and prevents NVMM corruption and elaborate on Pangolin's transaction implementation with support for efficient, concurrent updates of object parity. Finally, we discuss how Pangolin restores data integrity after corruption and crashes.

3.1 Pangolin's Data Organization

Pangolin uses replication for its internal metadata and RAID-style parity for user objects to provide redundancy for corruption recovery. The MCE mechanism described in Section 2.2 and object checksums in Pangolin detect corruption.

Pangolin views a zone's chunks as a two-dimensional array as shown in the middle of Figure 2. Each *chunk row* contains multiple, contiguous chunks and the chunks "wrap around" so that the last chunk of a row and the first chunk of the next are adjacent. Pangolin reserves the last chunk row for parity.

In our description of Pangolin, we define a *page column* as a one page-wide, aligned column that cuts across the rows of a zone. A *range column* is similar, but can be arbitrarily wide (no more than a chunk row's size).

Initializing a parity-coded NVMM pool requires zeroing out all the bytes in the file. This is a one-time overhead when creating a pool file and does not affect run-time performance. We report this latency in Section 4.

To detect corruption in user objects, Pangolin adds a 32-bit checksum to the object's header. The header also contains the object's size (64-bit) and type (32-bit). The compiler determines type values according to user-defined object types. Pangolin inherits this design from `libpmemobj` and changes the type identifier from 64-bit to 32-bit for the checksum.

Pangolin's object placement is independent of chunk and row boundaries. Objects can be anywhere within a zone, and they can be of any size (up to the zone size).

In addition to user objects, the library maintains metadata for the pool, zones, and chunks, including allocation bitmaps. Pangolin checksums these data structures to detect corruption and replicates the pool's and zones' metadata for fault tolerance. These structures are small (less than 0.1% for pools larger than 1 GB), so replicating them is not expensive. Pangolin uses zone parity to support recovery of chunk metadata.

Pangolin checksums transaction logs and replicates them for redundancy. It treats log entries in zone storage as zeros during parity calculations. This prevents parity update contention between log entries and user objects (see Section 3.5).

Fault Tolerance Guarantees Pangolin can tolerate a single 4 KB media error anywhere in the pool, regardless of whether it is a data page or a parity page. Based on the bad

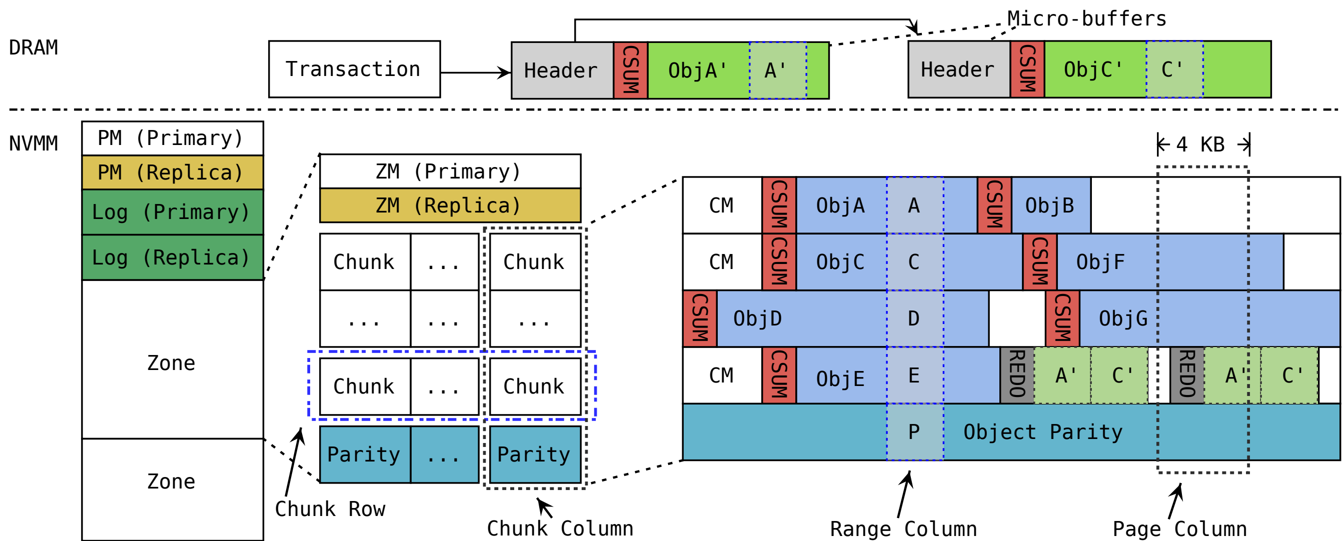

Figure 2: Data protection scheme in Pangolin – Pangolin protects pool metadata (PM), zone metadata (ZM), and chunk metadata (CM). In the highlighted range column, $P = A \oplus C \oplus D \oplus E$. One thread's transaction is modifying ranges A and C of two objects. Pangolin keeps modified data in redo log entries (checksummed and replicated) when the transaction commits. The DRAM part shows micro-buffers for the two objects.

page's address Pangolin can locate its page column and restore its data using other healthy pages.

Faults affecting two pages of the same page column may cause data loss if the corrupted ranges overlap. If an application demands more robust fault tolerance, it can increase the chunk row size, reducing the number of rows and, consequently, the likelihood that two corrupt pages overlap.

Pangolin can recover from scribbles (contiguous overwrites caused by software errors) on NVMM data up to a chunk-row size. By default, Pangolin uses 100 chunk rows, and parity consumes $\sim$1% of a pool's size (e.g., 1 GB for a 100 GB pool).

3.2 Micro-buffering for NVMM Objects

Pangolin introduces micro-buffering to hide the complexity of updating checksums and parity when modifying NVMM objects. Adding checksums to objects and protecting them with parity makes updates more complex, since all three – object data, checksum, and parity – must change at once to preserve consistency. This challenge is especially acute for the atomic programming model as shown in Listing 1 (line 3-5) because a single 8-byte NVMM write cannot host all these updates.

Micro-buffering creates a shadow copy of an NVMM object in DRAM, which separates an object's transient and persistent versions (Figure 2). In Listing 2, `pgl_open` creates a micro-buffer for the node object by allocating a DRAM buffer and copying the node's data from NVMM. It also veri-

```
1  struct node *n = pgl_open(node_oid);
2  n->val = value;
3  pgl_commit(pool, n);
```

Listing 2: A Pangolin transaction for a single-object - This snippet corresponds to line 3-5 of Listing 1.

fies the object's checksum and performs corruption recovery if necessary.

The application can modify the micro-buffered object without concern for its checksum, parity, and crash-consistency because changes exist only in the micro-buffer. When the updates finish, `pgl_commit` starts a transaction that atomically updates the NVMM object, its checksum, and parity (described below). Compared to line 3-5 of Listing 1, Pangolin retains the simple, atomic-style programming model for modifying a single NVMM object, and it supports updates within an object beyond 8 bytes.

Each micro-buffer's header contains information such as its NVMM address, modified ranges, and status flags (e.g., allocated or modified). We elaborate on Pangolin's programming interface and how to construct complex transactions with micro-buffering in Section 3.4.

Another important consideration for micro-buffering is to prevent misbehaving software from corrupting NVMM. If an application's code can directly write to NVMM, as `libpmemobj` allows to, software bugs such as buffer overflows and using dangling pointers can easily cause NVMM

Function	Semantics
`pgl_tx_begin()/commit()/end(), etc.`	Control the lifetime of a Pangolin transaction.
`pgl_tx_alloc()/free()`	Allocate or deallocate an NVMM object.
`pgl_tx_open(PMEMoid oid, ...)`	Create a thread-local micro-buffer for an NVMM object. Verify (and restore) the object integrity, and return a pointer to the micro-buffered user object.
`pgl_tx_add_range(PMEMoid oid, ...)`	Invoke `pgl_tx_open` and then mark a range of the object that will be modified.
`pgl_get(PMEMoid oid)`	Get access to an object, either directly in NVMM or in its micro-buffer, depending on the transaction context. By default, it does not verify the checksum.
`pgl_open(PMEMoid oid, ...)`	Create a micro-buffer for an NVMM object without a transaction. Check the object integrity, and return a pointer to the micro-buffered user object.
`pgl_commit(void *uobj)`	Automatically start a transaction and commit the modified user object in a micro-buffer to NVMM.

Table 1: The Pangolin API - Pangolin's interface mirrors `libpmemobj`'s except that Pangolin does not allow direct writing to NVMM. Pangolin provides single-object transactions using `pgl_open` and `pgl_commit` to convert application code using `libpmemobj`'s atomic updates.

corruption. Conventional debugging tools for memory safety, such as Valgrind [36] and AddressSanitizer [44], insert inaccessible bytes between objects as "redzones" to trap illegal accesses. This approach fails to work for directly accessed NVMM objects because once they are allocated, there is no guarantee for spacing between them, and thus, redzones may land on a nearby, accessible object. One viable approach to using these tools is to let the NVMM allocator insert redzones. However, the presence of redzone bytes will pollute the pool and may exacerbate fragmentation.

Using micro-buffers isolates transient writes from persistent data, and since micro-buffers are dynamically allocated using `malloc()`, they are compatible with existing memory debugging tools. Without using debugging tools, Pangolin also protects micro-buffers by inserting a 64-bit "canary" word in each micro-buffer's header and checks its integrity before writing back to NVMM. On transaction commit, if Pangolin detects a canary mismatch, it aborts the transaction to avoid propagating the corruption to NVMM. Pangolin uses checksums to detect corruptions that may bypass the canary protection.

3.3 Detecting NVMM Corruption

Pangolin uses three mechanisms to detect NVMM corruption. First, it installs a handler for `SIGBUS` (see Section 2.2) that fires when the Linux kernel receives an MCE. A signal handler has access to the address the offending load accessed, and Pangolin can determine what kind of data (i.e., metadata or a user object) lives there and recover appropriately. This mechanism detects media failures, but it cannot discover corrupted data caused by software "scribbles."

To detect scribbles, Pangolin verifies the integrity of user objects using their checksums. Verifying checksums on every access can be expensive. To limit this cost, by default Pangolin only verifies checksums during micro-buffer creation before any object is modified in a transaction. This keeps Pangolin from recalculating a new checksum based on corrupt data. For read-only objects that are accessed by `pgl_get` without micro-buffering, by default Pangolin does not verify checksums. To protect them, Pangolin provides two alternative operation modes: "Scrub" mode runs a scrubbing thread that verifies and restores the whole pool's data integrity when a preset number of transactions have completed, and "Conservative" mode verifies the checksum for every object access (including `pgl_get`). We evaluate the impact of different checksum verification policies in Section 4.

Finally, Linux keeps track of known bad pages of NVMM across reboots. When opening a pool or during its scrubbing, Pangolin can extract this information and recover the data in the reported pages (not currently implemented).

3.4 Fault-Tolerant Transactions

Failure-atomic transactions are central to Pangolin's interface, and they must include verification of data integrity and updates to the checksums and parity data that protect objects. Table 1 summarizes Pangolin's core functions.

Pangolin supports arbitrary-sized transactions and we have made similar APIs and macros as `libpmemobj`'s. The program in Listing 1 can be easily transformed to Pangolin using equivalent functions. One subtle difference is in the handling of atomic-style updates, as shown in Listing 2.

In Pangolin, each thread can execute one transaction or nested transactions (same as `libpmemobj`). Concurrent transactions can execute if each one is associated with a different thread. Currently, Pangolin does not allow concurrent transactions to modify the same NVMM object. Concurrently modifying a shared object may cause data inconsistency if one transaction has to abort. `Libpmemobj` has the same limitation [17].

Each transaction manages its own micro-buffers using a

thread-local hashmap [24], indexed by an NVMM object's `PMEMoid`. Therefore, in a transaction, calling `pgl_tx_open` for the same object either creates or retrieves its micro-buffer. Multiple micro-buffers opened in one transaction form a linked list as shown in Figure 2. Micro-buffers for one transaction are not visible in other transactions, providing isolation.

If a transaction modifies an object, Pangolin copies it to a micro-buffer, performs the changes there, and then propagates the changes to NVMM during commit. Since changes occur in DRAM (which does not require undo information), Pangolin implements redo logging.

At transaction commit, Pangolin recomputes the checksums for modified micro-buffers, creates and replicates redo log entries for the modified parts of the micro-buffers and writes these ranges back to NVMM objects. Then, it updates the affected parity bits (see Section 3.5) and marks the transaction committed. Finally, Pangolin garbage-collects its logs and closes thread-local micro-buffers.

If a transaction aborts, either due to unrecoverable data corruption or other run-time errors, Pangolin discards the transaction's micro-buffers without touching NVMM.

A transaction can also allocate and deallocate objects. Pangolin uses redo logging to record NVMM allocation and free operations, just as `libpmemobj` does.

For read-only workloads, repeatedly creating micro-buffers and verifying object checksums can be very expensive. Therefore, Pangolin provides `pgl_get` to gain direct access to an NVMM object without verifying the object's checksum. The application can verify an object's integrity manually as needed or rely on Pangolin's periodic scrubbing mechanism. Inside a transaction context, `pgl_get` returns a pointer to the object's micro-buffer to preserve isolation.

3.5 Parity and Checksum Updates

Objects in different rows can share the same range of parity, and we say these objects *overlap*. Object overlap leads to a challenge for updating the shared parity because updates from different transactions must serialize but naively locking the whole parity region sacrifices scalability.

For instance, using *ObjA* and *ObjC* in Figure 2, suppose two different transactions modify them, replacing A with A' and C with C', respectively. After both transactions update P, the parity should have the value $P' = A' \oplus C' \oplus D \oplus E$ regardless of how the two transaction commits interleave.

Pangolin uses a combination of two techniques that exploit the commutativity of XOR and fine-grained locking to preserve correctness and scalability.

Atomic parity updates The first approach uses the atomic XOR instruction (analogous to an atomic increment) that modern CPUs provide to perform incremental parity updates for changes to each overlapping object.

In our example, we can compute two parity patches: $\Delta A = A \oplus A'$, $\Delta C = C \oplus C'$ and then rewrite P' as $P \oplus \Delta A \oplus \Delta C$. Since XOR commutes and is a bit-wise operation, the two threads can perform their updates without synchronization.

Hybrid parity updates Atomic XOR is slower than normal or vectorized XOR. For small updates, the latency difference between them is not significant, and Pangolin prefers atomic XOR instructions to update parity without the need for locks. But for large parity updates, atomic XOR can be inefficient. Therefore, Pangolin's hybrid parity scheme switches to vectorized XOR for large transfers.

To coordinate large and small parity updates, Pangolin uses *parity range-locks*, that work similarly as reader/writer locks (or shared mutex): Small writes take shared ownership of a range lock and update parity with atomic XOR instructions. Large updates using vectorized XORs take exclusive ownership of a range-lock, and only one thread can modify parity in a locked range. If one update involves multiple range-locks, serialization happens on a per-range-lock basis.

The managed size of a parity range-lock depends on the performance trade-off between Pangolin's parity mode and `libpmemobj`'s replication mode. We discuss this in Section 4.

Pangolin refreshes an object's checksum in its micro-buffer before updating parity, and it considers the checksum field as one of the modified ranges of the object. Checksums like CRC32 requires recomputing the checksum using the whole object. This can become costly with large objects. Thus, Pangolin uses Adler32 [23], a checksum that allows incremental updates, to make the cost of updating an object's checksum proportional to the size of the modified range rather than the object size.

We implement Pangolin's parity and checksum updates using the Intelligent Storage Acceleration Library (ISA-L) [18], which leverages SIMD instructions of modern CPUs for these data-intensive tasks.

Protections for other transaction systems Other NVMM persistent object systems could apply Pangolin's techniques for parity and checksum updates. For example, consider an undo logging (as opposed to Pangolin's redo logging) system that first stores a "snapshot" copy of an object in the log before modifying the original in-place. In this case, the system could compute a parity patch using the XOR result between the logged data (old) and the object's data (new). Then, it can apply the parity patch using the hybrid method we described in this section.

3.6 Recovering from Faults

In this section, we discuss how Pangolin recovers data integrity from both NVMM corruption and system crashes.

Corruption recovery Pangolin uses the same algorithm to recover from errors regardless of how it detects them (i.e., via `SIGBUS` or a checksum mismatch).

The first step is to pause the current thread's transaction, and to wait until all other outstanding transactions have com-

pleted. Meanwhile, Pangolin prevents the initialization of new transactions by setting the pool's "freeze" flag. This is necessary because, during transaction committing, parity data may be inconsistent.

Once the pool is frozen, Pangolin uses the parity bits and the corresponding parts of each row in the page column to recover the missing data.

Pangolin preserves crash-consistency during repair by making persistent records of the bad pages under recovery. Recovery is idempotent, so it can simply re-execute after a crash.

Pangolin's current implementation only allows one thread to perform any online corruption recovery, and if the thread is executing a transaction, online recovery only works if the thread has not started committing. If two threads encounter faults simultaneously, Pangolin kills the application and performs post-crash recovery (see below) when it restarts. Supporting multi-threaded online recovery, and allowing it to work when threads have partially written NVMM is possible, but it requires complex reasoning about how to restore the data and its parity to a consistent state.

Crash recovery Pangolin handles recovery from a crash using its redo logs. It must also protect against the possibility that the crash occurred during a parity update.

To commit a transaction, Pangolin first ensures its redo logs are persistent and replicated, and then updates the NVMM objects and their parity. If a crash happens before redo logs are complete, Pangolin discards the redo logs on reboot without touching the objects or parity. If redo logs exist, Pangolin replays them to update the objects and then recomputes any affected parity ranges using the data written during replay (which is now known to be correct) and the data from the other rows.

Pangolin does not log parity updates because it would double the cost of logging. This does raise the possibility of data loss if a crash occurs during a parity update and a media error then corrupts data of the same page column before recovery can complete. This scenario requires the simultaneous loss of two pages in the same page column due to corruption and a crash, which we expect to be rare.

4 Evaluation

In this section, we evaluate Pangolin's performance and the overheads it incurs by comparing it to normal `libpmemobj` and its replicated version. We start with our experimental setup and then consider its storage requirements, latency impact, scalability, application-level performance, and corruption recovery.

4.1 Evaluation Setup

We perform our evaluation on a dual-socket platform with Intel's Optane DC Persistent Memory [19]. The CPUs are 24-core engineering samples of the Cascade Lake generation. Each socket has 192 GB DDR4 DRAM and 1.5 TB NVMM. We configure the persistent memory modules in *AppDirect* mode and run experiments on one socket using its local DRAM and NVMM. A recent report [21] studying this platform provides more architectural details.

Pmemobj	`libpmemobj` baseline from PMDK v1.5
Pangolin	Pangolin baseline w/ micro-buffering only
Pangolin-ML	Pangolin + metadata and redo log replication
Pangolin-MLP	Pangolin-ML + object parity
Pangolin-MLPC	Pangolin-MLP + object checksums
Pmemobj-R	`libpmemobj` w/ one replication in another file

Table 2: Library operation modes for evaluation - In the figures, we abbreviate Pangolin as `pgl`.

The CPU provides the `CLWB` instruction for writing-back cache lines to NVMM, non-temporal store instructions to bypass caches, and the `SFENCE` instruction to ensure persistence and memory ordering. It also has atomic XOR and AVX instructions that our parity and checksum computations use.

The evaluation machine runs Fedora 27 with a Linux kernel version 4.13 built from source with the NOVA [48] file system. We run experiments with both Ext4-DAX [27] and NOVA, and applications use `mmap()` to access NVMM-resident files. The performance is similar on the two file systems because DAX-`mmap()` essentially bypasses them.

On our evaluation machine, we found that updating parity with atomic XORs becomes worse than `libpmemobj`'s replication mode when the modified parity range is greater than 8 KB, so we set 8 KB as the threshold to switch between those parity calculation strategies (see Section 3.5).

Table 2 describes the operation modes for our evaluations. The Pangolin baseline implements transactions with micro-buffering. It uses buffer canaries to prevent corruption from affecting NVMM, but it does not have parity or checksum for NVMM data.

We evaluate versions of Pangolin that incrementally add metadata and log replication ("+ML"), object parity ("+MLP"), and checksums ("+MLPC"). We combine the impact of metadata updates with log replication because metadata updates are small and cheap in our evaluation.

Pmemobj-R is the replication mode of `libpmemobj` that mirrors updates to a replica pool during transaction commit. Comparing Pangolin-MLP and Pmemobj-R is especially useful because the two configurations protect against the same types of data corruption: media errors but not scribbles.

4.2 Memory Requirements

We discuss and evaluate Pangolin's memory requirements for both NVMM and DRAM.

NVMM All our Pangolin experiments use a single pool of 100 GB that contains 6× 16 GB zones. Pangolin replicates

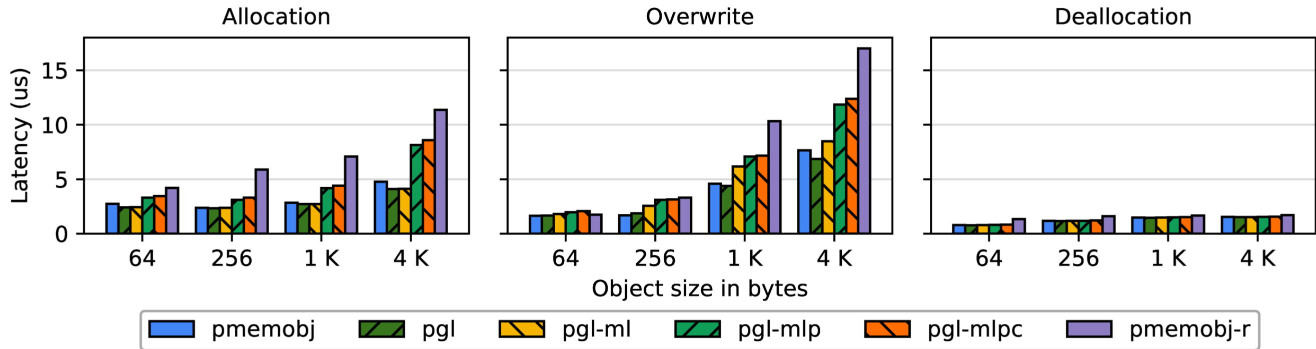

Figure 3: Transaction performance – Each transaction allocates, overwrites, or frees one object of varying sizes. Pangolin's latencies are similar to Pmemobj's. Pangolin-MLP is mostly better than Pmemobj-R because updating parity using atomic XOR and `CLWB` instructions is faster than mirroring data in a separate file.

all the pool's metadata in the same file, which occupies a fixed ~20 MB. The rest of the space is for user objects and their protection data. By default, Pangolin uses 100 chunk rows, so each zone has about 160 MB parity, and that totally occupies ~1% of the pool's capacity. Pmemobj-R uses a second 100 GB file as the replica, doubling the cost of NVMM space requirement.

When using parity, Pangolin has to zero out the whole pool to ensure all zones are initially parity-coded. This takes about 130 seconds. It is a one-time overhead for creating the pool and excluded from the following evaluations.

DRAM Pangolin uses `malloc()`'d DRAM to construct micro-buffers. The required DRAM space is proportional to ongoing transaction sizes. Table 3 summarized the transaction sizes for the evaluated key-value store data structures. Pangolin automatically recycles them on transaction commits. In our evaluation experiments, micro-buffering never exceeds using 50 MB of DRAM.

4.3 Transaction Performance

Figure 3 illustrates the transaction latencies for three basic operations on an NVMM object store: object allocation, overwrite, and deallocation. Each transaction operates on one object, and we vary the size of the object.

For allocation, latency grows with object size for all five configurations, due to constructing the object and cache line write-back latency. Pangolin incurs 2% - 13% lower latencies than Pmemobj due to its use of non-temporal stores for write backs. An allocation operation does not involve object logging, so Pangolin-ML shows performance similar to Pangolin. Pangolin-MLP adds overhead to update the parity data. It outperforms Pmemobj-R by between 1.2× and 1.9×. We found this is because updating parity using atomic XORs and `CLWB`s incurs less latency than mirroring data in a separate file, as Pmemobj-R does.

Adding checksum (Pangolin-MLPC) incurs less than 7% overhead compared to Pangolin-MLP. Parity's impact is larger than checksum's because updating a parity range demands values from three parts: the micro-buffer, the NVMM object, and the old parity data, while computing a checksum only needs data in a DRAM-based micro-buffer. Moreover, Pangolin needs to flush the modified parity range to persistence, which is the same size as the object. In contrary, updating a checksum only writes back a single cache line that contains the checksum value.

Overwriting an NVMM object involves transaction logging for crash consistency. Pangolin and Pmemobj store the same amount of logging data in NVMM, although they use redo logging and undo logging for this purpose, respectively. Since log entry size is proportional to an object's modified size, which is the whole object in this evaluation, this cost grows with the object. With Pangolin, log replication accounts for between 7% to 25% of the latency. Parity updates consume between 8% to 27% of the extra latency, depending on object size, and checksum updates account for less than 5%. Pangolin-MLP's performance for overwrites is 12% worse than Pmemobj-R for 64 B object updates and is between 1.1× and 1.5× better than Pmemobj-R for objects larger than 64 B.

Deallocation transactions only modify metadata, so their latencies do not change much.

4.4 Scalability

Figure 4 measures Pangolin's scalability by randomly overwriting existing NVMM objects and varying the object sizes and the number of concurrent threads.

Pangolin uses reader/writer locks to implement the hybrid parity update scheme described in Section 3.5. The number of rows in a zone and the zone size determine the granularity

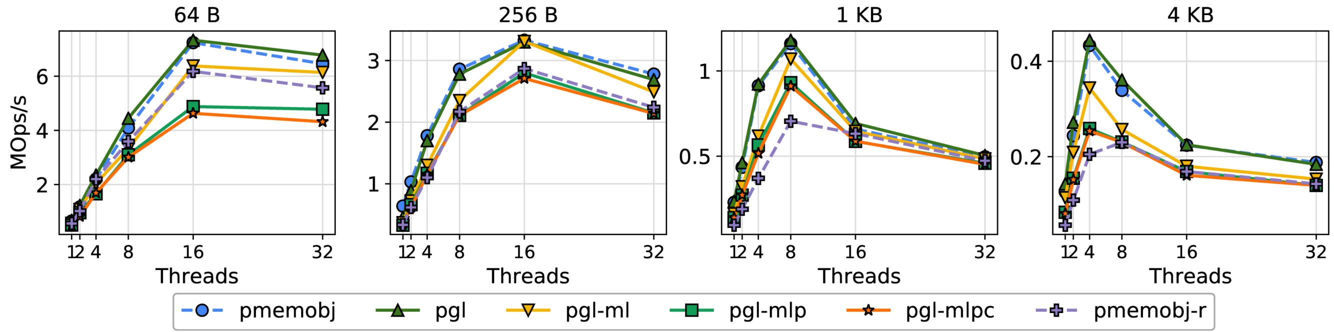

Figure 4: Scalability – Concurrent workloads randomly overwrite objects of varying sizes. Pangolin-MLP scales as well as Pmemobj-R or better for objects larger than 64 B. For 64 B objects, Pangolin-MLP is worse than Pmemobj-R by between 6% and 25% due to synchronization overhead for online recovery.

		ctree	rbtree	btree	skiplist	rtree	hashmap
Object size		56	80	304	408	4136	10 M (table), 40 (entry)
Insert	New	56 (1.00)	80 (1.00)	65.9 (0.22)	408 (1.00)	4502 (1.09)	60.9 (1.00)
	Mod	127.6 (3.28)	330.2 (5.13)	381.2 (1.47)	33.9 (2.50)	200.0 (5.05)	331.1 (4.21)
Remove	New	0	0	0	0	184.1 (0.05)	10.5 (1×10^{-5})
	Mod	28.0 (0.50)	202.8 (2.65)	268.3 (0.90)	16.9 (0.75)	98.6 (2.52)	254.3 (2.16)

Table 3: Data structure and transaction sizes - "Insert" and "Remove" show average transaction sizes for insertions and removals, respectively. "New" and "Mod" indicate average allocated and modified sizes. Value in parentheses is the average number of objects involved in the transaction.

of these locks: For a fixed zone size, more rows means fewer columns and fewer parity range-locks.

There is no lock contention in the results because the transactions use atomic XOR instructions and can execute concurrently (only taking the reader locks). Our configuration with 1% parity (160 MB parity per 16 GB zone) has 20 K range-locks per zone, so the chance of lock contention is slim even with large updates (more than 8 KB) and many cores.

The graphs also show how each Pangolin's fault-tolerance mechanisms affect performance. Pangolin's throughput is very close to Pmemobj. Pangolin-MLP mostly outperforms Pmemobj-R for object updates that are 256 B or larger, up to 1.5×. But for 64 B object updates, it performs worse than Pmemobj-R by between 6% and 25%. This is because when enabling parity, every Pangolin transaction checks the pool freeze flag (an atomic variable), incurring synchronization overhead. This overhead is noticeable for short transactions with 64 B objects but becomes negligible for larger updates. Pangolin-MLPC only performs marginally worse than Pangolin-MLP.

Scaling degrades for all configuration as update size and thread count grow because the sustainable bandwidth of the persistent memory modules becomes saturated.

4.5 Impacts on NVMM Applications

To evaluate Pangolin in more complex applications, we use six data structures included in the PMDK toolkit: crit-bit tree (ctree), red-black tree (rbtree), btree, skiplist, radix tree (rtree), and hashmap. They have a wide range of object sizes and use a diverse set of algorithms to insert, remove, and lookup values. We rewrite these benchmarks with Pangolin's programming interface as described in Section 3.4.

Table 3 summarizes the object and transaction sizes for each workload. The tree structures and the skiplist have a single type of object, which is the tree or list node. Hashmap has two kinds of objects. One is the hash table that contains pointers to buckets. The hash table grows as the application inserts more key-value pairs. Each bucket is a linked list of fixed-sized entry objects.

Each insertion or removal is a transaction processing a key-value pair. The workloads involve a mix of object allocations, overwrites, and deallocations. Table 3 shows, on average, the number of bytes and objects (in parentheses) involved in each data structure's transaction. Deallocated sizes are not shown because they marginally affect the performance differences (see Figure 3).

An average allocation size ("New" rows in the table) smaller than the object size means the data structure does not allocate a new object for every insert operation (e.g., btree).

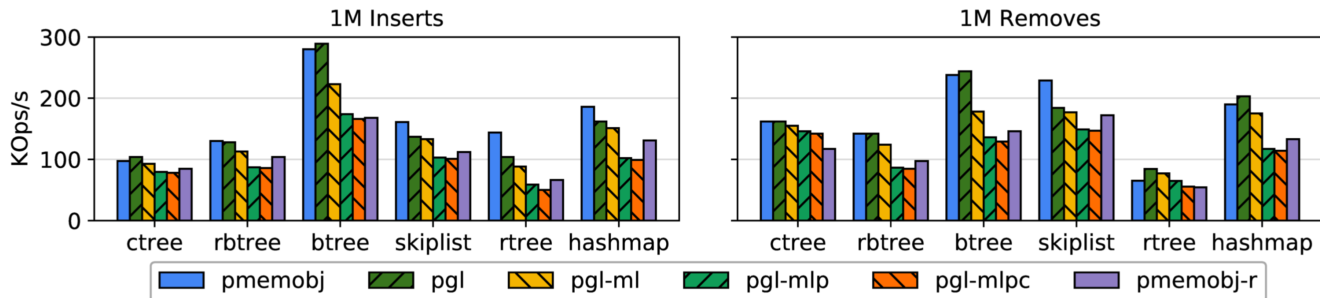

Figure 5: Key-value store performance – Each transaction either inserts or removes one key-value pair from the data store. Pangolin performs similarly to Pmemobj except for cases when a transaction's modified size is much less than an object's size (e.g., skiplist and rtree) due to micro-buffering overhead. Pangolin-MLP's performance is 95% of Pmemobj-R on average.

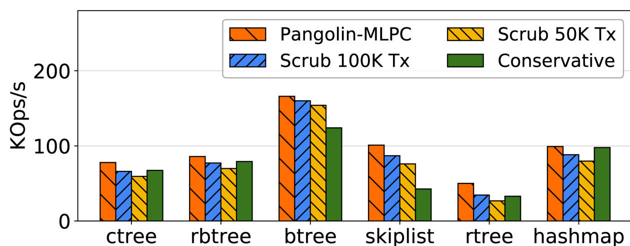

Figure 6: Checksum verification impact – Pangolin-MLPC bars are the same as those in Figure 5 for 1M Inserts. The cost of different policies depends strongly on data structures.

	ctree	rbtree	btree	sklist	rtree	hmap
Pmemobj	1.0	1.0	1.0	1.0	1.0	1.0
Pgl-MLPC	0.92	0.84	0.87	0.96	0.42	0.42
Scrub 100K	0.10	0.09	0.09	0.10	0.04	0.05
Scrub 50K	0.05	0.04	0.05	0.05	0.02	0.02
Conservative	0	0	0	0	0	0

Table 4: Vulnerability evaluation - Each row shows object bytes (normalized to Pmemobj) accessed without checksum verification.

The average modified sizes ("Mod" rows) determine the logging size and affect the performance drop between Pangolin and Pangolin-ML. Note that a transaction does not necessarily modify (and log) the whole range of an involved object. The performance difference between Pangolin-ML and Pangolin-MLP is a consequence of both allocated and modified sizes.

For insert transactions, Pangolin is faster than Pmemobj for ctree and btree, but slower than Pmemobj for other data structures. This is because the slower applications have relatively small modified sizes compared to the object sizes, and Pangolin's data movement from NVMM to micro-buffers overshadows its advantage for whole-object updates, as shown in Figure 3. For remove transactions, Pangolin is marginally faster than Pmemobj except for the case of skiplist, which is also because of the data movement caused by micro-buffering.

Pangolin-MLP's performance is 95% of Pmemobj-R on average, and it saves orders of magnitude NVMM space by using parity data as redundancy. Pangolin-MLPC adds scribble detection and performance drops by between 1.5% to 15% relative to Pangolin-MLP. Adding object checksums impacts rtree's transactions the most because the allocated object size is large, which requires more checksum computing time.

Pangolin does not impact the lookup performance because it performs direct NVMM reads without constantly verifying object checksums. Pangolin ensures data integrity with its checksum verification policy, as discussed in Section 3.3.

Figure 6 illustrates the impact of different strategies for checksum verification. We compare Pangolin's default mode (Pangolin-MLPC) with two "Scrub" modes and a "Conservative" mode. The default mode only verifies checksums for micro-buffered objects. In "Scrub" mode, a scrubbing thread verifies data integrity of the whole object pool when a preset number (indicated by legends in Figure 6) of transactions have completed. The "Conservative" mode verifies the checksum for every object access (including those read by `pgl_get` without micro-buffering).

Table 4 quantifies the vulnerability using the amount of object data that is accessed without checksum verification. The data accumulates across all transactions for Pmemobj, Pangolin-MLPC, and "Conservative" modes. For "Scrub" modes, we count the vulnerable data between two scrubbing runs. Numbers in Table 4 are normalized to Pmemobj, which does not have any checksum protection for object data.

The cost of verifying checksums for every object access depends strongly on the data structure size and its insertion algorithm. For small objects, such as ctree, rbtree, and hashmap, the cost is negligible. But for btree, skiplist, and rtree, due to their large object sizes, the cost is significant. Thus, a scrubbing-based policy could be faster, with more data subject

to corruption between two successive runs.

4.6 Error Detection and Correction

Pangolin provides error injection functions to emulate both hardware-uncorrectable NVMM media errors and hardware-undetectable scribbles.

We initially developed Pangolin using conventional DRAM machines that lack support for injecting NVMM errors at the hardware level. Therefore, we use `mprotect()` and `SIGSEGV` to emulate NVMM media errors and `SIGBUS`. When an NVMM file is DAX-mapped, the injector can randomly choose a page that contains user-allocated objects, erase it, and call `mprotect(PROT_NONE)` on the page. Later, when the application reads the corrupted page, Pangolin intercepts `SIGSEGV`, changes the page to read/write mode, and restores the page's data. The injector function can also randomly corrupt a metadata region or a victim object to emulate software-induced, scribble errors.

In both test cases, we observe Pangolin can successfully repair a victim page or an object and resume normal program execution. In our evaluation using a 100 GB pool and 1 GB parity, we measured 180 μs to repair a page of a page column.

We also intentionally introduce buffer overrun bugs in our applications and observe that Pangolin can successfully detect them using micro-buffer canaries. The transaction then aborts to prevent any NVMM corruption. We have also verified Pangolin is compatible with AddressSanitizer for detecting buffer overrun bugs (when updating a micro-buffered object exceeds its buffer's boundary), if both Pangolin and its application code are compiled with support.

5 Related Work

In this section, we place Pangolin in context relative to previous projects that have explored how to use NVMM effectively.

Transaction Support All previous libraries for using NVMMs to build complex objects rely on transactions for crash consistency. Although we built Pangolin on `libpmemobj`, its techniques could be applied to another persistent object system. NV-Heaps [3], Atlas [1], DCT [22], and `libpmemobj` [39] provide undo logging for applications to snapshot persistent objects before making in-place updates. Mnemosyne [47], SoftWrAp [11], and DUDETM [25] use variations of redo logging. REWIND [2] implements both undo and redo logging for fine-grained, high-concurrent transactions. Log-structured NVMM [12] makes changes to objects via append-only logs, and it does not require extra logging for consistency. Romulus [5] uses a main-back mechanism to implement efficient redo log-based transactions.

None of these systems provide fault tolerance for NVMM errors. We believe they can adopt Pangolin's parity and checksum design to improve their resilience to NVMM errors at low storage overhead. In Section 3.5 we described how to apply the hybrid parity updating scheme to an undo logging-based system. Log-structured and copy-on-write systems can adopt the techniques in similar ways.

Fault Tolerance Both Pangolin and `libpmemobj`'s replication mode protect against media errors, but Pangolin provides stronger protection and much lower space overhead. Furthermore, `libpmemobj` can only repair media errors offline, and it does not detect or repair software corruption to user objects.

NVMalloc [32] uses checksums to protect metadata. It does not specify whether application data is also checksum-protected, and it does not provide any form of redundancy to repair the corruption. NVMalloc uses `mprotect()` to protect NVMM pages while they are not mapped for writing. Pangolin could adopt this technique to prevent an application from scribbling its own persistent data structures.

The NOVA file system [48, 49] uses parity-based protection for file data. However, it must disable these features for NVMM pages that are DAX-mapped for writing in user-space, since the page's contents can change without the file system's knowledge, making it impossible for NOVA to keep the parity information consistent if an application modifies DAX-mapped data. As a result, Pangolin's and NOVA's fault tolerance mechanisms are complementary.

6 Conclusion

This work presents Pangolin, a fault-tolerant, DAX-mapped NVMM programming library for applications to build complex data structures in NVMM. Pangolin uses a novel, space-efficient layout of data and parity to protect arbitrary-sized NVMM objects combined with per-object checksums to detect corruption. To maintain high performance, Pangolin uses micro-buffering, carefully-chosen parity and checksum updating algorithms. As a result, Pangolin provides stronger protection, better availability, and much lower storage overhead than existing NVMM programming libraries.

Acknowledgments

This work was supported in part by Toshiba, and we are thankful for their continued sponsorship. We thank our shepherd, Kimberly Keeton and the anonymous USENIX ATC reviewers for their insightful comments and suggestions. We are also thankful for Intel to provide us early access to platforms with Intel's Optane DC Persistent Memory Modules.

Institute of Parallel and Distributed Systems (IPADS), Shanghai Jiao Tong University

Abstract

Persistent transactional memory (PTM) programming model has recently been exploited to provide crash-consistent transactional interfaces to ease programming atop NVM. However, existing PTM designs either incur high reader-side overhead due to blocking or long delay in the writer side (efficiency), or place excessive constraints on persistent ordering (scalability).

This paper presents Pisces, a read-friendly PTM that exploits snapshot isolation (SI) on NVM. The key design of Pisces is based on two observations: the redo logs of transactions can be reused as newer versions for the data, and an intuitive MVCC-based design has read deficiency. Based on the observations, we propose a dual-version concurrency control (DVCC) protocol that maintains up to two versions in NVM-backed storage hierarchy. Together with a three-stage commit protocol, Pisces ensures SI and allows more transactions to commit and persist simultaneously. Most importantly, it promises a desired feature: hiding NVM persistence overhead from reads and allowing nearly non-blocking reads.

Experimental evaluation on an Intel 40-thread (20-core) machine with real NVM equipped shows that Pisces outperforms the state-of-the-art design (i.e., DUDETM) by up to 6.3× for micro-benchmarks and 4.6× for TPC-C new order transaction, and also scales much better. The persistency cost is from 19% to 50% for 40 threads.

1 Introduction

Non-volatile memory (NVM) such as phase-change memory (PCM) [46, 67, 78], resistive random-access memory (ReRAM) [9, 45], and Intel/Micron's 3D-XPoint [2, 4], is revolutionizing the storage hierarchy thanks to the promising features like byte-addressability and non-volatility with a close-to-DRAM speed. By supporting persistent data access via CPU load/store instructions, these technologies bring ample opportunities for applications to achieve optimal performance as well as efficient crash consistency [20, 62].

To efficiently program on NVM with a balance among good programmability, high performance, and low software overhead, persistent transactional memory (PTM), also known as durable (memory) transactions, has been exploited by prior work [21, 37, 44, 49, 56, 74, 76]. Through combining transactional memory [29, 34, 66, 68, 70] and NVM, PTM offers the properties of atomicity, consistency, isolation, durability (ACID) to applications on NVM.

To ensure the durability for transactions, some prior designs [21, 44, 56, 74] need to persist a transaction's log while holding the locks of the data being modified or explicitly track the dependencies among transactions through locks. This, however, may block concurrent read operations on the same data. The long blocking duration may become a severe performance bottleneck due to the amplified persistence overhead incurred by high write latency of NVM (usually 10× compared to DRAM) (*low read efficiency*). This is especially true when read operations dominate in many workloads [15, 19, 52, 63]. In contrast, another design [49] eliminates the persistence latency from a transaction's critical path through relaxing the durability semantics, i.e., making a transaction's modifications visible before its log reaches NVM. However, such a design sacrifices the durability guarantee and requires to apply logs back to the durable data according to a total order. Unfortunately, such a strict persistence ordering may be the bottleneck of scalability since it is hard to parallelize the persistence operations. Overall, it is challenging to design a PTM system that insulates readers from being affected by high NVM persistence overhead while enforcing strong durability as well as avoids overly-constrained persistence ordering simultaneously.

We notice that *snapshot isolation* (SI) [8, 12] can avoid read-write conflicts and suffices for many real-world applications [6, 11, 26, 28, 33, 47, 48, 61, 68, 77], which makes it possible to design a PTM that allows a transaction to persist its log in its critical path (no sacrifice the durability), while hiding the high persistence overhead from concurrent read operations. Multi-version concurrency control (MVCC) [13, 28] is a common choice to achieve SI. We *observe* that the (redo) logs which will be finally applied to the durable data (old) can be regarded as a new data version, which enables us to efficiently introduce MVCC to PTM.

However, after a deep analysis, we *find* that a straightfor-

ward MVCC-based PTM design not only brings high reader-side overhead due to read-indirection problems (challenge-1), i.e., locating the consistent objects in the version lists, but also still leaves the readers affected by the NVM persistence overhead (challenge-2). So, we further present *Pisces*, a read-friendly PTM design that also embraces SI while solving the above two problems and achieves both high read efficiency and good scalability.

Specifically, Pisces proposes *dual-version concurrency control* (*DVCC*) inspired by MVCC and scalable synchronization primitives [18, 51, 54, 55], to solve challenge-1. DVCC still avoids read-write conflicts and thus allows high parallelism for transaction execution, but only keeps one or two versions (using the log as the newer version) for each data object, which minimizes the high cost for maintaining multiple versions in NVM as well as searching in the version lists. To solve challenge-2, Pisces hides the NVM persistence overhead from readers through *three-stage commit* that separates the durable point and the visible point of a (read-write) transaction and minimizes the possible read-blocking time to the duration of two DRAM stores. This blocking *rarely* happens since the possible blocking time is extremely short. A transaction persists its logs (new versions for objects) into NVM in a persist stage (durable) and makes its logs readable to other transactions in a following concurrency commit stage (visible). Note that the potential blocking period resides in the latter stage. Hence, the NVM persistence overhead can be hidden from readers. Besides, a transaction eagerly reclaims the old versions of objects and overrides them with new versions in the last write-back stage, which is for avoiding indirect reads. Furthermore, Pisces also enables *flush-diff* (persist modifications only) to prevent excessive NVM persistence operations and leverages *group-commit* to reduce the overhead for write transactions.

In all, Pisces hides the NVM persistence overhead from readers and promises *almost non-blocking* reads. Pisces guarantees *snapshot isolation* (a formal proof is also provided), and promises *crash consistency* that can restore the system to a consistent snapshot after crashes. In essence, Pisces explores a trade-off between isolation and performance by loosening the isolation level for better performance.

We have implemented and evaluated Pisces on a 40-thread machine. Evaluation results show that Pisces has a notably higher throughput and better scalability compared with the state-of-the-art design (i.e., DUDETM [49]). Specifically, Pisces achieves up to 6.3× throughput improvement in micro-benchmarks and can improve the throughput of TPC-C new order transaction [24] and TATP benchmark [72] by 460% and 64%, respectively.

In summary, this paper makes the following contributions:

- An observation that redo logs can be used as newer data versions and an intuitive MVCC-based PTM design with the observation. A careful analysis of the read-inefficiency of the MVCC-based design.
- A first PTM with snapshot isolation (Pisces), which leverages DVCC and three-stage commit to benefit readers most.
- An implementation and evaluation on a real machine with NVM that demonstrate Pisces's efficiency and scalability.

2 Background & Overview

Comparing with database transaction, Transactional memory (TM) [38] ensures atomicity, isolation and consistency (ACI), but lacks the important property of durability. However, the emergence of non-volatile memory provides an opportunity to equip TM with durability [44, 49, 56, 74, 76]. This section first introduces the backgrounds of NVM and PTM, then provides an overview of our system.

2.1 Background

NVM. The recent release of Intel Optane DC Persistent Memory [2] marks the transition of non-volatile memory (NVM) technology from research prototypes to mainstream products. NVM promises to provide fast data persistency. According to current studies [47, 79, 81], NVM has the following three features. First, most NVM designs are byte-addressable. This is one major reason why we can directly replace DRAM with NVM. Second, NVM has close-to-DRAM read latency, but about 10× write latency comparing with DRAM. For example, PCM's write latency is 150∼1000ns and ReRAM's is 500ns, while DRAM has only 60ns write latency [47, 79]. Third, special instructions [3] are provided to help persist the data: 1). *pflush* (e.g., *clwb*) will flush a cache line from CPU cache to NVM. 2). *pfence* (e.g., *mfence*) ensures all previous *pflush* instructions finish.

PTM. There are already various researches which build Persistent Transactional Memory (PTM) systems by leveraging NVM [21, 23, 44, 49, 56, 74]. However, most of them focus on optimizing the persistence overhead [21, 44, 56, 74]. For example, Kamino-tx [56] removes the overhead of data copy in a transaction's critical path by maintaining a backup of all the data. However, in these systems, an on-going write operations usually block conflicting read operations to ensure the consistency. As a result, these read operations will also suffer from NVM's high write latency.

A state-of-the-art design, called DUDETM [49], tries to address this issue with a decoupled PTM design: it temporarily buffers the running transaction's updates and its redo log in DRAM, then a number of threads will flush the log to NVM asynchronously. Furthermore, a dedicated thread (named reproduce thread) will replay the log to apply the updates to the persistent objects in NVM. However, once the log buffer becomes full because the reproduce thread cannot timely replay and clean the logs, the system needs to stall to wait for the reproduce thread to catch up. To ensure the consistency of the persistent state, the reproduce thread needs to replay the operations in the log sequentially. As a result,

the reproduce thread harms the system scalability. Figure 1-(a) shows the scalability issue of DUDETM: its performance can only scale up to 8 cores, after which the performance will be bottlenecked by the reproduce thread.

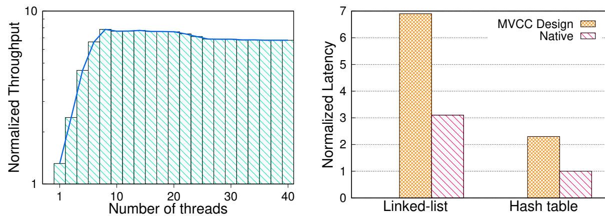

Fig. 1: (a) A hash table benchmark with 40% update rate. (b) A comparison on read-only transaction latency.

2.2 Overview

Goal. Comparing with existing works, Pisces is a PTM system with a read-friendly design, since lots of workloads using transactions are read-dominated [15, 19, 22, 30, 52, 63]: for example, the read-write ratio in the update operation of an 8 layer (8-15 keys per node) B+-tree is about 80:1; In the TPC-E and TATP [25, 72] benchmarks, about 80% of the transactions are read-only.

Strawman. Pisces is based on the intuition that *snapshot isolation* (SI) [8, 12] is able to avoid blocking reads by conflicting writes. At the same time, SI is applicable not only to database workloads [6, 11, 26, 28, 33, 47, 77], but also to TM workloads [48, 61, 68]. For example, Lu et al. [53, 68] prove that SI is enough to support a concurrent skip list. Thus, both database and STM systems have begun to use SI to improve concurrency [48, 61, 68].

However, is an intuitive SI implementation good enough to achieve our goal, a read oriented PTM? To answer this question, we implement a prototype system to provide SI based on multi-version concurrency control. Each object maintains a list of multiple versions and is identified by an ID. Each version has a timestamp to indicate its committed point-in-time. When a transaction starts, it sets a start timestamp based on the global timestamp kept by the system. During execution, to read an object, a transaction finds the most recent version which has a smaller timestamp than the transaction's start timestamp by traversing the object's list. For write, a transaction buffers updates in the write set and records the operation in a redo log. To commit its updates, a transaction first acquires the locks of all objects it tries to update. Then it detects write-write conflicts by checking the latest timestamp of these objects. If any object's latest timestamp is larger than the transaction's start timestamp, then the transaction is aborted. After passing the validation, the transaction retrieves its commit timestamp and updates the global timestamp. Then, the transaction flushes its log and the commit timestamp from CPU cache into the NVM, then flushes the updates in the write set to the persistent objects in NVM. At last, it releases all locks.

Issues. To analyze the efficiency of this design, we use it to implement concurrent data structures and compare with their native (single-threaded) implementations. Figure 1-(b) shows the evaluation results: the intuitive design has considerable overhead on read requests' latency because of the following problems:

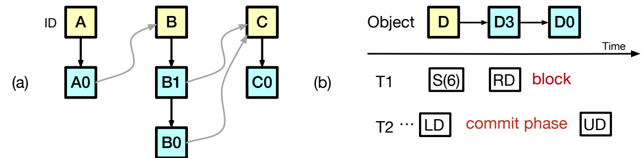

Fig. 2: (a) An ordered linked list structure in our MVCC-based PTM. Black arrows represent pointers in different version lists, while the gray arrows indicate the pointers in the linked list. (b) Read operations get blocked in MVCC.

First, traversing the multi-version list of each object increases the latency. This is not only because a transaction with small start timestamp may need to perform multiple indirect memory accesses, but also because the random accesses may harm the cache locality and get blocked due to the cache line being evicted to NVM. Figure 2 (b) gives a simple example: if a transaction traverses this 3-object list, it actually needs to traverse a much longer list which at least contains three objects and three object IDs.

Second, read operations may still be blocked by the NVM persist operations. Specifically, when a reader accesses an object which is locked by a writer, the reader may be blocked until the writer commits. The reason is the reader is not sure if the writer will have a smaller commit timestamp than its start timestamp or not. Unfortunately, the writer cannot commit until it flushes all its logs into NVM and applies the updates in its write set. Figure 2 (b) gives a simple example: T_1 starts with timestamp 6. When it reads object D, it finds D is locked by T_2. Then, it has to be blocked, as T_2 may update D with a timestamp smaller than 6.

Basic idea. We develop *Pisces* to solve above issues based on the following basic designs:

Dual-version concurrency control (DVCC). To reduce the cost of traversing an object's list, Pisces keeps up to two versions for each object: original object and object copy. When a transaction tries to write an object, it creates and links a new copy to the original object. When the transaction commits, it writes the object copy back to the original object. Concurrent transactions update the same object exclusively by acquiring a lock. Read transactions are able to directly access either version based on their timestamps. Furthermore, to reduce unnecessary NVM writes, we reuse the updates in the redo log as object copy. However, the challenge to implement DVCC is how to ensure an original object won't be overwritten when it may still be needed by some outstanding

transactions with smaller start timestamps.

Three-stage commit protocol. To reduce the blocking overhead in the MVCC design, Pisces proposes a three-stage commit protocol: the commit phase is divided into concurrency commit stage, and write-back stage. In the persist stage, a transaction flushes its log into NVM. In the concurrency commit stage, the transaction updates its end timestamp (commit timestamp) and the timestamps of all the object copies in the redo log atomically. In the write-back stage, the transaction writes all object copies back to their original objects. By decoupling different functionalities of the commit phase, Pisces allows nearly non-blocking reads. But the challenge lies in how to atomically update both the end timestamp and the timestamps of object copies efficiently.

Limitation. The main limitation of Pisces is it only provides SI which does not work for all applications, and SI suffers from the well-known write skew anomaly[1] under certain conditions. However, there is a long line of research [16, 33, 48, 53] on how to detect or eliminate write skew anomalies for SI. Moreover, making SI serializable is also well studied [59, 64, 69, 75]. Leveraging these techniques to provide a stronger isolation level is future work. Currently, careful programming on Pisces is required.

3 Design

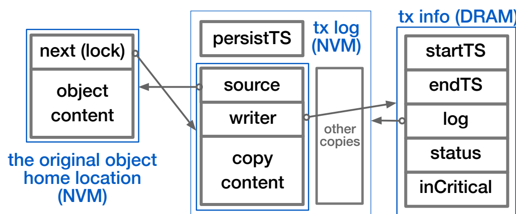

Fig. 3: The memory layout of an object, per-transaction log and per-thread metadata. Arrows represent pointers.

Layout. Figure 3 shows the memory layout of three critical components (data object, per-transaction log and per-thread metadata) in Pisces. Pisces attaches each object with a pointer (named *next* and initialized as 0) which may point to a next version of this object and is also used as a write lock that needs to be exclusively acquired by a writer. Pisces pre-allocates log area for each thread and each transaction gets its log from the log area of the execution thread when it begins. Pisces also keeps per-thread metadata to record the metadata of the running transaction in each thread (a thread executes at most one running transaction at a time). Object copies as the next (newer) versions of objects reside in the transactions' log and each object copy contains two pointers. One is named as *source* and points to the original object. The other is named as *writer* and points to the running transaction that owns this log (creates this copy).

[1] A typical write skew example is: One transaction reads A and writes B while another concurrent transaction reads B and writes A.

For the challenges mentioned in the above section, we provide simple but efficient solutions accordingly: First, to prevent an original version from being falsely overwritten, we leverage an RCU-similar design (grace period detection) to block the writer in the write-back phase until the original version in home location is safe to be overwritten. Note that the blocking time will not be exposed to readers. Second, to atomically update a transaction's end timestamp and each copy's version timestamp in an efficient way, we do not explicitly maintain the version timestamp for each copy. Instead, each copy contains the *writer* pointer and reuses the transaction's end timestamp as its version timestamp. As a result, atomicity is guaranteed by simply updating the end timestamp of the write transaction. Next, we discuss the details about the algorithm whose pseudo code is provided in Algorithm 1 and the correctness argument.

3.1 Algorithm

TM_Start begins a transaction. A transaction marks its status as ACTIVE first, executes a *fence* instruction and reads the global timestamp (globalTS) as its start timestamp (startTS). The *fence* instruction ensures line 2 is executed before line 4.

TM_Read returns a pointer for reading an object. It first reads the value of next pointer in the original object and returns the original object directly if next is zero. This is the *fast path*: accessing the pointer located just before the object introduces nearly-zero overhead because the CPU will prefetch adjacent cache lines. If next is non-zero, which means there exists an object copy, *TM_Read* returns the object copy when it is created by the current transaction (line 12) or its version is no greater than the current transaction's start timestamp (line 15). There is only one rare case in which *TM_Read* needs to wait (line 14). We discuss this later when introducing *TM_Commit*.

TM_Write returns a pointer for writing an object. A transaction can directly write a copy created by itself (line 21 to 23). When writing an object for the first time, a transaction reserves an area for the object copy in its log and tries to acquire the object's write lock (i.e., next pointer) with a compare-and-swap instruction (line 25). If fails to lock, the transaction aborts and restarts after a random delay, which also avoids deadlocks. Otherwise, it copies the original object's content to the object copy and can directly read or write the copy now. Pisces makes copies (redo log) at object granularity, which mitigates the *read-indirection problem* of redo logging at byte granularity. Pisces chooses encounter-time locking to detect conflicts early and thus can avoid unnecessary NVM writes. Also, an object's write lock ensures that it can only be updated sequentially.

TM_Commit always successfully commits a transaction. A transaction marks its status as INACTIVE, indicating it no longer reads any object. It commits directly if it is a read-only transaction. A read-write transaction needs to go through

Algorithm 1: Pseudo code of Pisces

```
1: Function TM_START(tx)
2:   tx.status = ACTIVE
3:   fence
4:   tx.startTS = globalTS
5:   tx.endTS = INF
6:
7: Function TM_READ(tx, p_obj)
8:   next = p_obj.next
9:   if next is EMPTY then
10:    return p_obj          // fast path
11:  wtx = next.writer
12:  if wtx is tx then
13:    return next
14:  wait until wtx.inCritical is FALSE
15:  if wtx.endTS ≤ tx.startTS then
16:    return next
17:  else
18:    return p_obj
19:
20: Function TM_WRITE(tx, p_obj)
21:  if p_obj.next is NON-EMPTY
22:  and p_obj.next.writer is tx then
23:    return p_obj.next
24:  copy = tx.log.alloc(p_obj)
25:  copy.writer = tx
26:  if CAS(p_obj.next, EMPTY, copy) fails then
27:    abort()
28:  copy.source = p_obj
29:  memcpy_content(copy, p_obj)  // p_obj -> copy
30:  return copy
31:
32: Function TM_COMMIT(tx)
33:  tx.status = INACTIVE
34:  // stage 1: persist stage
35:  if tx.log is EMPTY then
36:    return
37:  pflush(tx.log)
38:  pfence
39:  tx.log.persistTS = globalTS
40:  pflush(tx.log.persistTS)
41:  pfence
42:  // stage 2: concurrency commit stage
43:  tx.inCritical = TRUE
44:  fence
45:  tx.endTS = globalTS + 1
46:  tx.inCritical = FALSE
47:  AtomicInc(globalTS)
48:  // stage 3: write-back stage
49:  WRITEBACK(tx)
50:
51: Function WRITEBACK(tx)
52:  while exists an ACTIVE transaction t do
53:    if t.startTS < tx.endTS then
54:      wait
55:  for each copy in tx.log do
56:    memcpy_content(copy.source, copy)
57:    pflush(copy.source.content)
58:    copy.source.next = EMPTY
59:  pfence          // not necessary for correctness
```

three stages. In the *persist stage*, a transaction persists[2] all the object copies in its log into NVM (line 37-38). After that, it retrieves the value of the global timestamp as its log's persist timestamp (line 39) and makes the persistTS persistent (line 40-41). The *pfence* instruction in line 38 guarantees the log's content reaches NVM before its persistTS, and the *pfence* instruction in line 41 ensures both the log and its persistTS reaches NVM. A checksum can be appended to reduce the two fences to one [65]. A transaction's updates become durable once its persistTS reaches NVM (*durable point*). After a crash, a recovery procedure will replay transactions according to the redo logs and in persistTS order.

In the *concurrency commit stage*, the transaction updates its timestamp atomically by updating the 64 bit endTS with the globalTS (line 45). A boolean flag *inCritical* is used to protect this update to make sure the updated endTS is eventually visible to concurrent reads. For example, T_1 may read the globalTS and update its endTS. However, the updated endTS may be kept in the CPU store buffer and waits to be flushed to CPU cache. As a result, a concurrent transaction T_2 whose startTS is not less then T_1's endTS may fail to observe T_1's update. With the *inCritical* flag, T_1 will be blocked until *inCritical* is disabled before it tries to read T_2's endTS (line 14, 15). This ensures T_2's updates on endTS is eventually visible to T_1. As TSO architecture may reorder read-/write instructions, one fence[3] (line 44) is needed to ensure the execution order of line 43 and 45.

In the *write-back stage*, the transaction first waits for all active transactions whose startTS is less than its endTS to finish (line 52-54). This period actually is the *grace period*. It avoids falsely overwriting an original object which may be needed by transactions with small startTS. Because after this period, all threads are either in an inactive state (not executing transactions) or executing transactions with a startTS larger than the original object's timestamp. Therefore, the original object is *dead* which means it is no longer needed by any transactions. At the same time, this period also helps to detect write-write conflicts. Considering another conflicting transaction with smaller startTS, but access the same object after this transaction. This transaction will be blocked at the write-back stage and cannot release the lock. So, the conflicting transaction will abort since it fails to acquire the lock when accessing the object (line 26). At the end of the write-back stage, it writes each next object to the original object (line 56-57) and releases locks by clearing *next* fields (line 58).

Programming: Each transaction should be surrounded by *TM_Start* and *TM_Commit*. For reading/writing an object, it first uses *TM_Read*/*TM_Write* to achieve the ob-

[2] In the current implementation on Intel CPU, Pisces uses *clwb* to flush cacheline and *MFENCE* to ensure previous flushed cachelines reach NVM.

[3] Currently, Pisces uses *MFENCE* [3] instructions which ensures the CPU store buffer is always drained besides serializing load and store operations.

ject pointer and then directly accesses that object with the pointer. Pisces also offers helper functions (*TM_Read_Field* and *TM_Write_Field*) to ease programming.

3.2 Log Recycle

Pisces stores logs in per-thread ring buffers and lets each thread recycle its own logs. Generally speaking, there are two principles for log recycle in Pisces for snapshot isolation and crash consistency, separately.

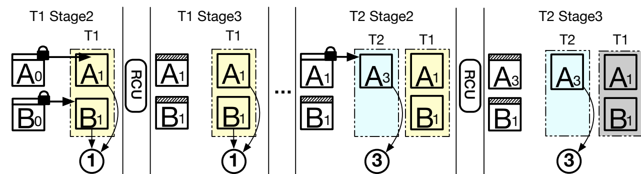

Fig. 4: T1 and T2 are two read-write transactions in one thread. T2 happens after T1. Colored rectangles represent transactions' logs.

P-1: A transaction log can only be recycled after all the copies in it are dead. A transaction creates new versions of objects in its log and exposes them to other transactions. As shown in Figure 4, after a transaction T1 writes the new versions back to the original objects, it is possible that the transaction's log is still required. For example, another transaction can read T1's log if it starts before T1 unlocks the objects and its startTS is no smaller than A's endTS. So, a transaction will not reclaim its own log. Instead, when a following read-write transaction (T2) finishes, the execution thread marks the log of the previous read-write transaction (T1) as reclaimable. Similar to how RCU grace periods can help safely overwriting original objects, the end of the grace period in T2's write-back stage can ensure other transactions no longer access T1's log. Specifically, the end of this grace period ensures (recall line 52-54 in Algorithm 1): previous transactions that may access A1 and B1 in T1's log due to smaller startTS are finished. Therefore, Pisces guarantees all the copies in a log are dead before recycling the log, which achieves *P-1*.

P-2: A transaction log can only be recycled no earlier than all the logs with smaller persist timestamps are recycled. Suppose a transaction A updates an object before another transaction B. If B's log is recycled before A and a crash happens, B's updates will lose after recovery because A will be redone according to its log. To enforce *P-2*, Pisces uses an epoch-based mechanism for recycling logs. It logically distributes logs to epochs according to their persist timestamps. First, an execution thread marks a transaction's log as reclaimable through recording the transaction's persist timestamp as the thread's *reclaim timestamp* (a per-thread variable). Second, an execution thread will atomically advance the global *epoch* when it finds that all the threads' *reclaim timestamp* exceeds the current global *epoch*. Once the global *epoch* increases, the logs belong to the previous epoch are no longer required, and the corresponding log area can be reused.

3.3 Proof Sketch of Snapshot Isolation

A formal proof can be found in [1]. According to the specification of snapshot isolation [8], we prove Pisces is correct by proving the following two theorems are correct.

THEOREM 1 (SNAPSHOT WRITE).

If two transactions update the same object, then one transaction's start TS (short for timestamp) should be greater than another's end TS.

PROOF. Based on the fact that, because of locking (line 26, 58), the conflicting transactions update the same object sequentially, we only need to prove the latter's start TS is always larger than the former's end TS. Pisces ensures this invariant by aborting the latter one when it gets a smaller (illegal) start TS: let's assume both of T_i and T_j access object x and T_i is before T_j. If T_j's start TS is smaller than T_i's end TS, T_i will be blocked by the active T_j at the write back phase (line 52-54). T_j must be active because, by the assumption, it will access x after T_i. Thus, when T_j accesses x, it will find the lock is held by T_i and abort itself. □

Before giving Theorem 2, we first define *the TS of an object* as the end TS of its last writer.

THEOREM 2 (SNAPSHOT READ).

If a transaction T_r reads an object x with timestamp TS_x, then: 1) T_r's start TS is not less than TS_x; and 2) There does not exist a transaction T_w that updates x and its end TS is larger than TS_x, but not greater than T_r's start TS.

PROOF. To prove Pisces holds the first invariant, we show that the x's copy returned by TM_READ must be committed by a transaction whose end TS is not greater than T_r's start TS. First, considering the case TM_READ returns x's original version (line 10, 18). On the one hand, Pisces ensures that, when T_r starts, all objects' original versions have timestamp which is not greater than T_i's start TS. On the other hand, Pisces also forbids any transaction whose end TS is greater than T_i's start TS to overwrite the original version (line 52-54). Next, we consider the case that TM_READ returns x's the next version (line 13, 16). Pisces ensures the invariant by adding an extra constraint that the writer's end TS must be not greater than T_r's start TS (line 15). [4]

Instead of directly showing Pisces holds the second invariant, we prove a variant: if T_w's end TS is not larger than T_r's start TS (assumption), then it is also not larger than TS_x. By the assumption above, we can have T_r starts (line 4) after T_w reads the global TS in commit phase (line 45). Now, let's consider two cases: 1). T_r reads x before T_w unlinks the next version from the object (line 58). Thus T_r is able to get the next version updated by T_w. Because the TSO architecture does not reorder the updates/reads on *endTS* and *inCritical* in TM_COMMIT/TM_READ, thus if T_r finds T_w's *inCritical* is false then it must be able to observe T_w's *endTS*. As a

[4]The detail proof of the consistency between the *next* copy and its *writer* pointer can be found in [1].

result, T_w's end TS should be equal to TS_x 2). T_r reads x after T_w writes back and unlinks the next copy. For this case, T_r will read the version committed by T_w or the transaction accessing x after TS_w. Then, we can have TS_x that must be less than T_w's end TS by simply deriving from Theorem 1. □

3.4 Crash Consistency

A recovery procedure will start after a crash and redo the durable transactions in a non-decreasing order of their logs' persistTS. The recovery time is affected by the length of the log which is decided by the log recycling frequency. By default, each execution thread in Pisces tries to recycle the logs after executing 3 (the default threshold) read-write transactions, so Pisces does not suffer from a high recovery cost. Also, Pisces provides a persistent allocator based on SSMalloc [50], which can recover the allocation information.

The key to ensuring crash consistency is that *dependent* transactions are (i) persisted and (ii) redone (after a crash) in the correct order that corresponds to their commit order. Two transactions are *dependent* if the read set or write set of the subsequent one overlaps with the write set of the previous one. In this subsection, we explain how Pisces achieves both (i) and (ii).

Achieving (i): Pisces guarantees the persistence ordering of dependent transactions by deferring the visibility of the updates of a transaction. Specifically, a transaction reaches its durable point (the end of *persist stage*) before it is visible (the end of *concurrency commit stage*). If transaction B observes (depends on) transaction A' updates (visible), A must already be persisted (durable). So, the persistence ordering of two dependent transactions must correspond to their commit order, as shown in Figure 5.

Fig. 5: Transaction B depends on A. Arrows mean happen-before.

Achieving (ii): On one hand, Pisces guarantees that if a transaction B depends on another transaction A, B's persist timestamp must be greater than A's (see Figure 5). On the other hand, Pisces's recovery procedure redoes the transactions' logs in a non-decreasing order of their persist timestamps after a crash. Therefore, transaction B that depends on A will be redone after A, which also corresponds to their commit order (B's endTS is greater than A's.) Besides, independent transactions that have the same persist timestamp can be redone in any order.

4 Optimizations

Flush-diff. Creating redo logs in the granularity of whole objects can avoid searching for new values in the address-value pairs. But it is quite expensive when the modification to an object is much smaller than the object size because the whole log (entire copy) has to be persisted into NVM. Therefore, we give an optimization named *flush-diff* that only persists the modifications. A transaction creates the object copies in DRAM instead of NVM and only records the updates (address-value pairs) in NVM. In the first commit stage, a transaction only needs to flush those updates into NVM; In the second commit stage, it lets the in-DRAM object copies (new versions) become readable; In the third commit stage, it only needs to apply the logged updates to the original objects in the NVM. Therefore, *flush-diff* can still embrace the advantage of logging a whole object (i.e., directly read/write the copy without the overhead of indirection) by keeping the volatile object copy in DRAM, and significantly reduce the amount of NVM persistence operations.

It is worth mentioning that DRAM footprint in Pisces is limited and not related to the amount of NVM in use. This is because Pisces only temporarily buffers the new object versions in DRAM and timely recycles the transactions' logs. Therefore, the DRAM needed for *flush-diff* is only related to the working set size of the transactions whose newly created copies may still be referenced.

Group Commit. Pisces chooses to eagerly write a new version back to an object's home location, which is for benefiting readers but makes the last commit stage for write transactions heavier. As mentioned in Section 3.1, a read-write transaction uses the RCU-like waiting mechanism to overwrite the objects in the home location. Besides, it is also costly to update *globalTS* with atomic instruction like *fetch_and_add* in a high-contention workload.

To amortize the overhead of both RCU reclamation and updating *globalTS*, Pisces batches and commits several write transactions together. An execution thread delays the commitment of a write transaction till the number of pending transactions (wait for commit) reaches a threshold or another transaction needs to update the same object with T. Then, the thread commits the pending transactions together, i.e., execute RCU mechanism and update the globalTS for one time. Thus, the overhead is amortized by these transactions.

5 Evaluation

5.1 Experimental Setup

Basic Setup. We conduct the experiments on a server provided by Intel. The server has two sockets, each containing a 10-core Intel Xeon Gold 5215M CPU, 128GB DRAM and 128GB Intel Optane DC Persistent Memory (NVM). We enable hyper-threading and bind each software thread to each hyper-thread (40 hyper-threads in all) that runs at 2.5GHz. The Linux kernel version is 4.19.32, and the GCC version is 8.3.1. Without an explicit statement, we use *clwb* instructions to persist data into NVM.

System for Comparison. *DUDETM* [49] maps persistent data in NVM to DRAM and uses TinySTM [35] which is a word-based STM to execute transactions in DRAM. A transaction only needs to write logs in a per-thread volatile log

buffer, and the background persist threads flush these volatile logs into persistent log buffer. DUDETM also requires another reproduce thread to write logs back to the persistent data. When evaluating DUDETM, we set the size of pre-allocated DRAM area the same as pre-allocated NVM area to make it able to cache all the NVM data in DRAM, which avoids the potential high overhead of page swapping. The volatile log buffer for each thread can hold 1 million log entries (default configuration), and we double the default size of persistent log buffer to make it able to hold 32 million log entries. In all the experiments for DUDETM, we wait for only foreground threads and not for background threads to finish. Thus, the committed transaction may be not durable yet. Besides, the background threads are not counted into the thread number. Currently, DUDETM does not implement multiple background persistent threads, but the support can be added without changing its design. However, the background reproduce thread needs to replay transactions' logs according to the unique transaction ID, i.e., a total order (hard to utilize multi-threading), which will become the bottleneck in some scenarios. To avoid the single persist thread becoming the bottleneck in the experiments, we allocate the persistent log buffer (should be in NVM actually) in DRAM.

Benchmarks. Generally speaking, to develop SI-safe applications, programmers need to analyze whether write skew anomalies may happen in some cases and then avoid the potential anomalies through making write-write conflicts in such cases. We manually ensure the presented benchmarks are SI-safe. referring to [48, 53, 54]. For examples, a transaction on a linked list (used in the following hash tables) adds all the modified nodes *including the nodes to be removed* into its write set in which each node object will be locked before updated; a transaction on the following tree structures traverses from the root node to some node in one way and also adds all the to-be-modified nodes into its write set.

5.2 Micro-benchmarks

Hash Table. Each hash table contains 10K buckets (implemented as linked lists) and initially contains 100K key-value pairs. We create different numbers of threads to execute search and insert/remove transactions. Figure 6 presents the evaluation results with various update rates. Note that the y-axis uses *log-scale*. Every test runs 30 seconds.

When the update rate is low, such as 0% and 2%, both Pisces and DUDETM scale well. Although Pisces's read-only transactions may load data from NVM when the data does not reside in CPU cache, they are still faster than that in DUDETM. It is because DUDETM requires a software page table mechanism for translating NVM addresses to DRAM addresses and validation for read operations. Different from DUDETM which incurs software overhead for read operations, Pisces embraces a read-friendly design, and thus its throughput is much higher and grows faster.

When the update rate is 20%, Pisces still scales well within

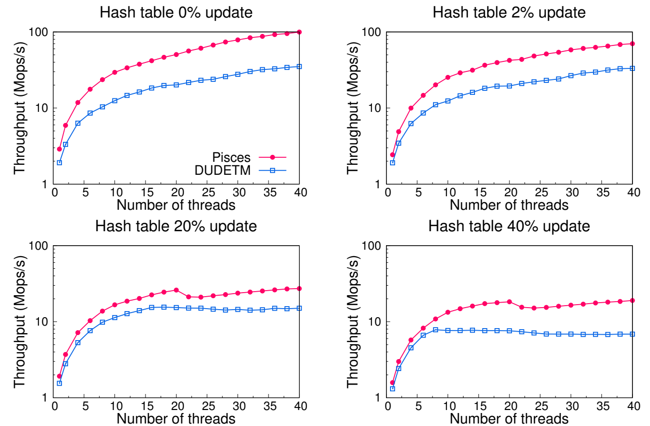

Fig. 6: The throughput of hash table (8-byte key and 64-byte value) at various update rates (legends in the first figure).

20 threads, i.e., a single NUMA (non-uniform memory access) node. The throughput of Pisces increases from ∼1.9 Mops/s to ∼26 Mops/s when the thread number increases from 1 to 20. However, there is an obvious performance drop when the thread number changes from 20 to 22. The main cause is cross-NUMA memory accesses. First, a global timestamp is updated in read-write transactions in Pisces, and a large number of read-write transactions incur high contention on that timestamp. Second, the grace period detection is another overhead for the read-write transactions, and its cost can be enlarged by frequent remote memory accesses. Recall that Pisces uses the RCU/RLU grace period detection mechanism (line 52-54 in Algorithm 1) to avoid overwriting in-use objects' versions. Therefore, while the total throughput of Pisces still grows as the thread number increases from 22 to 40, the growth speed is much slower than that within a single NUMA node.

The throughput of DUDETM grows from ∼1.5 Mops/s to ∼15 Mops/s as the thread number increases from 1 to 16. However, DUDETM's throughput cannot keep growing or even decreases a little when the thread number becomes larger. The reason is that the background threads fails to timely clean up the logs of transactions. Note that the reproduce thread has to modify the persistent objects according to the logs in the order of transaction execution, and make the modifications persistent with cacheline flush instructions. In contrast, Pisces lets each execution thread to persist and write-back the transactions' logs, which can better utilize the NVM write bandwidth.

Table 1: The average cost of a read-write transaction and one grace period detection in Pisces's hash table. The update rate is 40%.

#Thread	10	20	30	40
RW TX Latency (cycles)	2902	3986	7180	8496
Grace Period (cycles)	357	790	1689	2140

The performance of DUDETM and Pisces at 40% update rate shows similar trends with those at 20% update rate. Nev-

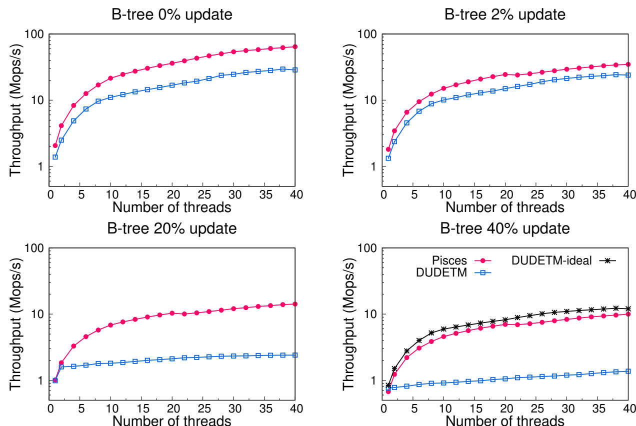

Fig. 7: The throughput of B+-tree whose node size is 256 bytes with various update rates (legends in the last figure).

ertheless, the throughput of DUDETM only grows within 8 threads because a higher update rate means more read-write transactions (generate more logs and fill the log buffer earlier). For Pisces, the growth speed of throughput becomes lower when the thread number exceeds 20. As presented in Table 1, the cost of grace period increases as the thread number increases. The reason is one thread has to check other threads' status for detecting the grace period.

In the case of 40 threads, Pisces's throughput is about 1.8× and 2.7× of DUDETM's when the update rate is 20% and 40%, respectively. And, its persistency cost is 19% at 40% update rate. Besides, the abort rates of both Pisces and DUDETM (if no blocking) are nearly zero since the hashing mitigates the contention among different threads. However, DUDETM's abort rate increases (up to 9%) if blocking happens because a thread may get blocked with holding locks.

We also evaluate the hash table with an occupancy of 0.75, i.e., 10K buckets and 7.5K key-value pairs. The evaluation results show similar trends. Specifically, at 20% update ratio, the throughput of DUDETM grows from ∼3.3 Mops/s to ∼15.9 Mops/s as the thread number increases from 1 to 16. As before, its throughput cannot grow when the thread number is larger than 16. Pisces's throughput grows from ∼2.7 Mops/s to ∼35.9 Mops/s as the thread number increases from 1 to 20. Nevertheless, when the thread number is 1 or 2, DUDETM has a higher throughput than Pisces for two reasons: first, DUDETM leverages extra CPUs (background threads) for persisting data; second, each transaction reads fewer data due to lower occupancy, which mitigates the benefits of read-friendly design in Pisces.

B+-tree. We construct B+-trees in which each node contains at most 16 children and randomly insert about 1 million key-value pairs at the beginning of each test. Figure 7 shows the evaluation results of executing search and insert transactions (an insert transaction will modify the target key-value pair if the pair already exists) on B+-trees. Each transaction goes down from the root node to some leaf node. For an insert transaction, before going down to some node, it first checks if the node is full. If the node is full, it splits the node for creating space. Since we only implement delete operations as marking the target node as deleted, we run every test for 10 seconds in case the trees get too large.

Similar to the results of hash table benchmark, both Pisces and DUDETM can scale well to 40 threads when the update rate is low such as 0% and 2%, because the number of NVM writes is small. Owing to the read-friendly designs, Pisces shows a better performance than DUDETM. Nevertheless, the performance gap between Pisces and DUDETM decreases when the update rate changes from 0% to 2% because Pisces synchronously persists data into NVM while DUDETM hides the persistence overhead through asynchronously persisting the data in the background.

At 20% update rate, DUDETM's throughput is almost the same as Pisces's when there is a single execution thread. However, DUDETM can only scale to two threads while Pisces has much better scalability. The scalability issue of DUDETM arises earlier in B+-tree benchmark than in hash table benchmark because the read-write transactions in B+-tree generates more log and thus burden the reproduce thread more. Enlarging the size of log buffer can mitigate/hide the problem to some extent but cannot eliminate/solve this problem. At 40% update rate, DUDETM actually outperforms Pisces when the thread number is 1. However, its scalability issue gets worse because of the higher update rate.

At 40% update rate, DUDTEM's throughput grows from 763 Kops to 1370 Kops as the thread number increases from 1 to 40. The reason is each execution thread has one volatile log buffer. Therefore, the total throughput grows a little when adding more threads (more buffer). Nevertheless, longer running time will further flatten the throughput.

To clearly show that the reproduce thread blocks the execution threads and restricts the overall performance, we also evaluate the performance of *DUDETM-ideal* in which the background reproduce thread directly marks the persistent log area as free without writing back the logs in it to persistent objects in NVM. In fact, *DUDETM-ideal* emulates the performance of DUDETM with an infinite persistent log buffer. As shown in the last sub-figure in Figure 7, *DUDETM-ideal* scales very well to 38 threads. The reason for the performance drop in 40 threads is the total thread number (40 execution threads together with 2 background threads) exceeds the hardware thread number (40 hyper-threads). Since the only difference between *DUDETM-ideal* with DUDETM is whether the background reproduce thread really flushes data to NVM, we can conclude the centralized reproduce thread severely harms the system's scalability.

When the update rate is 20% or 40%, the throughput of Pisces almost keeps growing as the thread number increases to 40. And, the persistency cost is 36% at 40% update rate. The NUMA problem in B+-tree is less severe than that in the hash table since the total throughput is lower in B+-tree

Table 2: The average cost of a read-write transaction and one grace period detection in Pisces's B+-tree. The update rate is 40%.

#Thread	10	20	30	40
RW TX Latency (cycles)	9,374	12,024	15,210	16847
Grace Period (cycles)	1,162	2,021	2,915	3528

(less read-write transactions). Nevertheless, the performance growth speed still becomes slower when the thread number exceeds 20. Table 2 presents the cost of grace period detection in Pisces's B+-tree.

5.3 Real-world Benchmarks

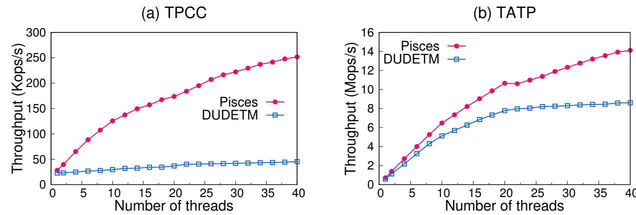

Fig. 8: (a) TPC-C new-order transactions and (b) TATP.

We also evaluate macro-benchmarks (i.e., TPC-C and TATP) which are tested in DUDETM. Besides, we further evaluate Pisces and DUDETM on *kmeans*, *ssca2*, and *vacation* which are popular transactional memory benchmarks [57, 58].

TPC-C. TPC-C is an online transaction processing (OLTP) benchmark. We implement its *new-order transaction* [24] with B+trees whose nodes contain at most 32 children as the tables. In this experiment, each execution thread works on its corresponding warehouse and executes new-order transactions (the update rate is 100%). On average, each transaction involves inserting over 10 new objects into different tables as well as modifying over 10 existing objects, which generates much more logs than the transactions in the previous micro-benchmarks.

Figure 8-(a) gives the evaluation results. Since there is no conflict among transactions from different execution threads, the throughput of Pisces continues to grow with the increase of thread number. There are no transaction aborts in this experiment for Pisces. For fairness, we also modify the TinySTM used by DUDETM (enlarge the *LOCK_ARRAY_LOG_SIZE*) to avoid false sharing of address locks and reduce the abort rate in DUDETM to zero. However, the throughput of DUDETM at 40 threads is only twice of that at 1 thread.

The evaluation results clearly demonstrate that Pisces utilizes the NVM bandwidth in a much better way than DUDETM. A centralized log-reproducing thread can hardly catch up with the progress of multiple execution threads. So the execution threads fill the log buffers in DUDETM. Once the log buffers are full, all the execution threads are blocked, and then the whole system's progress relies on the background log-reproducing thread. Instead of flushing data to NVM in a centralized way, Pisces lets each thread make the transactions' persistent and thus allows more parallelism in the NVM persistence operations. Since NVM device can serve the memory operation requests from different CPUs at the same time, the throughput of Pisces grows from ∼28 Kops/s to ∼252 Kops/s as the thread number increases from 1 to 40. The NVM hardware bandwidth limit is still not reached, inferred from the growth in throughput.

Compared with DUDETM, Pisces can achieve about 4.6× speedup when the thread number is 40. And, the persistency cost is about 50%.

TATP. TATP benchmark [72] is another OLTP application. We implement three read-only transactions and three read-write transactions of it. We use the same B+Tree in the TPC-C experiments as the data structure of tables, set the update ratio to 18% and initialize the population size to 200,000.

Different from the new-order transactions in TPC-C, the read-write transactions in TATP are much smaller. For example, the *update-location transaction* that occupies 14% of the total transactions only update one single existing object. So, each TATP read-write transaction involves less NVM writes than TPC-C transactions and even less than the B+-tree micro-benchmark in which most read-write transactions insert a new object. Thus, DUDETM can scale to 22 threads. However, its scalability issue still comes up when the thread number gets larger.

For Pisces, the throughput grows from ∼0.7 Mops/s to ∼14 Mops/s as the thread number increases from 1 to 40. Pisces's peak performance is about 64% higher than DUDETM's. And, the persistency cost is 26%. The NUMA issue also appears in this benchmark. The RCU grace period detection cost is higher if the total throughput of read-write transactions is higher because of the higher (cross NUMA nodes) cacheline contention (i.e., checking other thread's status). This is also why the NUMA issue is not obvious in the TPC-C benchmark. The NUMA issue also leads to a slower growth speed of the throughput after the thread number exceeds 20.

TM Applications. Referring to [7], we implement and evaluate *kmeans*, *ssca2*, and *vacation* in both Pisces and DUDETM. Currently, we only persist data that are surrounded/protected by TM interfaces.

Table 3: The execution time of *kmeans* (shorter is better).

#Threads	1	2	4	8	16	32
DUDETM (s)	5.5	5.0	3.8	2.6	0.25	0.54
Pisces (s)	3.2	2.4	1.3	0.8	0.7	1.2

Kmeans is a machine learning application and this experiment test it with low contention and medium data set. Table 3 shows the execution time. In this benchmark, both DUDETM and Pisces scale to 16 threads. However, there is a performance drop for both systems when the thread number

increases from 16 threads to 32 threads, because they both suffer from high abort rates (84% for DUDETM and 77% for Pisces). The performance of Pisces is also bottlenecked by grace periods' cost which is enlarged by NUMA. It is also worth mentioning that the foreground threads in DUDETM get blocked by full volatile logs (slow background threads) when the thread number is less than 8. As a result, DUDETM has an obvious performance improve when the thread number increases from 8 to 16. For the same reason, DUDETM performs worse than Pisces with no more than 8 threads. When there are more than 8 threads, DUDETM has better performance than Pisces because the foreground threads in DUDETM neither need to persist write transactions nor get blocked by background threads.

In this benchmark, with the increase of thread number, foreground threads in DUDETM are less likely to get blocked by the reproduce thread. The reason is that *kmeans* evenly distribute a specific amount of work to the foreground execution threads and thus each thread executes less transactions when there are more threads. Specifically, to finish this benchmark, all the threads need to commit 1M transactions in total and generate 40M log entries. When the thread number is more than 16, the foreground threads in DUDETM do not get blocked since each of them has a volatile buffer with 1M log entries. Nevertheless, when testing with large data set (10M transactions and 400M log entries), the foreground threads in DUDETM still get blocked when there are 32 threads.

Table 4: The execution time of *ssca2* (shorter is better).

#Threads	1	2	4	8	16	32
DUDETM (s)	17.2	13.1	12.0	11.6	9.3	9.3
Pisces (s)	18.8	13.8	8.4	5.4	3.6	3.7

Scalable Synthetic Compact Applications (*ssca2*) simulates the computation on graphs. Table 4 gives the evaluation result of ssca2 with medium data set (2^{18} nodes). Different from kmeans, ssca2 involves a larger number of transactions and DUDETM cannot scale well since the background reproduce thread cannot timely consume the logs. So for DUDETM, 32 threads cannot finish this benchmark faster than 16 threads since the execution threads get blocked. Nevertheless, if evaluating ssca2 benchmark with the small data set (2^{13} nodes), DUDETM can scale well but the performance of Pisces also gets much better.

Pisces scales better than DUDETM in this benchmark. However, the execution time of Pisces is longer than that of DUDETM when the thread number is 1 and 2. This is because foreground threads in DUDETM do not make the transactions' updates persistent, and we only calculate the runtime of the foreground threads. Similar to previous experiments, Pisces suffers from NUMA problem again. Since the throughput in this benchmark is high (executes ∼11M transactions in total) and the update rate is 100%, the NUMA problem is more severe and thus causes the performance to drop when threads number changes from 16 to 32.

Table 5: The execution time of *vacation* (shorter is better).

#Threads	1	2	4	8	16	32
DUDETM (s)	10.0	5.2	2.5	1.2	0.8	0.4
Pisces (s)	8.2	4.7	2.7	1.6	0.9	0.6

Vacation is an OLTP system which emulates a travel reservation system. The *vacation* benchmark has 100% update ratio, and each transaction has bigger read/write sets. We use hash tables to implement tables in the benchmark. Table 5 shows the evaluation result of this benchmark with medium data set and low contention.

As shown in Table 5, the execution time of both DUDETM and Pisces decreases as the thread number increases in this benchmark. In the case of 1 and 2 threads, Pisces performs better than DUDETM. The reason is that DUDETM introduces software overhead for the read operations in the transactions. Since the read sets are large, the software overhead such as read validation is non-negligible. But DUDETM scales well since this workload (executes 400K transactions in total) does not cause the full log problem.

Overall, Pisces does not scale as well as DUDETM. As the benchmark is update-only and the average transaction latency is long (big transaction), the grace period detection mechanism in Pisces becomes more time-consuming and brings high overhead. Hence, with the increase of thread number, transactions spend more time in the grace period detection mechanism, which leads to dissatisfactory performance. On average, the mechanism costs each transaction 30,433 cycles and 46,070 cycles when the thread number is 16 and 32, respectively. And the average transaction latency is about 168,000 cycles when there are 32 threads.

5.4 Other Performance Analysis

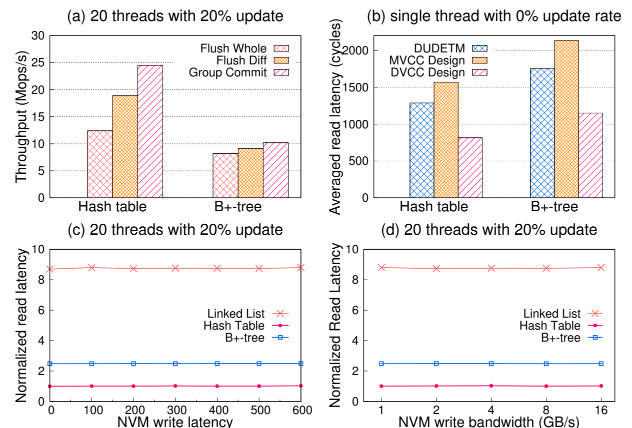

Fig. 9: (a) The performance gain break down. (b) The performance of read-only transactions. Read latency in Pisces with (c) increased NVM write latency and (d) increased NVM write bandwidth.

Figure 9-(a) shows step-wise performance gain from the

optimizations in Pisces. *Flush Diff* improves the throughput of hash table and B+-tree by 52% and by 11%, respectively, because it effectively reduces the number of NVM writes. Since a write transaction on a hash table changes a small portion of the nodes, there is more data that does not need to be logged and written back. However, a transaction on a B+-tree usually involves more data modification, especially, when node splitting is required. So *Flush Diff* benefits hash table more in the presented settings. *Group Commit* (setting group number as 3) brings a performance gain of 30% for hash table and 12% for B+-tree, through reducing the number of grace period detection and *fetch_and_add* instructions on the global timestamp. The performance improvement in hash table is larger for two reasons. First, Pisces has a higher throughput in the hash table benchmark which means higher contention on the global timestamp. Second, the grace period detection in hash table takes a higher percentage of cost in a write transaction than that in B+-tree. Note that the current *Group Commit* implementation will increase the latency of write transactions. Nevertheless, Pisces can only batch the write-back stages instead of the whole commit phases to mitigate this issue.

Figure 9-(b) compares the average latency of read-only transactions in micro-benchmarks. Compared with our MVCC-based design, the DVCC design in Pisces significantly reduces the read latency (about 2× faster). The reason is that each read operation in the MVCC-based design involves locating the version list of an object and traversing the list, leading to at least one more random memory access (i.e., read indirection). Compared with DUDETM (needs address translation and read validation), Pisces's read operations are also faster owing to the read-friendly design. For the hash table benchmark, the read-only transaction in Pisces is faster than DUDETM's by 472 cycles. While for the B+-tree benchmark, the read-only transaction in Pisces is faster than DUDETM's by 605 cycles. This is because a read transaction in B+-tree contains more read operations.

Different persistent memory technologies may have different persistent cost. We further use an NVM emulator which explicitly add delays to the NVM flush operations according to the NVM write latency and bandwidth (similar to prior work [17, 37, 49, 49]). As shown in Figure 9-(c) and Figure 9-(d), the average latency[5] of read-only transactions, each of which searches for an element in the corresponding data structure, is stable with various NVM write latency and bandwidth. The reason is that Pisces avoids writers blocking readers. Although the NVM write latency and bandwidth affect the latency of write operations in Pisces, the latency of read-only transactions is insensitive to that of write operations. Therefore, Pisces produces a stable average latency of read-only transactions with increased NVM write latency and bandwidth. Other experiments with different thread numbers or different update rates give similar results.

[5]We set the read latency in hash table in the case of zero NVM write latency to 1. Other results are normalized against it.

6 Related Work

Compared with most PTM designs (Mnemosyne [74], NV-Heaps [21], Kamino-Tx [56], and DCT [44]) which reduce the persistence latency of write transactions through various novel techniques but may expose NVM persist overhead to readers, Pisces focuses on benefiting read operations and can always hide NVM persist latency from readers. A most recent PTM named Romulus [23] promises never blocking read-only transactions through maintaining twin copies of the durable data. Pisces shares a similar idea to avoid blocking read-only transactions and further exploits SI to avoid blocking any read operation. Romulus instruments loads and stores to NVM through programming language feature, which is elegant and can be borrowed to Pisces. Besides, Romulus chooses a single writer design which can reduce the average number of fences for write transactions, however, limits the concurrency of NVM persistence. Some recent studies [42, 60, 71] leverage hardware modifications to implement efficient PTM systems. NVM is also exploited by in-memory database systems [27, 43] and new file systems [31, 32, 80]. Others [5, 37, 40, 41, 47] provide libraries for applications to utilize NVM.

Transactional Memory (TM) has been well studied [10, 14, 29, 34, 39, 66, 68, 70]. Some studies [36, 73] propose non-blocking designs and some others also investigate snapshot isolation to TM [48, 68], which significantly reduces the abort rates. But they do not consider crash consistency under NVM. Matveev et al. [54] propose a novel and lightweight synchronization mechanism (RLU) for concurrent programming. DVCC in Pisces is inspired by both MVCC and RLU. Thus, Pisces and RLU share a couple of similarities including maintaining two versions and allowing readers to read the write sets of writers. However, RLU neither provides a transactional programming semantic (no snapshot isolation) nor considers NVM (no durability and crash consistency).

7 Summary

This paper presents Pisces, a read-friendly PTM that provides transactional memory APIs for programming on NVM. With several techniques such as DVCC and three-stage commit, Pisces achieves both high throughput and good scalability while ensuring snapshot isolation and crash consistency.

EdgeWise: A Better Stream Processing Engine for the Edge

Abstract

Many Internet of Things (IoT) applications would benefit if streams of data could be analyzed rapidly at the Edge, near the data source. However, existing Stream Processing Engines (SPEs) are unsuited for the Edge because their designs assume Cloud-class resources and relatively generous throughput and latency constraints.

This paper presents EdgeWise, a new Edge-friendly SPE, and shows analytically and empirically that EdgeWise improves both throughput and latency. The key idea of EdgeWise is to incorporate a congestion-aware scheduler and a fixed-size worker pool into an SPE. Though this idea has been explored in the past, we are the first to apply it to modern SPEs and we provide a new queue-theoretic analysis to support it. In our single-node and distributed experiments we compare EdgeWise to the state-of-the-art Storm system. We report up to a 3x improvement in throughput while keeping latency low.

1 Introduction

Internet of Things (IoT) applications are growing rapidly in a wide range of domains, including smart cities, healthcare, and manufacturing [33, 43]. Broadly speaking, IoT systems consist of Things, Gateways, and the Cloud. Things are sensors that "read" from the world and actuators that "write" to it, and Gateways orchestrate Things and bridge them with the Cloud.

At the moment, IoT systems rely on the Cloud to process sensor data and trigger actuators. In principle, however, Things and Gateways could perform some or all data analysis themselves, moving the frontier of computation and services from the network core, the Cloud [17], to its Edge [21, 67], where the Things and Gateways reside. In this paper we explore the implications of this paradigm in a promising use case: *stream processing*.

Stream processing is well suited to the IoT Edge computing setting. Things generate continuous streams of data that often must be processed in a timely fashion; stream processing performs analysis on individual data points (*tuples*) rather than batches [24, 69]. As shown in Figure 1, stream processing is described by a directed acyclic graph, called a *topology*, whose vertices are data processing *operations* and edges indicate data flow.

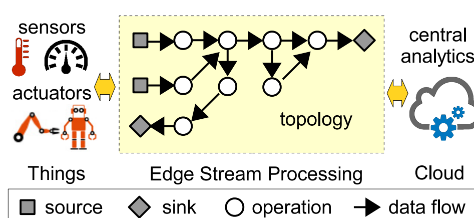

Figure 1: The Edge connects Things to the Cloud, and can perform local data stream processing.

Modern Stream Processing Engines (SPEs) such as Storm [15], Flink [13], and Heron [49] have mostly been designed for the Cloud, assuming powerful computing resources and plenty of memory. However, these assumptions do not hold at the Edge. In particular, these SPEs use a simple One Worker Per Operation Architecture (OWPOA). Given a dataflow topology and the degree of parallelism of each operation, OWPOA-style SPEs assign a dedicated *worker* thread to each *operation* instance, and link the worker-operation pairs with queues. Then, they rely on the operating system (OS) scheduler to choose which worker (operation) to schedule next, leading to *lost scheduling opportunities*: data propagates haphazardly through the topology because the scheduling of worker threads is left to the congestion-oblivious OS. With Cloud-scale resources these inefficiencies are amortized, but at the Edge they cannot be.

The database community studied efficient operation scheduling about a decade before modern SPEs came into vogue [18, 25]. Sadly, however, lessons learned from this

early research were not carried into the design of modern SPEs, leading to a sub-optimal performance when the existing OWPOA-style SPEs are used at the Edge setting. Existing IoT computing literature (e.g. [58, 64]) has ignored this history and has been building Edge computing platforms based on unmodified modern SPEs. This paper explores the impact of applying to modern SPEs these "lost lessons" of operation scheduling.

We present EdgeWise, an Edge-friendly SPE that revives the notion of engine-level operation scheduling to optimize data flows in a multiplexed (more operations than processor cores) and memory-constrained Edge environment. EdgeWise re-architects SPE runtime design and introduces an engine-level scheduler with a fixed-size worker pool where existing *profiling-guided* scheduling algorithms [18, 25] may be used. EdgeWise also proposes a *queue-length-based* congestion-aware scheduler that does not require profiling yet achieves equivalent (or better) performance improvement. EdgeWise monitors the numbers of pending data in queues, and its *scheduler* determines the highest-priority operation to process next, optimizing the flow of data through the topology. In addition, the EdgeWise's worker pool avoids unnecessary threading overheads and decouples the data plane (operations) from the control plane (workers).

We show analytically and empirically that EdgeWise outperforms Apache Storm [15], the exemplar of modern SPEs, on both throughput and latency. EdgeWise is a reminder of both the end-to-end design principle [65] and the benefits of applying old lessons in new contexts [61].

This paper provides the following contributions:

- We study the software architecture of existing SPEs and discuss their limitations in the Edge setting (§3). To the best of our knowledge, this paper is the first to observe the lack of operation scheduling in modern SPEs, a forgotten lesson from old SPE literature.
- We present EdgeWise, a new Edge-friendly SPE. EdgeWise learns from past lessons to apply an engine-level scheduler, choosing operations to optimize data flows and leveraging a fixed-size worker pool to minimize thread contention (§4).
- Using queuing theory, we argue analytically that our congestion-aware scheduler will improve both throughput and latency (§5). To our knowledge, we are the first to mathematically show balancing the queue sizes lead to improved performance in stream processing.
- We demonstrate EdgeWise's throughput and latency gains on IoT stream benchmarks (§7).

2 Background: Stream Processing

This section provides background on the stream processing programming model (§2.1) and two software architectures used in existing SPEs (§2.2).

2.1 Dataflow Programming Model

Stream processing uses the dataflow programming model depicted in the center of Figure 1 [24, 69]. Data *tuples* flow through a directed acyclic graph (*topology*) from *sources* to *sinks*. Each inner node is an *operation* that performs arbitrary computation on the data, ranging from simple filtering to complex operations like ML-based classification algorithms. In the Edge context a source might be an IoT sensor, while a sink might be an IoT actuator or a message queue to a Cloud service.

Though an operation can be arbitrary, the preferred idiom is *outer I/O, inner compute*. In other words, I/O should be handled by source and sink nodes, and the inner operation nodes should perform only memory and CPU-intensive operations [3, 41]. This idiom is based on the premise that the more unpredictable costs of I/O will complicate the scheduling and balancing of operations.

After defining the topology and the operations, data engineers convert the *logical* topology into a *physical* topology that describes the number of physical instances of each logical operation. In a distributed setting engineers can also indicate preferred mappings from operations to specific compute nodes. An SPE then deploys the operations onto the compute node(s), instantiates queues and workers, and manages the flow of tuples from one operation to another.

2.2 Stream Processing Engines

Starting from the notion of active databases [55, 76], early-generation SPEs were proposed and designed by the database community in the early 2000s: e.g. Aurora [24], TelegraphCQ [27], Stream [16], and Borealis [7, 28]. Interest in SPEs led to work on performance optimization techniques such as operation scheduling [18, 25] and load shedding [35, 70]. We will revisit these works shortly (§3.4).

The second generation of "modern SPEs" began with Apache Storm [15] (2012) as part of the democratization of big data. Together with Apache Flink [13] and Twitter's Heron [49], these second-generation SPEs have been mainly developed by practitioners with a focus on scalable Cloud computing. They have achieved broad adoption in industry.

Under the hood, these modern SPEs are based on the One Worker Per Operation Architecture (OWPOA, Figure 2). In the OWPOA, the operations are connected by queues in a pipelined manner, and processed by its

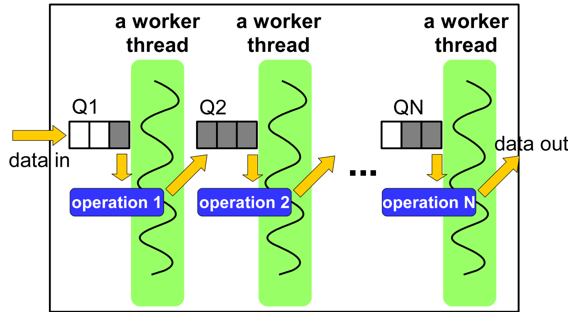

Figure 2: One Worker Per Operation Architecture (OWPOA). It assigns a worker thread for each operation. The example shows the case with `N` operations. `Q` represents a queue where a gray box means a pending data.

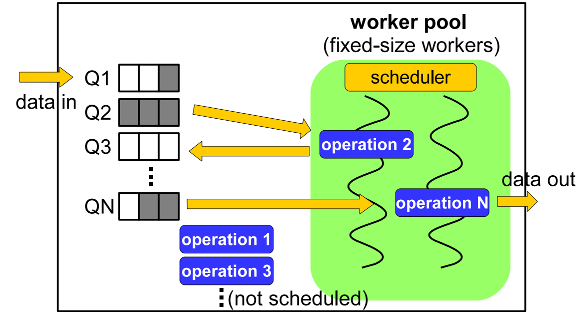

Figure 3: EDGEWISE Architecture (§4). The scheduler picks which operation to run. In this example, operation `2` and operation `N` had the longest queues, so they were scheduled.

own workers. Some operations may be mapped onto different nodes for distributed computing or to take advantage of heterogeneous resources (GPU, FPGA, etc.). In addition, the OWPOA monitors the health of the topology by checking the lengths of the per-operation queues. Queue lengths are bounded by a *backpressure* mechanism [32, 49], during which the source(s) buffer input until the operation queues clear.

3 Edge SPE Requirements Analysis

Stream processing is an important use case for Edge computing, but as we will show, existing SPEs are unsuited for the Edge. This section discusses our Edge SPE requirements analysis and the drawbacks of existing SPEs.

3.1 Our Edge Model

We first present our model for the Edge.

Hardware. Like existing IoT frameworks (e.g. Kura [36], EdgeX [2], and OpenFog [5]), we view the Edge as a distributed collection of IoT Gateways that connect Things to the Cloud. We consider Edge stream processing on IoT Gateways that are reasonably stable and well connected, unlike mobile drones or vehicles. We further assume these IoT Gateways have limited computing resources compared to the Cloud: few-core processors, little memory, and little permanent storage [17, 67]. However, they have more resources than those available to embedded, wireless sensor networks [50], and thus can afford reasonably complex software like SPEs. For example, Cisco's IoT Gateways come with a quad-core processor and 1GB of RAM [31].

Applications. Edge topologies consume IoT sensor data and apply a sequence of reasonably complex operations: e.g. SenML [44] parsers, Kalman filters, linear regressions, and decision tree classifications. For example, FarmBeats [72], a smart farm platform, uses IoT Gateways to collect data from various sensors and drones, to create summaries before sending them to the Cloud for long-term and cross-farm analytics, and to perform time-sensitive local data processing. We therefore assume a diverse set of workloads ranging from simple extraction-transform-load (ETL) and statistical summarization to predictive model training and classification.

3.2 Edge SPE Requirements

Every SPE aims for high throughput, and Edge SPEs are no exception. In addition, we see the following unique requirements for the Edge:

(1) Multiplexed. An Edge SPE must support an arbitrary topology on limited resources. We particularly focus on supporting a single topology in which there are more operations than processors, such that operation executions must be multiplexed on limited processors. Where a server-class machine can use threads unconcernedly, an Edge-class machine must be wary of unnecessary overheads.

(2) Low latency. An Edge SPE must offer low latency, else system architects should simply transmit raw data to the Cloud for analysis.

(3) No backpressure. The backpressure mechanism in Cloud SPEs is inadvisable at the Edge for two reasons. First, it is a "stop the world" scheme that destroys system latency, but latency is critical for Edge workloads. Second, it assumes that a data source can buffer pending data. While the Cloud can assume a persistent data source such as Kafka [4], at the Edge there is nowhere to put this data. Modern "real-time" SPEs such as Storm and Flink do not support file I/O based buffering. As a result the SPE must be congestion-aware to ensure queue lengths do not exceed available memory.

(4) Scalable. The SPE must permit scaling across multi-processors within an IoT Gateway and across multiple Gateways, especially to take advantage of locality or heterogeneity favorable to one operation or another.

3.3 Shortcomings of OWPOA-style SPEs

The OWPOA naturally takes advantage of intra-node and inter-node parallelism, especially when data engineers make a good logical-to-physical mapping. In the OWPOA, however, *multiplexing* becomes challenging in complex topologies, because each logical operation must have at least one worker and there may be more workers than cores on a compute node. If there are too many workers assigned to one compute node the poor scheduling of workers will artificially limit performance.

Let us explain the issue in detail. The OWPOA relies on the OS scheduler to decide which worker-operation pair to schedule next. If the input rate is low enough that most queues are empty (i.e. the SPE is over-provisioned), there is no harm in such an approach. Only some operations will have work to do and be scheduled, while the remainder will sleep.

But if the input rate rises (equivalently, if the SPE becomes less provisioned) then the SPE will become *saturated*, i.e. most or all queues will contain tuples. In this case any operation might be scheduled by the OS. As some operations take longer than others, a typical round-robin OS scheduler will naturally imbalance the queue lengths and periodically trigger backpressure. For example, in Figure 2, although Queue 2 is full, the OS may unwisely schedule the other worker-operation pair first, triggering *backpressure* unnecessarily and leading to significantly high *latency*.

3.4 A Lost Lesson: Operation Scheduling

As noted earlier (§2.2), the database community has studied different *profiling-guided* priority-based operation scheduling algorithms [18, 25] in the context of multiple operations and a single worker, before the modern OWPOA-style SPEs were born. For instance, Carney et al. [25] proposed a "Min-Latency" algorithm which assigns higher (static) priority on latter operations than earlier operations in a topology and processes old tuples in the middle of a topology before newly arrived tuples, with a goal to minimize average latency. For a topology with multiple paths, the tie is broken by the profiled execution time and input-output ratio of each operation. With a goal to minimize queue memory sizes, Babcock et al. [18] proposed a "Min-Memory" algorithm (called Chain) which favors operations with higher input-output reduction and short execution time (e.g., faster filters).

Unfortunately, however, modern OWPOA-style SPEs (e.g. Storm [15], Flink [13], Heron [49]) have not adopted these research findings when designing multi-core multi-worker SPEs and simply relied on the congestion-oblivious OS scheduler. *This paper argues that Edge SPEs should be rearchitected to regain the benefits of engine-level operation scheduling to optimize data flows in a multiplexed Edge environment.* In particular, we compare the effectiveness of both profiling-based (old) and dynamic balancing (new) scheduling algorithms, and report that all offer significant throughput and latency improvements over modern SPEs.

4 Design of EDGEWISE

This section presents EDGEWISE, an Edge-friendly SPE, that leverages a congestion-aware scheduler (§4.1) and a fixed-size worker pool (§4.2), as illustrated in Figure 3. EDGEWISE achieves higher throughput and low latency by *balancing the queue lengths*, with the effect of *pushing the backpressure point to a higher input rate*. Thus EDGEWISE achieves higher throughput without degrading latency (no backpressure). We later analyze the improved performance mathematically in §5.

4.1 Congestion-Aware Scheduler

EDGEWISE addresses the scheduling inefficiency of the OWPOA by incorporating a user-level scheduler to make wiser choices. In the OWPOA design, physical operations are coupled to worker threads and are scheduled according to the OS scheduler policy. The EDGEWISE scheduler separates the threads (execution) from the operations (data). Prior work has proposed using profiling-based operation scheduling algorithms [18, 25]. Instead, we propose a profiling-free dynamic approach that balances queue sizes by assigning a ready thread to the operation with the most pending data.

The intuition behind EDGEWISE is shown in Figure 4, which compares the behavior of an OWPOA-style SPE to EDGEWISE in a multiplexed environment. Figure 4(a) shows the unwise choice that may be made by the random scheduler of the OWPOA, leading to backpressure (high latency). Figure 4(b) contrasts this with the choice made by EDGEWISE's congestion-aware scheduler, evening out the queue lengths to avoid backpressure.

We believe EDGEWISE's congestion-aware scheduler would be beneficial to the Cloud context, as an intra-node optimization. In practice, however, we expect that EDGEWISE will have greater impact in the Edge setting, where (1) with few cores, there are likely more operators than cores, (2) latency is as critical as throughput, and (3) memory is limited.

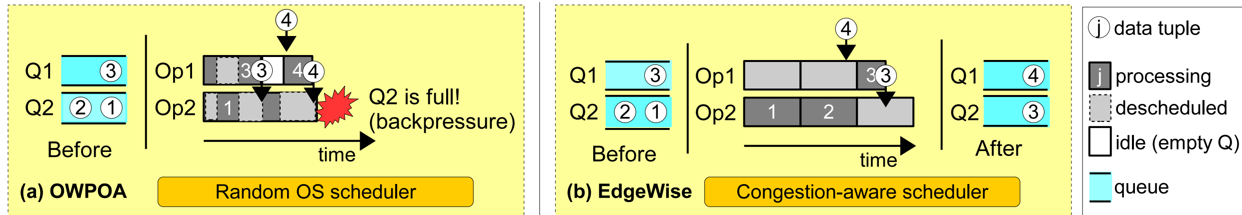

Figure 4: A scheduling example with two operations, multiplexed on a single core. The Q(ueue) size is two. Initially, Q1 has one tuple and Q2 is full. (a) The random OS scheduler in OWPOA lets Op(eration) 1 process tuples ③ and (newly coming) ④ first, overflowing Q2 and triggering unnecessary backpressure. (b) EDGEWISE knows Q2 has more pending data, and thus schedules the more critical Op2 first, avoiding congestion.

4.2 Fixed-size Worker Pool

EDGEWISE's scheduler decouples data from execution, requiring some changes in how EDGEWISE realizes the physical topology supplied by data engineers. Rather than dedicating a worker to each operation as in the OWPOA, EDGEWISE processes data on a fixed set of workers in the worker pool (Figure 3). These workers move from operation to operation as assigned by the scheduler. EDGEWISE could in principle work solely from the logical topology, in effect dynamically rearranging the physical topology (# workers assigned to each operation). However, this would violate any assumptions about thread safety or physical topology embedded in the logical topology. Thus, EDGEWISE uses the existing physical topology to bound the number of workers assigned to any operation at one time.

The worker pool size is configurable. By default it is set to the number of processors, because we assume that most operations are CPU-intensive per the recommended stream programming model (§2.1). If there are many I/O-bound operations, a fixed-size worker pool may lead to sub-optimal performance, requiring users to tune the pool size.

Putting it together. The scheduler dynamically chooses which operation a worker should perform. When a worker is ready, it asks the scheduler for an assignment, and the scheduler directs it to the operation with the longest pending data queue. Without work, it sleeps. When new data arrives, the scheduler wakes up the worker. The worker *non-preemptively*[1] completes the operation, and EDGEWISE directs the output to the downstream operation queue(s). Different operations may run in parallel: e.g., operations `2` and `N` in Figure 3. However, for FIFO guarantees, EDGEWISE schedules at most one worker to any operation instance (i.e. to any queue).

EDGEWISE supports three different data consumption policies for each scheduling turn: (1) `All` consumes all the tuples in the queue; (2) `Half` consumes half of the tuples in the queue; and (3) `At-most-N` consumes at most `N` tuples in the queue. Intuitively, in a saturated system, consuming a small constant number in each quantum will cause the scheduler to make more decisions overall. As our scheduler is fast, the more decisions it makes the better it should approximate the ideal schedule (evaluated in §7.4). Such consumption policies are not possible in OWPOA-style SPEs.

EDGEWISE meets the Edge SPE design goals, listed in §3.2. EDGEWISE retains the achievements of the OWPOA, and to these it adds the multiplexed, low-latency, and no-backpressure requirements. EDGEWISE's scheduler allows it to balance queue lengths, improving average latency and avoiding the need for backpressure by keeping heavier operations from lagging behind.

[1]More precisely, it is non-preemptive at the engine level. EDGEWISE can still be preempted by the underlying OS scheduler.

5 Performance Analysis of EDGEWISE

This section shows analytically that EDGEWISE will achieve higher throughput (§5.1) and lower latency (§5.2) than OWPOA. Lastly, in §5.3 we discuss how to measure relevant runtime metrics for the performance analysis. To the best of our knowledge, we are the first to apply queueing theory to analyze the improved performance in the context of stream processing. Prior scheduling works in stream processing either provide no analysis [25] or focus only on memory optimization [18].

5.1 Higher Throughput

First we show that maximum end-to-end throughput depends on scheduling heavier operations proportionally more than lighter operations. This is impossible to guarantee in the scheduler-less modern SPEs, but easy for EDGEWISE's scheduler to accomplish.

Our analysis interprets a dataflow topology as a queuing network [38, 46]: a directed acyclic graph of stations. Widgets (tuples) enter the network via the queue of the first station. Once the widget reaches the front of a station's queue, a server (worker) operates on it, and then it advances to the next station. The queuing theory model

allows us to capture the essential differences between EDGEWISE and the OWPOA. In the rest of this section we draw heavily on [38, 46], and we discuss the model's deviations from real topology behavior at the end.

Modeling. Given the input rate λ_i and the service rate μ_i of a server i, the server utilization ρ_i (fraction of time it is busy) is defined as:

$$\rho_i = \frac{\lambda_i}{\mu_i} \tag{1}$$

A queuing network is *stable* when $\rho_i < 1$ for all servers i. If there is a station to which widgets arrive more quickly than they are serviced, the queue of that station will grow unbounded. In an SPE, unbounded queue growth triggers the backpressure mechanism, impacting system latency.

Suppose we want to model a topology with M operations in this way. We can represent the input and server rates of each operation as a function of λ_0 and μ_0, the input and service rates of the first operation, respectively. We are particularly interested in λ_0 as it is the input rate to the system; higher λ_0 means higher throughput. Expressing the input scaling factors and relative operation costs for an operation i as q_i and r_i, we can write the input rate λ_i and the service rate μ_i for operation i as:

$$\lambda_i = q_i \cdot \lambda_0 \qquad \mu_i = r_i \cdot \mu_0$$

In queuing theory, each node is assumed to have an exclusive server (worker). However, in the Edge, there may be fewer servers (processor cores) than stations (operations). If there are C processor cores, we can model processor contention by introducing a scheduling weight w_i, subject to $\sum_i^M w_i = C$, yielding the effective service rate $\mu_i{}'$:

$$\mu_i{}' = w_i \cdot \mu_i = w_i \cdot (r_i \cdot \mu_0)$$

For instance, when one core is shared by two operations, a fair scheduler halves the service rate ($w_1 = w_2 = \frac{1}{2}$) as the execution time doubles. The constraint $\sum_i^M w_i = C$ reflects the fact that C processor cores are shared by M operations.

Similarly, the effective server utilization $\rho_i{}'$ can be redefined based on $\mu_i{}'$. To keep the system stable (eliminate backpressure), we want $\rho_i{}'$ to be less than one:

$$\forall i, \quad \rho_i{}' = \frac{\lambda_i}{\mu_i{}'} = \frac{q_i \cdot \lambda_0}{w_i \cdot r_i \cdot \mu_0} < 1 \tag{2}$$

which can be rearranged as

$$\forall i, \quad \lambda_0 < w_i \cdot \frac{r_i}{q_i} \cdot \mu_0 \tag{3}$$

Optimizing. Remember, λ_0 represents the input rate to the system and is under our control; a higher input rate means higher throughput (e.g. the system can sample sensors at a higher rate). Assuming that μ_0, r_i, and q_i are constants for a given topology, the constraint of Equation (3) implies that the maximum input rate λ_0 that an SPE can achieve is upper-bounded by the minimum of $w_i \cdot \frac{r_i}{q_i}$ over all i. Thus, our optimization objective is to:

$$\begin{aligned} &\text{maximize} \quad \min_i (w_i \cdot \frac{r_i}{q_i}) \\ &\text{subject to} \quad \sum_i^M w_i = C \end{aligned} \tag{4}$$

It is straightforward to show that the maximum input rate can be achieved when $w_i \cdot \frac{r_i}{q_i}$ are equal to each other for all i: i.e.,

$$w_1 : w_2 : \cdots : w_N = \frac{q_1}{r_1} : \frac{q_2}{r_2} : \cdots : \frac{q_M}{r_M}$$

In other words, the scheduling weight w_i should be assigned proportional to $\frac{q_i}{r_i}$. This is indeed very intuitive. An operation becomes heavy-loaded when it has a higher input rate (higher q_i) and/or a lower service rate (lower r_i). Such an operation should get more turns.

Scheduling. EDGEWISE's scheduler dynamically identifies heavily loaded operations and gives them more turns. The queue of an operation with higher input rate and higher compute time (lower service rate) grows faster than the others. By monitoring queue sizes, we can identify and favor the heavy-loaded operations with more frequent worker assignments.

Compare this behavior to that of the OWPOA. There, the "fair" OS scheduler blindly ensures that w_i is the same for each operation, unaware of relative input and service rates, leading to suboptimal throughput. Once saturated, one of the heavy operations will reach the utilization cap of $\rho_i = 1$, become a bottleneck in the topology, and eventually trigger backpressure and latency collapse. Data engineers can attempt to account for this by profiling their topologies and specifying more workers for heavier operations. Fundamentally, however, this is an ad hoc solution: the OS scheduler remains blind.

In our evaluation (§7.3.1) we show that EDGEWISE achieves $w_i \cdot \frac{r_i}{q_i}$ equality across operations at runtime, leading to an optimal balanced effective server utilization $\rho_i{}'$. In contrast, we report that in the OWPOA approach, increasing the input rate leads to increasingly unbalanced $\rho_i{}'$ across operations.

Runtime deviations from the model. Our queuing theory model captures real SPE behavior in the essentials, but it deviates somewhat in the particulars. We give two prominent examples. The first deviation is that our queuing theory model assumes predictable widget fan-in and fan-out ratios at each operator (i.e. constant q_i and r_i). In reality these are distributions. For example, an operation that splits a sentence into its constituent words

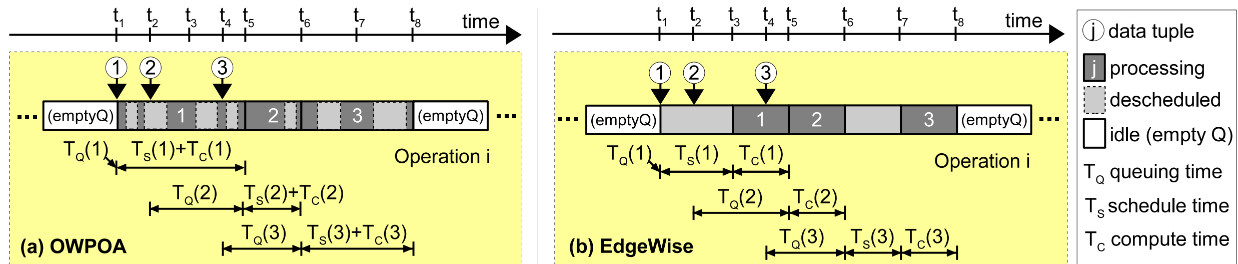

Figure 5: A per-operation latency breakdown example of (a) OWPOA, and (b) EDGEWISE. Incoming data tuples ①, ②, and ③ are being queued. When scheduled (dark gray box), the operation *i* processes a pending tuple. A tuple *j* can be in one of three states: waiting in the middle of the queue (T_Q), at the head of the queue waiting to be scheduled (T_S), or being computed (T_C). Later in §7.3.2, we show that T_Q dominates the per-operation latency in a saturated system.

will emit one tuple for "Please", two tuples for "Please accept", and so on. The second deviation is that we assumed that operations have constant costs. In reality it will take such a sentence-splitting operation more time to process longer sentences.

Considering these deviations, the difficulty data engineers face when generating physical topologies for a OWPOA SPE is clear: it is difficult to identify a single integer quantity of workers to assign to each operation, and even then balance will only be achieved probabilistically over many scheduling cycles. In contrast, EDGEWISE automatically balances the assignment of workers to operations.

5.2 Lower Latency

Now we show that EDGEWISE can achieve lower end-to-end *latency* than the OWPOA without compromising throughput. Our analysis hinges on the observation that unbalanced queue lengths have an outsized effect on latency, so that balancing queue lengths leads to an overall improvement in latency.

The total latency for a completed tuple equals the sum of the latencies paid at each operation it visited on its way from source to sink, plus communication latencies outside of our control:

$$Latency = \sum_{i}^{M}(L_i + Comm.) \approx \sum_{i}^{M} L_i \quad (5)$$

In stream processing, the per-operation latency consists of (1) the queue time T_Q, waiting in the queue; (2) the schedule time T_S, waiting for a turn at the head of the queue; and (3) the (pure) compute time T_C, being processed. As illustrated in Figure 5, these times come at a different form. In OWPOA (a), the preemptive OS scheduler makes T_S and T_C interleaved. In EDGEWISE (b), the non-preemptive scheduler makes clear distinction because an operation is not scheduled until a worker is available, and when scheduled, it completes its work.

In a saturated system, we treat T_S and T_C as constants, while T_Q will grow with the input rate to dominate L_i.

$$L_i = T_Q + (T_S + T_C) \approx T_Q \quad (6)$$

Assuming that the input and service rates, λ and μ, can be modeled as exponential random variables[2], Gross et al. [38] show that the queue time T_Q can be expressed as

$$T_Q = \frac{\rho}{\mu - \lambda} = \frac{\lambda}{\mu(\mu - \lambda)} \quad (7)$$

Note that T_Q has a vertical asymptote (approaches ∞) at $\mu = \lambda$, and a horizontal asymptote (approaches 0) when $\mu >> \lambda$. In other words, for a given λ, a tuple will wait longer in the queues of heavier operations, and crucially *the growth in wait time is non-linear (accelerates) as* μ *approaches* λ. This means that heavier operations have a much larger T_Q and thus L_i (Equation (6)) than lighter operations, and an outsized impact on overall latency (Equation (5)).

Though the effect of heavy operations may be dire when using the OWPOA's random scheduler, EDGEWISE's congestion-aware scheduler can avoid this problem by giving more hardware resources (CPU turns) to heavier operations over lighter ones. In effect, EDGEWISE balances the T_Q of different operations, reducing the T_Q of tuples waiting at heavy operations but increasing the T_Q of tuples waiting at lighter operations. According to Gross et al.'s model this balancing act is not a zero-sum game: we expect that the lighter operations sit near the horizontal asymptote while the heavier operations sit near the vertical asymptote, and balancing queue times will shift the entire latency curve towards the horizontal asymptote. In our evaluation we support this analysis empirically (§7.3.2).

[2] For λ and μ with general distributions, the curve in the $\lambda < \mu$ region is similar. The exponential model simplifies the presentation.

5.3 Measuring Operation Utilization

In our evaluation we compare EDGEWISE with a state-of-the-art OWPOA. For a fine-grained comparison, in addition to throughput and latency we must compare the operation utilization $\rho = \frac{\lambda}{\mu}$ discussed in §5.1. This section describes how we can fairly compare EDGEWISE against a baseline OWPOA system in this regard.

We want to compare the server (operation) utilization of EDGEWISE and the baseline. As argued in §5.1, an ideal result is a balanced utilization vector consisting of equal values $1-\varepsilon$, with ε chosen based on latency requirements. As operation utilization may change over the lifetime of an SPE run (e.g. as it reaches "steady-state"), we incorporate a time window T_w into the metric given in Equation (1).

During a time window T_w, an operation might be performed on N tuples requiring a total of T_E CPU time. The input rate for this operation during this window is $\lambda_w = \frac{N}{T_w}$ and the service rate is $\mu_w = \frac{1}{T_E}$, so we have windowed utilization ρ_w as:

$$\rho_w = \frac{\lambda_w}{\mu_w} = T_E \cdot \frac{N}{T_w} \tag{8}$$

Unsurprisingly, we found that this is the utilization metric built into Storm [15][3], the baseline system in our evaluation.

In the OWPOA, computing ρ_w is easy. T_w is fixed, N is readily obtained, and T_E can be calculated by monitoring the beginning and ending time of performing the operation on each tuple:

$$T_E = \frac{1}{N}\sum_{j}^{N}(T_{end}(j) - T_{begin}(j)) \tag{9}$$

Equation (9) would suffice to measure ρ_w for the OWPOA, but for a fair comparison between the OWPOA and EDGEWISE we need a different definition. Note that $T_{end}(j) - T_{begin}(j)$ captures the total time a worker spends applying an operation to a tuple, and in the OWPOA (Figure 5 (a)) this calculation includes both T_C (pure computation) and T_S (worker contention). As EDGEWISE's scheduler is non-preemptive (Figure 5 (b)), measuring T_E in this way would capture only EDGEWISE's T_C. Doing so would ignore its T_S, the time during which EDGEWISE's scheduler decides *not* to schedule an operation with a non-empty queue in favor of another operation with a longer queue. This would artificially decrease T_E and thus ρ_w for this operation.

To capture T_S for an operation in EDGEWISE, we can instead amortize the schedule time T_S across all completed tuples, and describe the operation's time during this window as spent either executing or idling with an empty queue:

$$T_w = T_E \cdot N + T_{emptyQ} \tag{10}$$

Solving Equation (10) for T_E and substituting into Equation (8), we can compute ρ_w in EDGEWISE:

$$\rho_w = 1 - \frac{T_{emptyQ}}{T_w} \tag{11}$$

The windowed utilization metric ρ_w given in Equation (11) applies equally well to SPEs that use the OWPOA or EDGEWISE.

[3] In Apache Storm this metric is called the operation's *capacity*.

6 Implementation

We implemented EDGEWISE on top of Apache Storm [15] (v1.1.0). Among modern SPEs, Storm was the most popular for data science in 2018 [20] and has the lowest overall latency [29]. We made three major modifications: (1) We implemented the congestion-aware scheduler (§4.1), and added two data structures: a list of operations with non-empty queues as scheduling candidates; and a list of running operations to ensure FIFO per queue; (2) We removed the per-operation worker threads, and added one worker pool of (configurable) K worker threads (§4.2); and (3) We introduced two queuing-related metrics, T_{emptyQ} and T_Q, for server utilization and latency breakdown analysis (§5.3).

EDGEWISE can be applied to other OWPOA-style SPEs such as Flink [13] and Heron [49]. In Flink, multiple operators may be grouped in a single Task Slot, but each operator (called "subtask") still has its own worker thread. Task Slot separates only the managed "memory" of tasks, but there is no CPU isolation. As a result, worker threads will still contend and cause congestion if there are more operators than CPUs. Thus, EDGEWISE's congestion-aware scheduler and fixed-size worker pool will be equally beneficial for Flink.

The EDGEWISE prototype is available at `https://github.com/VTLeeLab/EdgeWise-ATC-19`. It adds 1500 lines of Java and Clojure across 30 files.

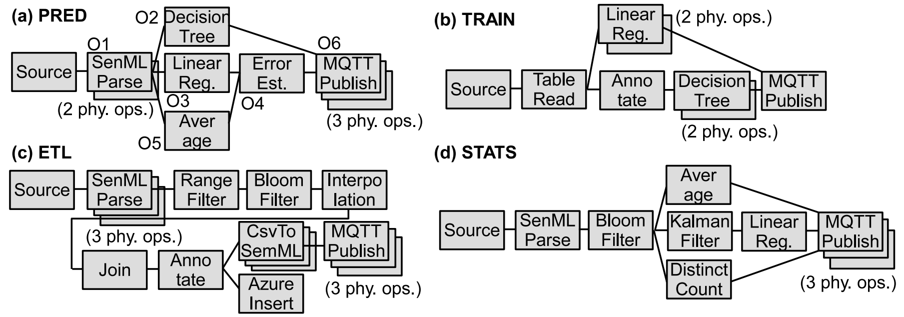
7 Evaluation

Our evaluation first shows EDGEWISE's throughput-latency performance on representative Edge stream processing workloads (§7.2), followed by detailed performance analysis (§7.3). Then we present a sensitivity study on different consumption policies (§7.4), and a distributed (inter-node) performance study (§7.5).

7.1 General Methodology

Hardware. EDGEWISE is designed for the Edge, so experiments use an intermediate-class computing device

Figure 6: Tested Topologies in RIoTBench [68]: (a) PREDictive analytics, (b) model TRAINinig, (c) Extract, Transform, and Load, and (d) STATistical summarization. The (tuned) number of physical operations are shown as the overlapped, multiple rectangles: e.g., 3 MQTT Publish operations in (a).



representative of IoT Edge devices (§3.1): weaker than Cloud-class servers but stronger than typical embedded systems. Specifically, we use Raspberry Pi 3 Model B devices (raspbis), which have a 1.2GHz quad-core ARM Cortex-A53 with 1GB of RAM and run Raspbian GNU/Linux 8.0 v4.1.18.

Baseline. We used Storm [15] as the OWPOA baseline. We set up Storm's dependencies, Nimbus and a Zookeeper server, on a desktop machine, and placed the Storm supervisors (compute nodes) on the raspbis. Because EDGEWISE optimizes the performance of a single compute node, all but our distributed experiment (§7.5) use a single raspbi. As our raspbis are quad-core, EDGEWISE uses four worker threads.

Schedulers. In addition to EDGEWISE's queue-length-based approach, we also evaluated implementations of the Min-Memory [18] and Min-Latency [25] schedulers, as well as a Random scheduler. All schedulers used our `At-most-50` data consumption policy (§4.2), based on our sensitivity study §7.4.

Benchmarks. We used the RIoTBench benchmark suite [68], a real-time IoT stream processing benchmark implemented for Storm[4]. The RIoTBench benchmarks perform various analyses on a real-world Smart Cities data stream [22]. Each input tuple is 380 bytes. The sizes of intermediate tuples vary along the topology.

Figure 6 shows RIoTBench's four topologies. We identified each physical topology using a search guided by the server utilization metric (§5.1), resulting in physical topologies with optimal latency-throughput curves on our raspbi nodes [40]. We used the same physical topologies for both Storm and EDGEWISE.

We made three modifications to the RIoTBench benchmarks: (1) We patched various bugs and inefficiencies. (2) We replaced any Cloud-based services with lab-based ones; (3) To enable a controlled experiment, we implemented a timer-based input generator that reads data from a replayed trace at a configurable input rate. To be more specific, the Smart Cities data [22] is first loaded into the memory, and a timer periodically (every 100 ms) feeds a fixed-size batch of them into `Spout`, the source operator in Storm. We changed the batch size to vary the input rate. This simulates a topology measuring sensor data at different frequencies, or measuring different number of sensors at a fixed frequency.

Metrics. Measurements were taken during the one minute of steady-state runs, after discarding couple minutes of initial phase. We measured *throughput* by counting the number of tuples that reach the `MQTT Publish` sink. Measuring throughput at the sink results in different throughput rates for each topology at a given input rate, since different topologies have input-output tuple ratios: e.g., 1:2 in `PRED`, 1:5 in `STATS`. We measured *latency* by sampling 5% of the tuples, assigning each tuple a unique ID and comparing timestamps at source and the same sink used for the throughput measurement. We measured *operation utilization* using ρ_w (Equation (11)). Each experiment was performed 5 times with each configuration. The error bars indicate one standard deviation from the average. Most data points had small variances.

7.2 Throughput-Latency Performance

We measured the throughput-latency performance curve for each of the RIoTBench applications on one raspbi across a range of input rates. The curves for `PRED`, `STATS`, and `ETL` are shown in Figure 7; the curve for the `TRAIN` application (not shown) looks like that of the `ETL` application. In general, both Storm and EDGEWISE have excellent performance when the system is under-utilized (low throughput). Latency performance collapses at high throughput rates as a result of frequent backpressure.

The results show that an SPE with an engine-level operation scheduler and a worker pool (WP) significantly outperforms Storm (an OWPOA-based SPE) at the Edge, in effect shifting the Storm throughput-latency curve down (lower latency) and to the right (higher throughput). First, the gaps between Storm and WP+Random indicate

[4] Other benchmarks [6, 53] seemed too unrealistic for our use case.

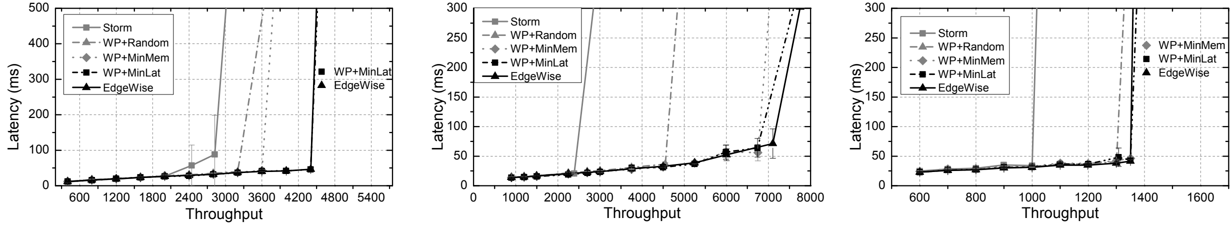


Figure 7: Throughput-latency of (a) `PRED`, (b) `STATS`, and (c) `ETL` topologies.

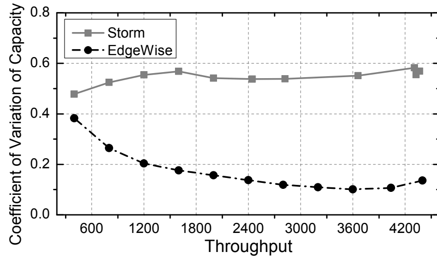

Figure 8: In `PRED`, as the input rate (thus throughput) increases, the coefficient of variation (CV) of capacities grows in Storm, but it decreases in EDGEWISE.

the benefit of avoiding unnecessary contentions in OW-POA. More importantly, the engine-level schedulers in effect push the backpressure point to a higher input rate, allowing the SPEs to achieve higher throughput at a low latency. The high variance in the Storm curves at higher throughput rates indicate early, random backpressure.

Among the variants that use a scheduler and WP, EDGEWISE's queue-length-based scheduler matches or outperforms WP+MinLat on latency and throughput, while WP+MinMem leads to improved (but not the best) performance as it is optimized for memory. Note that EDGEWISE does not require profiling per-operation execution time and input-output ratio as do MinLat and MinMem. For `PRED`, while keeping the latency low (say $\leq$100 ms), EDGEWISE improves its throughput by 57% (from 2800 to 4400). EDGEWISE is particularly effective in the `STATS`, where it achieves a 3x throughput improvement with low latency. For `ETL`, EDGEWISE improves throughput from 1000 to 1350 under 50ms latency.

7.3 Detailed Performance Breakdown

This experiment investigates the underlying causes of the throughput and latency gains described in §7.2, lending empirical support to our analysis in §5. We use the `PRED` application as a case study, though results were similar in the other RIoTBench applications.

7.3.1 Fine-Grained Throughput Analysis

Our analysis of throughput in §5.1 predicted that balancing effective server (operation) utilization would yield gains in throughput. To measure the extent to which Storm and EDGEWISE balance server utilization, in this experiment we calculated the windowed utilization ρ_w of each operation using Equation (11) and then computed the coefficient of variation ($CV = \frac{stddev}{avg}$) of this vector. A lower utilization CV means more balanced server utilization.

Figure 8 plots the coefficient of variation for Storm and EDGEWISE for different input rates. As the input rate (and thus output throughput) increases, the utilization CV increases in Storm, indicating that the operations become unbalanced as Storm becomes saturated. In contrast, in EDGEWISE the utilization CV decreases for larger input rates (and the raw ρ_w values approach 1). As predicted, EDGEWISE's throughput gains are explained by its superior ρ_w balancing.

7.3.2 Fine-Grained Latency Analysis

Our analysis of latency in §5.2 noted that in a congestion-blind scheduler, heavier operations would develop longer queues, and that the queuing time at these operations would dominate end-to-end latency. We showed that an SPE that reduced queuing times at heavy operations, even at the cost of increased queuing times at lighter operations, would obtain an outsized improvement in latency. In this experiment we validate this analysis empirically.

For this experiment we break down per-operation latency into its constituent parts (Equation (6)) and analyze the results in light of our analysis.

Figure 9 shows the per-operation latency for the 6 non-source operations in the `PRED` topology in the baseline Storm. Its logical and physical topology is shown in Figure 6 (a). Where our physical topology has multiple instances of an operation (two instances of `O1`, three of `O6`), we show the average queuing latency across instances.

Note first that the queue time T_Q dominates the per-operation latency L_i. Then, as the input rate increases from L(ow) to H(igh), the queues of heavier operations (`O1`, `O6`) grow much longer than those of lighter operations, and the queue time at these operations dominates the overall latency. Also note that the latency of lighter operations may decrease at high throughput, as tuples are

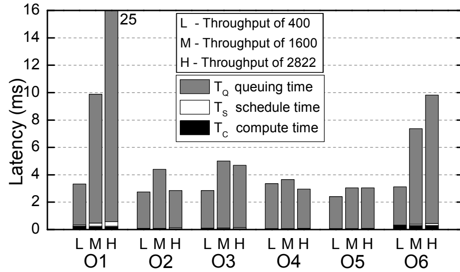

Figure 9: In Storm, as the throughput increases from L(ow) to M(edium) to H(igh), the queuing latency of heavy operations (e.g., `O1` and `O6`) increases rapidly.

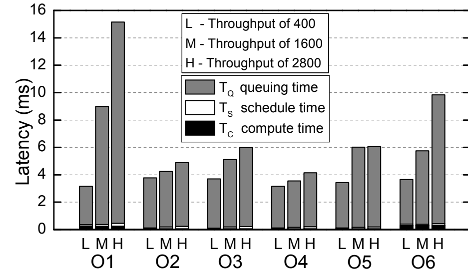

Figure 10: In EDGEWISE, as the throughput increases, the queuing latency of heavy operations (e.g., `O1` and `O6`) increases slowly.

mostly waiting in the queue of heavy operations, reflecting the effects of the non-deterministic OS scheduler.

In contrast, we observed different behavior for EDGEWISE as shown in Figure 10. The heaviest operation `O1` is still noticeable but its queue time under High input rate is only 15 ms, much smaller than the 25 ms of Storm. Of course this penalizes the lighter operations, but as we argued in §5.2 this is not a zero-sum game; the improvement in end-to-end latency outweighs any small per-operation latency increase.

The schedule time T_S includes both the scheduling overhead and the waiting time due to contention. Across all throughput rates and operations, T_S remains very small, implying that the overhead of EDGEWISE's scheduler is negligible.

7.4 Data Consumption Policy

In this experiment we explored the sensitivity of EDGEWISE's performance to its data consumption policies: a constant number (`At-most-N`) or a number proportional to the queue length (`All`, `Half`).

In Figure 11 you can see the effect of these rules in the `STATS` topology, as well as the Storm performance for comparison. As expected, the constant consumption rules consistently performed well in `STATS`. The `PRED` showed the trend similar to the `STATS`. The `TRAIN` and `ETL` topologies were not sensitive to the consumption policy. The `At-most-50` rule (solid black line) offers good latency with the highest throughput for all, so we used it in our other experiments.

7.5 Performance on Distributed Edge

Streaming workloads can benefit from scaling to multiple compute nodes, and supporting scaling was one of our design goals (§3.2). In this experiment we show that EDGEWISE's intra-node optimizations benefit an inter-node (distributed) workload.

We deployed the `PRED` application across 2, 4, and 8 raspbis connected on a 1G Ethernet lab network, simply

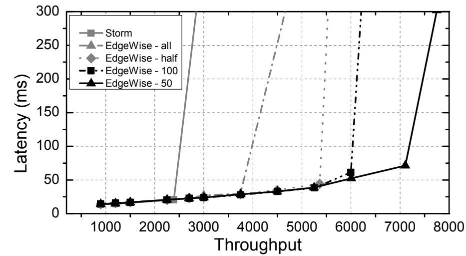

Figure 11: Sensitivity study on various consumption policies with `STATS` topology.

increasing the physical operation instances proportional to the number of raspbis and assigning them uniformly across nodes. Identifying an optimal distributed topology (and optimal partitioning across nodes) is out of scope for our work, which focuses on the optimal scheduling of the topology deployed on a single node. Experiments on visionary hundred- or thousand-node cases are left for future work. We used the same methodology as in §7.2 to collect metrics.

As expected, EDGEWISE's intra-node optimizations prove beneficial in an inter-node setting. Figure 12 shows the maximum throughput achieved by Storm and EDGEWISE with latency less than 100 ms. The scalability curve shows about 2.5x throughput improvement with 8 nodes, suggesting that a combination of networking costs and perhaps a non-optimal topology keep us from realizing the full 8x potential improvement. On this particular physical topology, EDGEWISE achieves an 18–71% improvement over Storm's maximum throughput, comparable to the 57% improvement obtained in the 1-node experiment.

8 Related Work

To the best of our knowledge, Edgent [12] is the only other SPE tailored for the Edge. Edgent is designed for data preprocessing at individual Edge devices rather than

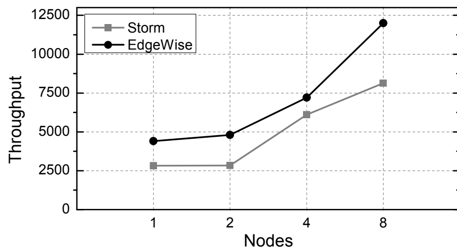

Figure 12: The maximum throughput achieved with the latency less than 100 ms, using the PRED topology with 1, 2, 4, and 8 distributed nodes (log-scale). EDGEWISE's intra-node optimizations extend to a distributed setting.

full-fledged distributed stream processing. We believe the Edge is powerful enough for more intelligent services, and thus EDGEWISE targets a more expressive SPE language with balanced throughput and latency.

Targeting distributed Cloud settings, a variety of academic [26, 39, 52, 62, 73] and industry/open-source [15, 49, 66] SPEs have been proposed. Some [8, 9, 11, 13, 14] support both stream and batch processing. Most use the OWPOA design and differentiate themselves on large-scale distributed processing and fault tolerance. None has our notion of an engine-level scheduler.

Researchers have studied distributed "job placement" schedulers for Storm [10, 23, 60, 77] and Spark Streaming [47, 51]. They determine where to distribute computing workloads across nodes in the Cloud. EDGEWISE does not focus on how to partition a physical topology for distributed computing.

Recent single-node SPE solutions leverage modern many-core and heterogeneous architectures. For example, GStream [78] describes an SPE tailored to GPUs, while Saber [48] is a hybrid SPE for mixed CPU/GPU computing that schedules operations on different hardware depending on where they perform better. StreamBox [56] explores the high-end server space, demonstrating high throughput by extracting pipeline parallelism on a state-of-the-art 56-core NUMA server. StreamBox uses a worker pool (like EDGEWISE) to maximize CPU utilization, but does not maintain a queue for each operation, making it hard to apply the Storm-like distributed stream processing model. EDGEWISE targets the opposite end of the spectrum: a compute cluster composed of Edge-class devices where intra-node scale-up is limited but inter-node scale-out is feasible. Thus, EDGEWISE adopts the general distributed streaming model (scale-out) and enables additional intra-node scale-up.

The Staged Event Driven Architecture (SEDA) [75] was proposed to overcome the limitations of thread-based web server architectures (e.g., Apache Httpd [1]): namely, per-client memory and context-switch overheads. EDGEWISE shares the same observation and proposes a new congestion-aware scheduler towards a more efficient EDA, considering how to stage (schedule) stream processing operations.

Mobile Edge Computing (MEC) [42, 59] uses mobile devices to form an Edge. Unlike EDGEWISE, they focus on mobile-specific issues: e.g., mobility, LTE connections, etc. Two works support stream processing on mobile devices. Mobile Storm [57] ported Apache Storm as is. MobiStreams [74] focuses on fault tolerance when a participating mobile disappears. On the other hand, Mobile-Cloud Computing (MCC) [30, 34, 37, 45, 63] aims to offload computation from mobile to the Cloud. There will be a good synergy between EDGEWISE and MEC/MCC. EDGEWISE could be viewed as a local cloud to which they can offload computations.

Lastly, queueing theory has been used to analyze stream processing. The chief difference between previous analyses and our own lies in the assumption about worker sharing. In traditional queueing theory, each operation is assumed to fairly share the workers. For example, Vakilinia et al. [71] uses queueing network models to determine the smallest number of workers under the latency constraint, under the assumption that workers are uniformly shared among operations. The same is true for the analyses of Mak et al. [54] for series-parallel DAG and Beard et al. [19] for heterogeneous hardware. On the other hand, our analysis identifies the benefit of a non-uniform scheduling weight, assigning more workers to heavy-loaded operations.

9 Conclusion

Existing stream processing engines were designed for the Cloud and behave poorly in the Edge context. This paper presents EDGEWISE, a novel Edge-friendly stream processing engine. EDGEWISE improves throughput and latency thanks to its use of a congestion-aware scheduler and a fixed-size worker pool. Some of the ideas behind EDGEWISE were proposed in the past but forgotten by modern stream processing engines; we enhance these ideas with a new scheduling algorithm supported by a new queuing-theoretic analysis. Sometimes the answers in system design lie not in the future but in the past.

Abstract

With widespread advances in machine learning, a number of large enterprises are beginning to incorporate machine learning models across a number of products. These models are typically trained on shared, multi-tenant GPU clusters. Similar to existing cluster computing workloads, scheduling frameworks aim to provide features like high efficiency, resource isolation, fair sharing across users, etc. However Deep Neural Network (DNN) based workloads, predominantly trained on GPUs, differ in two significant ways from traditional big data analytics workloads. First, from a cluster utilization perspective, GPUs represent a monolithic resource that cannot be shared at a fine granularity across users. Second, from a workload perspective, deep learning frameworks require gang scheduling reducing the flexibility of scheduling and making the jobs themselves inelastic to failures at runtime. In this paper we present a detailed workload characterization of a two-month long trace from a multi-tenant GPU cluster in Microsoft. By correlating scheduler logs with logs from individual jobs, we study three distinct issues that affect cluster utilization for DNN training workloads on multi-tenant clusters: (1) the effect of gang scheduling and locality constraints on queuing, (2) the effect of locality on GPU utilization, and (3) failures during training. Based on our experience running a large-scale operation, we provide design guidelines pertaining to next-generation cluster schedulers for DNN training workloads.

1 Introduction

Recent advances in machine learning have led to tremendous improvements in tasks ranging from object detection [31] to speech recognition [34] and language translation [47]. As a result a number of enterprises are now incorporating machine learning models in various products [1,4]. To facilitate model training, enterprises typically setup a large cluster shared by users belonging to a number of different production groups. Similar to clusters setup for big data analysis [12,50], using shared clusters can facilitate better utilization and reduce development overheads.

However deep learning workloads pose a number of new requirements or constraints on cluster management systems. Since machine learning algorithms are floating point computation intensive, these workloads require hardware accelerators like GPUs. However, unlike CPUs, accelerators do not typically have proper hardware support for fine-grained sharing [21]. While there are software mechanisms to enable sharing, they often have high overhead making it challenging to share resources across jobs [40,53]. Furthermore, training on large datasets often requires the use of multiple GPUs [20] and machine learning frameworks typically require that tasks on each GPU be scheduled at the same time, i.e., gang scheduled [18]. This increases the risk of resource fragmentation and low utilization in shared clusters. Finally, multi-GPU training also implies synchronization of model parameters across GPUs and hence it is important to achieve better *locality* while scheduling to allow for the use of faster interconnects for both intra- and inter-machine communication.

Despite their growing popularity, to the best of our knowledge, there has been no systematic study of multi-tenant clusters used to train machine learning models. In this paper, we present the design of a large, multi-tenant GPU-based cluster used for training deep learning models in production. We describe Philly, a service in Microsoft for training machine learning models that performs resource scheduling and cluster management for jobs running on the cluster. Using data from this system, we then present a detailed workload characterization and study how factors such as gang scheduling, locality requirements and failures affect *cluster utilization*.

Our analysis spans across two months and uses around 100,000 jobs run by hundreds of users. We combine logs from Apache YARN [48], our cluster scheduler, utilization information from Ganglia [33], and logs from each job to perform a systematic analysis of cluster utilization.

We study two main aspects of how locality-aware scheduling affects performance and utilization. First, we study how waiting for locality constraints can influence queuing delays

before training jobs are run. Training jobs need to be gang scheduled, as hyper-parameters are picked for specific GPU count configurations. Given that training jobs take a long time to run, and greater locality improves performance due to the availability of faster interconnects for parallel training [52], the scheduler in Philly waits for appropriate availability of GPUs before beginning to run the training job. Our study shows that as one might expect, relaxing locality constraints reduces queueing delays, especially for jobs that use many GPUs – our emphasis here is not on presenting this as a new insight, but instead on highlighting this using real-world data from production clusters.

Next, we study how locality-aware scheduling can affect the GPU utilization for distributed training jobs. Even though most GPUs within a cluster are allocated to users, thus *suggesting* high cluster utilization, this metric alone is misleading. We show that the hardware utilization of GPUs in use is only around 52% on average. We investigate two reasons which contribute to low GPU utilization: (1) the *distribution* of *individual* jobs across servers, ignoring locality constraints, increases synchronization overheads, and (2) the *colocation* or packing of *different* jobs on same server leads to interference due to contention for shared resources.

Finally, we look at why jobs might fail to complete successfully and offer a detailed characterization of the causes for such failures in our clusters. Around 30% of jobs are killed or finish unsuccessfully due to failures. Failures are caused by errors across the stack, with programming errors dominating failures and occurring early in the training process; failures due to cluster components like HDFS tend to occur much later in the training lifecycle.

Based on the lessons learnt from data analysis and our experiences running a large-scale operation over the years, we provide three guidelines to improve the next generation of cluster schedulers for DNN workloads. First, because the lack of locality impacts both utilization and job runtime, and because DNN training jobs are long running, schedulers should trade queueing delay for adhering to locality constraints. Second, different jobs that share a single server may interfere with each other and thus adversely affect their training time. Schedulers should thus aim to isolate the jobs on dedicated servers while implementing techniques like migration for defragmentation, to support the locality constraints of jobs that need more GPUs. Third, many failures ought to be caught early, well before they are scheduled on a larger shared cluster. This can be achieved by scheduling each incoming job on a small dedicated pool of servers or even using a single GPU should be able to catch simple programming and configuration errors from multi-GPU jobs. Furthermore, an online analysis of failures at runtime can let schedulers adapt their retry policies thus avoiding wasteful re-execution.

Philly's design does not stand in isolation. There are many open platforms for DNN job scheduling that use designs similar to Philly, e.g., OpenPAI [36] and Submarine [44]. We hope that insights and data from our study, and the accompanying traces, inform the burgeoning work of scheduling research for machine learning workloads.

2 Philly: System Overview

In this section we provide an overview of the design and architecture of Philly. First, we describe the workloads that are supported in our system and then describe the hardware characteristics of the clusters. Next, we describe the lifecycle of a job. Finally, we explain our data collection pipeline and highlight the data we use to perform our analysis in subsequent sections. The authors would like to note that Philly has been developed over the past few years by a team of developers in our company and has gone through multiple generations of design.

2.1 Workloads

Philly is designed to support workloads that perform supervised machine learning where jobs learn a model given training data and the corresponding labels. This includes training jobs from production groups developing products that use models for image classification, speech recognition, etc. The system supports jobs written using any machine learning framework like TensorFlow [5], CNTK [42], Caffe [29], and PyTorch [39]. Jobs are based on recently proposed learning architectures like convolutional neural networks [31], LSTMs [45] and RNNs [35].

All jobs, irrespective of the framework or model being used, rely on iterative optimization methods [19] like stochastic gradient descent (SGD). In each iteration, the gradient computation is performed by translating the model components into code that can be executed on accelerators like GPUs. The gradient values are then aggregated to compute a model update and these iterations are repeated until convergence. Training a model could require thousands to millions of iterations [46], and result in multiple passes or *epochs* over the entire dataset.

To scale training across larger datasets, a number of jobs use distributed training across machines. Distributed training typically uses data parallelism where each worker loads a complete copy of the model into its own memory. In each iteration, every worker performs training using a subset of the input data, and at the end of the iteration all workers exchange gradients to synchronize model updates. This synchronization phase is performed using either parameter servers [32] or high performance libraries for collective communication (such as MPI, NCCL, etc).

2.2 Cluster Architecture

Our system is deployed on large GPU clusters shared across many groups in the company. Our clusters has grown significantly over time, both in terms of the number of machines

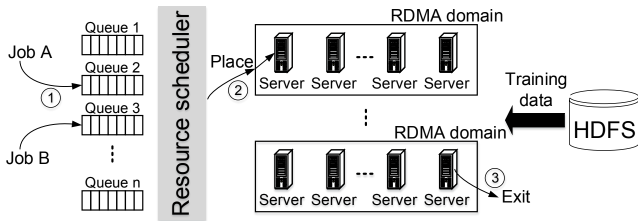

Figure 1: The lifecycle of deep learning jobs in Philly.

(5× increase in one year) as well as the number of GPUs per machine (2-GPU to 8-GPU servers).

Our clusters have high-speed network connectivity among servers and GPUs in the cluster. This is to speed up distributed training where workers need to exchange model updates promptly for every iteration. There is a hierarchy of network links available in our cluster for communication across GPUs. For example, machines within the same rack (*RDMA domain*) are connected via 100-Gbps RDMA (InfiniBand) network, while cross-rack traffic goes through Ethernet. To improve communication performance, workers in a distributed training job must either be colocated on the same machine or preferably communicate over a higher-speed network such as say InfiniBand. Thus, our framework considers both GPUs and network connectivity for scheduling.

Similar to existing big data analytics clusters, our clusters use HDFS [43] as the distributed storage system and our resource manager is based off Apache YARN [48]. Input data for the machine learning jobs is stored in HDFS and read by jobs during training. Users provide a Docker container with their training code and its dependencies. Each training job requests 1 or more GPUs which can be allocated across multiple machines. Philly instantiates one container per machine allocated to the job when it is scheduled for execution.

2.3 Job Scheduling and Execution Workflow

Figure 1 shows the lifecycle of a deep learning job in Philly and the various stages of execution that it goes through.

Incoming jobs and queueing ①. As a part of job submission, users specify *the number of GPUs* required. To facilitate host resource allocation, we perform an allocation of CPU cores and memory capacity proportional to the requested GPU count. Once a job has been received by the scheduler it is queued while the necessary GPUs are allocated. To support multiple production groups we create a virtual cluster for each group and associate a *resource share* or *quota* in terms of number of GPUs to each virtual cluster. Each virtual cluster has a separate allocation queue in Apache YARN and we use the Fair Scheduler to manage these queues [2]. Our scheduler not only respects the configured resource shares but also allocates unused GPUs to a queue which has additional demand. Jobs can be preempted based on fair share of resources among virtual clusters. Our scheduler starts preemption only when a majority (90%) of total GPUs are being used.

For distributed learning, deep learning frameworks require all the GPUs to be available at the same time [22]. Thus the scheduler needs to perform *gang scheduling* while being *locality-aware*, i.e., pack a job's GPUs onto the smallest number of servers and within an RDMA domain. Locality awareness improves training time by bringing down the time needed for parameter synchronization [22,52] due to the availability of: (i) fast intra-server interconnects (such as PCIe and NVLink), and (ii) for jobs that do not fit on a single server, high-bandwidth links available within an RDMA domain. We implement these goals by acquiring resources for a job as GPUs become available and waiting for a pre-specified timeout (2–3 minutes in our setup) to acquire all the necessary GPUs with the locality constraints. To facilitate locality-aware GPU scheduling, our job scheduler keeps track of all idle GPUs in the cluster and ranks the corresponding racks and servers. Specifically, racks are ranked by increasing order of allocation or occupancy, and the machines in a rack are ordered the same way. This allows the scheduler to first consider racks and then servers within those racks that have most GPUs available.

If the request is not fulfilled by the timeout, any partially acquired resources are relinquished and we retry scheduling after a back-off (2 minutes in our setup). To avoid starvation, the locality constraints are relaxed after a scheduling request has been retried a fixed number of times. We analyze corresponding queuing delays in Section 3.1.

Job placement and utilization ②. While the scheduler tries to maximize locality for distributed jobs as described before, at the same time the scheduler also aims to avoid fragmentation of resources from smaller jobs (e.g., 1-GPU jobs) by packing them into a fewer servers. However colocating different jobs on the same server could lead to lower GPU utilization due to interference in shared system resources such as PCIe bus [52]. In order to better understand this trade-off we study the effects of colocation vs. distribution and measure how that affects utilization.

Once the job is scheduled to run, its GPUs are *not shared* with other jobs. This is because model training can be computation intensive and we need consistent performance among workers of the job without having stragglers. However, dedicated GPUs may be underutilized for many reasons, e.g., inefficiencies in the code generated by the machine learning frameworks or programs blocking on I/O when reading data from storage. GPU underutilization also comes from distributed training where computation may block during model synchronization among the workers. We analyze the effects of job placement and GPU utilization in Section 3.2.

Table 1 qualitatively compares Philly with the state-of-the-art DNN cluster schedulers, showing both similarities and differences exist. Nonetheless, locality and colocation are the common issue for all contemporary clusters, and that insights

Table 1: Comparison of DNN cluster schedulers. JCT means job completion time.

	Philly	Gandiva [52]	Optimus [38]	Tiresias [22]
Objective	Consolidation	Consolidation	Average JCT	Average JCT

Preemption	Model checkpoint	Context switch	Model checkpoint	Model checkpoint

obtained in this study are widely valuable.

Training progress and completion ③. Jobs can finish with one of three statuses: passed, killed, or unsuccessful. Passed indicates that the job completed successfully, while killed indicates that the job was terminated by the user.

Among successful jobs, every job runs a number of iterations to improve the model incrementally, and the number of iterations to run is typically a static parameter set by the user. In cases where a job is configured with too many iterations, it is possible to deliver the same (or similar) quality of trained model with fewer iterations. Failed jobs in our system are retried a fixed number of times. This is useful for overcoming non-deterministic failures and if the job does not succeed after retries then it is marked as unsuccessful. As failures also contribute to ineffective cluster utilization, we perform a detailed study to understand the reasons behind failures in Section 4.2.

While our focus in this section is specifically about the lifecycle and execution flow in Philly, there are many open platforms for ML job scheduling that use a similar design. Platforms like OpenPAI [36] and Submarine [44] also use a centralized scheduler with support for running machine learning frameworks as Docker containers. While the details of the scheduling algorithm vary across systems, a number of aspects we study in this paper are independent of the choice of scheduler: e.g., failures due to programming errors and bugs in popular frameworks, effect of distributed training across machines, etc. Thus, we believe that lessons from Philly are generally applicable to other clusters as well.

2.4 Data Collection and Analysis

The cluster under study consists of hundreds of machines accounting for thousands of GPUs of the same model. The cluster has 2 server SKUs – one with 2 GPUs per server and another with 8 GPUs per server; RDMA domains are homogeneous with respect to server SKUs. To get a comprehensive understanding of the characteristics of our system and workloads, we developed a data collection and analysis pipeline and collect logs over a 75-day period from Oct. 2017 to Dec. 2017. Our logs contain a total of 96260 jobs over 14 virtual clusters.

The analysis pipeline combines three main log sources in our system as follows. (1) We collect the YARN scheduler logs to obtain job arrival time, number of GPUs requested, GPU allocation status, and job finish status. (2) We collect stdout and stderr logs from the machine learning frameworks

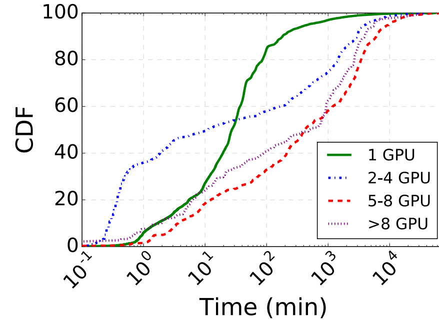

Figure 2: CDF of job run times for 1 GPU, 2-4 GPU, 5-8 GPU, and >8 GPU jobs.

that execute scheduled jobs. (3) We collect logs from Ganglia monitoring system that reports per-minute statistics on hardware usage on every server, including CPU, memory, network, GPU utilizations. Combined with GPU allocation status in YARN scheduler logs, we can track how a scheduled job utilizes cluster hardware resources.

Our collected data contains jobs from a wide spectrum in terms of their run times and sizes, and consequently cluster resources demands. Jobs run from minutes to days or even weeks, as shown in Figure 2. In contrast, in big data analytics, job execution times range from only tens of milliseconds to a few hours [11, 37, 41]. Furthermore, we see that our workload has significant skewness in run time, with 0.5% jobs taking more than a week to be finished. Figure 2 also shows how jobs of different sizes vary in terms of execution times. We see that jobs with more GPUs tend to run longer. This results in most of the cluster resources demands coming from the larger jobs, and resource availability status changing relatively slowly over time.

3 Impact of Locality Awareness

Our scheduler trades off locality for lower waiting. Thus placement choices made by the scheduler affects the efficiency of DNN training in two parts: queueing delay (before job execution) and hardware utilization of in-use GPUs (after job execution). The effect of locality constraints on queuing delays has been extensively explored in large-scale resource allocation [7, 11, 26, 54]. Machine learning workloads introduce similar constraints driven by gang scheduling and the requirement for using fast interconnects. In Section 3.1, we an-

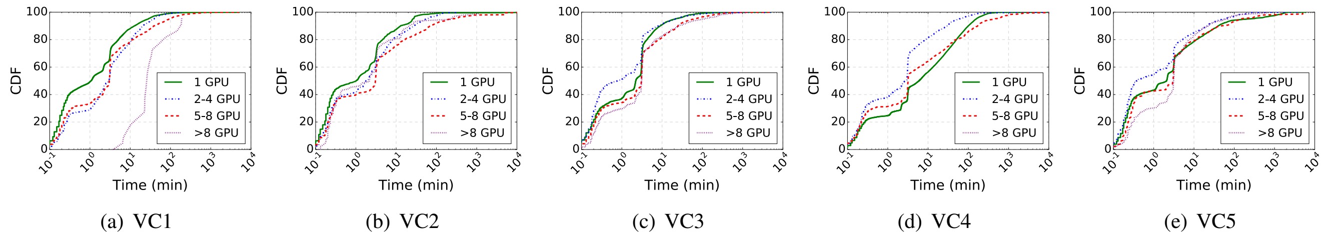

Figure 3: CDF of scheduler queueing delay for five of the largest virtual clusters in our deployment. Note that VC4 contains no jobs with >8 GPU.

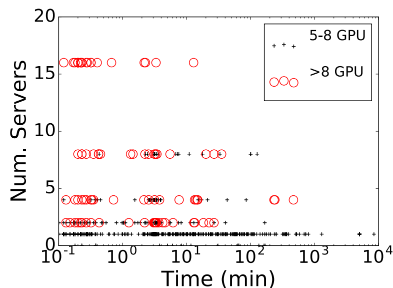

Figure 4: For a given GPU count, relaxing locality constraints reduces queueing delays (VC2).

Delay	2-4 GPU	5-8 GPU	>8 GPU
Fair-share	5168 (40.6%)	3793 (25.8%)	66 (2.1%)
Fragmentation	7567 (59.4%)	10928 (74.2%)	3117 (97.9%)

Table 2: Frequencies of two types of queueing delay.

alyze queueing delays in the context of DNN training cluster using real-world data in detail. Next, we study utilization of processing cycles for GPUs allocated to training jobs in Section 3.2. In particular, while prior work discusses efficiency of distributed training for a certain job size or a configured placement [22, 52], we perform an analysis on the aggregated efficiency for a range of job sizes for the first time.

3.1 Queueing Delays

We first consider overall queueing delay observed during job scheduling. We plot the CDF of queueing delay in Figure 3 for all jobs in five of the largest virtual clusters (VCs). Jobs that need more than 4 GPUs tend to have a slightly longer tail in the distribution of queueing delays compared to their 1 GPU and 2-4 GPU counterparts. For example for VC2, 25% of jobs using >4 GPUs, which include both 5-8 GPU and >8 GPU, experience a queueing delay of at least 10 minutes; in comparison, only 10% of 1 GPU jobs experience a queueing delay of at least 10 minutes.

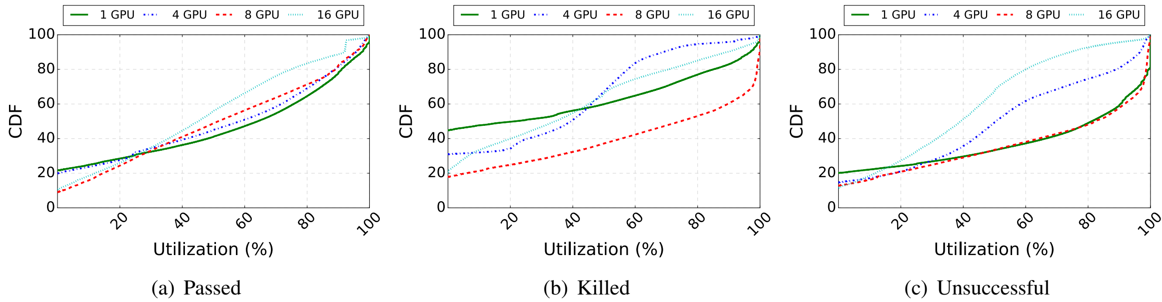
But overall, queuing delays for jobs, irrespective of their GPU demand, are not markedly distinct. This is partially a consequence of our scheduling policy that chooses to relax locality constraints in order to start a job without incurring a very long queueing delay penalty. To highlight the relation between locality constraints and queueing delays, we next consider jobs with 5-8 GPU and >8 GPU. We correlate scheduler waiting times with number of servers on which the jobs are placed, and show the results in Figure 4. As expected, most of jobs with 5-8 GPU are scheduled with high locality, i.e., placed on one or two servers. On the other hand, we find that jobs with >8 GPU are spread across a wider range from 2 to 16 servers. Clearly, when jobs end up running on 16 servers, they start execution much sooner than running on 2 or 4 servers. This confirms how our scheduler works in practice to trade-off locality for lower scheduling delay.

While effective, we find that this decision affects the GPU utilization as discussed in Section 3.2. We next look at more details on the queuing delay characteristics and break down the delay by different causes.

3.1.1 Impact of Locality-Driven Scheduling

Queuing delay can be caused by two primary factors: fairness (which is common in conventional data analytics clusters), and locality requirement and resource fragmentation (which is more prevalent in deep learning clusters). We call queueing caused by the first factor as *fair-share delay*, as it happens when the virtual cluster uses up its assigned quota (i.e., number of GPUs). However, it is possible that a job arrives within the quota but fails to be scheduled, mainly because resource fragmentation makes it hard to find enough GPUs with high locality. We call this queuing delay as *fragmentation delay*. In practice, we find that resource fragmentation is very common. For example, we observe that (i) when two thirds of the total GPUs are being used, the fraction of servers that are completely empty is less than 4.5% and that (ii) these servers are spread across RDMA domains.

We next see how frequently fair-share delay and fragmentation delay occur for different job sizes in our workloads. Since some jobs are quickly terminated, we only consider jobs that run for at least one minute. Further, since fragmentation influences distributed training jobs only, we consider jobs that



(a) Passed (b) Killed (c) Unsuccessful

Figure 5: CDF of per-minute GPU utilization for passed, killed, unsuccessful jobs in different sizes.

use 2 or more GPUs. Table 2 shows the frequencies for the two types of delay. For jobs with 5-8 GPU, fragmentation delay is responsible for 74.2% of occurrences, and it dominates for larger jobs. In contrast, for smaller jobs, we see that the two causes are more balanced. Further, we also observe that across all jobs fragmentation delay is responsible for around 80% of the delay in terms of waiting time. This is because fair-share delays are easy to mitigate with preemption, but fragmentation delays are much harder to overcome in our current design.

Finally, we note that the queuing delay fractions vary across virtual clusters. Among the five largest virtual clusters, VC5 often over-subscribes its quota and thus the proportion of fair-share delay is overall higher at 37%.

Does out-of-order scheduling exacerbate job queueing? Given the resource fragmentation and the fact that the YARN scheduler is work-conserving, larger jobs could be additionally negatively affected by out-of-order scheduling. To see how, consider a job that requires 24 GPUs spread across three machines. While this job is waiting for such configuration, if a smaller job requests 2 GPUs, it is scheduled on machines where two GPUs become available. This could cause further fragmentation and lead to the 24-GPU job needing to retry after a backoff. In our workload, out-of-order scheduling is quite common, with 38.1% of scheduling decisions, and occurs 100% for jobs with 5-8 GPU or >8 GPU. However, we find that most out-of-order scheduling decisions do not greatly affect the waiting time for resource-intensive jobs. For example, for out-of-order scheduling occurrences of jobs with 5-8 GPU or >8 GPU, as much as 85.0% corresponds to cases where idle GPUs are effectively utilized without prolonging the scheduling time of those waiting jobs.

In summary, our analysis shows why it makes sense to relax locality over time to mitigate queuing delays for distributed training. We also find that in addition to fair-share queuing delay, the need for gang scheduling and locality introduces fragmentation delay for machine learning jobs.

Job size	Passed	Killed	Unsuccessful	All
1 GPU	53.51	37.02	62.82	52.38
4 GPU	51.13	34.39	50.95	45.18
8 GPU	51.09	60.63	64.34	58.99
16 GPU	44.88	36.98	39.02	40.39
All	52.43	42.98	60.43	52.32

Table 3: Mean GPU utilization for different job sizes.

3.2 GPU utilization

GPUs are the most expensive resources in our cluster and this makes their efficiency an important factor in assessing the cost-effectiveness across the entire cluster. For each individual GPU, Ganglia [33] reports aggregate performance counters every minute, including utilization of processing cycles and memory, temperature, power usage, etc [3]. We next present how efficiently training jobs use processing cycles in their (exclusively) allocated GPUs. Note that our current generation of GPUs only report coarse-grained utilization for processing cycles that can only be used to detect if any of the streaming multiprocessors (SMs) are being utilized [3]. They do not report what fraction of the SMs are being actually used within a single GPU. Therefore, our analysis presents an "upper bound" of actual effective SM utilization.

Overall, deep learning training jobs underutilize GPU processing cycles regardless of their job sizes. Figure 5 shows CDFs of per-minute GPU utilization of passed, killed, and unsuccessful jobs for different sizes. Table 3 reports averages for each job size, including averages for different job status; we use these job sizes as representative of small, medium and large jobs based on the GPU request distribution in our cluster. Surprisingly we find that around 47.7% of in-use GPUs' cycles are wasted across all jobs, with jobs using 16 GPUs exhibiting the lowest utilization at 40.39%. Moreover, across job status in Figure 5, the median utilization for 16 GPU jobs is 45.00%, 34.24%, 39.54% for `Passed`, `Killed`, and `Unsuccessful`, respectively. These are 6.46%, 40.25%, and 42.63% lower than the 8 GPU jobs in the corresponding job status. We study the efficiency of such jobs in the next section in detail.

Metric	SameServer	DiffServer	IntraServer	InterServer
GPU util.	57.7	49.6	37.5	36.5
Images/s	114.8	98.0	75.6	74.1

Table 4: Mean GPU utilization and training performance of ResNet-50 over different locality/colocation configurations.

3.2.1 Impact of Distributed Learning

Given that the 8 GPUs mounted in each server can communicate more efficiently without using the network, our job scheduling strategy is to favor intra-server locality when assigning each job to available GPUs. At the same time, the scheduler attempts to pack small jobs into fewer servers to avoid fragmentation. This leads to *job colocation* on the same server and consequently could lead to interference in shared system resources (e.g., RDMA and PCIe) [52]. This creates an interesting utilization spectrum for multi-GPU jobs. In particular, jobs using more than 8 GPUs must *distribute* training instances across multiple servers and may be dynamically colocated with other jobs. This scenario also involves communication overheads since each server has to periodically wait for model aggregation to happen over the network.

To confirm that such distribution and colocation factors indeed relate to the efficiency of GPUs in use, we first characterize utilization of processing cycles for various job placement scenarios using a popular image recognition model, ResNet-50 [23]. Specifically we train ResNet-50 with 2 GPUs using TensorFlow and perform offline experiments with placements that exercise shared resources differently. Then using our telemetry data, we attempt to infer correlations between those factors and the observed efficiency in our cluster.

Analysis using ResNet-50. Table 4 shows the impact of distribution only, by comparing a ResNet-50 job placed in a single server (`SameServer`) with the job placed in two servers connected with RDMA network (`DiffServer`). Each server has four NVIDIA Tesla P100 GPUs attached to a CPU socket. The table reports GPU utilization when processing a batch size of 32 images during training. First we observe that the training does not fully utilize GPUs even for single machine execution. In particular, `SameServer` achieves utilization of 57.7% for GPUs in use. It increases to 71.1% for twice the batch size but only increases marginally for larger batches. Also the table shows that using distributed training achieves lower utilization of 49.6% in `DiffServer`. This shows that even for 2-GPU jobs, there is a cost to not achieving locality.

Given a distributed training setup, contention for shared resources like RDMA and PCIe further lowers the efficiency of utilized GPUs. To show this we set `DiffServer` as our baseline and measure changes in the efficiency while populating additional ResNet-50 jobs in the same servers. First, we measure GPU utilization when the colocated jobs do not use RDMA network at all: we place two `SameServer` jobs, one on each server in the same CPU socket as the job under

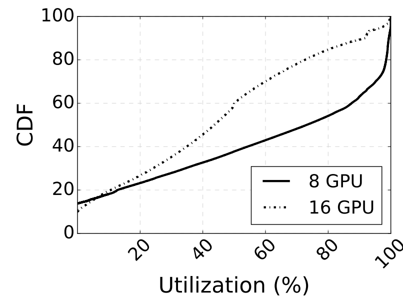


Figure 6: GPU utilization when running 8 and 16 GPU jobs on dedicated servers.

study. Thus, these jobs interfere with the job under study in the use of PCIe buses while reading training inputs, aggregating model updates, and so on. The observed efficiency is shown as `IntraServer` in Table 4, and we see that having such intra-server interference lowers the utilization by as much as 12.1%. We also study if such interference matters for the RDMA network in `InterServer`. For this setup we use two `DiffServer` jobs instead of two `SameServer` jobs as background traffic, so that all the jobs are distributed across two servers and share the RDMA network. In this case, we see a 13.1% decrease in utilization compared to the baseline.

Our experimental study reveals that efficiency of allocated GPUs varies according to locality and colocation scenarios that could occur in the cluster. Further, any placement that causes lowered GPU utilization also results in slowdown in training performance (i.e., images processed per second) as shown in Table 4. Next, we analyze utilization for our aggregate workload. We note that unlike the controlled experiment, the type of model trained and the batch sizes used vary across jobs in our aggregate workload making it harder to establish a baseline utilization without distribution or inference.

Distributed training with dedicated servers. First, to study the effects of distribution, we restrict our study to look at 8 GPU and 16 GPU jobs that are packed on one or two servers. In this case, the 8 GPU jobs uses all 8 GPUs in a single server while the 16 GPU jobs uses all the GPUs in two servers. The network over which the servers for these jobs are connected to each other is shared. Figure 6 shows the results of our comparison. Compared to the 8 GPU jobs, we see that 16 GPU jobs, which have the additional model aggregation step in distributed mode, have significantly lower utilization. Specifically, for 8 GPU jobs, GPU cycles are utilized 56.9% of time on average while this is only 34.3% for 16 GPU jobs. Furthermore, the median is 73.12% for 8 GPU jobs, which is 1.67x the median in the 16 GPU case.

Distributed training with shared servers. When locality constraints are relaxed, a job may have to be distributed over many servers while sharing them with other jobs. Distributing a job over many shared servers can further lower utilization of GPUs. This drop in utilization occurs not only due to a higher network overhead but also because of interference from

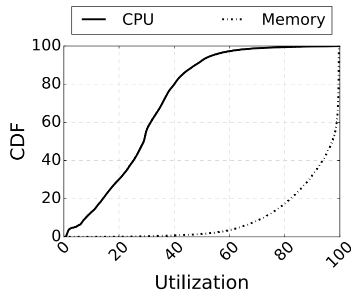

Figure 7: Host resource utilization.

Degree	Mean	50%ile	90%ile	95%ile
2 servers	43.66	43.69	91.77	97.06
4 servers	40.94	39.85	83.28	91.97
8 servers	28.56	25.71	65.68	78.85

Table 5: GPU utilization for 16-GPU jobs that are spread over 2, 4, and 8 servers.

unrelated but co-located jobs. To study this, we see how the GPU utilization of 16-GPU jobs varies as as we move from dedicated GPUs to a larger number of shared servers. Table 5 shows the average and percentiles for GPU utilization across the different allocation scenarios.

When running on 2 8-GPU servers, a 16-GPU job has dedicated servers. When running on 4 servers, the 16-GPU job may occupy 4 GPUs on each server, and will be colocated with other jobs on those servers. We find that the degree of interference is larger if the job is distributed on more servers. Table 5 shows that in addition to the inefficiency caused by distribution (Figure 6) there is additional underutilization caused by colocation. We see that for 16-GPU jobs distributed across 8 servers, the average utilization is as low as 28.26% and more than 90% of jobs have less than 66% utilization.

Among host resources, our scheduler dedicates CPU and memory along with GPU to each job. In deep learning clusters, these host resources are used for many useful tasks including caching training inputs, model aggregation, and periodic model validation and progress report. By default, we allocate CPU and memory capacity proportional to the number of requested GPUs. Figure 7 shows CDFs of utilization of these host resources observed in our servers. In general, many servers underutilize CPU cycles yet highly utilize memory. This indicates that a useful feature in the scheduler would be to observe if a particular job requires disproportionate amount of host memory and isolate memory used by jobs colocated on the same server.

In summary, our data analysis shows how GPUs are underutilized in shared clusters. We presented correlations of how distribution and interference affect utilization and validated this using a controlled experiment to break down the importance of locality and interference. We discuss some implications for scheduler design in Section 5.

Status	Count(%)	GPU times used (%)
Passed	66696 (69.3%)	44.53%
Killed	12996 (13.5%)	37.69%
Unsuccessful	16568 (17.2%)	17.76%
Total	96260 (100.0%)	100.0%

Table 6: Distribution of jobs by their final status.

4 Training Progress and Completion

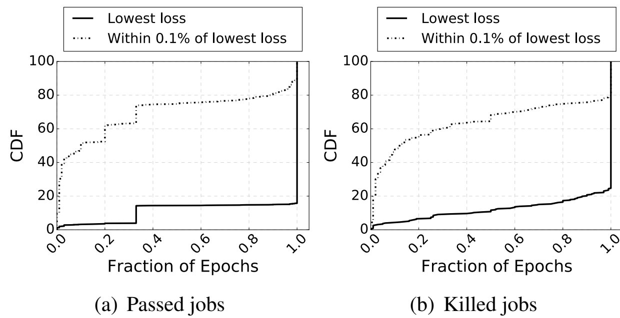
Jobs in our system finish with one of three statuses: passed, killed or unsuccessful. Similar to iterative online computations [6, 16], our machine learning job utilizes cluster resources to improve the model over time. However as opposed to prior study on big data traces [30], we see a significant fraction of jobs (30.7% as shown in Table 6) are either terminated unsuccessfully or killed by users. They constitute around 55% of the total GPU time used during our trace collection period. Thus it is important to understand the reason behind these failures as fewer unsuccessful jobs would mean that more of the cluster resources can be used for successful jobs.

4.1 Effectiveness of Training Iterations

Most deep learning jobs optimize a non-convex loss function and the optimization algorithms do not necessarily guarantee that the loss always decreases with more training. Thus, similar to [22], users in our system submit model training jobs using a larger number of epochs than necessary to get the optimal model. To analyze the magnitude of this effect we study how the training loss for a job varies across epochs and measure the epoch at which we achieve the best training loss. As this information is not printed in the log by every user/framework, we are only able to obtain convergence information for around 2502 jobs.

First, Figure 8(a) shows the fractions of epochs required to reach the lowest loss across all passed jobs. From the figure we see that around 80% of passed jobs require all the epochs executed to reach the lowest loss. We repeat this study for killed jobs and see a similar pattern as shown in Figure 8(b).

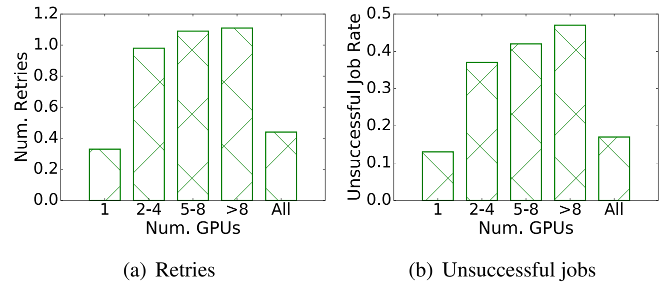
However we also see that a majority of jobs improve the loss marginally using a large fraction of epochs. In particular, Figure 8(a) shows the fraction of epochs required to reach within 0.1% of the lowest loss across all passed jobs. Around 75% of jobs reach within 0.1% of the lowest loss using only 40% of the epochs. Again, a similar pattern is shown for killed jobs in Figure 8(b). While we do not present data from user surveys, this suggests that machine learning practitioners can early terminate jobs to save use of GPU times considerably when the loss change is less than a particular threshold in successive epochs. Essentially, we look into much resources are used to improve 0.1% of convergence accuracy in terms of the fraction of GPU times for each job. In our workload, this accounts for 62% and 56% on average for passed jobs and killed jobs, respectively.



(a) Passed jobs

(b) Killed jobs

Figure 8: Fraction of epochs necessary to achieve a particular loss threshold for (a) passed jobs and (b) killed jobs.



(a) Retries

(b) Unsuccessful jobs

Figure 9: (a) Average number of job retries for using different number of GPUs, and (b) subsequent unsuccessful jobs.

4.2 Job Failures

We next present a detailed analysis on job failures, including why/when/how frequently jobs fail and what their impact is on effective cluster usage. We remind the reader that in our cluster scheduler, a job is retried upon failure. If the job repeatedly fails it is marked as unsuccessful as further retries are deemed no longer effective. Figure 9 presents a high-level summary of job retries/failures and shows that jobs using more than 4 GPUs not only retry execution more often but also finish unsuccessfully at higher rate. The reasons behind job retries/failures are diverse, and failures occur at different times during job execution. We thus investigate failures by classifying them across layers of our system stack.

4.2.1 Failure Classification

Table 7 presents analysis results of failures based on two classification factors. First, failures are classified from different sources (Column 2): the sources include (i) Infrastructure (`IF`) which includes YARN, HDFS and all other framework components, (ii) AI Engine (`AE`) which includes TensorFlow, Torch, and any other platforms, and (iii) User (`U`) which represents programmers. Column 1 lists a number of reasons for failures we observe from the workload.

Most failure reasons in the table are self-explanatory, and we describe six important ones in more detail here.

(1) **Incorrect inputs**: Model files or input data stored in the external HDFS storage cannot be read.

(2) **Semantic error:** Errors that happen due to library version mismatch or other dependencies of the user training program not being setup correctly.

(3) **Model checkpoint error:** The job is not able to successfully create a model checkpoint after a certain number of epochs complete. This is usually due to either transient error in HDFS or HDFS name node recovery.

(4) **MPI runtime failure:** This is usually due to either a failure of network connection to peer MPI process, or possibly an internal failure of the MPI daemon itself.

(5) **Job preempted:** YARN reclaims any GPU currently in use to schedule another job.

(6) **Invalid memory access:** Training job dies because of violating access on memory address space e.g., using an invalid pointer value, or having race condition while copying data. This failure is observed in both CPU memory and memory allocated for GPU access.

While bridging failure category and failure reason, we observe that a failure reason can appear in multiple categories, even in all involved categories, as shown in Column 2 of Table 7.

Building failure classifier. There exists causality among various failure reasons. For example, *traceback from crash* is a consequence of an *invalid memory access*. Our first mission in building a classifier is identifying signatures of failure reasons closer to the root cause. We capture root-cause signatures from stdout or stderr logs of a failed job. If not explicit from the logs, we then attempt to capture implicit ones such as *traceback from crash*. In consequence, our classifier has in total **more than 230 rules** to find both explicit signatures and implicit signatures. If there is no signature for a failure, we tag it as *no signature*, which constitutes 4.2% of the total failures.

4.2.2 Failure Frequency

Column 3 of Table 7 summarizes the occurrence frequency of the classified failure reason. `Trial` counts the number of failure events observed in our workload: failure reasons are sorted by it. We further group `Trial` occurrences by job ID (`Job`) and user ID (`User`) to see if failures are localized according to the same job or user.

Failures repeat for the same job/user. Our analysis shows that across failure reasons, failures repeat at both job level and user level. In particular, we measure repetition factors (i.e., `Trial` divided by `Job` or `User`) for top-8 failure reasons, which cover 88.9% of the total failures. The measured repetition factors are 2.3 and 38.8 on average for `Job` and `User`, respectively, meaning a single job and a single user on average cause 2.3 and 38.8 occurrences of failure, respectively, during

Failure Reason	Category			Num Occurrences			RTF: Runtime to Failure (mins)				GPU Demand			RTF×Demand (%)

Table 7: Failures classified into failure reasons (sorted based on the number of occurrences). There are largely three categories that cause the failures: Infrastructure (IF), AI Engine (AE), and User (U). A failure reason may be observed in multiple categories.

the data collection period. The most critical one is *CPU out of memory*, where we see 185.7 as the `User` repetition factor. Interestingly, profiling shows that a certain engineer issued a number of training jobs, all of which suffer from the same out-of-memory issue, resulting in high concentration of failures. This motivates the need for runtime detection mechanisms that can correlate errors from the same user even though her jobs are independent from job management point of view.

User/programming errors lead to a lot of failures. Failures incurred by user errors, such as configuration/syntax/semantic errors in program and script, are dominant. These failures are very prevalent across our top-8 failure reasons. As explained, *CPU out of memory* is the most frequent with its failures significantly concentrated on a few users. Other frequent failures such as *incorrect inputs* and *semantic error* are more spread out across different users. From our profiling, the primary factor that causes those failures is a lot of independent components involved in a training job. For example, by definition, *incorrect inputs* happens when there is a failure in reading model or input data stored in external HDFS store. This is due to any error ranging from the data path is not correct, data format is inconsistent, data itself is corrupted on HDFS etc. Often, issues in data format affect multiple engineers in the same team (e.g., speech recognition team) as they often share the same training data or reference model.

4.2.3 Runtime to Failure

Column 4 of Table 7 presents runtime to failure (RTF) for each classified failure reason. To capture the summary of RTF distribution, in addition to the average, we also present the 50th-percentile (or median) and higher percentiles such as 90th-percentile and 95th-percentile.

The runtime to failure (RTF) exhibits high variability, with mainly short RTFs. Many failures of training jobs happen quickly, for example within 10 mins. This is mostly the case for failures driven by users in syntax, semantic, and configuration errors, which we can also infer from low 50P RTFs in the corresponding failure reasons. Note that most of those failures are deterministic and are caught when the runtime begins to execute the program. One of exceptions that is noteworthy is failure corresponding to inconsistent/corrupted input data. We can only detect this at the moment we actually read the erroneous data and attempt to parse it. This is the primary reason for having high 95P in *incorrect inputs*.

Infrastructure failures occur infrequently but have much longer runtime to failure (RTF). This analysis focuses on two failure reasons in infrastructure category: *model checkpoint error* and *MPI runtime failure*. They represent program-to-storage and program-to-program communication, which are both critical for reliable distributed deep learning training. In general, these errors are relatively infrequent compared to other common errors, constituting only 6.2% of the total `Trials`. However, our analysis shows that these errors tend to appear after a long execution duration, and thus dominate the time until failure detection. In particular, Table 7 shows that when the corresponding RTFs are summed up (i.e. `Total`), the two failure reasons, *model checkpoint error* and *MPI runtime error*, occupy as much as 21.73% and 14.63%, respectively.

4.2.4 Impact of GPUs Allocated

For jobs with the same RTF, the impact on the amount of utilized resources is proportional to the number of allocated GPUs. The larger the allocation, the bigger the impact.

Large jobs with programming semantic errors tend to fail a while after execution. Column 5 of Table 7 presents GPU demand across failure reasons. To simplify the analysis, we select four most-dominant failure reasons each contributing around 10% or more of failures. When we correlate RTF with GPU demand, among the four failure types, *semantic error* exhibits a markedly distinct trend, with jobs that have higher GPU demand having relatively large RTFs, as compared to jobs having lower GPU demand. This results in disproportional impact on the actual resources utilized by failed jobs. We show this in Column 6 of Table 7.

Column 6 presents actual GPU times for failures while multiplying RTF by GPU demand. As the results show, compared to the RTF only, the impact of *semantic error* increases up to 17.06% from 9.22% while the other three types of failure are either decreased or unchanged. This corresponds to the fact that semantic error is relatively frequent in larger-demand larger-RTF jobs. Looking deeper, we observe that training program instances sometimes send, receive, and access data in an inconsistent way during model parameters synchronization. As a consequence, *semantic error* ranks the second in terms of GPU resources used among failures in our workload.

5 Design Implications for Future Schedulers

Based on our experiences and data-driven analysis so far, in this section we discuss guidelines pertaining to the design of next-generation schedulers for DNN training workloads.

Prioritizing locality. One of the main results from our analysis of GPU scheduling was that lack of locality impacts both utilization and job running time. Our current scheduler adopts a classic approach where it waits for a limited time to see if locality can be achieved and if not the job is scheduled with the resources available at relaxed locality. The main reason for this approach is to keep queuing time low as longer wait times affect user experience.

However given that deep learning jobs run for many hours or even days, incurring a 10% or 20% drop in efficiency could extend the job running time by multiple hours. Thus in such scenarios, waiting for locality for a longer time could be more beneficial. However this requires inferring long-running jobs and appropriately setting user expectations. An alternate strategy could be to *migrate* a job to machines with better locality if resources become available during the execution.

Mitigating interference. Another critical guideline for schedulers would be to consider job placement policies to mitigate inter-job interference. Instead of packing *different* small jobs on a single server, one option would be place them on dedicated servers, reducing sharing and thus interference among such jobs. Such an option would increase fragmentation and will result in larger jobs having to wait for longer if we have to prioritize for intra-job locality. Support for job migration to *defragment* the cluster [52], especially applied to smaller jobs, will mitigate interference for small jobs, and will improve intra-job locality for large jobs.

Improving failure handling. A large number of job failures we see come from user errors in code or configuration. This is primarily because programming languages in use are typically not strongly typed. We have found that simple syntax checking could prevent many errors (e.g., missing quotes or parenthesis) and some of the more sophisticated runtime failures can be captured by running the first iteration of training. We plan to set up a pool of cheaper VMs to pre-run jobs. Even running multi-GPU jobs on a single GPU will catch such errors before they run on larger shared clusters and thus prevent *wasted* GPU cycles on them. Training failures also happen due to erroneous data format (e.g., inconsistent columns in samples). We plan to investigate having a well defined schema for datasets used in machine learning, and perform a schema check while accessing data to reduce such errors.

Another useful extension for multi-tenant GPU clusters would be to develop a system to predictively mitigate failures by proactively observing related failures. The main goal of such a system would be to (i) classify error messages in real time from logs that training jobs generate, and (ii) adapting scheduling parameters per job (e.g., number of retries) as well as across jobs (e.g., input data blacklisting) to reduce failure occurrences. For example, the scheduler could stop retrying for failure categories like incorrect data/model input and continue retrying for network timeouts.

6 Related Work

Failure analysis of data analytics jobs in shared clusters. Prior work has looked at designing large-scale data analytics platforms assuming that failures are common [10, 17, 50]. They focus on framework support for fault-tolerance and reliable job execution. In this paper, we focus instead on understanding job failures in deep learning specific platforms.

Kavulya *et al.* conducted a detailed characterization for job failures in a production MapReduce cluster [30]. Some of their findings include: (1) Many jobs fail within a few minutes while the worst-case job takes up to 4.3 days for its failure to be detected. These failures occur due to data copy errors and are similar to HDFS-related failures that we observe taking much longer to detect; (2) Many failures are related to either exceptions due to array indexing errors or IO exceptions. We again see some similarity to our work where coding errors lead to a number of failure cases.

Scheduler and runtime for efficient machine learning execution. SLAQ schedules concurrent machine learning

training jobs based on quality improvement for resource usage, allocating cluster resources for average quality improvement [56]. While this may improve the quality across jobs, each individual job may take longer time to finish. Optimus [38] leverages the convergence curve to predict job remaining time for dynamic resource scheduling and reduces average job completion time. It adopts an online fitting model to derive a proper number of servers and workers for MxNet [15] jobs in parameter server architecture. Tiresias [22] reduces job completion times when many training jobs undergo a *trial-and-error* exploration where job remaining time to complete training cannot be estimated from the convergence curve. In this work, we found that a large job experiences highly varying efficiency over placement spectrum (e.g., Table 5), and that future schedulers may need to consider the trade-off between reducing queueing time and reducing job running time more carefully over a wide range of locality choices.

We also note that an earlier technical report of our work [27] was used to motivate new scheduling primitives in recent work on scheduling like Gandiva [52]. More importantly, our paper presents a systematic study of a large-scale production cluster, covering the whole lifecycle of deep learning jobs including queuing, execution, and failure. We hope that our study of large clusters dedicated to deep learning workloads will continue to motivate novel research in deep learning platforms and schedulers for these workloads.

GPU resource management for machine learning. There are recent efforts on GPU sharing for simpler machine learning tasks. Baymax [14] explores GPU sharing as a way to mitigate both queuing delay and PCIe contention. Following that, Prophet [13] proposes an analytical model to predict performance of GPU workloads. Gandiva [52] proposes GPU time-sharing in shared GPU clusters through checkpointing at low GPU memory usage of training job. Future work includes integrating these prior work to improve cluster utilization and capacity to run more jobs.

Many training networks are memory bound, especially by capacity. Ryu *et al.* analyzed memory allocation for ImageNet [25], with recent VGG-16 model consuming up to 28 GB of memory [40]. Therefore, vDNN [40] proposes virtualized memory manager, and SuperNeurons [51] adopts fine-grained layer-wise memory control to schedule memory flexibly between CPU and GPU. Our work shares some similarity with prior findings (*i.e.*, some large networks do not fit in GPU memory) in real-world data.

Approximate data processing. Approximate data processing allows trading off accuracy for earlier completion times [6, 9, 16, 24, 28, 55]. In databases, online aggregation has been studied in the context of SQL queries [16, 24, 55]. More recently, approximation has been used in batch processing [6, 8, 49]. Machine learning training presents a fertile ground for exploring trading off accuracy for early completion. In this paper, for the training workloads run on our clusters, we quantify how trading off a very small amount of accuracy (0.1%) can result in significant savings in GPU execution time.

7 Conclusion

In this paper we analyzed a trace of deep learning jobs run on a large multi-tenant cluster of GPUs and studied various factors that affect cluster utilization. Our findings indicated the importance of locality for distributed training jobs and also how interference from other colocated jobs could lead to lower GPU utilization. We also performed a detailed analysis of various failure causes and showed how errors from various parts of the stack contribute to failures. Based on our data analysis and experiences running a large-scale operation, we also described guidelines that could help future research and development of machine learning schedulers.

Finally, we have publicly released the scheduler trace containing information about job arrivals, job size, placement and runtime to the community. As far as we know, this is the only trace that includes rich information about deep learning training jobs run in production. By making such a trace available, we hope to spur future research in this area.

Abstract

Modern datacenters increasingly use flash-based solid state drives (SSDs) for high performance and low energy cost. However, SSD introduces more complex failure modes compared to traditional hard disk. While great efforts have been made to understand the reliability of SSD itself, it remains unclear what types of system level failures are related to SSD, what are the root causes, and how the rest of the system interacts with SSD and contributes to failures. Answering these questions can help practitioners build and maintain highly reliable SSD-based storage systems.

In this paper, we study the reliability of SSD-based storage systems deployed in Alibaba Cloud, which cover near half a million SSDs and span over three years of usage under representative cloud services. We take a holistic view to analyze both device errors and system failures to better understand the potential casual relations. Particularly, we focus on failures that are **R**eported **A**s "**S**SD-**R**elated" (**RASR**) by system status monitoring daemons. Through log analysis, field studies, and validation experiments, we identify the characteristics of RASR failures in terms of their distribution, symptoms, and correlations. Moreover, we derive a number of major lessons and a set of effective methods to address the issues observed. We believe that our study and experience would be beneficial to the community and could facilitate building highly-reliable SSD-based storage systems.

1 Introduction

Flash-based solid state drives (SSDs) have become an indispensable component of modern datacenters due to its superior performance and low power draw [6]. Various applications, including databases [14], social network [15], and online shopping [41], have been supported by large-scale SSD-based storage systems. Therefore, the reliability of such systems is of critical importance.

However, it is challenging to maintain the high reliability of SSD-based storage systems. First, unlike hard disk drives (HDDs), SSDs may experience unique flash errors (e.g. program errors [20, 38]) which are sensitive to the environment (e.g., temperature [30]). Therefore, our decades of collective wisdom on HDDs is not fully applicable. Second, issues in the traditional HDD-based storage stack (e.g., faulty interconnection and human mistakes [28]) may continue to haunt SSD-based storage systems. In addition, due to the complexity of storage systems, the potential correlations among various events across different levels/components are not well-understood, rendering extreme difficulty in pinpointing the root causes of system failures or comping up with effective fixes.

To address the challenges, substantial efforts have been made to understand the reliability of SSD itself [24, 33, 38, 44]. For example, Schroeder et al. [38] study flash errors and discover correlations between flash errors and other device attributes (e.g., age, wear, lithography). Zheng et al. [44] analyze the behavior of SSDs under power faults. Narayanan et al. [33] analyze a diverse set of device factors (e.g., design and provisioning) and their correlations with failed SSDs. Hao et al. [24] study the performance instability involving millions of drive hours, especially the device latency in RAID groups. While these studies provide valuable insights on the characteristics of SSDs, it remains unclear how SSDs interact with the rest of the system and contribute to system failures.

Besides the work on SSDs, studies on HDD-based storage systems are also abundant [7, 8, 28, 35, 37]. Apart from understanding HDD errors in the field [7, 35, 37], researchers analyze the correlations between HDD errors and system failures [8, 28]. However, since SSD-based systems are significantly different from HDD-based systems (e.g., the TRIM command support throughout the OS kernel [2]), it is unlikely that these studies and findings are directly applicable to SSD-based storage systems.

In this paper, we look into the storage systems deployed in 7 datacenters of Alibaba Cloud, which includes around 450,000 SSDs over 3 years' deployment. Similar to other large-scale deployed systems [16, 17, 29, 42], our target systems are equipped with system monitoring daemons de-

ployed on each node of the clusters. The daemon monitors abnormal behaviors by constantly checking the BIOS messages at boot time, the kernel syslog at runtime, and the functionality and availability of the cloud services. Upon an abnormal event, the daemon will report a failure ticket with the timestamp, the component involved, and a snippet of corresponding logs.

Among all failure tickets, we focus on failures that are **R**eported **A**s "**S**SD-**R**elated" (**RASR**) in this paper. Also, we collect the corresponding repair logs of the failures as well as the SMART [4] logs of the SSDs involved. By holistically analyzing the three datasets (i.e., failure tickets, repair logs, and SMART logs) in the context of the storage systems design and deployment, we identify a number of interesting characteristics of RASR failures in terms of distributions, symptoms, and correlations. Moreover, we perform field studies and validation experiments to understand in depth the factors affecting RASR failures, and to derive a number of major lessons as well as realistic remedies for hardware architects, software engineers, and system administrators. More specifically, our contributions include the following:

(1) Characteristics of RASR Failures. We collect about over 150K failure tickets in total from the target systems. Among these failure tickets, we find that 5.6% are RASR failures (i.e., about 10K instances), which manifested in five symptoms: *Node Unbootable*, *File System Unmountable*, *Drive Unfound*, *Buffer IO Error*, and *Media Error*. By correlating the RASR failures with the repair logs, we find that a significant number (34.4%) of RASR failures are *not* caused by the SSD device. For example, plugging SSDs into wrong drive slots, a typical *human mistake*, accounts for 20.1% of RASR failures. Moreover, for RASR failures caused by SSDs, we find that both the location of devices (i.e., in different datacenters) and the type of cloud services may affect SSD failure rates.

(2) Lessons and Actions for Hardware Architects. We find that the suboptimal intra-node SSD stacking and intra-rack node placement can lead to *passive heating* (i.e., heating on *idle* SSDs by neighboring active SSDs), which may in turn cause a large number of device errors and high failure rates. Moreover, by experimenting on a dedicated cluster with continuous temperature monitoring, we are able to verify that the poor rack architecture can increase the temperature of *idle* SSDs by up to 28 C°, resulting in 57% more device errors after 128 hours of passive heating.

To reduce the impact of passive heating, we formulate a new strategy for intra-rack node placement. Furthermore, we propose a proactive approach to alleviate the passive heating by routinely scanning the entire device to trigger the FTL internal read refresh [11]. Different from the traditional data scrubbing [5, 31], the scanning is lightweight enough to be scheduled more frequently to reduce the effect of passive heating. Our results show that performing a scanning every 4 hours can offset most negative impact of passive heating. Although not observed in our experiments, the scanning may potentially lead to more read disturbs [10], affecting the device negatively. Therefore, we believe it would be ideal for the vendors to implement the proactive scanning at the FTL.

(3) Lessons and Actions for Software Engineers. We find that both the data allocation scheme in the service software stack and the I/O pattern of cloud services play important roles in affecting SSD reliability and leading to RASR failures. For example, the Block service, empowered by a direct mapping based data allocation scheme, can cause severe imbalance of SSD usage when running on top of an HDFS-like distributed file system (DFS): 15-20% SSDs are overly used, which causes up to 77.3% more device errors and up to 18.7% higher device failure rate. Inspired by the log-structured file system [36], we optimize the data allocation scheme on the target systems by adding a shared appending log, and thus mitigate the imbalance issue.

(4) Lessons and Actions for System Administrators. By co-analyzing device-level and system-level logs, we discover a strong correlation between one type of RASR failures (i.e., those caused by faulty interconnection) and one type of device errors (i.e., Ultra-DMA CRC or UCRC). Based on this observation, we design an indicator for the faulty interconnection issue based on the accumulation of UCRC errors, which significantly improves the repair procedure of relevant failures. In addition, we find that SSDs on the target systems serve three different purposes (i.e., system drives, storage, and buffering), but they all use the same SATA interface. This causes much confusion for system administrators who need to replace drives. To reduce the chance of plugging SSDs into wrong drive slots (cause of 20.1% RASR failures), we adapt the systems to use different SSD interfaces for different purposes (e.g., U.2/M.2 for system drives and SATA for storage). This optimization effectively eliminates the confusion and reduce the corresponding failures.

To the best of our knowledge, our work is the first effort on understanding the characteristics of RASR failures as well as the causal relation between SSD errors and the system design and usage, in large-scale production systems. Based on this study, we have significantly improved the reliability of practical systems through a number of simple yet effective mechanisms (e.g., proactive data scanning, UCRC-based indicator and specializing interfaces). We believe that our study and lessons would be beneficial to the community, and could facilitate building highly-reliable SSD-based storage systems.

The rest of the paper is organized as follows: §2 introduces our methodology; §3 analyzes the characteristics of RASR failures; §4 - §6 discusses our lessons and actions for hardware architects, software engineers, and system administrators, respectively; §7 discusses related work, and §8 concludes the paper.

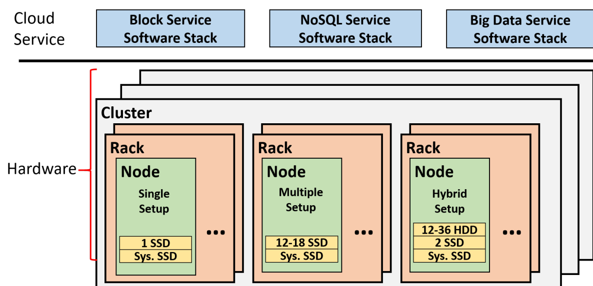

Figure 1: Architecture of target systems.

Model	Capacity	Lithography	Age	Vendor
M1	480 GB	20 nm	2-3 yrs	A
M2	800 GB	20 nm	2-3 yrs	A
M3	480 GB	16 nm	1-2 yrs	A
M4	480 GB	20 nm	2-3 yrs	B
M5	480 GB	20 nm	1-2 yrs	C

Table 1: Characteristics of SSDs in the target systems.

2 Methodology

2.1 System Architecture

We study SSD-based large-scale storage systems deployed in 7 datacenters. The architecture of the target systems is shown in Figure 1.

At the device level, the systems include around 450,000 SSDs spanning three years of deployment. As shown in Table 1, these SSDs cover a spectrum of variability in terms of capacity, lithography, age, and vendors. Note that all five models in our dataset are using SATA interfaces and based on MLC NAND cells.

Each node in the systems employs one of three different setups of SSDs: (1) *Single*: a node contains one SSD for storing temporary data; (2) *Multiple*: a node contains 12 to 18 SSDs for persistent storage; (3) *Hybrid*: a node contains 2 SSDs and 12 to 36 HDDs where the SSDs are used for buffering incoming writes. In addition, each node has one SSD serving as the system drive.

A rack consists of 16 to 48 nodes, and a DFS cluster spans 12 to 18 racks. On top of the DFS, the system supports three types of cloud services, including Block service, NoSQL service, and Big Data service. As shown in Table 2, the cloud services may run on different setups where the SSDs are used for different purposes.

2.2 Raw Datasets

The target systems include sophisticated monitoring mechanisms, similar to other large-scale systems [16, 17, 29, 42]. The monitoring daemons are deployed on each node of the clusters, and they log various events either periodically or upon the occurrence of an event.

At the system level, the daemons monitor BIOS messages,

Service	SSD Model	Setup	Usage
Block	all models	Hy/Mul	Pers/Buf
NoSQL	M1, M3, M4, M5	Hy/Mul	Pers/Buf
Big Data	M1, M2, M4	Single	Temp

Table 2: Cloud services and SSD usages. ***Hy****: Hybrid;* ***Mul****: Multiple;* ***Pers****: Persistent storage;* ***Buf****: Buffering writes;* ***Temp****: Temporarily storing intermediate data.*

kernel syslogs, and the service-level verification of data integrity. Upon an abnormal event, the daemon reports a failure ticket with the timestamp, the related hardware component, and a log snippet describing the failure. Each failure ticket is tagged based on the component involved. For example, if an SSD appears to be missing from the system, the failure ticket is tagged as ”SSD-related”. If there is no clear hardware component recorded in the logs, the ticket would be tagged as Unknown.

At the device level, the daemons record SMART attributes [4] on a daily basis, which cover a wide set of device behaviors (e.g., total LBA written, uncorrectable errors).

Besides the failure tickets and SMART logs, we collect the repair logs of all RASR failures, which are generated by onsite engineers after fixing the failures. For each failure event, the corresponding repair log records the failure symptom, the diagnosis procedure, and the successful fix.

2.3 Study Approaches

After collecting the failure tickets, the SMART logs, as well as the repair logs, we apply the following approaches to derive insights:

- **Log analysis:** We calculate the distributions of failure events along multiple dimensions (e.g., hardware types, manifestation symptoms). Moreover, since the number and the variety of events in the logs is large, we leverage classic statistical algorithms (e.g., Spearman Rank Correlation Coefficient [12]) to analyze the characteristics of individual events as well as the potential correlations among different events.
- **Field studies:** Besides the log analysis, we visit the datacenters in person to investigate the potential variance of target systems in terms of cluster architectures, which turns out to be critical for discovering the passive heating phenomenon (§4). Also, we discuss with on-site engineers to empirically verify our hypothesis on RASR failures.
- **Validation.** We build a dedicated cluster to validate our hypothesis. Moreover, to address the issues exposed in our study, we design a set of remedy methods, and validate the effectiveness and practicability on production systems.

2.4 Limitations

Failure Reporting. Our study relies on the failure tickets reported by distributed daemons that automatically monitor the health condition of system components from hardware to software. The daemons may fail to record (e.g. network

RASR Failure Symptom	Meaning	Distribution
Node Unbootable	Unable to boot the OS on a node	2.6%
File System Unmoutable	Unable to mount a local file system	7.4%
Drive Unfound	A device cannot be found by the system software	53.7%
Buffer IO Error	Unable to write data from memory buffer to the device	17.3%
Media Error	Unable to read correct data from the device	19.0%

Table 3: Distribution of RASR failures based on manifestation symptoms. *This table shows five different symptoms of RASR failures and the corresponding percentage.*

Hardware Type		Distribution
CPU		0.7%
Memory		8.5%
Network		34.0%
Motherboard		5.4%
Storage	HDD	22.1%
	SSD	5.6%
Unknown		23.7%

Table 4: Distribution of failure tickets based on hardware types. *This table shows the distribution of failure tickets that are tagged as related to major hardware components.*

RASR Failure Symptom	Affected Rate (‰)				
	M1	M2	M3	M4	M5
Node Unbootable	0.24	0.42	0.15	0.13	0.07
FS Unmountable	1.28	1.05	0.42	2.90	2.04
Drive Unfound	11.19	8.58	5.31	11.51	4.38
Buffer IO Error	3.73	1.34	1.36	4.06	1.21
Media Error	3.42	5.24	2.81	5.73	1.33

Table 5: Distribution of RASR failures among five SSD models. *This table shows the affected rate of each SSD model (M1-M5), which is the number of SSDs involved in one type of RASR failures divided by the total number of SSDs with the same model.*

failure during log collection) or inaccurately tag the events (e.g. a node crash tagged as "Unknown" due to insufficient logs). However, to the best of our knowledge, the way the tickets are reported is the common practice widely used in major large-scale production systems and previous studies on large-scale deployed systems also rely on similar mechanisms for collecting datasets [16, 17, 29, 42].

Software Stack Design. Our software stack includes OS, DFS and service components. Apart from using a major distribution of Linux, our DFS and service software are not open-source. Nonetheless, they share generic similarities with popular large-scale storage systems such as HDFS [39] and Google File System [19], and similar high-level services are provided by other companies such as EBS [1] and DataStore [3].

Hardware Products. Like previous works [32, 33], the target systems use off-the-shelf hardware products such as SSDs and interconnects. Many products are also widely deployed in the datacenters of other organizations. Therefore, users from other organizations may encounter the same or similar hardware-related issues, and we hope they can benefit from our experiences.

3 Characteristics of RASR Failures

3.1 Overview of Failure Tickets

We collect all failure tickets reported as related to hardware components, over 150K tickets in total. Table 4 shows the distribution of the failure events based on the types of hardware components involved, including CPU, Memory, Network, Motherboard, HDD/SSD, and Unknown. The Unknown type refers to the failures where a relevant component is not specified in the daemon-reported ticket. The second column shows the percentage of failure events for each type of hardware. According to our daemon setup, no failure event is tagged with more than one type.

As shown in Table 4, storage components (i.e., HDD and SSD combined) contribute to 27.7% (i.e., 22.1% + 5.6%) of all hardware-related failure events. RASR failures alone account for 5.6%. Compared with other hardware components (e.g., Network which accounts for 34.0%), RASR failures are much fewer in our dataset. This is consistent with the findings from previous studies that SSD is a relatively reliable component among all hardware components deployed in datacenters [6, 33].

Nonetheless, since the total number of failure events is large (i.e., over 150K), even a relatively small percentage (i.e. 5.6%) of failures cannot be ignored. Therefore, we perform an in-depth analysis on RASR failures in this study and present detailed results in the following sections.

3.2 Symptoms of RASR Failures

After analyzing all RASR failure logs, we find that RASR failures can manifest in multiple ways. As shown in Table 3, there are five different types of manifestation symptoms, including *Node Unbootable, File System Unmountable, Drive Unfound, Buffer IO Error,* and *Media Error*. The meaning of each symptom is described in the second column of the table. Also, the distribution of each type of symptoms is listed in the last column of Table 3.

Among the five symptoms, the Drive Unfound type, which means the device cannot be found by the system software, is the dominant one (i.e., accounts for 53.7%). Based on

Node Unbootable	File System Unmountable	Drive Unfound	Buffer IO Error	Media Error
1.Slot Check(53.8%) 2.Repl. SSD(46.2%)	1.Mnt. Opt. Check(5.4%) 2.FSCK(40.5%) 3.Repl. SSD(54.1%)	1.Rebooting(22.2%) 2.Slot Check(34.8%) 3.Repl. Cable(25.9%) 4.Repl. SSD(16.1%)	1.FSCK(79.8%) 2.Repl.SSD(20.2%)	1.Data Check(30.2%) 2.Repl. SSD(69.8%)

Table 6: Repairing procedures of RASR Failures and their successful rates grouped by symptom. *The first row shows five manifestation symptoms of RASR failures. The 2nd row lists repairing procedures for each symptom. The repairing follows an order as indicated by the number before each fix approach. The rate in the parentheses after each fix indicates within that symptom group the percentage of failures fixed by that approach. Repl.: replacing; Mnt. Opt.: Mount Options.*

RASR Failure Symptom	Affected Rate (‰)		
	Block	NoSQL	BigData
Node Unbootable	0.27	0.12	0.35
FS Unmountable	1.43	1.05	1.42
Drive Unfound	13.25	10.58	9.31
Buffer IO Error	5.73	2.34	5.36
Media Error	8.42	3.24	3.77

Table 7: Distribution of RASR failures among cloud services. *This table shows the affected rate of each cloud service (i.e. Block service, NoSQL service and Big Data service), which is the number of M1 SSDs involved in one type of RASR failures divided by the total number of M1 SSDs within the same cloud service.*

RASR Failure Symptom	Affected Rate (‰)				
	DC1	DC2	DC3	DC4	DC5
Node Unbootable	0.35	0.31	0.21	0.27	0.23
FS Unmountable	1.08	1.25	1.42	1.90	1.04
Drive Unfound	10.33	12.72	13.31	13.96	14.10
Buffer IO Error	2.95	2.14	1.98	1.86	2.12
Media Error	2.06	3.04	2.85	**7.73**	3.75

Table 8: Distribution of RASR failures among datacenters. *This table shows the affected rate of each M1 SSD under the Block service from 5 datacenters (DC1-DC5), which is the number of M1 SSDs involved in one type of RASR failures divided by the total number of M1 SSDs under the Block service within the same datacenter.*

our discussion with on-site engineers, a Drive Unfound event may be masked by the system software (e.g., automatic redirection of I/O requests and re-replication of data), and may not necessarily lead to data loss. However, the event can still cause additional latency on the I/O requests involved, and usually requires engineers to diagnose the issue on site. Similarly, other types of RASR failures may also affect system performance and consume manual efforts. Therefore, it is important to understand the root causes of RASR failures and improve the failure handling. We discuss the analysis on fix procedures in §3.3.

After observing the distribution of RASR failure symptoms, we further study the correlation between RASR failure symptoms and other important factors, including SSD models, service workloads, and datacenter locations.

As mentioned in Table 1, there are five different SSD models in our target systems. To further understand the potential impact of SSD models on RASR failures, we calculate the failure affected rate for each model, which is the number of SSDs involved in one type of RASR failures divided by the total number of SSDs with the same model. As summarized in Table 5, the five RASR failure symptoms have been observed on all five SSD models (M1-M5). The affected rate ranges from 0.07‰ (i.e., M5 SSDs with the Node Unbootable symptom) to 11.51‰ (i.e., M4 SSDs with the Drive Unfound symptom). We do not observe statistically significant difference among SSD models in terms of the affected rate of RASR failures, which suggests that RASR failures may not be directly related to the characteristics of SSD models.

To study the correlation between RASR failures and service workloads running on the target systems, we use M1 SSDs, a popular model accounting for 35% of the drive population. Table 7 shows the affected rates of M1 SSDs under three cloud services. We observe that the Block service (2nd column) has the highest affected rates in four out of five types of RASR failures (except Node Unbootable). This finding motivates us to further investigate the cloud services with their designs, drive usage and device level errors in §5.

In addition, we study whether the location (i.e. datacenters) plays a role in RASR failures. We evaluate the affected rates of M1 SSDs under the Block service (i.e. the main service accounting for for 57% of SSD deployment) in different datacenters (DCs). Table 8 summarizes the results. Note that M1 SSDs of the Block service are only used in five datacenters, i.e., from DC1 to DC5. From the table, we observe that while no DC dominates all failure types, DC4 has substantially more Media Errors (i.e. last row), indicating more data corruptions. To better understand the potential root causes, we study the uniqueness of DC4 in terms of hardware architectures, especially the SSD placement in §4.

3.3 Fixes of RASR Failures

To understand the potential root causes of RASR failures, we further analyze the corresponding repair logs. For each failure, administrators apply a symptom-based repairing procedure, i.e., trying a pre-defined sequence of fix candidates one by one based on the failure symptom until the failure dis-

appears. Each repair log records the repairing process and the successful fix of a failure event. Table 6 summarizes the pre-defined sequence of fix candidates for each RASR failure symptom. Also, for each fix candidate, we calculate its successful rate in the group of failures with the same symptom (shown in the parentheses).

For instance, after observing a Drive Unfound failure (3rd column of Table 6), administrators will first attempt to remotely reboot the node to check whether the failure is transient ("Rebooting"). If not, administrators will manually check whether the device is plugged into the correct slot ("Slot Check"). If the slot is correct, administrators will then try replacing the cable ("Repl. Cable"), followed by replacing SSD ("Repl. SSD") as a final resort until the failure is resolved. Note that all RASR failures are eventually fixed by replacing SSDs if previous attempts do not work.

One observation on Table 6 initially puzzling us is that the first fix attempt is not always the most effective one within each group of failures. For example, "Mnt. Opt. Check" (Mount Options Check) works only for around 5% of File System Unmountable failures (2nd column). Similarly, "Data Check" cures 30.2% of Media Error events (last column). After discussing with administrators, we realize that the symptom-based repairing procedure overall is simple yet effective. Specifically, the order of the fix candidates for each failure symptom is first based on their costs, followed by their effectiveness. As a result, the set of software-based fixes (i.e., checking mount options, rebooting, FSCK, and data check) are always preferred over the set of manual or hardware-based ones (i.e., slot check, replacing cable, and replacing SSD). The order within either set of fix candidates is based on their effectiveness to solve the failure symptoms in administrators' past experiences. The sequence of fix candidates for repairing Drive Unfound (3rd column) clearly demonstrates the ordering consideration.

Although existing fix procedure is effective to certain degree, it is a black-box approach (trail-and-error) since the administrators do not know the root causes before applying the fix candidates. This motivates us to conduct in-depth study on the potential root causes of RASR failures for helping system administrators with better fix strategy. As will be discussed in §6, we identify an accurate indicator for one type of failures (§6.1) and propose a method for avoiding another type of failures (§6.2).

3.4 SMART Logs under RASR Failures

The device level SMART [4] log is an important dataset for analyzing SSD behaviors and failures in the field [32, 33, 38]. Similar to previous studies [32, 33, 38], we analyze a subset of SMART attributes (as shown in Table 9) on our target systems in depth and observe a number of characteristics which are consistent with the prior work (e.g., the prevalence of uncorrectable errors and the high raw bit error rate on failed drives). Due to space limit, we do not discuss the observations or the distribution of SMART attributes that are similar to prior work. Instead, we correlate the SMART logs with RASR failures in later sections and analyze the impact of different factors (e.g., hardware architecture and software design) on drive behaviors.

Device Level Event	Definition
Host Read	Total amount of host LBA read from SSD
Host Write	Total amount of host LBA write to SSD
Program Error	Total # of errors in NAND programming operation
Raw Bit Error Rate (RBER)	Total bit corrupted divided by total bits accessed
End-to-End Error (E2E)	Total # parity check failures between drive and host
Uncorrectable Error	Total # of data corruption beyond ECC's ability
UDMA CRC Error (UCRC)	Total # of CRC check failures during Ultra-DMA

Table 9: Device level events collected in our study.. *Device level events are collected via SMART [4]. All events are recorded in a cumulative manner.*

4 Lessons & Actions for Hardware Architects

During our characteristics study of RASR failures (§3), we observe that SSDs deployed in one particular datacenter (DC4) experience much more Media Error under the Block Storage service (Table 8). Moreover, these SSDs have higher Raw Bit Error Rate (RBER) and Uncorrectable Bit Error Rate (UBER) based on the SMART logs.

To understand why the Block service in DC4 is so unique, we perform field studies at DC4 and other datacenters. We find that there are two potential factors. First, in DC4, about 27.1% Block service nodes are equipped with 18 SSDs, while in other datacenters less than 5.3% Block service nodes have 18 SSDs (most nodes have 12 SSDs). Second, in DC4, nodes for different services are often co-located in the same rack, while in other datacenters a rack is exclusively used for a single service. In this paper, we refer to the two factors as *intra-node SSD stacking* and *intra-rack node placement*, respectively, both of which affect the SSD placement in the systems. Since NAND flash memory is known to be less reliable under higher temperature [9] due to the Arrhenius Law[34], we suspect that the SSD placement may affect the airflow in nodes and racks, which may in turn affect the operating temperature of neighboring SSDs, and then lead to abnormal behaviors. We refer to this hypothesis as *passive heating*.

Note that passive heating is different from heating mechanisms used in prior work for analyzing NAND flash or

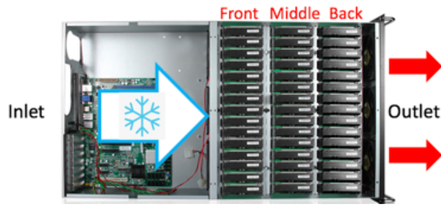

Figure 2: Intra-node SSD stacking and the airflow. *This figure shows the stacking of SSDs within a node, which include three groups:front, middle and back. The arrows indicate the direction of the airflow for cooling. Note that due to confidentiality, we cannot show the real photo of the node deployed in our target systems; however, the actual node is very similar to this example.*

SSD under high temperatures. Specifically, in the studies on NAND retention errors, NAND chips are heated to high temperature without power supply (e.g., heating in the oven) [9]. Differently, SSDs in our study are always powered on, where the FTL may proactively reduce NAND errors. In previous studies on the impact of SSD temperatures, they mostly focus on active heating, i.e., heating the SSDs by *heavily accessing* them. In such case, high temperature may trigger the throttling mechanism in FTL to reduce errors [32]. On the contrary, the passing heating we observe may affect *idle* SSDs, which cannot be remedied by throttling (because there is no heavy on-the-fly flash operations to throttle). Therefore, we believe it is necessary to investigate the passive heating further.

4.1 Identify and Verify Passive Heating

With the help of on-site engineers, we identify three potential scenarios where SSDs may suffer from excessive passive heating:

- **Hot Airflow.** Figure 2 shows an example of stacking of multiple SSDs within a node and the airflow for cooling. In this design, idle SSDs at the outlet of the airflow may be heated up when the front SSDs are being accessed heavily.
- **Hot Neighbors.** If an idle node is close to another node running intensive workloads, SSDs in the idle node may be heated up by the hot neighboring node.
- **Hot Air Recirculation.** When a node is removed out of the rack, the empty node slot may serve as a channel for tunneling hot airflow and passing heat to nearby nodes (one empty node slot away).

To verify and measure the passive heating, we build an experimental cluster with continuous monitoring of SSD temperatures and controlled workloads. The cluster includes 8 nodes in a dedicated rack, and each node has 18 SSDs. We perform the following experiments to analyze the passive heating in each of the aforementioned scenarios.

For Hot Airflow, we first record the initial temperature of the SSDs near the outlet of the airflow when a node is just powered on. Then, we run intensive workloads to access the 6 front SSDs (i.e. SSDs close to the inlet of the airflow), but leave the remaining 12 SSDs idle. We compare the temperatures of the idle drives before and after running the workloads.

For Hot Neighbors, we run intensive workloads on some nodes, and keep monitoring the temperatures of the SSDs on the neighboring idle nodes. We try three configurations where the hot neighbor(s) is atop, below, or are at both sides of the idle node.

For Hot Air Recirculation, we remove a node from the rack and examine whether the temperature of the SSDs of an idle node can be affected by a hot neighbor that is one node slot away.

Our experiments show that for an idle SSD initially at 25 C°, it can be heated up by 23 C°, 9 C°, and 17 C° (i.e., reaching 48 C°, 34 C°, and 42 C°) via Hot Airflow, Hot Neighbors, and Hot Air Recirculation, respectively. Moreover, when combining the three effects, an idle SSD can be heated up by 28 C° (i.e., reaching 53 C°) on our cluster.

4.2 Effects of Passive Heating on SSDs

After verifying that the suboptimal SSD placement may generate undesirable passive heating on SSDs, we look into the impact of passive heating on SSDs' behavior. In this set of experiments, we compare the raw bit errors of SSDs at three levels of temperatures under passive heating: 35C°, 45C°, and 55C°. Note that we use a fixed temperature interval (i.e., 10C°) to make the correlation between errors and passive heating more clear.

Specifically, in each experiment, we heat up idle SSDs (initially 25C°) through passive heating until they reach one of the three levels of higher temperatures, i.e., 35C°, 45C°, or 55C°. At each level, we maintain the same temperature for a range of time durations, i.e., from 1 to 128 hours, by carefully adjusting the workloads on neighboring nodes based on the feedback of the measured SSD temperature. After the stable passive heating period finishes, we scan the whole device and measure the Raw Bit Errors[1] newly generated during the heating period.

Figure 3 summarizes the results. We find that all three levels of passive heating (i.e., 35C°, 45C°, and 55C°) may lead to more Raw Bit Errors compared with normal case (i.e., 25C°). Additionally, a higher level of passive heating (e.g., 55C°) for a longer period of time (e.g., 64 hours) can generate more Raw Bit Errors, and the increasing trend is non-linear. Moreover, after 128 hours of heating, we observe that idle SSDs suffer from 57% more Raw Bit Errors.

Note that our observation in this set of experiments (i.e., higher temperature leads to more retention errors) aligns well with previous studies and industry standards[27, 32]. However, it contradicts to a recent study on 3D NAND flash chips [30]. This is likely because the structure and characteristics of 3D NAND are different from those used in our systems

[1] We do not use the Raw Bit Errors Rate (RBER) attribute directly because it is a cumulative value over the entire lifespan of a device.

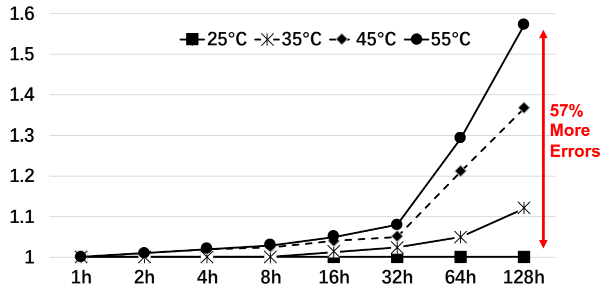

Figure 3: Raw Bit Errors generation under passive heating through time

(e.g., charging trap versus floating gate).

Although in our small scale experiments we do not observe uncorrectable errors or RASR failures, we believe that the results (e.g., increasing Raw Bit Errors) indicate that SSDs may become less reliable due to passive heating, and the phenomenon deserves more attention.

4.3 Offset the Impact of Passive Heating

Since the idle SSDs that are suffered from passive heating do not serve any I/O (before measuring the Raw Bit Errors), the increased Raw Bit Errors are most likely due to a retention issue. Classic techniques like data scrubbing can effectively mitigate retention issue by scanning and checking data integrity. However, it is unrealistic to apply such techniques frequently due to the prohibitive performance overhead.

On the other hand, we realize that the FTL in SSDs usually has a mechanism called Read Refresh [11] to correct bit errors and reallocate data during reading. So we propose to apply a lightweight regular software-based scanning to trigger read refresh (without computing checksums) to offset the negative impact of passing heating on idle SSDs. To verify our proposed method, we experiment on different intervals of scanning (e.g., 1 to 128 hours) and measure the reduction of Raw Bit Errors. Our experimental results are very promising: a routine scanning of every 4 hours can effectively control Raw Bit Errors without incurring too much overhead in our target systems. For example, after we perform a 4-hour routine scanning on the idle SSD during its 128 hours of passive heating under 55 C°, we only observe 1% more Raw Bit Errors, which is in stark contrast to 57% more Raw Bit Errors without scanning. Further increasing the frequency of scanning do not reduce the errors much. Therefore, the 4-hour-scanning routine achieves a good balance between the effectiveness and overhead in our systems.

While triggering read refresh by routine scanning is helpful for offsetting the impacts from passive heating, there are other potential issues with its direct deployment on production systems. First, the routine scanning requires fine-grained temperature monitoring to detect passive heating. Currently, the SSD temperature on our target systems is obtained by querying the SMART logs. Similar to other cloud companies [32, 33], the SMART logs are pulled on a daily basis in our production systems, which is insufficient for monitoring passive heating. Increasing the query rate requires changes to the distributed monitoring daemons and may affect the quality of service. While some hardware-based temperature querying methods (e.g., IoT sensors [18]) are relatively lightweight, integrating them into production systems may require significant efforts.

Second, the scanning might introduce more read disturb errors [10]. Although the scanning does not necessarily read the entire disk (i.e. only the stored data) or blindly get executed every 4 hours (i.e. only when SSD is in passive heating for more than four hours), the SSD may still suffer from increasing device errors due to read disturbance. This may further deteriorate as the lithography becomes smaller. Therefore, while effective, it is difficult to directly apply the routine scanning used in our experiments to production systems.

Alternatively, it is possible to implement our proposed technique of detecting and remedying passive heating in FTL with vendors' support. First, many SSDs today support heat throttling in the FTL, which implies that the temperature is already closely monitored by the device. Second, the FTL has the best knowledge of which parts of the data have higher error rates, and thus can react accordingly by proactively read refreshing the corresponding data. Therefore, the FTL-based solution may be more effective. We hope our study can raise the awareness of passive heating and facilitate addressing the issue.

5 Lessons & Actions for Software Engineers

As shown in Table 7, the SSDs under the Block service suffer more RASR failures than the devices under the other two services. This finding motivates us to further investigate the behavior differences of the SSDs among the three services, as well as the potential causes and fixes.

5.1 Usage Imbalance in Block Service

We start with the SSD usage, the most fundamental statistics of device behaviors. The three cloud services (i.e. Block, NoSQL, and Big Data Analytics) supported by our target systems are intrinsically different in terms of data placement policies and I/O patterns, which may lead to different usage patterns of SSDs. To understand the basic usage, we compare two device-level events: *Host Read* and *Host Write*, which measure the amount of data read from or written to the device by the host.

More specifically, we measure the hourly average value of host read/write (i.e., total sizes of host read/write divided by total power-on hours) on all SSDs under each cloud service. Moreover, we calculate the variability of the two metrics among SSDs under the same service using the coefficient of variation (CV), which is the ratio of standard deviation to

		Host Read	Host Write
Avg. Value /Hour	Block	7.69 GB	6.56 GB
	NoSQL	6.10 GB	5.28 GB
	BigData	1.57 GB	1.22 GB
CV	Block	35.5%	24.9%
	NoSQL	3.2%	6.2%
	BigData	1.8%	3.7%

Table 10: Comparison of SSD usages under three services in terms of host read and host write. *CV: Coefficient of Variance, the ratio of standard deviation to mean.*

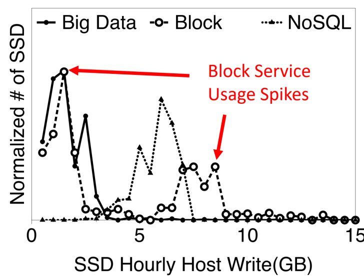

Figure 4: Distribution of SSDs under three services. *This figure shows the distribution of SSDs in terms of hourly host write under three services. The arrows mark the bimodal usage under the Block service.*

mean. Intuitively, a higher CV indicates that the hourly host read/write varies more across SSDs.

Table 10 summarizes the results. We can see that the hourly average value of host read and host write of the Block service are 7.68 GB and 6.56 GB, respectively, which are similar to those of the NoSQL service. However, the Block service has much higher variances for the two metrics (i.e., 35.5% and 24.9%), which implies that the usage of SSDs under this service is much more unbalanced.

Figure 4 further illustrates the distribution of SSDs in terms of hourly host write under the three services by using a histogram with 0.5 GB buckets along the x-axis. Each dot on the line (e.g., solid line for Big Data) represents the cumulative count of SSDs in the corresponding usage bucket. We can see from the figure that the majority of SSDs under NoSQL and Big Data Analytics services have similar usages (i.e., one major spike on the corresponding curve). In contrast, the SSDs under Block Storage service shows bimodal usages (i.e., two spikes far apart) as marked in the figure. Further analysis shows that the overly used drives (i.e. the right spike) account for around 17% of all SSDs in the Block Storage service and have 227.1% more write usage. The distribution of SSDs in terms of hourly host read exhibits similar pattern.

With such an unbalanced usage pattern, the overly-used set of SSDs may be worn out quickly. As a result, compared with averagely-used SSDs (i.e., balanced usage), overly-used

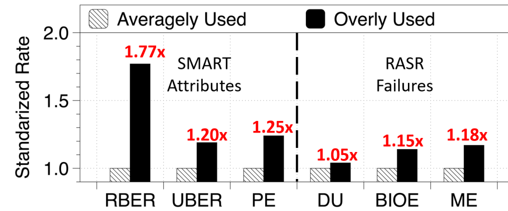

Figure 5: Comparison of overly used SSDs and averagely used SSDs. *This figure shows overly used SSDs exhibit more device level errors and RASR failures compared with averagely used SSDs. RBER: raw bit error rate; UBER: uncorrectable bit error rate; PE: program error count; DU: Drive Unfound; BIOE: Buffer IO Error; ME: Media Error.*

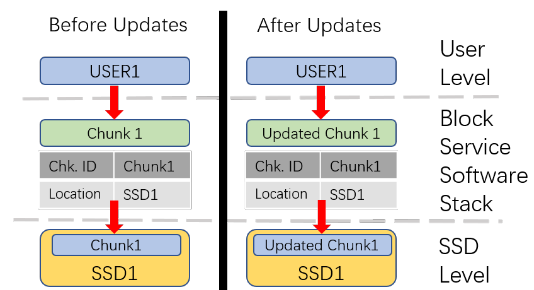

Figure 6: The data path of an update operation (original).

SSDs may exhibit more device-level errors and potentially lead to more RASR failures. To verify this hypothesis, we quantitatively measure such difference based on our dataset. We use the classic 80/20 rule to group the SSDs. The SSDs with top 20% usage within the Block Service are labeled as overly-used and the rest are labeled as averagely-used. As shown in Figure 5, overly-used SSDs have noticeably higher numbers of device errors including RBER (1.77X), UBER (1.20X) and PE (1.25X). Moreover, they tend to incur more RASR failures including Drive Unfound (1.05X), Buffer IO Error (1.15X), and Media Error (1.18X). This result suggests that load balancing is indeed important.

5.2 Root Causes of Usage Imbalance

After looking into the design of software stacks of the three cloud services, we identify two major factors for the unbalanced usage of SSDs in the Block service: the update policy and the user I/O patterns.

Figure 6 shows the simplified update policy in the Block service (for clarity, irrelevant details such as sharding and replication are omitted). The Block service offers users the storage capacity at the granularity of chunks. The left part of the figure shows that USER1 subscribes one chunk ("Chunk1") from the service. The software stack of the Block service maintains a mapping table from the chunk to a fixed SSD (i.e., storing "Chunk1" on"SSD1").

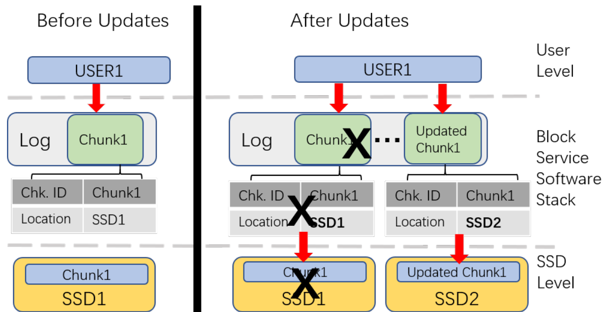

Figure 7: The data path of an update operation (optimized).

Upon an update operation, shown in the right part of Figure 6, the software stack queries the mapping table and writes the updated chunk to the *same* SSD (i.e., "Updated Chunk1" on "SSD1"). In other words, in the Block service performs *in-place* updates, i.e., updates are always flushed to the initially-allocated SSDs.

In addition, we find that the Block service receives a diverse set of I/O requests from different users. Some users generate many update operations while others do not. This diversity and the in-place update policy lead to the unbalanced usage of SSDs under the Block service.

Unlike Block Service, the other two cloud services do not cause severe usage imbalance because they have a different update policy or I/O pattern. Particularly, the NoSQL service merges small updates together and always generates a new chunk for the updated data, which can be mapped to a different SSD. In the Big Data service, reading and adding new data are consistently much more frequent than updating existing ones. Therefore, SSDs under both services have a relatively balanced usage.

5.3 Mitigating Usage Imbalance

To address the usage imbalance issue, we optimize the software stack of the Block service by adding a shared append-only log, similar to LFS [36].

Figure 7 shows the update operation after the optimization. Similar to Figure 6, USER1 subscribes a chunk from the Block Service. Unlike the original design, the chunk is now maintained in a log which appends the latest update to its end. Upon receiving an update, the software stack invalidates the previous chunk (marked with an "X"), appends the update to the log, and changes the mapping table to map the updated chunk to a new SSD ("SSD2"). The outdated chunk will be invalidated for garbage collection. This log-based design mitigates the usage variance among SSDs, as each updated chunk will be allocated to a different SSD based on the wear among available drives. Note that, in certain cases, the updated chunk may still mapped to the original SSD if the original one happens to be the most appropriate candidate.

After applying the optimized design on a subset of our target systems for 7 months, we observe that the coefficient of variance (CV) of host read/write under the Block service reduces significantly (i.e., from 24.9% to 5.2% among all SSDs under the same service). The log-structured design also provides other benefits for our target systems (e.g., better support for snapshots), which are beyond the scope of this paper.

Fix	Percentage	Root Cause
Rebooting	11.9%	Transient
Mount Options Check	0.4%	Human Mistake
FSCK	16.5%	Undetermined
Data Check	6.0%	Undetermined
Slot Check	20.1%	Human Mistake
Replacing Cable	13.9%	Faulty Cable
Replacing SSD	31.2%	Failed Device

Table 11: Working fixes of RASR failures. *The first column shows working fixes of RASR failures. The 2nd column lists the percentage of RASR failures repaired by each fix. The 3rd column lists the corresponding root cause derived from the working fix.*

6 Lessons & Actions for System Admins

To help system administrators with better fix strategy, we need better understanding of the root causes of RASR failures. While the repair log of a RASR failure does not explicitly state the root cause, we can infer the potential root cause based on the successful fix in the log. For example, if a failure can only be fixed by replacing the SSD, it is likely that the root cause is a failed SSD. Table 11 shows all the seven fixes deployed in the repairing procedure of RASR failures, the percentage of RASR failures being successfully repaired by each fix, and the potential root causes.

We observe that not all RASR failures are caused by failed SSDs. There are two main non-SSD causes for RASR failures: (1) *human mistakes* contribute 20.5% of RASR failures, including plugging the device to the wrong slot ("Slot Check") and incorrect configuration ("Mount Options Check"); and (2) *faulty interconnections* fixed by replacing cable, which is outside of SSD, account for 13.9% of RASR failures. Note that, although "Replacing SSD" accounts for the most (31.2%) of RASR failures, we still leave it as the last resort in the fix strategy due to the high cost of the devices and labors. Hence, we are interested in whether faulty interconnections and human mistakes can be quickly diagnosed or largely avoided.

6.1 Faulty Interconnection

Faulty interconnection is a well-known issue in large-scale storage systems [28]. To fix the RASR failures (Drive Unfound) caused by faulty interconnection, replacing the cable between SSD and host is an effective method. However, our symptom-based repairing procedure (shown in Table 6) lists replacing cable as the third step to try out if a Drive Unfound

Fix	Heavy Group	Light Group
Rebooting	4.4%	25.0%
Slot Check	7.6%	35.7%
Repl. Cable	70.6%	24.2%
Repl. SSD	17.4%	15.1%

Table 12: Success rates of fixes in two SSD groups. *This table shows the success rate of each fix for the "Drive Unfound" failures in two SSD groups classified by the indicator.*

failure occurs. This incentivizes us to quest for good indicators of faulty interconnection. If successful, administrators can directly replace cable instead of trying the first two failed attempts – significantly improving the repairing procedures of Drive Unfound (a major source of RASR failures).

6.1.1 Identifying Potential Indicators

To find a suitable indicator for faulty interconnection, we study the correlation between five representative device errors (i.e., Ultra-DMA CRC (UCRC), RBER, Uncorrectable Errors, Program Errors, and End-to-End Errors) and faulty interconnection by using Spearman Rank Correlation Coefficient [12]. The result shows that only the UCRC has strong correlation with faulty interconnection. This generally indicates that the more UCRC errors an SSD has, the more likely a Drive Unfound failure is caused by faulty interconnection. Therefore, we select the number of UCRC errors for designing the indicator.

6.1.2 Refining the Indicator

Since UCRC errors may also occasionally caused by transient factors (e.g., voltage spike), it is necessary to set a proper threshold for indicating faulty interconnection. To this end, we apply a set of classic statistics methods (e.g., Kolmogorov-Smirnov Test [13]) to analyze the UCRC errors and derive the optimal threshold. We find that the distribution of UCRC errors follows the 80/20 rule (i.e., Pareto Law [13]). So if the accumulation of UCRC errors on an SSD is in the top 20% among all drives, we assign the SSD to the "Heavy" group. Our analysis shows that 17 is the best threshold for our systems. In other words, when an SSD has 17 or more UCRC errors, it is a strong indication of a faulty interconnection in the target systems. Note that the threshold can be re-calculated and updated periodically for the change of systems and environment (e.g., aging of SSDs, workload changes). We leave the sensitivity study of the threshold as future work.

6.1.3 Verifying the Indicator

We further use our existing dataset to verify the effectiveness of the UCRC-based indicator. Specifically, we first divide all SSDs into two groups based on the threshold: "Heavy" (above or equal to the threshold) and "Light" (below the threshold). Then, we calculate the successful rate of each fix candidate for the "Drive Unfound" failures in each group.

Table 12 demonstrates that our indicator for faulty interconnection would be very effective for improving the repairing procedure of Drive Unfound failures. Most (i.e., 70.6%) SSDs in the "Heavy" group have been successfully repaired by replacing cable. On the contrary, only 12.0% of SSDs in the group are fixed by the first two candidates (i.e., node rebooting and slot check). This result suggests that, it can significantly improve the successful rate of the first attempt if we directly replace cables for the drives that are severely affected with UCRC errors. As for the "Light" group of SSDs, whose root causes are not identified as faulty interconnection by our indicator, the successful rate of replacing cable is similar to the first two fix candidates. This shows that the existing repair procedure is good for "Light" group of SSDs.

6.1.4 Benefits of Using Indicator

We have applied the UCRC-based indicator to our target systems. With the new repairing procedure for Drive Unfound failures, if the number of UCRC errors in SSD is higher than the threshold, on-site engineers will start with replacing cable first.

One might think that rebooting is simple and it should be the first attempt no matter what the root cause is. However, the side effect of rebooting can be notable and cascading in large-scale production systems. For example, a node may hang at BIOS during reboot if the system drive is inaccessible due to a faulty cable, which may further trigger large data transfer in a 3-replica system. Therefore, when the root cause is likely to be a faulty cable (i.e., the heavy group), we use cable replacement first.

Based on the feedback of the on-site engineers on the new 89 cases of Drive Unfound (not included in our dataset), the indicator helps them reduce the repairing time by 21.1%, because of the saving on time that would have been spent on the first two unsuccessful attempts (i.e., node rebooting and slot check).

6.2 Human Mistakes & Solution

As shown in Table 11, human mistake is another major source of RASR failures. Particularly, plugging the device to the wrong slot (i.e., fixed by "Slot Check") accounts for 20.1% RASR failures. Although it may be part of human nature to err, we believe such mistakes should be avoided.

To address the issue, we design an approach called One Interface One Purpose (OIOP) for our latest and future deployment, where SSDs serve for different purposes use different hardware interfaces. Table 13 lists the interface for each type of SSD functionality in our target systems. We use U.2/M.2 interface for system drives as our motherboard usually has 1 or 2 such sockets. The NVMe interface is used for temporary storage and buffering as these SSDs require high bandwidth and low latency. The SATA interface is used for persistent storage for compatibility concerns (i.e., re-using current SSDs on new racks). With such an OIOP design, the

SSD Functionality	SSD Interface
System drive	U.2/M.2
Temporary storage	NVMe
Buffering writes	NVMe
Persistent storage	SATA

Table 13: Mapping between SSD functionality and interface.

SSDs and slots for different purposes are easily differentiable by system administrators. Note that these interfaces are unlikely to be transitional as each interface has its unique market/purpose (e.g., U.2/M.2 for embedded, NVMe for high-performance).

Although simple, the OIOP design has effectively reduced the RASR failures caused by human mistakes in practice. In the 6-month deployment of an OIOP storage system with about 100K SSDs, we only observe 3 RASR failures caused by plugging a device to a wrong slot. In stark contrast, we observe an average of 47 such cases on comparable size of current storage systems without OIOP.

Besides OIOP, another possible solution is to use a status light to differentiate the functionalities of drives. Status light has been used for indicating drive status in RAID systems [40], and it can be applied to motherboards without multiple interfaces. However, adding status lights requires support from hardware manufacturers.

7 Related Works

Our work is mainly related to the following three lines of research studies: (1) reliability of SSDs and SSD-based storage systems, (2) reliability of HDD-based storage system, and (3) large-scale failure studies.

Great efforts have been made on analyzing the reliability of SSDs and SSD-based storage systems [32, 33, 38, 43, 44, 45]. For example, Schroeder et al. [38] conduct a large-scale field study covering millions of drive days and analyze a wide range of device characteristics and errors (especially RBER and UBER) as well as their correlation. Meza et al. [32] study flash memory failures in the field as well as their correlation with other factors (e.g., data written from OS). Narayanan et al. [33] analyze the correlation between failed SSDs and other factors (e.g., hardware utilization). Our work is different in a number of ways. First, we focus on RASR failures, which have not been studied before. Second, our study covers system-level failure symptoms, repair procedures, root causes, as well as the casual relations among events. Third, we design and validate a set of simple yet effective solutions. Therefore, we believe our work is complementary to the existing efforts.

Research efforts on HDD-based storage stack are also abundant [7, 8, 28, 35]. For example, Jiang et al. [28] study the logs from around 40K storage systems and discover several findings including the significant contribution of physical components and protocol stacks in failures, the "bursty" failure pattern, and the benefit of using redundant interconnection. Bairavasundaram et al. [7] analyze over 1.5 million hard drives and find out the severity differences of data corruption among enterprise and nearline disks, the spatial and temporal locality of checksum mismatches, and the correlation of data corruption across different disks. Based on the same dataset, Bairavasundaram et al. [8] also analyze factors that contribute to the latent sector errors along with the trends and further explore possible remedies towards building a more robust storage subsystem. However, due to the difference in both hardware design and software support, their findings may not be directly applicable to SSD-based storage systems.

In addition, our work is closely related to two groups of studies on large-scale failures. The first group focuses on using failure reports (e.g., news and descriptive records) to understand failures in modern storage systems [21, 22, 23, 43]. For example, Gunawi et al. [23] collect around 100 hardware fail-slow reports across multiple large-scale deployments from several institutions and study the behaviors, root causes and lessons for dianosis of fail-slow failures. In the second group of studies, researchers have made efforts on diagnosing and detecting failures from software perspective. For instance, Huang et al. [25, 26] analyze the production systems deployed at Microsoft and discover a key feature of the gray failure, differential observability, which leads them to build a fast detection tool. Regarding the first group, our work is different as we use multiple log sources (e.g. SMART logs, kernel logs) to conduct quantitative analysis and further derive the causal relationships of the failures. Compared with the second group, our work targets the various aspects of system reliability maintenance, including not only the software but also the hardware and administration.

8 Conclusions

We study the characteristics of RASR failures in large-scale storage systems in this paper. Our study reveals the distribution, symptoms, and causes of RASR failures. Moreover, we derive several lessons on system reliability, including the passive heating phenomenon, the usage imbalance, human mistakes, etc. In addition, we design and validate a set of simple yet effective methods to address the issues observed. We believe our findings and solutions would be beneficial to the community, and could facilitate building highly-reliable SSD-based storage systems.

Abstract

Due to its high performance and decreasing cost per bit, flash storage is the main storage medium in datacenters for hot data. However, flash endurance is a perpetual problem, and due to technology trends, subsequent generations of flash devices exhibit progressively shorter lifetimes before they experience uncorrectable bit errors. In this paper, we present an approach for addressing the flash lifetime problem by allowing devices to operate at much higher bit error rates. We present DIRECT, a set of techniques that harnesses distributed-level redundancy to enable the adoption of new generations of denser and less reliable flash storage technologies. DIRECT does so by using an end-to-end approach to increase the reliability of distributed storage systems.

We implemented DIRECT on two real-world storage systems: ZippyDB, a distributed key-value store in production at Facebook that is backed by and supports transactions on top of RocksDB, and HDFS, a distributed file system. When tested on production traces at Facebook, DIRECT reduces application-visible error rates in ZippyDB by more than 100× and recovery time by more than 10,000×. DIRECT also allows HDFS to tolerate a 10,000–100,000× higher bit error rate without experiencing application-visible errors. By significantly increasing the availability of distributed storage systems in the face of bit errors, DIRECT helps extend flash lifetimes.

1 Introduction

Flash has become the dominant storage medium for hot data in datacenters [64, 72], since it offers significantly lower latency and higher throughput than hard disks. Many storage systems are built atop flash, including databases [6, 11, 15, 44], caches [5, 36, 57, 58, 78], and file systems [48, 67].

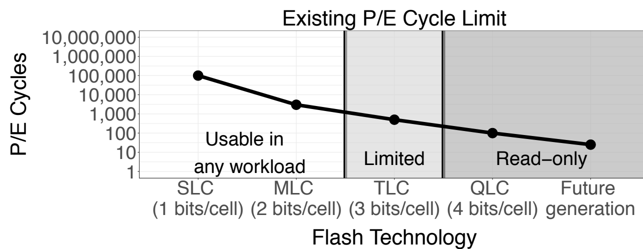
However, a perennial problem of flash is its limited endurance, or how long it can reliably correct raw bit errors. As device writes are the main contributor to flash wear, its lifetime is measured in the number of writes or program-erase (P/E) cycles the device can tolerate before exceeding an uncorrectable bit error threshold. Uncorrectable bit errors are errors that are exposed externally and occur when there are too many raw bit errors for the device to correct.

In hyper-scale datacenters, operators constantly seek to reduce flash wear by limiting flash writes [21, 64]. At Facebook, for example, a dedicated team monitors application writes to ensure they do not prematurely exceed manufacturer-defined device lifetimes. Even worse, each subsequent flash generation tolerates a smaller number of writes before reaching end-of-life (see Figure 1a) [42]. Further, given the scaling challenges of DRAM [49, 56] and the increasing cost gap between DRAM and flash [2, 37, 38], many operators are migrating services from DRAM to flash [7, 37], increasing the pressure on flash lifetime.

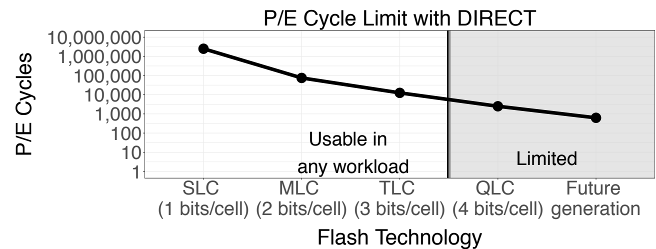
There is a variety of work that attempts to extend flash lifetime by delaying the onset of bit errors [6, 12, 30, 36, 47, 59, 61, 62, 63, 77, 82, 83]. This paper takes a contrarian approach. We observe that flash endurance can be extended by *allowing* devices to go beyond their advertised uncorrectable bit error rate (UBER) and embracing the use of flash disks that exhibit much higher error rates; Google recently released a whitepaper suggesting a similar approach [28]. We can do so without sacrificing durability because datacenter storage systems replicate data on remote servers, and this redundancy can correct bit error rates orders of magnitude beyond the hardware error correction mechanisms implemented on the device. However, the challenge with higher flash error rates is maintaining availability and correctness.

We introduce Distributed error Isolation and RECovery Techniques (DIRECT), which is a set of three simple general-purpose techniques that, when implemented, enable distributed storage systems to achieve high availability and correctness in the face of uncorrectable bit errors:

1. **Minimize data error amplification.** DIRECT detects errors using existing error detection mechanisms (e.g., checksums) and recovers data from remote servers at the smallest possible granularity.
2. **Minimize metadata error amplification.** A corruption in local metadata (e.g., database index), often requires a large amount of data to be re-replicated. DIRECT avoids



(a) Existing hardware-based error correction.



(b) Augmenting existing error correction with DIRECT.

Figure 1: For each generation of flash bit density, the average number of P/E cycles after which the uncorrectable bit error rate falls below the manufacturer specified level (10^{-15}). Beyond MLC, the number of flash writes the application can issue is limited [29]. With current hardware-based error correction, QLC technology and beyond can only be used for applications that are effectively read-only [8, 22, 76]. DIRECT enables the adoption of denser flash technologies by handling errors in the distributed storage application. We use the model from §3 to compute the UBER tolerated by DIRECT, while the UBER to P/E conversion was derived from data in a Google study [72].

this by adding redundancy locally to local metadata.

3. **Ensure safe recovery semantics** by treating recovery operations as write operations. DIRECT serializes recovery operations on corrupted data against concurrent operations with respect to the system's consistency guarantees.

The difficulty of implementing DIRECT depends on two properties of the underlying storage system. The first property is whether the system is physically or logically replicated. Physically-replicated systems replicate *data blocks* between servers, while logically-replicated systems replicate the *commands* (e.g., write, update, delete). In physically-replicated systems, a certain object is stored in the same block or file on another server and therefore can be recovered efficiently by simply re-replicating the remote data block. This does not work for logically-replicated systems, where physical blocks are not identical across replicas. The second property is whether the data store supports versioning. In systems with versioning, we need to guarantee the recovered object does not override a more up-to-date version.

We demonstrate how to generalize DIRECT techniques by implementing them in two popular systems that are representative of two different classes of storage systems: (1) the Hadoop Distributed File System (HDFS), which is a physically-replicated storage system without versioning, and (2) ZippyDB, a distributed system that implements logical replication and transactions on top of RocksDB, a popular key-value store that supports key versioning. Objects in HDFS are physically-replicated, so it is straightforward for DIRECT to find the corrupt object in another replica and recover it at a high granularity (§4.1). On the other hand, recovery is challenging in ZippyDB since the corrupted region of one replica is stored in a different location on another replica, so the recovered key-value pairs might not have consistent versions ZippyDB (§4.2).

DIRECT Limitations and Lessons Learned. We chose to implement DIRECT by retrofitting existing datacenter storage applications, rather than as a general-purpose application library. The latter design would be particularly challenging since DIRECT depends on application-specific details such as file layout and recovery semantics. Note that the storage systems we retrofitted (HDFS and RocksDB) and their relatives serve as the base layer for many storage services and databases (e.g., MyRocks, Ozone, HBase, Cassandra). Furthermore, we learned that to implement the first and third DIRECT techniques, storage systems must have a key requirement: we must be able to infer logical objects from the physical location (on the application's file format) of the bit error. In §6 we discuss PostgreSQL, which does not satisfy this requirement, and therefore is difficult to retrofit with DIRECT.

DIRECT leads to significant increases in device lifetime, since systems can maintain the same probability of application-visible errors (durability) at much higher device UBERs. In Figure 1b, we estimate the number of P/E cycles gained with DIRECT using an empirical UBER vs P/E cycle comparisons in a Google study [72]. Depending on workload parameters and hardware specifications, DIRECT can increase the lifetime of devices by 10-100×. This allows datacenter operators to replace flash devices less often and adopt lower cost-per-bit flash technologies that have lower endurance. DIRECT also provides the opportunity to rethink the design of existing flash-based storage systems, by removing the assumption that the device fixes all corruption errors. Furthermore, while this paper focuses on flash, DIRECT's principles also apply in other storage mediums, including NVM, hard disks, and DRAM.

In summary, this paper makes several contributions:

1. We observe flash lifetime can be extended by allowing devices to operate at much higher bit error rates.
2. We propose DIRECT, general software techniques that enable storage systems to maintain performance and high availabily despite high hardware bit error rates.
3. We design and implement DIRECT in two storage systems, HDFS and ZippyDB, that are representative of physical and logical replication, respectively. Applying DIRECT results in significant end-to-end availability improvements: it enables HDFS to tolerate bit error rates that are 10,000×-100,000× greater, reduces application-

visible error rates in ZippyDB by more than 100×, and speeds up recovery time in ZippyDB by 10,000×.

2 Motivation

What Limits Flash Endurance? Flash chips are composed of memory cells, each of which stores an analog voltage value. The flash controller reads the value stored in a certain memory cell by sensing the voltage level of the cell and applying quantization to determine the discrete value in bits. The more bits stored in a cell, the narrower the voltage range that maps to each discrete bit, so more precise voltage sensing is required to get a correct read. A primary way to reduce cost per bit is to increase the number of bits per cell, which means that even small voltage perturbations can result in a misread.

Multiple factors cause voltage drift in a flash cell. The dominant source, especially in datacenter settings where most data is "hot," is the program-erase (P/E) cycle, which involves applying a large high voltage to the cell in order to drain its stored charge, thus wearing the insulating layer in the flash cell [30]. This increases the voltage drift of subsequent values in the cell, which gradually leads to bit errors.

3D NAND is a recent technology that has been adopted for further increasing flash density by stacking cells vertically. While 3D NAND relaxes physical limitations of 2D NAND (traditional flash) by enabling vertical stacking, 3D NAND inherits the reliability problems of 2D NAND and further exacerbates them, since a cell in 3D NAND has more adjacent (vertical) neighbors. For example, voltage retention is worse, because voltage can now leak in three dimensions [54, 63, 65]. Similarly, disturb errors that occur when adjacent cells are read or programmed are also exacerbated [50, 75].

Existing Hardware Reliability Mechanisms and Limitations. To correct bit errors, flash devices use error correcting codes (ECC), which are implemented in hardware. After the ECC pass, there could still be incorrect bits on the page. To address this, SSDs also employ internal RAID across the dies of a flash device [16, 19]. After applying coding and RAID within the device, there will remain a certain rate of *uncorrectable bit errors* (UBER). Together, ECC and internal RAID mechanisms can drive the error rates of SSDs from the raw bit error rate of around 10^{-6} down to the 10^{-17} to 10^{-20} UBER range typical of enterprise SSDs [14]. "Commodity" SSD devices typically guarantee an UBER of 10^{-15}.

While it is possible to create stronger ECC engines, the higher the corrective power of the ECC, the more costly the device [4, 10]. Furthermore, the level of internal RAID striping is constant across generations, because the number of dies inside a flash device remains constant. This means that the corrective power of RAID is fixed.

Similarly, while RAID across devices [53, 69, 74] can add redundancy, a main design goal of DIRECT is to avoid adding unnecessary overhead. We avoid turning to RAID because it is inflexible since its recovery power is fixed at deployment time, and, more importantly, it imposes storage and write overheads, in particular generating additional flash writes that further reduce endurance.

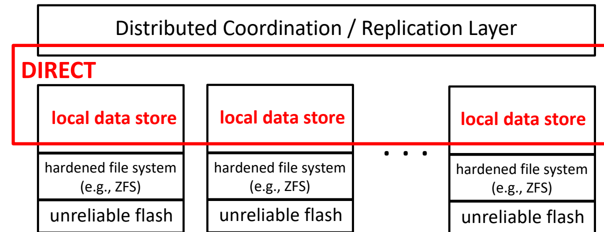


Figure 2: DIRECT fixes errors in the local data store, sometimes requiring interaction with the distributed coordination layer.

Implications of Limited Flash Endurance. Flash technology has already reached the point where its endurance is inhibiting adoption and operation in various datacenter use cases. For example, QLC was recently introduced as the next generation flash cell technology. However, in the worst case, it can only tolerate ~150 P/E cycles [8, 22, 76], so it can only be used for read-heavy use cases, e.g., a 2 TB QLC drive with a lifetime of 150 P/E cycles can only write at a rate of 2 MB/s or less in order to preserve its advertised lifetime of 5 years. In the best case, some QLC devices can tolerate ~1000 P/E cycles for completely sequential write workloads, due to an internal SLC cache [8]. But since datacenter applications like databases and analytics that deal with hot data typically need to update objects frequently, the adoption of QLC has been more limited and is the reason that Facebook has avoided QLC flash. Subsequent cell technology generations will suffer from even greater problems.

Operational issues also often dictate a device's usage lifetime. Flash is typically only used for its advertised lifetime to simplify operational complexity [72]. Further, in a hyperscale datacenter where it is common to source devices from multiple vendors, the most conservative estimate of device lifetime across vendors is typically chosen as the lifetime for a fleet of flash devices, so that the entire fleet can be installed and removed together. If the distributed storage layer could tolerate much higher device error rates, then datacenter operators would no longer have to make conservative and wasteful estimates about entire fleets of flash devices.

Finally, because of the increase in DRAM prices due to its scaling challenges and tight supply [2, 38, 49, 56], datacenter operators are migrating services from DRAM to flash [7, 37]. This means flash will be responsible for many more workloads, further exacerbating its endurance problem.

3 DIRECT Design

DIRECT is a set of techniques that enables a distributed storage system to maintain high availability and correctness in the face of high UBER.

We define a distributed storage system as a set of many local stores coupled with a distributed protocol layer that replicates data and coordinates between the local stores. Figure 2

shows an ideal storage stack that runs on unreliable flash (flash that exposes high UBERs). Note that there is existing work on how to make local file systems tolerate corruption errors (we survey these in §6), so our efforts in this paper focus on hardening the application-level storage system.

We observe that redundancy already exists in distributed storage systems in the form of distributed replication [27, 32, 40], which maintains multiple remote copies of each piece of data, or distributed erasure coding [45, 71, 80], which maintains remote parity bits for each piece of data. However, many systems do not systematically use this redundancy to recover individual bit errors [39], even though it can significantly boost resilience to bit errors. We focus on using distributed replicas to correct bit errors, but the DIRECT principles presented in the paper also apply to systems that use erasure coding; for example, error amplification — the number of bits required to recover an error — can be reduced in erasure coding schemes by reducing the size of a stripe.

Distributed Redundancy. Consider the following example of a physically replicated storage system, such as HDFS. Suppose the minimum unit of recovery is a data block[1], which is replicated in each of three data stores. If the block has size B, and the uncorrectable bit error rate (UBER) is E, then the expected number of errors in the block will be $B \cdot E$. Since the block is replicated across R different servers, the only way that the storage system would encounter an application-observable read error is when at least one error exists in *every* copy of the block. Therefore, the probability of an application-level read error can be expressed as:

$$\mathbb{P}[error] = (1-(1-E)^B)^R \approx (B \cdot E)^R$$

where we assume $B \cdot E << 1$ and use a Taylor series approximation.

Then, for an UBER of $E = 10^{-15}$, a block size of $B = 128\ MB$ (typical of distributed file systems), and a replication factor of $R = 3$, the probability of a read error is 10^{-18} (files are measured in bytes, while UBER is in bits).

However, with relatively large blocks, the probability of encountering at least one error in all block replicas quickly increases as UBER increases. For example, for an UBER of $E = 10^{-10}$, the expected number of errors in a single block will be $B \cdot E = 0.1$ for 128 MB blocks (Table 1). Then in this case $\mathbb{P}[error] \approx 0.001$. We observe that reducing $B \cdot E$, by reducing B, will dramatically reduce the probability of error.

Minimizing Error Amplification of Data Blocks. DIRECT captures this intuition with the notion of *error amplification* (B in the previous example), or the number of bytes required to recover a bit error. DIRECT observes that *the lower the error amplification, the lower the probability of error and the faster recovery can occur*. This similarly implies a shorter period of time spent in degraded durability

[1]Note that in HDFS while errors can be detected using checksums at a smaller granularity than the block size, actual recovery and replication is conducted at the granularity of a block.

UBER	*Probability of Application-Observable Error* Block Recovery	Chunk Recovery
10^{-10}	$1 \cdot 10^{-3}$	$3 \cdot 10^{-10}$
10^{-15}	$1 \cdot 10^{-18}$	$1 \cdot 10^{-28}$

Table 1: Probability of application-observable error comparing block-by-block recovery to chunk-by-chunk recovery, with an UBER of 10^{-10}, and 10^{-15}. Finer granularity recovery provides significantly higher protection against corruptions.

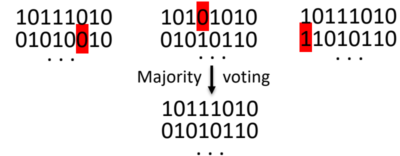

Figure 3: Even if the same chunk is corrupted on all replicas, bit-by-bit majority voting can reconstruct the correct chunk, by taking the majority vote of each bit across all chunks.

and thus higher availability.

In the example above, suppose the system can recover data at a finer granularity, for example, at chunk size $C = 64$ KB. Then a read error would occur if all three replicas of the same *chunk* have at least one bit error. The revised probability of read error becomes:

$$\mathbb{P}[error] = 1-(1-(1-(1-E)^C)^R)^{\frac{B}{C}}$$

Assuming $E \cdot C << 1$, Taylor series approximation leads to $(1-(1-E)^C)^R) \approx (E \cdot C)^R$, and assuming this value is much smaller than $\frac{B}{C}$, the probability of an application-observable error when correcting chunk-by-chunk is:

$$\mathbb{P}[error] \approx (E \cdot C)^R \cdot \frac{B}{C}$$

When $C = 64$ KB and $E = 10^{-10}$, this probability is $3 \cdot 10^{-10}$, which is much lower than the probability when recovering at the block level (see Table 1).

We can further reduce B by using bit-by-bit majority voting, i.e., the recovered value of a bit in the chunk is the majority vote across the three chunk replicas (Figure 3). Bit-by-bit majority voting further reduces the application-observable error beyond chunk-by-chunk recovery, because the only way an application-observable error would occur is if an error occurs in the same bit across two chunks or more.

In a physically-replicated system like HDFS, minimizing error amplification is straightforward because corrupted blocks (and even bits) can be directly recovered from remote replicas. For a logically-replicated system like ZippyDB, however, blocks are not identical across replicas. This makes minimizing error amplification more challenging, since DIRECT cannot simply recover from a remote physical chunk. For example, bit-by-bit majority voting is not possible in ZippyDB, because the replicas do not store the same physical bits. For such systems, DIRECT must instead first isolate the region where the error might have occurred and then retrieve objects one-by-one from the other servers (see §4.2).

Minimizing Metadata Error Amplification. Error amplification can be even more severe if the error occurs in local metadata. For example, a corrupt index in a key-value store can prevent a data store from starting up, which can mean re-replication of hundreds of GBs of data. Thus even though the likelihood of errors in metadata is lower than in data blocks (metadata typically takes up less space than data), it still requires protection. Hence DIRECT either locally duplicates metadata or applies local software error correction.

Safe Recovery Semantics. DIRECT must also ensure recovery operations preserve the correctness of the distributed storage system, which might be dealing with concurrent write and read operations.

This is relatively straightforward in systems that do not support versioning or transactions, such as HDFS, since an object is up-to-date as soon as it is recovered from a remote replica. Systems like RocksDB which support versioning are more challenging, because if the system re-writes an object from a remote replica, recovery might overwrite a newer version with a stale version. In particular, the versions of the corrupted key-value pairs *are not known*, because (a) the corruption prevents the data from being read and (b) due to logical replication, the data's location does not provide information on its version. Hence to correctly recover corrupted key-value pairs, the system must locate some consistent (up-to-date) version of each pair. To do this, DIRECT forces recovery operations to go through a fault-tolerant log (for ZippyDB we use its existing Paxos log), which can provide correct ordering (§4.2.3).

DIRECT Techniques. To summarize, DIRECT includes the following techniques.

1. Systems must reduce error amplification of data objects and fix corruptions from remote replicas.
2. Systems must reduce local metadata error amplification, which is much higher than data error amplification.
3. Systems must ensure safe recovery semantics.

Note that the first and second techniques apply exclusively to the local data store and affect *performance*, while the third technique may require that the local data store interact with the distributed coordination layer to ensure *correctness*.

4 Implementing DIRECT

To demonstrate the use of the DIRECT approach, we integrate it into two systems: HDFS, a popular distributed file system, and ZippyDB, a distributed key-value store backed by RocksDB. The techniques used to implement DIRECT in HDFS can be applied to other physically replicated systems, such as GFS [40], Windows Azure Storage [31], and RAMCloud [66], which write objects into large immutable blocks that are replicated across several servers. Similarly, the techniques used to implement DIRECT in ZippyDB and RocksDB can be applied to other logically replicated systems, such as Cassandra [79], MongoDB [9], and CockroachDB [1]. In these systems a distributed coordination layer manages the replication of objects across different servers and uses versioning to execute transactions.

4.1 HDFS-DIRECT

4.1.1 HDFS Overview.

HDFS is a distributed file system that is designed for storing large files that are sequentially written and read. Files are divided into 128MB blocks, and HDFS replicates and reads at the block level.

There are three types of HDFS servers: NameNode, JournalNode, and DataNode. The NameNode and JournalNodes store cluster metadata by running a protocol similar to Multi-Paxos; we note that this protocol can tolerate bit errors by writing an additional entry per Paxos entry (for more information, see PAR [20]). DataNodes (the local data stores in Figure 2) store HDFS data blocks, and they respond to client requests to read blocks. If a client encounters errors while reading a block, it will continue trying other DataNodes from the offset of the error until it can read the entire block. After an error on a DataNode, the client will not try that node again. If there are no more DataNodes and the block is not fully read, the read fails and that block is considered missing.

Additionally, HDFS has a configurable background "block scanner" that periodically scans data blocks and reports corrupted blocks for re-replication. But the default scan interval is three weeks, and the scanner still recovers at the 128 MB block granularity. If there is a bit error in every replica of a block, then HDFS cannot recover the block.

4.1.2 Implementing DIRECT

Minimizing Error Amplification of Data Blocks. We leverage the observation that HDFS checksums every 512 bytes in each 128 MB data block. Corruptions thus can be narrowed down to a 512 byte chunk; verifying checksums adds no overhead, because by default HDFS will verify checksums during every block read. For streaming performance, the smallest-size buffer that is streamed during a data block read is 64 KB, so we actually repair 64 KB everytime there is a corruption. To mask corruption errors from clients, we repair a data block synchronously during a read. Under DIRECT, the full read (and recovery) protocol is the following.

Each 128 MB block in HDFS is replicated on three DataNodes, call them A,B,C. An HDFS read of a 128 MB block is routed to one of these DataNodes, say A. A will stream the block to the client in 64 KB chunks, verifying checksums before it sends a chunk. If there is a checksum error in a 64 KB chunk, then A will attempt to repair the chunk by requesting the 64 KB chunk from B. If the chunk sent by B also contains a corruption, then A will request the chunk from C.

If C *also* sends a corrupted chunk, then A will attempt to construct a correct version of the chunk through bit-by-bit majority voting: the value of the bit in the chunk is the majority vote across the three versions provided by A, B, and C. After reconstructing the chunk via majority voting (Figure 3), A will verify the checksums again; if the checksums fail, then the

read fails. Majority voting allows HDFS-DIRECT to tolerate on the order of $10^4 - 10^5$ times more bit errors than HDFS. In fact, as we show in Section 5.1, UBERs can be as high as 10^{-5} before majority voting failures are detectable in our experimental framework

Safe Recovery Semantics. Safety is straightforward in HDFS because data blocks are immutable once written, so there are never updates that will conflict with chunk recovery. Before a client does a block read, it first contacts the NameNode to get the DataNode IDs of all the DataNodes on which the block is replicated. In HDFS-DIRECT, when a client sends a block read request to a DataNode, it also sends this set of IDs. Because blocks are immutable and do not contain versions, these IDs are guaranteed to be correct replicas of the block, *if they exist*. It could be that a concurrent operation has deleted the block. In this case, if chunk recovery cannot find the block on another DataNode because it has been deleted, then it cannot perform recovery, so it will return the original checksum error to the client. This is correct, because there is no guarantee in HDFS that concurrent read operations should see the instantaneous deletion of a block.

Minimizing Metadata Error Amplification. Each server in HDFS has local metadata files that must be correct, otherwise it cannot start. These files include a VERSION file, as well as special files on the NameNode and JournalNode. Metadata files are not protected in HDFS, thus a single corruption will prevent the server from starting. DIRECT adds a standard CRC32 checksum at the beginning of each file and replicates the file twice so that there are three copies of the file on disk.

4.2 ZippyDB-DIRECT

4.2.1 ZippyDB Overview

We also implemented DIRECT on a logically replicated system, ZippyDB, a distributed key-value store used within Facebook that is backed by RocksDB (i.e., RocksDB is the local data store in Figure 2), which is a versioned key-value store.

ZippyDB runs on tens of thousands of flash-provisioned servers at Facebook, which makes it an ideal target for DIRECT. ZippyDB provides a replication layer on top of RocksDB. ZippyDB is logically separated into shards, and each shard is fully replicated at least three ways. Each shard has a primary replica as well as a number of secondary replicas, wherein each replica is backed by a separate RocksDB instance residing on some server. Each ZippyDB server contains hundreds of shards, including both primary and secondary replicas. Hence, each ZippyDB server actually contains a large number of separate RocksDB instances.

ZippyDB runs a Paxos-based protocol for shard operations to ensure consistency. The primary shard acts as the leader for the Paxos entry, and each shard also has a Paxos log to persist each Paxos entry. Writes are considered durable when they are committed by a quorum of shards, and write operations are applied to the local RocksDB store in the order that they are committed. A separate service is responsible for monitoring the primary and triggering Paxos role changes.

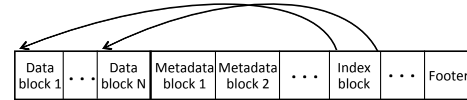

Figure 4: RocksDB SST file format. Index block entries point to keys within data blocks. Therefore, consecutive index entries form a key range. DIRECT modifies this file format by writing each metadata block at least twice in-line.

4.2.2 RocksDB Overview

RocksDB is a local key-value store based on a log-structured merge (LSM) tree [68]. RocksDB batches writes in-memory—each write receives a sequence number that enables key versioning—and flushes them into immutable files of sorted key-value pairs called sorted string table (SST) files. SST files are composed of individually checksummed blocks, each of which can be a data block or a metadata block. The metadata blocks include index blocks whose entries point to the keys at the start of each data block (see Figure 4) [13].

SST files are organized into levels. A key feature of RocksDB and other LSM tree-backed stores is background compaction, which periodically scans SST files and compacts them into lower levels, as well as performs garbage collection on deleted and overwritten keys.

4.2.3 Implementing DIRECT

ZippyDB has high error amplification since a single bit error can cause migration of terabytes of data: if a compaction encounters a corruption, an entire server, which typically has hundreds of gigabytes to terabytes of data, will shutdown and attempt to drain its RocksDB shards to another machine. Meanwhile, this sudden crash causes spikes in error rates and increases the load on other replicas while the server is recovering. To make matters worse, the new server could reside in a separate region, further delaying time to recovery.

Minimizing Error Amplification of Data Blocks. We observe that checksums in RocksDB are applied at the data block level, so a data block is the smallest recovery granularity. Data blocks are lists of key-value pairs, and key-value pairs are replicated at the ZippyDB layer. A corrupted data block can be recovered by fetching the pairs in the data block from another replica. However, this is challenging for two reasons.

First, compactions are non-deterministic in RocksDB and depend on a variety of factors, such as available disk space and how compaction threads are scheduled. Hence, *two replicas of the same RocksDB instance will have different SST files*, making it impossible to find an exact replica of the corrupted SST file and the corrupted data block, unlike in HDFS. Second, because the block is corrupted, it is impossible to know the exact key-value pairs that were stored in that block.

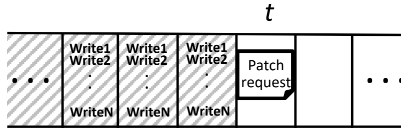

Figure 5: To serialize a patch properly, we add it as a request in the Paxos log. If the patch request is serialized at point t, then it must reflect all entries $t' < t$ (shaded). Furthermore, the patch request is not batched with any writes to ensure atomicity.

Therefore, not only do we not know what data to look for on the other replica, we also don't know where to find it.

Instead of repairing the exact keys that are lost, we rewrite a larger key range that covers the keys in the corrupted block. The key range is determined from index blocks, which are a type of metadata block in SST files that has an entry for the first key of each data block (Figure 4). Hence, consecutive index block entries form a key range which is guaranteed to contain the lost keys. Note that relying on these index entries requires that the index block, a metadata block, be error-free. See below for how we ensure the index block is uncorrupted.

Unfortunately, just knowing the key range is not enough: the existence of key versions in RocksDB and quorum replication in ZippyDB compounds the problem. In particular, a key must be recovered to a version greater than or equal to the lost key version, which could mean deleting it as key versions in RocksDB can be deletion markers. Additionally, if we naïvely fetch key versions from another replica, we may violate consistency.

Safe Recovery Semantics. To guide our recovery design, we introduce the following correctness requirement. Suppose we learn from the index entries that we must re-replicate key range $[a,b]$. This key range is requested from another replica, which assembles a set of fresh key-value pairs in $[a,b]$, which we call a patch.

Safety Requirement: *Immediately after patch insertion, the database must be in a state that reflects some prefix of the Paxos log. Furthermore, this prefix must include the Paxos entries that originally updated the corrupted data block.*

In other words, patch insertion must bring ZippyDB to some consistent state *after* the versions of the corrupted keys; otherwise, if the patch inserts prior versions of the keys, then the database will appear to go backwards.

Because the Paxos log serializes updates to ZippyDB, the cleanest way to find a prefix to recover up to is to serialize the patch insertion via the Paxos log. Then if patch insertion gets serialized as entry t in the log, the log prefix the patch must reflect is all Paxos entries $t' < t$, as shown in Figure 5. Serializing a patch at index t tells us exactly how to populate the patch. In particular, each key in the patch must be recovered to the largest entry $s < t$ such that s is the index of a Paxos entry that updates that key.

Furthermore, patch insertion must be atomic. Otherwise, it could be interleaved with updates to keys in the patch, which would violate the safety requirement, because then the version

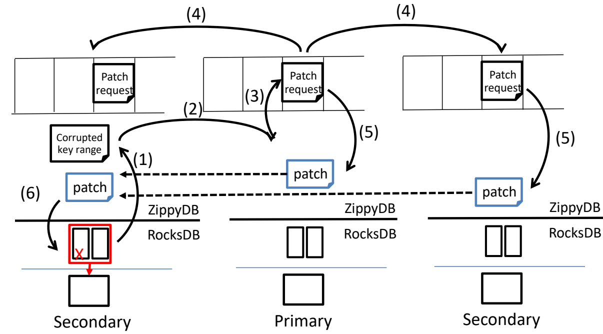

Figure 6: The process of recovering a corrupted RocksDB data block: (1) RocksDB compaction iterator determines the corrupted key range(s) based on the index blocks of the SST files and reports it to ZippyDB. (2) ZippyDB reports this error to the primary of that replica. (3) Primary shard adds patch request to Paxos log. (4) Paxos engine replicates the request to all replicas. (5) Each replica tries to process the patch request. If the processing shard is *not* the corrupted shard (which it knows because the patch request contains the shard ID of the corrupted shard), then it prepares a patch from its local RocksDB state and sends it to the corrupted shard. If the processing shard *is* the corrupted shard, then it waits for a patch from any replica. (6) Corrupted shard applies the fresh patch to its local RocksDB store.

of the key in the patch would not reflect a prefix of t. This is actually a subtle point because ZippyDB batches many writes into a single Paxos entry, as shown in Figure 5. If patch insertion is batched with other writes, then the patch will not reflect the writes that are in front of it in the batch. Hence, we force the patch insertion to be its own Paxos entry.

Minimizing Metadata Error Amplification. There are two flavors of metadata in RocksDB: metadata files and metadata blocks in SST files. Metadata files are only read during startup and then cached in memory. We can easily protect them with local replication, which adds a minimal space overhead (on the order of kilobytes per server). We protect metadata blocks by writing them several times in-line in the same SST file. In our implementation, we write each metadata block twice[2]. Protecting metadata enables us to isolate errors to a single data block, rather than invalidating an entire SST file.

As with the HDFS JournalNode, we can protect against errors in the ZippyDB Paxos log with an additional entry [20].

4.2.4 DIRECT Recovery in ZippyDB

ZippyDB-DIRECT triggers a recovery procedure when RocksDB encounters a corruption error during compaction. For user reads, ZippyDB does not synchronously recover corrupted blocks, unlike in HDFS. Instead, it returns the error to the client, which will retry on a different replica, and ZippyDB will then trigger a manual compaction involving the file of the corrupted data block.

Figure 6 depicts this process. Importantly, we do not release a compaction's output files until the recovery procedure

[2] For increased protection, metadata blocks can be locally replicated more than twice or protected with software error correction.

finishes; otherwise, stale key versions may reappear in the key ranges still undergoing recovery. Fortunately, because compaction is a background process, we can wait for recovery without affecting client operations.

Step (1) is implemented entirely within RocksDB. A RocksDB compaction iterator will record corrupted key ranges as they are encountered and withhold them from appearing in the compaction's result. At the end of the iterator's lifetime, ZippyDB is notified about the corrupted key range. Note that the compaction may encounter multiple corrupt key ranges, which are batched into a single patch request.

In step (2), the patch is reported to the primary. Step (3) must go through the primary because the primary is the only shard that can propose entries to the Paxos log. Note this does not mean primaries cannot recover from corrupted data blocks. The patch request in the Paxos log is simply a no-op that reserves a point of reference for the recovery procedure and includes information necessary for recovery, such as the corrupted key ranges and the ID of the corrupted shard. Any replica that encounters the patch request in the log is by definition up-to-date to that point in the Paxos log, which means any replica that isn't the corrupted replica is eligible to send a patch to the corrupted replica. In step (4), ZippyDB waits for the Paxos log to replicate the Paxos entry as well as for other replicas to consume the log until they encounter the patch request.

In step (5), an uncorrupted replica assembles a patch on the specified key range(s) with a RocksDB iterator. To do this, the uncorrupted replica opens a range scan iterator on each key range. Note that this replica might encounter a bit corruption while assembling the patch. In practice the probability of this is small because the number of keys covered by the patch is on the order of kilobytes (§5.2), and any scans to find such keys would predominantly look through metadata blocks, such as bloom filter or index blocks. However, if a replica does encounter a corruption while assembling a patch, it simply does not send a patch. Therefore, for the patch request to fail, *both* (or more, if the replication factor is more than 3) uncorrupted replicas will have to encounter a bit corruption, and this probability is low.

Step (6) is also implemented at the RocksDB level. When a replica applies a patch, simply inserting all the key-value pairs present in the patch is insufficient because of deleted keys. In particular, any key present in the requested key range and *not* present in the patch is an implicit delete. Therefore, to apply a patch, the corrupted shard must also delete any keys that it can see that aren't present in the patch. This case is possible because RocksDB deletes keys by inserting a tombstone value inline in SST files, but such a tombstone might have already been compacted away on the replica providing the patch. Hence the corrupted data block may contain tombstone operators that delete a key, and these must be preserved.

4.2.5 Transactions and Invalidating Snapshots

ZippyDB uses RocksDB snapshots to execute transactions. RocksDB snapshots are represented by a sequence number, s. Then, for as long as the snapshot s is active, RocksDB will not compact any version, s', of a key where s' is the greatest version of the key such that $s' < s$. If RocksDB invalidates a snapshot, then the ZippyDB transaction using that snapshot will abort and retry.

A subtle side-effect of a corrupted data block is snapshot corruption. For example, suppose the RocksDB store has a snapshot at sequence number 100 and the corrupted data block contains a key with sequence number 90. Because the data block is corrupted, it cannot be read, so we do not know whether the corruption affects snapshot 100. Then for safety, we need to invalidate all local snapshots, because any of them could have been affected by the corrupted key range. In practice, this is reasonable because most ZippyDB transactions (and hence RocksDB snapshots) have short lifetimes.

More generally, any transactional system that relies on versioning (e.g., MyRocks that is built on RocksDB), through either optimistic concurrency control or multi-version concurrency control (MVCC) can similarly deal with corruptions by aborting ongoing transactions.

4.3 Cascading Errors

In both HDFS-DIRECT and ZippyDB-DIRECT, the system will visit multiple replicas if necessary to resolve a bit error. However, currently DIRECT ignores and does not try to fix any cascading errors encountered during this process. For example, if a replica tries to assemble a patch in ZippyDB-DIRECT and fails because the iterator encounters a corruption, the replica will simply cleanup, ignore the patch request, and move to executing the next request in the Paxos log. We ignore cascading errors for simplicity but can easily incorporate recovery of cascaded errors in the future.

5 Evaluation

This section evaluates DIRECT by answering the following questions: (1) By how much does DIRECT decrease application-level errors in both HDFS and ZippyDB? In HDFS, how far can DIRECT drive UBER while avoiding application-level errors? (2) How much does DIRECT decrease time to recovery from corruption errors in ZippyDB?

Note we do not measure recovery time in HDFS because DIRECT handles bit errors *synchronously*, which means read errors only propagate to the application level if DIRECT cannot fix them. Therefore, "recovery time" can be measured by its effect on read latency. On the other hand, in ZippyDB, DIRECT handles bit errors asynchronously because recovery procedures must go through the coordination layer, as described in Section 4.2.

Experimental Setup. To evaluate ZippyDB, we set up a cluster of 60 Facebook servers that capture and duplicate live traffic from a heavily loaded service used in computing

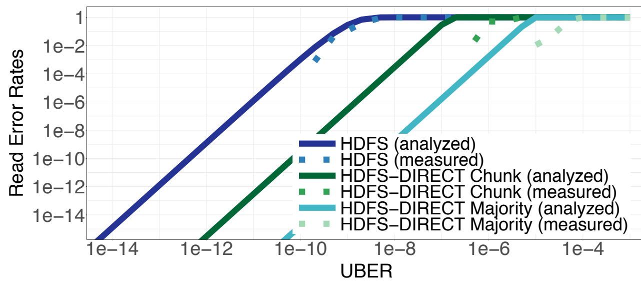

Figure 7: Read error rate for HDFS with varying UBER. HDFS-DIRECT Chunk is based on chunk-by-chunk recovery, while HDFS-DIRECT Majority is computed on bit-by-bit majority. The analyzed data is computed using the formulas in §3.

user feeds. To evaluate HDFS, we set up an HDFS cluster on machines with 8 ARMv8 cores at 2.4 GHz, 64 GB of RAM, and 120 GB of flash. The cluster has three DataNode machines, and four machines act as HDFS clients. The machines are connected with 10Gb links. HDFS experiments have a load and read phase: in the load phase, we load the cluster with 500, 128MB files with random data. In the read phase, clients randomly select files to read. After the load phase, we clear the page cache.

Error Injection. To simulate UBERs, we inject bit errors into the files of both systems. In ZippyDB, we inject errors with a custom RocksDB environment that flips bits as they are read from a file. In HDFS, we run a script in between the load and read phases that flips bits in on-disk files and flushes them. For an UBER of μ, e.g. $\mu = 10^{-11}$, we inject errors at the rate of 1 bit flip per $1/\mu$ bits read. We tested with UBERs higher than the manufacturer advertised 10^{-15} to test the system's performance under high error rates, and so that we can measure enough bit errors during an experiment time of 12 hours rather than several days (or years)[3].

Baselines. We compare against unmodified HDFS and ZippyDB, both systems used in production for many years. Although unmodified HDFS does compute checksums for chunks, it does not recover at that granularity. HDFS-DIRECT leverages these checksums during recovery, which allows it to recover blocks synchronously within client reads. In unmodified ZippyDB, when a RocksDB instance encounters a compaction error, the entire ZippyDB server crashes. While this may seem like an overly aggressive baseline, due to the difficulty of recovering an individual object in a logically-replicated system, we did not find an alternative baseline that was correct and easier to implement. One possible strawman is to recover the individual RocksDB instance that encountered a bit error. Even this approach has significant error amplification (tens of GBs per bit error), and suffers from high implementation complexity, as ZippyDB has no existing logic for recovering individual RocksDB instances.

[3] Note that an UBER 10^{-11} is $10,000\times$ *higher* than 10^{-15}.

UBER	HDFS Thruput [GB/s]	HDFS-DIRECT Thruput [GB/s]
10^{-7}	0.00 ± 0.00	2.09 ± 0.08
10^{-8}	0.00 ± 0.00	2.56 ± 0.09
10^{-9}	2.46 ± 0.08	2.55 ± 0.07
10^{-10}	2.89 ± 0.10	2.84 ± 0.07
No errors	2.83 ± 0.07	2.88 ± 0.07

Table 2: Throughput of HDFS and HDFS-DIRECT. At UBER of 10^{-8}, HDFS throughput collapses due to bit errors.

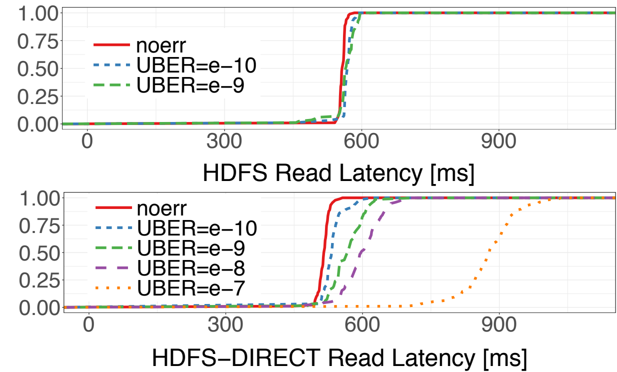

Figure 8: Read latencies (128 MB) of HDFS and HDFS-DIRECT. All reads fail in HDFS an UBER of 10^{-8} and higher. (Note that all latencies in HDFS-DIRECT are shifted slightly to the left, and this is due to temporal variations in our shared, experimental testbed.)

5.1 HDFS

UBER Tolerance. The main advantage of HDFS-DIRECT over HDFS is the ability to tolerate much higher UBERs with chunk-level recovery and majority voting. Figure 7 reports block read error rates of HDFS with varying UBERs. In HDFS, read errors are also considered *data loss*, because the data is unreadable (and hence unrecoverable) even after trying all 3 replicas. The figure shows the measured read error on our HDFS experimental setup, within the UBER range in which we could effectively measure errors, as well as the computed read error based on the computation presented in §3. We compared unmodified HDFS, with chunk-by-chunk recovery and bit-by-bit majority. The experimental read error is collected by running thousands of file reads and measuring how many fail. The measured results are relatively close to the analytical results, and in fact experience even fewer errors than the analytical model (the measured curves are shifted to the right of the analytic curves). We believe the primary reason is that the Taylor's approximation used in the analytical model does not hold for high UBERs. As expected, bit-by-bit majority (green lines) reduces the read error rate even further due to its lower error amplification (it can recover bit-by-bit). Both our analysis and the experimental results show that HDFS-DIRECT can tolerate a $10,000\times$–$100,000\times$ higher UBER and maintain the same read error rate.

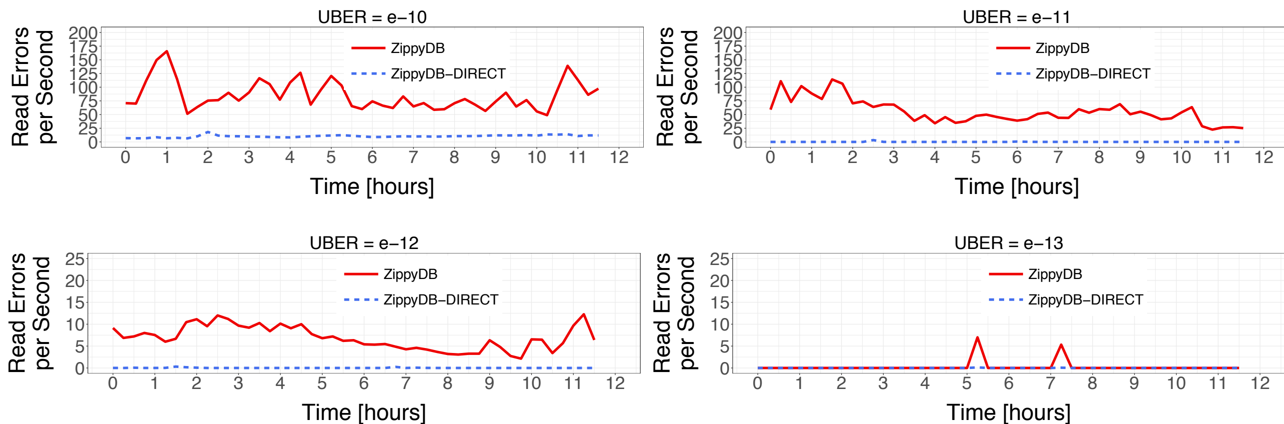

Figure 9: Read error rates over time in ZippyDB and ZippyDB-DIRECT, under varying UBERs.

UBER	Time to Complete Benchmark (s)
10^{-7}	177.4 ± 2.5
10^{-8}	169.4 ± 2.1
No errors	166.2 ± 1.8

Table 3: Time for HDFS-DIRECT to complete TeraSort benchmark. Note that we do not present results for unmodified HDFS, because for the UBERs tested, HDFS cannot complete any reads.

Overhead of DIRECT. Because DIRECT corrects bit errors synchronously in HDFS, error correction poses an overhead on reads that encounter bit errors. Table 2 shows the throughput of both systems, measured by saturating the DataNodes with four, 64-threaded clients that are continuously reading random files. The throughput of HDFS goes to zero at an UBER of 10^{-8}, because it cannot complete any reads due to corruption errors. Such failures do not occur in HDFS-DIRECT, although its throughput decreases modestly due to the overhead of synchronously repairing corrupt chunks during reads.

For HDFS-DIRECT, we are also interested in latency incurred by synchronous chunk recovery. We compare the CDF of read latencies of 128 MB blocks for different UBERs in Figure 8. The higher the UBER, the more chunk recovery requests that need to be made during a block read and the longer these requests will take. The results in Figure 8 (and Table 2) highlight the fine-grained tradeoff between performance and recoverability that is exposed by DIRECT. We also report HDFS read latencies, but there is little difference across UBERs because only latency for successful block reads are included; again, we do not report results for UBERs higher than 10^{-8}, since at those error rates HDFS cannot successfully read any blocks.

We also note that the latencies reported are the time it takes to read an entire 128 MB *file*, which is composed of many (64K) chunks. Hence Figure 8 hides a small *chunk* tail latency introduced by DIRECT. For example, chunks can now encounter errors on 0, 1, 2, or 3 of its replicas. Most chunks will encounter 0 errors, but some may encounter errors on all 3 of its replicas, which will require a relatively costly majority voting round. However, these disparate chunk latencies are hidden in the file latency, because all files have almost the expected number of errors (128 MB$\cdot UBER$).

Interestingly, these overheads become minimal when we run an end-to-end benchmark. We ran the TeraSort benchmark, a canonical Hadoop benchmark. We configured TeraSort to generate and sort 20 GB of data. Table 3 shows the time it takes HDFS-DIRECT to complete the TeraSort benchmark. Note that at an UBER of 10^{-8}, the time it takes to complete the benchmark is similar to when there are no errors (in fact, we do not report results for UBERs lower than 10^{-8} because they are so similar to results when there are no errors). Even at an UBER of 10^{-7}, the performance overhead is relatively low, because TeraSort is dominated by sort time in the mappers and reducers, rather than the time it takes to read the data into memory. These results suggest that even at very high UBERs, DIRECT imposes a low recovery overhead in workloads that are not disk-bound.

5.2 ZippyDB

UBER Tolerance. One main difference between unmodified ZippyDB and ZippyDB-DIRECT is that ZippyDB-DIRECT avoids crashing when encountering a bit error. To characterize how many server crashes are mitigated with DIRECT, we measured the average rate of compaction errors per hour *per server*, over 12 hours. The results are shown in Table 4. Figure 9 shows the read error rate over time of both systems, and Table 4 also shows the number of read errors as a percentage of all reads. Note that the error rate patterns across UBERs are different because they are run during different time intervals, so each UBER experiment sees different traffic. We did try to ensure read/write QPS and query distribution remain steady throughout the experiments[4].

The error rate is much higher for ZippyDB than ZippyDB-DIRECT because not only do clients see errors from regular read operations, but also they experience the spike in errors when a server shuts down due to a compaction corruption.

[4]Unfortunately, there is no tracing system set up for ZippyDB, so we were unable to capture and replay traces for consistency.

	Read Errors		Compaction Errors per Hour per Server
UBER	ZippyDB	ZippyDB-DIRECT	ZippyDB
10^{-10}	2.7308%	0.1865%	0.1991 ± 0.1077
10^{-11}	1.9808%	0.0400%	0.0621 ± 0.0455
10^{-12}	0.2650%	0.0008%	0.0038 ± 0.0035
10^{-13}	0.0108%	0.0002%	0.0003 ± 0.0005

Table 4: Read and compaction errors with ZippyDB and ZippyDB-DIRECT. The read errors are a percentage of the total number of reads, and the compaction errors are the number of errors per hour per server. ZippyDB-DIRECT is able to fix all compaction errors in our experiment, while the server crashes in ZippyDB.

Time Spent in Reduced Durability. With DIRECT, we also seek to minimize the amount of time spent in reduced durability to decrease the likelihood of simultaneous replica failures. Figure 10 shows a CDF of the time it takes to recover from compaction errors in ZippyDB-DIRECT. The graph shows the amount of time it takes for replicas to process the Paxos log up until the patch request, as well as the overhead of constructing and inserting the patch. With DIRECT, this recovery time is on the order of *milliseconds*. In contrast, the period of reduced durability in unmodified ZippyDB due to a compaction error is on the order of *minutes*, depending on the amount of data stored in the crashed ZippyDB server. This is due to the high error amplification of ZippyDB, which invalidates 100s of RocksDB shards due to a single compaction bit error. With DIRECT, ZippyDB can reduce its recovery time due to a bit error by around $10,000\times$. Even with a more reasonable baseline that only invalidates the single RocksDB shard that experienced the error, we estimate that DIRECT can reduce the recovery time by around 100x.

We also found that the recovery latency is dependent on the size of the patch required to correct the corrupted key range. Figure 11 presents a CDF of the size of the patches generated during the recovery process. Patch size is also interesting because the recovery mechanism described in Section 4.2.4 recovers a *range* of keys, since the exact keys on the corrupted data block are impossible to identify. As we see in Figure 11, even though recovering a range can in theory increase error amplification, the number of keys required for recovery is still low (a single RocksDB instance contains on the order of millions of key-value pairs). Figure 11 also confirms that, generally, as the UBER increases, patch sizes increase due to more key ranges getting corrupted during a single compaction operation. We note that UBER=10^{-12} yielded an anomalous line, but by the time we analyzed the data, we no longer had access to the experimental system to rerun the results. We speculate that a variety of factors could have caused the anomaly: 1) The corruption error could have occurred on a particularly dense subset of the key space. 2) the corruption error might have occurred during a read to a bottom-level SST file in RocksDB; due to compaction, key-ranges used for recovery grow progressively larger in lower levels of the RocksDB LSM tree.

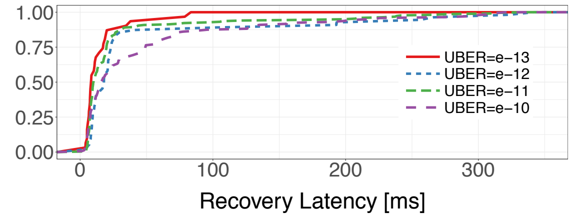

Figure 10: CDF of compaction recovery latencies in ZippyDB-DIRECT. ZippyDB-DIRECT takes milliseconds to recover from corruptions, while ZippyDB takes *minutes*.

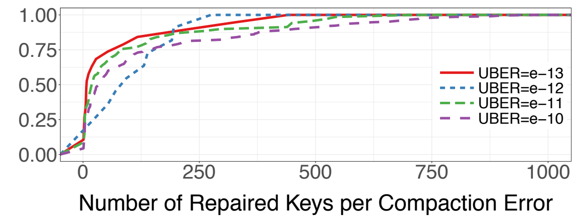

Figure 11: CDF of patch sizes generated during the ZippyDB-DIRECT recovery process. The patch size is small, which means low error amplification.

Measuring Cost. DIRECT trades off higher reliability and longer device lifetime for engineering and operational costs. We are unable to capture these costs in our evaluation but describe the changes to the software stack needed in order to run DIRECT in production. For example, ZippyDB-DIRECT required around 1200 lines of C++ code and HDFS-DIRECT required around 450 lines of Java code. As we discuss in Section 6, a DIRECT stack will also require running a hardened filesystem, such as ZFS, so that the local filesystem can continue functioning after encountering bit errors.

6 Discussion

Local File System Error Tolerance. When devices exhibit higher UBERs, local file systems also experience higher UBERs. DIRECT protects application-level metadata and data, which are data blocks to the local file system. Protecting local file system metadata such as inodes, the FS journal, etc. is beyond the scope of this paper. Several existing file systems protect metadata against bit corruptions [3, 17, 18, 43, 55, 70, 81]. The general approach is to add checksums and locally replicate for error correction. Another approach is to use more reliable hardware for metadata and less reliable hardware for data blocks [55].

Support for DIRECT. Some simple device-level mechanisms would help datacenter operators run devices past their manufacturer defined UBER. First, it would be beneficial if devices have a less aggressive "bad block policy", which is a firmware protocol for retiring blocks once they reach some heuristic-defined level of errors.

Second, it would be helpful if devices return the content of corrupted pages, although this is not a hard requirement This enables distributed storage applications to minimize recovery amplification by recovering data at a granularity smaller than

a device page. For example, to use majority voting, a system operator must use devices that return the content of corrupted pages, such as Open-Channel SSDs [25]. Fortunately, majority voting is optional and only applicable to block-replicated systems, and all other aspects of DIRECT apply if the system operator uses traditional flash devices. In case corrupt pages cannot be read, copies of local metadata must be stored on separate physical pages. Otherwise, a page error could invalidate all copies of the metadata.

Retrofitting PostgreSQL. As we discussed earlier, PostgreSQL is difficult to retrofit with DIRECT. This is because Postgres pages do not have indexing information; indexes in Postgres are stored on separate pages, if at all (no indexes are built without explicit user commands). Postgres checksums are at the page granularity, so if there is a bit error on a data page, DIRECT would need to figure out all the tuples stored on the page in order to both minimize error amplification and do correct recovery (Postgres uses MVCC to support transactions). The only way to determine these tuples and their versions is to comb through the index pages for any pointers to the corrupt page: in particular, we observe that what we need for DIRECT is a *reverse* index, one that maps from pages to tuples, rather than from tuples to pages. Generally, for DIRECT to be efficient in logically-replicated systems, the page layout must provide insight into what tuples are stored on a page. For example, RocksDB builds such a reverse index implicitly in the index blocks of its file format.

Network Partitions. Because DIRECT uses remote redundancy to correct bit errors, network failures can now affect the recovery process. Fortunately, real-world studies have shown that the most common kind of network failure— link failures — do not greatly affect application availability, because there are enough redundant paths built into the network topology [41]. In future work, we plan to both model and evaluate how transient or permanent network failures affect both recovery latency and error rate.

7 Related Work

Our work departs from existing work on data integrity in data storage systems [24, 26, 53, 73] because we expose bit corruptions at the distributed layer, rather than containing them in the storage layer. Furthermore, DIRECT does not stop at identifying corruptions but introduces a principled and performant way of fixing them to achieve high availability.

Software-level Redundancy. DIRECT is related to PAR [20] and PASC [33], which demonstrate how consensus-based protocols can be adapted to address bit-level errors. Unlike both of these works, which only address consensus protocols, our work tackles bit-level errors in general purpose storage systems. We also show how increasing the resiliency to bit errors can significantly reduce storage costs and improve live recovery speed in datacenter environments.

Other related work use different approaches. HARDFS [35] hardens local HDFS nodes by augmenting each node with a lightweight version that verifies its behavior. HDFS-DIRECT generalizes HARDFS, by only applying local protection to metadata and leveraging distributed replicas to recover data. FlexECC [46] and Duracache [60] are flash-based key-value caches that use less reliable disks by treating devices errors as cache misses. D-GRAID is a RAID storage system that gracefully degrades by minimizing the amount of data needed to recover from bit corruptions [74]. AHEAD and EDB-Tree apply software-level error detection and correction to address DRAM corruption in databases [51, 52].

There is a large number of distributed storage systems that use inexpensive, unreliable hardware, while providing consistency and reliability guarantees [23, 34, 40]. However, these systems treat bit corruptions similar to entire-node failures and suffer from high recovery amplification.

Hardware-level Redundancy. Several studies explore extending SSD lifetime via more aggressive or adaptive hardware error correction. Tanakamuru *et al.* [77] propose adapting codeword size based on the device's wear level to improve SSD lifetime. Cai *et al.* [30] and Liu *et al.* [61] introduce techniques to dynamically learn and adjust the cell voltage levels based on retention age. Zhao *et al.* [83] propose using the soft information with LDPC error correction to increase lifetime. Our approach is different: instead of improving hardware-based error correction, we leverage existing software-based redundancy to address bit-level errors.

8 Conclusion and Future Work

This paper presents DIRECT, a set of general techniques that use the inherent redundancy that exists in distributed storage applications for live recovery of bit corruptions. We showed with implementations of DIRECT in HDFS and ZippyDB that these techniques are widely applicable and, once implemented, can increase the bit error rate tolerance of distributed systems by orders of magnitude.

We envision extending the DIRECT approach in several directions. First, distributed storage systems can control error correction depending on how sensitive particular data is to bit corruptions (e.g. critical metadata). Second, distributed storage systems can control hardware mechanisms that influence the reliability as well as the performance of the device. For example, storing fewer bits per cell may reduce the latency of the device (at the expense of its capacity), and offer higher reliability. Certain applications may prefer to use a hybrid of low latency and low capacity devices for hot data, while reserving the high capacity devices for colder data.

Abstract

This paper tries to accelerate data recovery in a large-scale storage system with minimal interference to foreground traffic. By investigating I/O and failure traces from a real-world large-scale storage system, we find that because of the scale of the system and the imbalanced and dynamic foreground traffic, no existing recovery protocols can generate a high-quality recovery strategy in a short time.

To address this problem, this paper proposes Dayu, a timeslot-based recovery protocol, which only schedules a subset of tasks which are expected to finish in one timeslot: this approach reduces the computation overhead and naturally can cope with the dynamic foreground traffic. In each timeslot, Dayu incorporates four key algorithms, which enhance existing solutions with heuristics motivated by our trace analysis.

Our evaluations in a 1,000-node real cluster and in a 25,000-node simulation both confirm that Dayu can outperform existing recovery protocols, achieving high speed and high quality.

1 Introduction

This paper describes our experience and methods to accelerate data recovery in Pangu [1] , a real-world large-scale storage system with 10K nodes and tens of TBs of storage per node.

As a cloud storage provider, AliCloud, the owner of Pangu, needs to make a promise of data durability to its customers (*i.e.*, the chance of data loss is smaller than a threshold). For marketing reasons, the owner has a strong motivation to improve data durability, so that its promise can be appealing compared to its competitors. This motivates us to investigate whether it is possible to accelerate data recovery in Pangu, because recovery speed is one of the determining factors of data durability [2].

Similar to previous works [3–7], Pangu divides data into chunks (usually tens of MBs), replicates these data chunks, and distributes these replicas to different nodes. When a node fails, Pangu re-replicates its data chunks: since the replicas of these chunks are distributed to different nodes, Pangu asks all these nodes to copy chunks in parallel [4, 8].

To re-replicate data chunks of the failed node, the recovery protocol needs to schedule a source, a destination, and a bandwidth for each of these data chunks. An ideal scheduling algorithm should achieve at least the following two goals: first, the algorithm should generate a high-quality strategy, which should allow data re-replication to be completed as soon as possible under the constraint that it has minimal impact on foreground traffic; second, the speed of the scheduling algorithm itself should be high enough so that it does not become the bottleneck of data recovery.

To understand the quality and speed of existing scheduling algorithms, we analyze the failure and I/O traces from a real deployment of Pangu. We find none of the existing algorithms can achieve both acceptable quality and acceptable speed, because of the following challenges:

- *Very-large scale*: the largest deployment of Pangu has more than 10K nodes and up to 72 TBs of storage (about 1.5M chunks) per node. Therefore, when a node fails, the algorithm needs to decide how to recover all these data chunks and each chunk has about 10K nodes as candidate destinations.
- *Tight time constraint*: given the scale of the system, data chunks of a failed node can be re-replicated with a high degree of parallelism. Our simulation shows that if the idle bandwidth can be fully utilized, the recovery can be finished within tens of seconds, which means the scheduling algorithm itself should complete within seconds.
- *Imbalanced foreground traffic and available data*: we find a two-fold imbalance, which poses challenges to the quality of scheduling. First, a number of nodes can have significantly heavier foreground traffic than the others; and second, some nodes can have more data chunks available for re-replication.
- *Dynamic foreground traffic*: the foreground traffic can change dramatically over time. To cope with such dynamic traffic, the recovery protocol needs to adjust its

[*]Corresponding author: gyzh@tsinghua.edu.cn

plan when it observes a significant change in the foreground traffic, which again calls for fast scheduling.

Our simulation of existing scheduling algorithms shows that, on the one hand, simple and decentralized algorithms like random selection or best-of-two-random [9] can finish scheduling quickly (*i.e.*, high speed), but they often cause a small number of nodes to be overloaded, increasing the recovery time and impairing the performance of foreground traffic (*i.e.*, low quality). On the other hand, sophisticated and centralized algorithms, such as Mixed-Integer Linear Programming [10–12], can effectively utilize available bandwidth and avoid overloading a node (*i.e.*, high quality), but they can take prohibitively long to compute a plan given the scale of our target system (*i.e.*, low speed).

This paper proposes Dayu, a high-speed and high-quality recovery protocol for large-scale, imbalanced, and dynamic storage systems. The key idea of Dayu is motivated by the observation that, to cope with dynamic foreground traffic, we need to periodically monitor the foreground traffic and adjust the recovery plan: in such a design, scheduling for all data chunks of the failed node together is both computationally heavy and unnecessary, since the plan is likely to be adjusted later. Following this observation, Dayu incorporates a timeslot-based solution: it divides time into multiple slots, whose length is determined by how frequent the underlying storage system monitors and reports idle bandwidth; based on such report, Dayu tries to schedule a subset of chunks so that they can be re-replicated within the current timeslot; if the actual re-replication of some chunks takes longer than expected for whatever reason, Dayu will re-schedule them in the next timeslot.

This approach brings two benefits: first, it reduces the computation overhead of scheduling because in each timeslot, the algorithm only needs to schedule a subset of tasks (about one third on average in our experiments). Second, this solution can naturally cope with the dynamic foreground traffic because Dayu's decision is based on the information collected at the beginning of each timeslot.

To realize this idea, Dayu incorporates four key techniques, which enhance existing algorithms based on our observations:

- *Greedy algorithm with bucket convex-hull optimization to schedule tasks*: Dayu uses a greedy algorithm to iteratively choose the most under-utilized candidate as the source and destination for each task, till it finds enough tasks to fill a timeslot. To reduce the computation overhead, Dayu incorporates the convex-hull optimization [13] and further proposes a bucket approximation to reduce the size of the candidate set.
- *Prioritizing nodes with high idle bandwidth but few available chunks*: Our observation shows that such nodes are likely to get under-utilized, if the scheduling algorithm decides to replicate their chunks from other nodes. Therefore, Dayu enhances the aforementioned greedy algorithm with the following heuristic: if a chunk to be re-replicated has a replica in such a prioritized node, Dayu will assign the node as the source.
- *Iterative WSS to allocate bandwidth for each task*: To minimize the completion time of chosen tasks, Dayu enhances the weighted shuffle scheduling algorithm (WSS) [14]: in each iteration, Dayu uses WSS to identify the bottlenecks in the remaining tasks, assigns a weighted fair share of bandwidth to each task correspondingly, and removes the bottleneck tasks and allocated bandwidth.
- *Re-scheduling stragglers*: Straggler tasks will inevitably occur due to mis-prediction of the foreground traffic or unexpected hardware faults, so Dayu has to re-schedule them in the next timeslot. Straggler tasks are different from new tasks, since we prefer keeping their destinations unchanged: otherwise, we will lose their existing progress. Dayu first estimates whether it is worth changing their destinations, and then re-computes their sources and allocated bandwidth.

Our evaluation of Dayu on a real deployment of 1,000 nodes shows that, compared to Pangu, Dayu increases the recovery speed by 2.96× and increases the p90 latency (i.e., tail latency at 90th percentile) of the foreground traffic during recovery by only 3.7%. Our simulation shows that Dayu outperforms various existing solutions and can scale to a cluster of 25K nodes.

2 Background and Observations

2.1 Background of Pangu

Pangu is the underlying storage system of AliCloud, one of the largest public cloud providers in Asia [1]. Pangu inherits the classic distributed file system architecture from previous works like GFS [3], HDFS [5], Cosmos [6], and Azure [7]. It splits data into multiple chunks (the most common chunk size is 64MB) and stores data chunks on a large number of data servers called *ChunkServers*. A metadata server called *MetaServer* maintains the metadata of the distributed file system, such as the locations of data chunks. Given its very large scale, Pangu incorporates multiple *MetaServers*, each responsible for a subset of metadata [15–17]. Besides, Pangu incorporates a *RootServer* to route clients to the corresponding *MetaServer*. To achieve uniform data distribution, Pangu uses random or weighted random mechanism to place data on different *ChunkServers*.

Like most existing systems, Pangu replicates data chunks (most chunks have three replicas) so that if a node fails, Pangu can recover its data chunks by copying from other replicas. For each data chunk to be recovered, Pangu needs to choose a source and a destination for data copy: there are usually a few candidate sources depending on the number of replicas and a

large number of candidate destinations. The current version of Pangu randomly picks a source and a destination for each data chunk to be recovered.

In the current deployment of Pangu, we observe that the network bandwidth is usually the bottleneck when performing such data recovery: most Pangu nodes are equipped with 1Gb or 10Gb Ethernet, whose bandwidth is smaller than the aggregate disk bandwidth; the deployment of high-speed devices, such as Infiniband, is limited due to cost reasons. Pangu's core network switches are organized using CLOS topology or fat-tree topology [18–21], so that there is no oversubscription. The core-to-rack link may be oversubscribed depending on the configuration: if the link is oversubscribed, the rack switch is usually the bottleneck; if not, the NICs of end-hosts are the bottlenecks.

During data recovery, Pangu is still servicing foreground applications, which may contend for network bandwidth. To limit the interference of data recovery on foreground traffic, Pangu provides a mechanism to limit the bandwidth utilization of one or a group of links on a node. With this mechanism, we can set a limit on the bandwidth of the recovery traffic, depending on how much interference one is willing to tolerate and the bandwidth of the foreground traffic. In Dayu, we limit the bandwidth of the recovery traffic on each node to be

$$B_{recover} = max(\alpha \times B_{total} - B_{foreground}, B_{min}) \qquad (1)$$

In this equation, B_{total} is the total bandwidth of the node; $B_{foreground}$ is the bandwidth of the foreground traffic; and α is a parameter to control the interference of the recovery traffic on the foreground traffic. We set α to be 75% and our experiments show that using this setting will incur negligible impact on p90 latency of the foreground traffic. As a storage system mainly designed for large files, Pangu does not aim at optimizing extreme tail latency (e.g. 99.9 percentile [22]), so this setting can satisfy our requirement, and if one is targeting even smaller interference, he/she can further decrease α. B_{min} is the minimal bandwidth the node will assign for recovery, which is to ensure that recovery will not be too slow. Both Pangu and Dayu set B_{min} to 30MB/s.

2.2 Observations

In this subsection, we analyze the workload and data placement from one deployment of Pangu to understand how they affect data recovery. We acquire such information from a data center of approximately 3500 nodes, each with two 1G NICs and 11 2TB hard drives. In this case, the aggregate bandwidth of hard drives is larger than that of the NICs. The storage system mainly serves online data processing service (*ODPS*), including MapReduce and data query. What we analyze includes 1) a checkpoint of a *MetaServer* in April 2018, which records the metadata related to the size and distribution of the data chunks, and 2) the trace of the foreground traffic and background recovery traffic in the coming week. Unless otherwise noted, our simulation experiments are on this 3500-node cluster throughout this paper. We study the scalability of Dayu beyond 3500 nodes in Section 5.2.

We make the following observations from the analysis:

Observation 1 *Each node stores hundreds of thousands of chunks.*

Figure 1(a) shows the CDF of the number of chunks on each node. We can observe that a majority of the nodes have around 250K chunks per node. This observation suggests two things: first, a recovery protocol needs to schedule how to recover so many chunks when a node fails. Second, when one node fails, each of the remaining nodes will participate in the re-replication of about 70 chunks on average (250K/3500).

Observation 2 *The foreground traffic consumes less than half of the bandwidth on average. If all available bandwidth (computed using Equation 1) can be used for recovery, the system can recover 250K chunks in 51 seconds on average.*

We calculate the optimal recovery time for 50 different cases, assuming all available bandwidth can be utilized, and present the CDF of the recovery time in Figure 1(b).

This observation suggests that, although there are a large number of chunks to recover for each node failure, the highly parallel recovery in a large-scale system can recover these chunks in a short time, which calls for fast scheduling during the recovery protocol. However, the actual recovery in the trace often takes 2-4 minutes, i.e. $2.35 - 4.70\times$ of the ideal recovery time, which motivates our further investigation.

Observation 3 *The foreground traffic is experiencing significant short-term load imbalance.*

The trace we analyze records the foreground bandwidth of each node every 15 seconds. To understand whether the foreground traffic is balanced, we compute the coefficient of variation (CoV, standard deviation as a percentage of the mean) of foreground bandwidth in each timeslot, which is a standard metric to measure the variation of values. Then we draw the distribution of CoVs of different timeslots in Figure 1(c) and Figure 1(d). As shown in this figure, the CoVs of most timeslots are between 0.4 and 0.6, which is quite significant. Interestingly, if we measure such imbalance in a coarser granularity (i.e. one hour and one day), the imbalance becomes much smaller. Such results indicate that the system is relatively load balanced in a long term, but more imbalanced in a short term, which creates a challenge for data recovery: traditional load balancing techniques, such as data migration, mainly targets long-term imbalance, because they cannot run very frequently; data recovery, however, is mainly affected by short-term imbalance, because it can finish within tens to a few hundred seconds. This observation suggests that our recovery protocol must take such short-term imbalance into consideration, without relying on load balancing techniques.

(h) OB5: Bandwidth utilization variance.

Figure 1: Observations from a 3500-node real-world system

Observation 4 *Replicas of chunks on a given nodes are distributed unevenly among the other nodes.*

To understand how replicas of chunks on a given node are distributed among the other nodes, we define SC_j^i as the size of the chunks held by both node i and node j, which shows how much data node j can provide as source during recovery if node i fails.

We first sample a specific node $i = 100$. Figure 1(e) shows the distribution of SC_j^{100} for different j values. We can see that the histogram of the distribution fits the bell curve: this is actually mathematically provable (i.e. Central Limit Theorems) if we assume chunk placement is random. To understand such imbalance in the whole cluster, for each node i, we calculate the CoV of all the SC_j^i values and then we draw the CDF of CoVs of all nodes in Figure 1(f). One can observe that for a large portion of nodes, the distribution of SC_j^i is not balanced.

To understand how such imbalance affects recovery, we simulate the failure of node 100 with Pangu's random node selection strategy (Figure 1(g)) and find that there is a strong correlation between the size of outgoing recovery traffic of node j and SC_j^{100}. That means a node with a few (many) common chunks with the failed node will do little (much) work during recovery, but if the node has much (little) available bandwidth, it will get under-utilized (overloaded).

Observation 5 *Foreground traffic usually fluctuates within 14.4% of max bandwidth, but sometimes can change dramatically.*

Figure 1(h) shows how one node's foreground traffic changes in 5 hours. The delta bandwidth is the difference of the average bandwidth utilization in two adjacent timeslots. We can observe that in more than 95% of the cases (between "p2.5" and "p97.5" in Figure 1(h)), the absolute delta bandwidth is lower than 36MB/s, which is 14.4% of the maximum bandwidth (250 MB/s since each node has two 1Gb NICs). However, in the remaining 5% cases, the delta bandwidth can reach up to two thirds of the maximum bandwidth. Although the percentage of such extreme cases is small, they frequently happen in recovery, because the highly parallel recovery usually involves many nodes. Our simulation shows that they can create stragglers in recovery and thus are one of the major reasons why recovery speed is not ideal.

3 Dayu Overview

We call the re-replication of one data chunk a "recovery task" in the rest of the paper. Dayu achieves fast data recovery and low application interference by introducing a centralized scheduler called an *ObServer*, which performs timeslot-based recovery task scheduling.

Dayu assumes all the data servers periodically report their chunk placement and network utilization to the *ObServer*, and all the metadata servers send information of the recovery tasks to the *ObServer*. The rest of this paper presents the *ObServer*'s scheduling algorithm, which decides the source, the destination, and the bandwidth of a recovery task.

To achieve high-speed and high-quality scheduling, the key idea of Dayu is to schedule recovery tasks in multiple batches, instead of scheduling all of them together. This design choice is motivated by several reasons: first, since each node is usually involved in tens of recovery tasks (Observa-

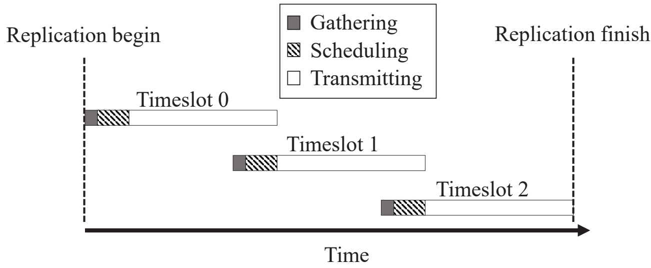

Figure 2: Timeslot-based scheduling in Dayu

$T_{timeslot}$	Length of a timeslot
$B^i_{recover_in/out}$	Node i's available incoming/outgoing bandwidth for recovery (by Equation 1)
s_t	Size of recovery task t
$c^i_{in/out}$	Total size of incoming/outgoing recovery tasks assigned to node i
α, β	Parameters

Table 1: Denotations

tion 1), scheduling tasks in multiple batches can still allow each node to fully participate in each batch and thus fully utilize its available bandwidth; second, scheduling tasks in batches can naturally cope with dynamic foreground traffic and infrequent measurement errors, because when observing any changes in the foreground traffic, Dayu can make adjustment in the next batch; finally, scheduling tasks in batches naturally reduces the computation overhead of the scheduling algorithm, because for each batch, the algorithm only needs to schedule a subset of tasks.

To implement this idea, as shown in Figure 2, Dayu divides the whole recovery time into multiple fixed-length time slices (called *timeslots* throughout the paper). At the beginning of a timeslot, the *ObServer* collects the latest state of the data servers. Using the state obtained, the *ObServer* chooses and schedules a subset of recovery tasks in this timeslot, including those recovery tasks scheduled in the last timeslot but unfinished yet. To fully utilize the available bandwidth, Dayu overlaps multiple timeslots so that the information gathering and task scheduling of slot n is executed before the end of slot $n-1$. The length of a timeslot is determined by how frequently the underlying storage system collects and reports state.

As mentioned in Section 2.1, the bottleneck of data recovery is either the NICs of the end hosts or the rack switch, and to simplify description, the following text assumes the NICs of the end hosts are bottlenecks, and one can easily extend it to support bottleneck rack switches. Table 1 lists the denotations used in the paper.

Goals. Dayu tries to achieve the following goals.

- **Goal 1: Utilize the available bandwidth as much as possible.** This is a natural goal to minimize the overall recovery time. If we were to fully utilize the available bandwidth in one timeslot, the total size (S) of the chunks that can be replicated in the timeslot would be:

$$S = min(\sum_{i \in Nodes} B^i_{recover_in}, \sum_{i \in Nodes} B^i_{recover_out}) \times T_{timeslot} \quad (2)$$

- **Goal 2: Finish as many tasks as possible in the target timeslot.** We hope that the scheduled tasks can actually finish within the target timeslot: otherwise, we have to re-schedule them again, which increases the computation overhead. This goal may look similar to the first one, but it is not: the first goal suggests us to oversubscribe the network bandwidth (i.e. schedule more tasks than the bandwidth can handle), so that if the foreground traffic drops, we can still utilize such extra available bandwidth; the second goal, however, suggests us to undersubscribe the network bandwidth so that if the foreground traffic increases, we can still finish the scheduled tasks. Therefore, Dayu has to make a trade-off between these two goals.
- **Goal 3: Minimize the chance of significant stragglers.** Because we cannot accurately predict the future foreground traffic, stragglers will inevitably occur. We prefer many small stragglers to a few significant stragglers, because many small stragglers can be re-scheduled and executed in parallel to minimize the recovery time. However, this goal obviously contradicts with the second goal, so Dayu has to make a trade-off as well.

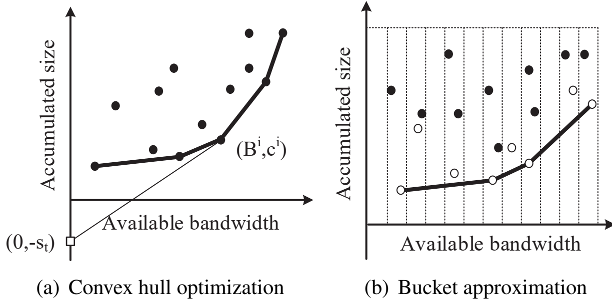
Overview of Dayu's algorithm. To achieve these goals, Dayu incorporates four key techniques, by enhancing existing algorithms with heuristics and approximations motivated by our observations: 1) a greedy algorithm with bucket convex hull optimization to select the source and the destination for each recovery task (§4.1); 2) a heuristic-based algorithm to prioritize nodes with a few common chunks with the failed node but a high available bandwidth (§4.2); 3) an iterative WSS algorithm to assign bandwidth for each task (§4.3); and 4) a heuristic-based algorithm to minimize the cost of re-scheduling straggler tasks (§4.4).

4 Design of Dayu

4.1 Selecting Source and Destination

Dayu iteratively scans all tasks and determines the source and the destination for each task, till it can find enough tasks to fill S (Equation 2). The candidate sources of a task include all nodes which hold a replica of the corresponding chunk; the candidate destinations of a task include all nodes which are not in the same rack of its sources.

To achieve the goals given in Section 3, Dayu incorporates a greedy algorithm: for each task, Dayu chooses the most under-utilized node in its candidate sources and destinations;



(a) Convex hull optimization (b) Bucket approximation

Figure 3: Reduce computation overhead with dynamic convex hull optimization. B^i and c^i are short for $B^i_{recover_in}$ and c^i_{in}.

if Dayu finds that even the most under-utilized candidate is going to be saturated, Dayu will skip this task.

The first question we need to answer is how to quantitatively measure the utilization of a node. We have tried several options, and through simulation, we decide to use the expected task finish time $\frac{c_{in/out}}{B_{recover_in/out}}$ ($c_{in/out}$ is the total size of the incoming/outgoing tasks assigned to this node) as the metric to evaluate the utilization of a node, because this metric achieves a nice balance between our first two goals.

Therefore, when choosing the source for task t, Dayu scans all its candidate nodes and chooses the one with the minimal $\frac{s_t+c_{out}}{B_{recover_out}}$ as the source. Such scanning is not computationally expensive, since most chunks have three replicas and one of them is already lost. Afterward, Dayu checks whether assigning task t to the source will saturate the source, i.e. its $\frac{s_t+c_{out}}{B_{recover_out}} > T_{timeslot}$: if so, Dayu will drop task t, because this means there is no way to complete task t in this timeslot.

Likewise, when choosing the destination for task t, Dayu chooses the node with the minimal $\frac{s_t+c_{in}}{B_{recover_in}}$. However, naively scanning all candidate destinations is computationally heavy, since the number of candidate destinations is large. To make things worse, greedy algorithms cannot be parallelized because each iteration depends on the result of the previous iteration. Our simulation on a 3500-node cluster shows that naively scanning all candidate destinations for each task can only achieve a speed of less than 30,000 tasks per second. Since our statistics shows that in one timeslot, Dayu can usually complete 60,000—150,000 tasks, this means naively scanning itself will take 2-5 seconds, which is not ideal. To address this challenge, we incorporate the dynamic convex hull optimization to accelerate this computation.

One can refer to [13] for the formal description of the convex hull optimization, and here we present an intuitive description. For each surviving node i, we draw a point $(B^i_{recover_in}, c^i_{in})$ in Cartesian coordinate system, as shown in Figure 3(a). Then for task t with size s_t, we draw another point $(0, -s_t)$ in Figure 3(a). Afterward, we draw a line from $(0, -s_t)$ to each other point: since the slope of each line is $\frac{c^i_{in}+s_t}{B^i_{recover_in}}$, finding the destination node for task t is equivalent to finding the line with the lowest slope.

We can maintain a dynamic convex hull to quickly search the line with the lowest slope. In a two-dimensional space, a convex hull is like a rubber band that wraps all the points tightly, where the lower convex shell is the lower part of this convex hull. We refer the point set of the lower convex shell as H (here we connect points in H together to form the lower convex shell as shown in Figure 3(a)). The points in H are connected counterclockwise. Then for a point p_h with precursor point and successor point in set H, the slope of line $p_{h-1} \rightarrow p_h$ must be less than or equal to the slope of line $p_h \rightarrow p_{h+1}$. We can find the node c in set H whose connection with point $(0, -s_t)$ has the smallest slope using binary search and the time complexity is $O(\log|H|)$.

After Dayu assigns task t to node i, its c^i_{in} is incremented by s_t. Therefore, Dayu needs to adjust the point of node i as well as the lower convex shell H: when a point p_h in H moves up, Dayu identifies the precursor (p_{h-1}) and successor (p_{h+1}) of p_h in original H, and scans all the points between them to find the new member(s) of H. The convex hull optimization reduces the complexity of scanning destination nodes from linear to sub-linear, without affecting the results of the greedy algorithm.

We further propose an approximate solution to reduce the candidate set of the lower convex shell, in turn boosting the speed of the algorithm. As shown in Figure 3(b), we divide the range of available incoming bandwidth into multiple equal-sized buckets. If nodes i and j are in the same bucket, they are considered to have approximately identical available bandwidth, i.e. $B^i_{recover_in} \approx B^j_{recover_in}$. Without loss of generality, we suppose $c_i > c_j$. Then node i cannot be the member of the lower convex shell. Therefore, only the lowest node within the same bucket can become the member of the lower convex shell. All those lowest nodes (hollow circles in Figure 3(b)) form a reduced candidate set, denoted C. We can construct the convex shell H from this reduced candidate set C, instead of the full set of nodes. After Dayu assigns a task to a node, it adjusts the point of this node as well as the reduced candidate set.

The bucket size determines the reduction degree of the bucket approximation. We use 1 MB/s as the bucket size in our experiments, and our simulation shows an average reduction factor of 22.8, and as a result, Dayu can complete selecting sources and destinations for about 210,000 chunks within one second—this is seven times faster than naive scanning.

Such bucket approximation certainly brings inaccuracy to the greedy algorithm, but such inaccuracy already exists as a result of measurement errors and fluctuation of foreground traffic. Therefore, as long as the bucket size is small, our approximation should not significantly increase such inaccuracy.

4.2 Prioritizing Underemployed Nodes

Our simulation on our greedy algorithm reveals the same problem as our Observations 3 and 4: nodes with high available bandwidth but only a small number of available chunks are likely to get under-utilized, which violates our first goal. We call them *underemployed nodes* in the rest of the paper. For example, suppose node A has an available outgoing bandwidth of 50MB/s and can be the source of Tasks 1 and 2; node B has an available outgoing bandwidth of 60MB/s and can be the source of Tasks 1-4; all tasks have the same size. In this example, the optimal schedule should let A be the source of Tasks 1 and 2, and B be the source of Tasks 3 and 4. However, if our greedy algorithm scans Task 1 first, it will assign it to node B, because B has more available bandwidth than A at this moment.

This observation suggests that, for a chunk which has a replica in an underemployed node, it's better to use the underemployed node as the source. To achieve this goal, we incorporate a distribution-driven prioritizing strategy: the *ObServer* first sorts all the nodes according to their available outgoing bandwidth in descending order, and sorts all the nodes according to their total sizes of common chunks in ascending order. Then, the *ObServer* picks the first β (5% in our typical settings) nodes from those two node lists respectively to form two sets, and gets the underemployed node set by computing the intersection of those two sets. Next, the *ObServer* selects all the recovery tasks that have replicas in the underemployed nodes, and puts them in a queue called "prioritized queue"; the *ObServer* puts the rest of the tasks in another queue called "normal queue".

We modify our greedy algorithm (§4.1) to incorporate this heuristic: the *ObServer* will first scan tasks in the prioritized queue and directly use the corresponding underemployed server as the source, instead of using the most under-utilized candidate. There are two corner cases: 1) it is possible that a prioritized task has replicas in more than one underemployed servers. In this case, the *ObServer* chooses the most under-utilized one among them; 2) though rare, it is possible that the underemployed server is saturated. In this case, the *ObServer* degrades the prioritized task into the normal queue, so that later we can still try its non-prioritized candidates.

Overhead. When searching underemployed nodes, Dayu maintains two heaps, whose keys are the available outgoing bandwidth and the total size of common chunks respectively, and whose values are the IDs of nodes. The *ObServer* will first build these two heaps, which is an $O(n)$ operation (n is the number of nodes) [23], and then pop 5% entries from these two heaps, with each pop an $O(\log n)$ operation. Our experiment shows that heapifying 10,000 entries and then popping up 5% of them only take a few miliseconds.

4.3 Allocating Bandwidth for Each Task

Given the source and destination of each recovery task, we need to answer how fast each task should proceed. A naive solution is to set a coarse-grained limit on all tasks within one node using $B_{recover_in/out}$ and let them compete for bandwidth. However, our experiments have revealed two problems with this approach: first, this approach may cause a congestion when the source's outgoing limit is larger than the destination's incoming limit. Although TCP can resolve such congestion eventually, it will cause packet drops and slow down recovery. Second, the competition may cause one task to be significantly slower than others, causing a significant straggler and violating our third goal.

Therefore, in this step, Dayu tries to set a constant rate for each task in one timeslot, with the goal of maximizing bandwidth utilization. Recall that we assume the NICs of the end hosts are the bottlenecks, so this step only considers the bandwidth utilization at the end hosts. Even so, this is still a challenging problem, since allocating bandwidth for a task will consume the bandwidth on both sides.

Dayu's solution is based on weighted shuffle scheduling (WSS) [14], a mature network scheduling algorithm designed for scheduling large data flows like data shuffle in MapReduce [24]. The key idea of WSS is that, to finish all the pairwise transfers at the same time, it guarantees that 1) transfer rates are proportional to data sizes for each transfer, and 2) at least one link is fully utilized. With WSS, only the bottleneck links (quite a minority) are fully used, while all the others have an amount of bandwidth left. In our scenario, however, WSS is not ideal: when considering unpredictable growth in foreground traffic, which may cause a non-bottleneck link to become a bottleneck in the middle of a timeslot, WSS may cause a waste of bandwidth, because Dayu could utilize more bandwidth of this link at the beginning.

To this end, Dayu introduces an iterative WSS solution to allocate bandwidth for each task. Its key idea is that, without delaying the bottleneck tasks, we should finish other tasks as early as possible, so as to reduce their completion time and to improve bandwidth utilization. Following this idea, if there is any remaining bandwidth after running one iteration of WSS, Dayu will use another iteration of WSS to identify the next bottleneck and allocate the remaining bandwidth.

To be specific, Dayu maintains a remaining incoming and outgoing bandwidth $B^i_{remain_in}$ and $B^i_{remain_out}$ for each node, whose initial values are $B^i_{recover_in}$ and $B^i_{recover_out}$. In each iteration, Dayu first finds the node with the longest $\frac{c^i_{in}}{B^i_{remain_in}}$ or $\frac{c^i_{out}}{B^i_{remain_out}}$, denoted T^*: the corresponding tasks are the bottlenecks. Then, Dayu allocates $B_t = \frac{s_t}{T^*}$ bandwidth to each task t, indicating that to minimize the completion time, the bottleneck tasks must be assigned a weighted fair share of the bandwidth, such that the weight of the share is proportional to s_t. Afterward, Dayu updates the remaining bandwidth as

$B^i_{remain_in} - = \frac{c^i_{in}}{T^*}$ and $B^i_{remain_out} - = \frac{c^i_{out}}{T^*}$ for each node i, removes the bottleneck tasks from their corresponding nodes, and updates the $c_{in/out}$ values of these nodes. Then Dayu moves to the next iteration with the remaining tasks, till there are no tasks remaining or the remaining tasks have an acceptable transmission time (i.e., less than or equal to the length of a timeslot) with their allocated bandwidth. Note that if a task goes through multiple iterations, its allocated bandwidth is the sum of the allocated bandwidth in each iteration.

Iterative WSS overcomes the drawbacks of WSS: since iterative WSS tries to allocate all bandwidth, it is not possible for the system to waste bandwidth when there are tasks that can utilize such bandwidth.

Our experiment shows that for a 3500-node cluster, each iteration will take at most 15 *ms*. Since dynamic convex hull node selection algorithm keeps the "$\frac{c}{B}$" values of most nodes to be close, the iterative WSS algorithm can usually finish within five iterations (i.e. 75 *ms*), which is acceptable.

4.4 Re-scheduling Straggling Tasks

Due to inaccurate workload estimation, sub-optimal scheduling, hardware exceptions, and etc., some tasks could not be finished at the end of one timeslot. Dayu has to re-schedule such straggler tasks in the next timeslot, but cannot simply treat them as new tasks, because changing the destination of one straggler task requires re-transmitting the task from the beginning, causing waste of bandwidth. Therefore, Dayu should avoid changing the destination when possible—this is a constraint new tasks do not have.

Identifying stragglers. Recall that Dayu overlaps different timeslots so that the scheduling phase of the current timeslot happens a short period of time (denoted as $T_{schedule}$) before the end of the last timeslot (Figure 2). Therefore, Dayu has to predict which tasks will become stragglers: for one unfinished task, Dayu uses its speed so far to estimate its speed till the end of the last timeslot; if the task cannot finish given the estimated speed, Dayu puts those tasks into a straggler set.

Prediction can certainly be inaccurate. If Dayu marks a task as a straggler but it actually finishes with the last timeslot, the corresponding nodes will simply ignore the new transmission plan scheduled by Dayu. Conversely, if a task is not marked as a straggler but it cannot finish within the last timeslot, the corresponding node will not get a new transmission plan, and thus will stick with the old plan. Both cases may cause inefficiency, but since $T_{schedule}$ is much smaller than $T_{timeslot}$, these two kinds of misidentification have little impact in our experiments.

Scheduling stragglers. First, Dayu will check whether the straggler set itself will saturate some nodes in the current timeslot. If any, the *ObServer* iteratively evicts the least finished task from each saturated node until it is no longer saturated. Those evicted tasks are categorized into two groups: tasks evicted from their sources and tasks evicted from their destinations. They are rescheduled in different manners.

- For each straggler task in the first group, the *ObServer* chooses a source and a transfer rate (the same as a new task), while keeping the destination unchanged, which means the task can resume from its current progress.
- For each straggler task in the second group, the *ObServer* reschedules it as a new task.

For unevicted straggler tasks, Dayu keeps their sources and destinations unchanged, and allocates the bandwidth with the iterative WSS algorithm. They can resume from their current progress.

Compared to treating stragglers as new tasks, Dayu tries to minimize re-transmitting data, since it only changes the destination of the second group of stragglers (quite a minority) and re-transmits their data. Compared to letting stragglers continue with their original plans, our experiments show that the introduction of straggler adjustment improves the overall recovery speed by 15.6%.

It should also be noted that how to detect and report slow hardware is an orthogonal problem [25–27]. Dayu assumes the system has some mechanism to measure and report the actual bandwidth of each node.

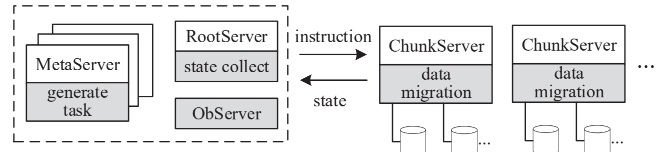


Figure 4: Our implementation of Dayu on Pangu. Gray boxes stand for functions or components Dayu adds to Pangu.

5 Evaluation

Our evaluation tries to answer the following questions:

1. How fast can Dayu complete one typical full node recovery and how much interference does Dayu introduce between background and foreground? (§5.1)
2. Could Dayu scale to even larger systems? (§5.2)
3. In Dayu, how much benefit does each key technology bring? (§5.3)
4. How does the setting of the parameters affect the performance of Dayu? (§5.4)

Implemention. We implement Dayu upon Pangu, by modifying *MetaServers*, *RootServer*, and *ChunkServers* of Pangu and introducing Dayu's *ObServer* into Pangu, as shown in Figure 4. The *ObServer* is aware of the information of all the recovery tasks as well as the global information provided by the *RootServer*, such as the chunk placement and the network utilization at each *ChunkServer*. As Pangu monitors and reports the states of *ChunkServers* every 15 seconds, the

timeslot length of this implementation is set to 15 seconds. Upon detection of a node failure in Pangu, *MetaServers* report all the data chunks of the failed node to the *ObServer*, which schedules how to re-replicate these data chunks. Afterwards, the *ObServer* instructs the *ChunkServers* to execute recovery tasks (i.e. re-replicate data chunks). Finally, after a recovery task is completed, the *ObServer* updates the *MetaServers* to reflect the locations of the newly-re-replicated chunk.

Testbed. We have deployed the Pangu-based Dayu implementation on a 1000-node cluster. Each node has two 12-core Intel E5-2630 processors, 96GB DDR4 memory, two 10Gbps NICs, 10 or 11 2TB hard disks, and Linux 3.10.0. Since our traces are collected from a cluster with 1Gbps NICs but our testbed is equipped with 10Gbps NICs, we add a traffic control to our testbed so that each NIC can only use 1Gbps bandwidth.

We have also built a simulation environment to test Dayu with the scale of 3,500 nodes or more. We run the simulation in a server with two 16-core Intel E5-2620 processors, 64GB DDR4 memory, and Linux 3.10.0.

Methodology. For experiments on real-world systems, we trigger data recovery by shutting down one *ChunkServer*. When performing recovery, we replay the trace collected from the real-world cluster system (§2.2). Since our testing cluster is smaller than the cluster where the trace is from, we reshape the trace to fit the cluster size by trimming or redirecting some requests, while keeping the ratio of read and write, the pressure on each node, and the degree of imbalance among nodes [28]. We record both the recovery time and the interference between the foreground and recovery traffic, which is measured by comparing the p90 latency (i.e., tail latency at 90th percentile) of the foreground requests with and without recovery traffic.

In the simulation experiments, we simulate the failure of a *ChunkServer* by sending its chunk information to Dayu. Since we do not actually run the system, we need to simulate the interference between the foreground and the recovery traffic. Due to the scale of the system, request level simulation takes very long, so we use flow level simulation as in [29, 30]. It simulates the bandwidth utilization of each link and periodically updates the utilization according to the foreground and recovery traffic information. We define the interference factor as the ratio between the overload traffic size and the link bandwidth, as follows:

$$B^i_{overload} = max(B^i_{recover} + B^i_{foreground} - 75\% \times B^i_{total}, 0) \quad (3)$$

$$F_{interference} = \frac{\sum_{i \in Nodes} B^i_{overload}}{\sum_{i \in Nodes} B^i_{total}} \quad (4)$$

The reason we define such an interference factor is that if the total bandwidth utilization exceeds 75% of the NIC's bandwidth, the foreground latency will increase significantly. To quantitatively understand this simulated interference factor, we map them to the p90 latency in the real-world experiments (§5.4): the short conclusion is that an interference factor smaller than 2% indicates very small interference and a factor close to or larger than 6.5% indicates very large interference. In our simulation experiments, we simulate 50 failure cases by randomly choosing 50 pairs of failed nodes and their failure time. For each algorithm, we simulate its performance on all the 50 cases and report its average performance numbers.

In our following experiments, Figure 5 presents the results from the real-world systems and the other figures present the results from the simulation experiments.

Comparison. In the experiments on the real-world systems, we compare Dayu with Pangu's original re-replication strategy, which adopts disk utilization aware random data placement and static rate control. We use three configurations Pangu-slow (limit recovery traffic to 30MB/s, which is the default configuration in production systems), Pangu-mid (90MB/s), Pangu-fast (150MB/s) as the baselines.

In the simulation experiments, we compare Dayu with different scheduling algorithms used in state-of-the-art systems (Table 2), with the exception of MCMF since its optimized solver is not open sourced. For fairness, we keep the node prioritizing and straggler adjustment part of Dayu, and plug in different node selection and bandwidth allocation algorithms. Specifically, when selecting the destination of recovery tasks, we compare Dayu's bucket dynamic convex hull algorithm (C) to the following algorithms: 1) *Random* (R), which randomly selects a node as the transmission source and destination; 2) *Best-of-two-random* (B2R), which first chooses two *ChunkServers* randomly, and then picks the lighter-loaded one as the source or destination [4, 9]; 3) *Weighted random* (WR), which uses the available bandwidth as the weight to randomly select a node; 4) *Greedy1* (G1), which scans all candidate *ChunkServers* as [31, 32], then in our scenario finds the one with minimal $\frac{c}{B}$. 5) *Greedy2* (G2), which chooses the lightest-loaded *ChunkServer*, by maintaining a red-black tree. All greedy algorithms, including Dayu, are executed using a single thread; all random-based algorithms are executed using 16 threads. Note that although random-based algorithms can be distributed to reach even higher speed, we find their speed is not the bottleneck anyway in our experiments. We also test the MILP algorithm with a state-of-the-art MILP solver Gurobi [33], but find it can only finish computation for a small-scale cluster; for a 3500-node cluster and only 2000 tasks, it cannot finish computation after 125 seconds and thus we do not report its results. When determining the rate of each task, we compare Dayu's iterative WSS (W) with deadline-based allocation (DA), which assigns a rate of $\frac{s_t}{T_{timeslot}}$ to task t so that a task can be finished in one timeslot.

5.1 Overall Performance

Evaluation on the Real-world Systems. Figure 5 shows the recovery times and the p90 latency of the foreground re-

Sparrow [36]	Best-of-two-random
Firmament [37]	MCMF

Table 2: State-of-the-art systems and their algorithms.

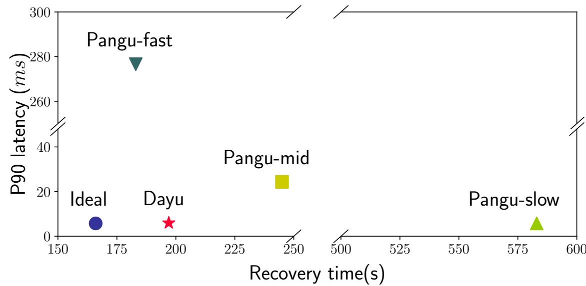

Figure 5: The recovery time and the p90 latency during recovery in real-world experiments

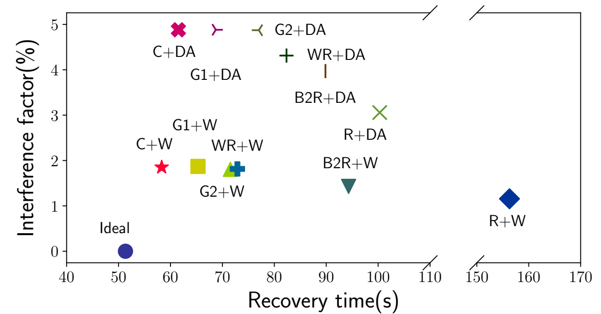

Figure 6: Data recovery in simulation (Dayu uses C+W)

quests during recovery. In this test, we shutdown a server to create 15TB of data to recover, and approximately 990 surviving *ChunkServers* are responsible for recovery. For comparison, we add an "Ideal" entry in Figure 5, which estimates the optimal recovery time assuming all available bandwidth ($\alpha = 75\%$) can be utilized, and introduces no interference on the foreground traffic (i.e., the foreground latency is identical to the one without recovery).

As shown in the figure, Dayu achieves near-optimal recovery speed as well as low interference. First, Dayu is approaching the ideal recovery speed, as its recovery time is 1.19× longer than "Ideal": this is 2.96× and 1.24× faster than Pangu-slow (default) and Pangu-mid configurations respectively. Compared with the Pangu-fast configuration, although Dayu has a slightly slower recovery speed (0.93×), it introduces far less interference on the foreground traffic. Considering the interference of the recovery traffic on the foreground traffic, Dayu's p90 latency is only 1.04× longer than "Ideal". Pangu-slow has a slightly lower interference with its p90 latency nearly the same as "Ideal"; Pangu-mid and Pangu-fast create unacceptable interference as their p90 latencies are 4.23-48.14× higher than "Ideal". Due to the high interference to the foreground traffic, Pangu-mid and Pangu-fast are seldom used on production clusters. In summary, compared with the different settings in Pangu, Dayu achieves close-to-optimal recovery time and interference.

Evaluation on the Simulation Systems. Figure 6 shows the results of simulation experiments. Again, compared with other algorithms, Dayu achieves a good balance between recovery speed and interference.

In terms of recovery speed, Dayu's combination of dynamic convex hull node selection and iterative WSS (C+W) can achieve the shortest recovery time among all algorithms, which is 1.14× longer than the ideal recovery time. Compared to other algorithms, dynamic convex hull node selection achieves the fastest recovery speed, which is 1.12× faster than G1, the second best one. Note that though G1 is close to Dayu in this experiment, it does not scale well due to its high computation overhead (§5.2). For the greedy-based algorithms including Dayu, iterative WSS is slightly faster than deadline-based allocation, because the former can finish the last timeslot early when tasks are rare, while the latter must finish tasks at the end of the last timeslot. For random-based algorithms, such effect is unclear because the recovery speed is mainly determined by the selection of the sources and destinations.

In terms of interference on foreground, Dayu has acceptable interference factor (recall that a factor of 2% is small and a factor larger than 6.5% is unacceptable). With the same bandwidth allocation strategy, Dayu's node selection algorithm and other greedy algorithms have slightly larger interference than those random based algorithms, because greedy algorithms usually utilize more estimated available bandwidth. When the estimation of the foreground traffic has some errors, the interference will be slightly larger. With the same node selection algorithm, iterative WSS consistently brings lower interference than deadline-based allocation (DA).

5.2 Scalability

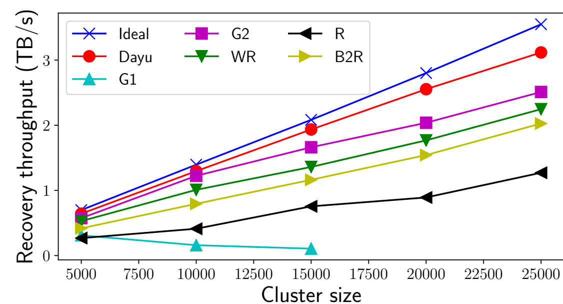

Figure 7: Dayu's scalability

We evaluate the scalability of Dayu beyond 3,500 nodes. To measure the full capability of different algorithms, we assume there are infinite number of recovery tasks and simulate how much data each algorithm can recover in 20 timeslots. As the scale of the simulated clusters are larger than our observed cluster, we randomly generate block placement based on the statistics from our collected traces; we randomly pick the foreground trace from one real node for one simulated node.

As shown in Figure 7, Dayu can scale to 25,000 nodes and till that point, the performance of Dayu is higher than all other algorithms. We do not test even larger scales because they are too far away from our target (10K nodes). Besides Dayu, all random algorithms scale pretty well, which is as expected, though their performance is not as good as Dayu. G1 does not scale to more than 5,000 nodes because of its high computation overhead. Note that as greedy algorithms, Dayu and G2 will eventually stop scaling at some point because of their centralized computation, but at least for the scale we target now and in the near future, the simulation shows that Dayu is fast enough and can provide better quality.

5.3 Effects of Individual Techniques

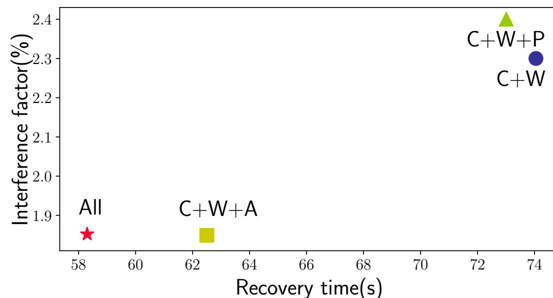

Figure 8: Effects of prioritizing underemployed node (P) and re-scheduling stragglers (A)

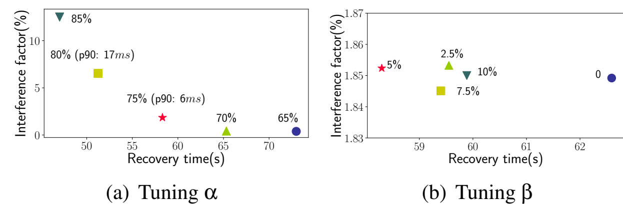
We further investigate the effects of prioritizing underemployed nodes (P) and re-scheduling stragglers (A) described in Section 4.2 and 4.4. We use Dayu equipped with convex hull node selection (C) and iterative WSS bandwidth allocation (W) as the baseline (C+W), which scans tasks with no prioritization and executes stragglers with the original plan (i.e. P and A are disabled). Note that in this baseline, Dayu is aware of those stragglers and will use their information to schedule the current timeslot but won't re-schedule stragglers.

Figure 8 presents Dayu's schedule results with and without P and A. As shown in the figure, the re-scheduling of stragglers is keen to the performance: compared with the baseline (C+W), re-scheduling stragglers (C+W+A) reduces recovery time by 15.6% and reduces the interference as well. Though prioritizing underemployed nodes has limited effect without re-scheduling stragglers, it accelerates the recovery speed by 7.2% when straggler re-scheduling is already equipped (compare "All" to the case C+W+A).

5.4 Impacts of Key Parameters

Finally, we measure the impacts of key parameters of Dayu. The first one is α in Equation 1, which controls the interference of recovery traffic on foreground traffic. Figure 9(a) plots the recovery time and interference factor as α increases from 65% to 85% with the step size of 5%. One can see that the larger the α, the shorter the recovery time but the larger the interference factor. In this figure, we further map some of these simulated interference factors to the p90 latencies from the real-world experiments, so that we can quantitatively understand the values of the simulated interference factors. Our decision to use the value 75% for α is mainly based on these p90 latencies from real-world experiments: with $\alpha = 75\%$, Dayu achieves close-to-optimal recovery time and p90 latency (§5.1); with $\alpha = 80\%$, although Dayu decreases recovery time by 9.1%, it almost triples the p90 latency of the foreground traffic.



(a) Tuning α (b) Tuning β

Figure 9: Effects of tuning α and β

The next parameter, β, denotes the ratio of selected nodes from two sorted lists when choosing underemployed *ChunkServers* in Section 4.2. We change β from 0% to 10% with the step size of 2.5%. As shown in Figure 9(b), the value of β has no significant impact on the interference factor and setting it to 5% achieves the lowest recovery time, which is why Dayu sets β to 5%.

Another important parameter is the length of a timeslot ($T_{timeslot}$), but since this parameter affects the overall overhead of Pangu, we were not allowed to change it in the production system and thus we were not able to record and analyze a trace with a different $T_{timeslot}$. In general, shorter $T_{timeslot}$ will benefit Dayu by allowing it to react to foreground fluctuation more quickly but will increase the overhead of Pangu.

6 Related Work

Data Recovery. Popular distributed filesystems such as GFS [3], HDFS [5], Cosmos [6], and Windows Azure Storage [7] use random node selection and static rate control for data recovery, same as Pangu. RAMCloud [4, 38] uses the best-of-two-random algorithm to select the source and destination for a recovery task. Constrained by the deterministic placement, consistent hashing based storage systems [17, 22, 39–41] have little flexibility to choose the destination. Our work shows that randomized algorithms may not have a good quality in a highly imbalanced environment.

Some works improve data recovery in erasure-coded storage, by accelerating recovery of one failed block [31, 42, 43] or designing new recovery-efficient codes [44–47]. Applying Dayu to erasure-coded storage is our future work.

Data migration. Data recovery can be viewed as a subtopic of data migration. A number of distributed filesystems [3, 5] trigger data migration with a simple strategy or even manually (e.g., running HDFS balancer [48]). Mirador [34] uses a priority queue to greedily migrate data objects according to pre-defined rules. However, experiments in [34] report it does not scale well due to its greedy algorithm. Curator [49] uses a reinforcement learning solution to determine when to start a migration task, but it does not choose sources and destinations for data migration. DH-HDFS [35] utilizes MILP solver to manage migration of large scale storage system, but for our problem, MILP is too slow.

Constrained data placement strategies. Besides consistent hashing based storage systems [17, 22, 39–41], there are other systems restricting the data placement. Facebook [50] modifies native HDFS to constrain the placement of block replicas into smaller node groups (i.e., with a smaller scatter width), reducing the probability of losing data due to simultaneous node failures. With a fixed scatter width, CopySets [51] and Tiered Replication [52] further try to minimize the number of the distinct copysets in the whole system to reduce the probability of data loss due to correlated node failures. We plan to investigate the applicability and effectiveness of Dayu on these strategies in the future.

Large scale scheduling. Many large-scale computation platforms need to schedule computation tasks, which is similar to schedule recovery tasks in Dayu. Most centralized schedulers [53, 54] have poor computation performance at a large scale, and thus distributed schedulers are widely discussed [36, 55, 56]. However, due to the lack of coordination and the latest state, these schedulers often fail to generate high quality decisions [37]. Firmament [37], a centralized scheduler, succeeds to scale to a 12500-node cluster [57] , but experiments in [37, 58] report it has limited scalability with massive short tasks, which is exactly our scenario (§2.2).

7 Conclusion

Our work shows that a centralized scheduler has better scheduling quality, especially in a dynamic and imbalanced environment; its weakness, i.e. relatively low speed compared to the decentralized schedulers, can be mitigated by different optimizations (e.g. timeslot-based scheduling, convex hull optimization, etc). As a result, it can support a reasonably large system we target.

8 Acknowledgment

We thank all reviewers for their insightful comments, and especially our shepherd Sudarsun Kannan for his guidance during our camera-ready preparation. We also thank Tianyang Jiang for helpful discussions, and Alibaba Cloud for providing us the evaluation cluster. OPTR: Order-Preserving Translation and Recovery Design for SSDs with a Standard Block Device Interface

Yun-Sheng Chang and Ren-Shuo Liu
Department of Electrical Engineering, National Tsing Hua University, Hsinchu, Taiwan

Abstract

Consumer-grade solid-state drives (SSDs) guarantee very few things upon a crash. Lacking a strong disk-level crash guarantee forces programmers to equip applications and filesystems with safety nets using redundant writes and flushes, which in turn degrade the overall system performance. Although some prior works propose transactional SSDs with revolutionized disk interfaces to offer strong crash guarantees, adopting transactional SSDs inevitably incurs dramatic software stack changes. Therefore, most consumer-grade SSDs still keep using the standard block device interface.

This paper addresses the above issues by breaking the impression that increasing SSDs' crash guarantees are typically available at the cost of altering the standard block device interface. We propose Order-Preserving Translation and Recovery (OPTR), a collection of novel flash translation layer (FTL) and crash recovery techniques that are realized internal to block-interface SSDs to endow the SSDs with *strong request-level crash guarantees* defined as follows: 1) A write request is not made durable unless all its prior write requests are durable. 2) Each write request is atomic. 3) All write requests prior to a flush are guaranteed durable. We have realized OPTR in real SSD hardware and optimized applications and filesystems (SQLite and Ext4) to demonstrate OPTR's benefits. Experimental results show 1.27× (only Ext4 is optimized), 2.85× (both Ext4 and SQLite are optimized), and 6.03× (an OPTR-enabled no-barrier mode) performance improvement.

1 Introduction

Storage systems are constructed layerwise; thus the overall system performance depends on an appropriate division of labor between layers. For example, for applications and filesystems that run on top of flash-based solid-state drives (SSDs), if the underlying SSDs focus too much on optimizing their own performance and maintain too weak guarantees upon a crash or power loss (crash for short), programmers are forced to equip the applications and filesystems with safety nets using redundant writes and flushes [24, 26, 33, 41], which in turn complicate the overall system and degrade the overall performance.

That being said, widely used, consumer-grade SSDs (baseline SSDs for short) guarantee very few things upon a crash:

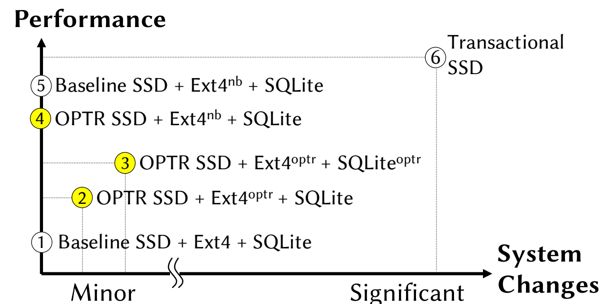

Figure 1: OPTR SSD vs baseline and transactional SSDs. Ext4^{optr} and SQLite^{optr} denote our optimized versions of Ext4 and SQLite, respectively. Ext4^{nb} denotes Ext4 mounted with the -o nobarrier option.

each individual sector that is written since the last flush may either be done or left undone, which means there is an enormous set of post-crash states for applications and filesystems to handle. Lacking a strong disk-level crash guarantee has caused deep, long-term consequences. For example, the ordering constraint among user data, metadata, journal, and commit records should be enforced to prevent sensitive user data and inconsistent states from being accidentally exposed. However, disks are not obligated to preserve any write order, and filesystems are reluctant to use flushes to enforce a write order due to severe performance penalties. Therefore, Linux Ext3 even turned off flushes for many years at the risk of crash vulnerabilities [20]. Another alarming example is that since the crash guarantees of underlying disks are weak, various filesystems struggle to provide a standardized and strong crash guarantee at their level, and this struggle consequently makes applications have difficulty ensuring correct recovery from a crash. For example, LevelDB and Git were recently found to contain many crash vulnerabilities owing to this reason [39].

Despite many issues, SSDs with a weak crash guarantee are still widely used for two reasons. First, the weak crash guarantee has existed since the hard disk drive (HDD) era. This design choice was unavoidable for optimizing HDD performance and remains as a matter of course for optimizing SSD performance. For example, HDDs were permitted to freely reorder requests according to the position of pickup

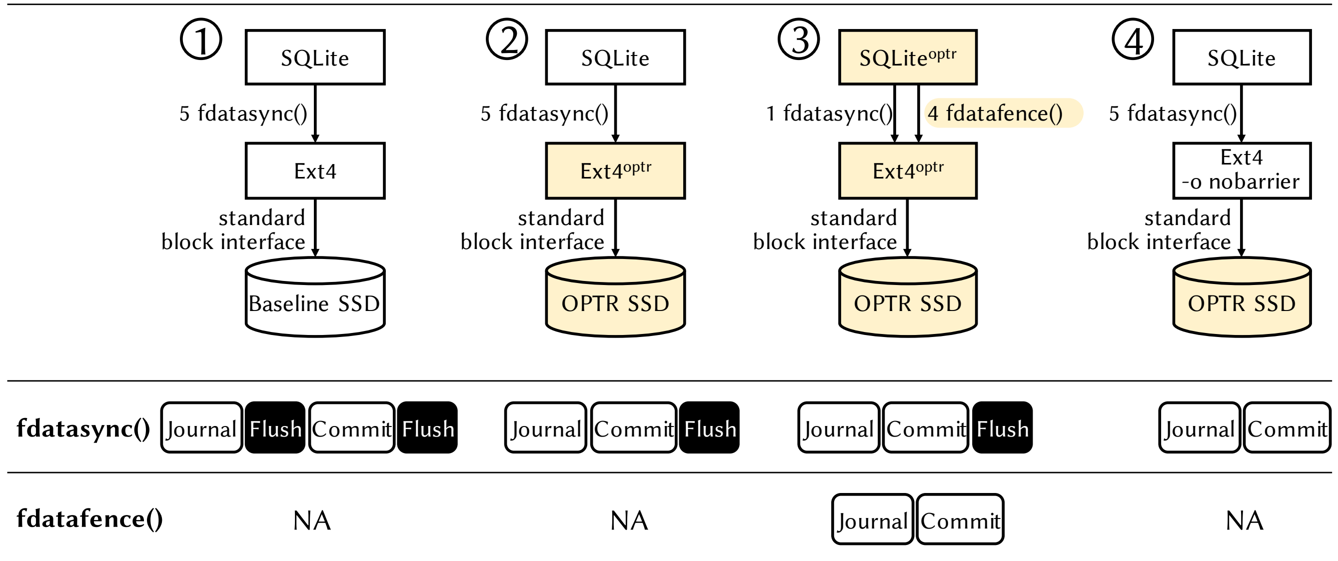

Figure 2: Usage modes of OPTR SSDs and their filesystem and disk interfaces. *fdatafence* is our newly proposed filesystem primitive that incurs no flush. More details on the original five *fdatasync* and the use of *fdatasync* are in Section 4.

heads to minimize seek and rotational latency, and thus, SSDs are also allowed to reorder or parallelize requests to maximize their internal channel- and chip-level parallelism. The second reason is that although novel SSDs with revolutionized interfaces that offer transaction-level crash guarantees (transactional SSDs for short) [28, 32, 37, 40, 44] have recently been studied, the fact is that there has been a vast body of software and systems developed based on a *standard block device interface* (block interface for short, e.g., SATA). Therefore, as shown in Figure 1, although transactional SSDs (⑥) can potentially offer much higher performance than baseline SSDs (①), only few systems can adopt such dramatic changes. Not surprisingly, most consumer-grade SSDs keep using the block interface, and thus, the benefits of transactional SSDs are not widely available.

This paper addresses the above issues by breaking the impression that increasing SSDs' crash guarantees is typically available at the cost of altering the block interface. We propose Order-Preserving Translation and Recovery (OPTR), a collection of novel flash translation layer (FTL) and crash recovery techniques that are realized internal to a block-interface SSD to endow the SSD with ***strong request-level crash guarantees*** as defined as follows:

1. **Prefix Semantics**: The SSD does not make a write request durable unless all the write requests received previously by the SSD are durable (stronger than baseline SSDs).
2. **Request Atomicity**: Each write request received by the SSD is atomic regardless of the request size (i.e., number of sectors) (stronger than baseline SSDs).
3. **Flush Semantics**: The SSD guarantees durability to all write requests that are received prior to a flush (identical to baseline SSDs).

Figure 3 uses a four-sector SSD to demonstrate the *strong request-level crash guarantees*. The four sectors initially store four version numbers, 0, 0, 0, and 0, respectively. The SSD receives four write requests and one flush request before a crash occurs. Each write request is specified by its *lba* and *size* in parentheses. We assume that write requests always increment the version number(s) of the written sector(s). For example, the first write request touches the first and second sectors, and thus the four version numbers become 1, 1, 0, and 0. As shown in the figure, each sector of a baseline SSD can exhibit two to three valid post-crash version numbers; therefore, the baseline SSD can exhibit $2\times2\times3\times3=36$ valid post-crash results. In comparison, an OPTR SSD guarantees to complete write requests in order and atomically, and there are only two write requests after the last flush; therefore, the number of valid results is significantly confined to three.

The *strong request-level crash guarantees* and our intentional choice to use a *standard block interface* bring several benefits. First, for programmers who want to develop new applications or filesystems, since the crash guarantees of OPTR SSDs are truly intuitive, the chance of making mistakes decreases. Additionally, since OPTR significantly confines the number of valid post-crash states, testing or verifying the correctness of a program becomes more manageable. Second, in addition to developing new programs, it is also simple for programmers to optimize existing applications and filesystems to benefit from OPTR. For example, Ext4 and SQLite resort to flushes to realize barriers because barriers are unavailable to most SSDs [45]. We refer to these flushes as ***unnecessary flushes***. With OPTR's *strong request-level crash guarantees*, we can optimize Ext4 and SQLite to remove

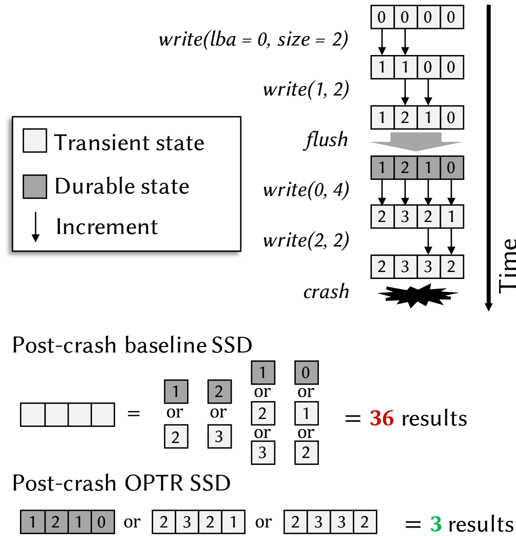

Figure 3: Post-crash states of OPTR SSDs vs. those of baseline SSDs.

unnecessary flushes (Section 4). The changes made to SQLite and Ext4 code are minor, and the achieved performance is significant, as illustrated by ② (optimizing Ext4 only) and ③ (optimizing both Ext4 and SQLite) in Figures 1 and 2. Finally, all existing, unmodified applications and filesystems can still run on OPTR SSDs, and this backward compatibility enables an *OPTR-enabled no-barrier mode* as described as follows.

In the ***OPTR-enabled no-barrier mode***, a filesystem is mounted with a no-barrier option (e.g., -o nobarrier for Ext4) and run on top of an OPTR SSD, as illustrated by ④ in Figures 1 and 2. In contrast to mounting the filesystem with the no-barrier option on a baseline SSD (⑤ in Figure 1), this mode achieves the best of both worlds, i.e., high performance (which is the reason why Ext3 used to disable flushes [20]) and consistency guarantees (because OPTR preserves order without the need for explicit flushes). This mode is practical and useful for smartphones, consumer-grade computers, and less-critical database systems such as SQLite [3] and some key-value stores [18][1].

This work makes the following contributions.

- This is the first SSD work with *strong request-level crash guarantees* and a standard block interface. We change the impression that increasing SSDs' crash guarantees is typically available at the cost of altering the standard block device interface. We present the address translation, garbage collection (GC), and crash recovery algorithms internal to SSDs to achieve OPTR.
- We extend and restructure the FTL of an academic domain SSD project (OpenSSD [2]) to equip it with a write cache as our baseline. This FTL implementation is more sophisticated and modularized.
- We extend the FTL mentioned above to realize OPTR.
- We develop a functional simulator that can simulate an FTL given IO requests and crash events at high speed to test whether the FTL can recover from a crash and meet the OPTR requirement. We have validated this simulator and our implemented FTLs against each other. We anticipate that the simulator itself will be a useful tool for future FTL research.
- We exploit the *strong request-level crash guarantees* by optimizing the *fsync* primitive of Ext4 and newly proposing an *ffence* primitive for Ext4. These two primitives help to eliminate *unnecessary flushes*. We also demonstrate optimizing a database system, SQLite, to exploit the two primitives.

The rest of this paper is organized as follows. Section 2 describes the background of SSDs. Section 3 presents the detailed design and implementation of OPTR. Section 4 demonstrates the filesystem and application optimizations enabled by OPTR. Section 5 shows the results of validating OPTR using our developed functional simulator. Section 6 evaluates OPTR's gain and overhead. Section 7 analyzes the FTL in more detail. Section 8 surveys related work, and Section 9 concludes this work.

2 Background

2.1 Flash Translation Layers

In the core of an SSD lies an FTL. FTLs are responsible for translating a sequence of host-issued requests, including *write*, *read* and *flush*, into a sequence of flash operations, including *page-program*, *page-read*, and *block-erase*. Both read and write requests specify the address range of the data at the sector granularity; flush instructs an SSD not to acknowledge the host until the SSD persists all cached writes on stable media.

Upon receiving a write request, the FTL segments the write data into pages based on the given address range. A write request involves modifications to the logical-to-physical (L2P) mapping table. Many mapping schemes have been proposed (e.g., page-level, block-level, and hybrid) for various cost-performance tradeoffs. This work is based on page-level FTLs. Page-level FTLs divide the logical address space of SSDs into pages, which are indexed by a logical page number (LPN). Each entry in the L2P table maps an LPN to the location of a flash page indexed by a physical page number (PPN).

To handle a read request, the FTL translates the address range into LPNs and performs L2P table lookups to obtain the PPNs of the requested pages. If the cache happens to have a requested page, the contents are returned to the host; otherwise, a page-read is performed to retrieve the contents from the flash memory.

Flush requests are synchronous; thus, upon receiving a flush, the FTL must persist all dirty data in the write cache

[1]Note that this mode is not suitable for critical systems such as financial transaction processing systems because it relaxes durability.

and ensure no ongoing page-program operation exists before returning a success acknowledgment to the host.

As flash memory forbids in-place updates, overwriting data is done by writing the updated data to a free page and leaving the outdated data in the original page. A dedicated routine, called GC, is designed to reclaim these invalid pages, which store outdated data. The GC routine starts with choosing a victim block based on, e.g., the greedy policy [29, 42]. Then, this routine performs a series of page-reads and page-programs to relocate the valid data in the victim block. Finally, the victim block is erased and added to the free-block list.

2.2 High-Performance Schemes

Modern SSDs achieve significant performance mainly owing to the following three schemes: internal parallelism, request scheduling, and write caching. Note that these high-performance schemes all break the write order.

SSDs typically consist of multiple independent internal channels for transferring data and commands. Each channel connects to multiple flash chips. The **internal parallelism** of SSDs comes from these channels and chips, which can perform flash operations independently.

The goals of **request scheduling** are to increase the number of parallelized flash operations and to decrease the latency of each request. The former can be achieved by reordering requests to reduce resource conflicts [34]. The latter can be achieved by prioritizing requests with lower latency [22, 27].

Write caching removes slow storage accesses from the critical path. As the access speed of flash memory is often orders of magnitude slower than that of DRAM, most commercial SSDs employ a DRAM-based write-back cache for better performance. Another advantage of write caching is write coalescing. Multiple writes targeting the same LPN have the opportunity to be merged into one page-program operation, resulting in higher throughput and longer flash lifetimes.

2.3 SSD Recovery

The recovery mechanism of SSDs rebuilds the L2P table after a system crash. Some previous works have studied SSD recovery [7, 8, 11, 17, 30]. Leaving LPN information in the spare area of each written page during writes is the most common strategy [7], and the L2P information can be reconstructed after a crash by scanning this information. As multiple physical pages may contain the same LPN, a sequence number is often used to determine their validity.

The process of rebuilding the L2P table may need to read the spare areas of an enormous number of pages, leading to long recovery times. For an SSD with 512 GB capacity, assuming that each page is 32 KB and reading 32 pages in parallel takes 100 μs, reading the spare area of all the flash pages can cost up to three minutes, which is unacceptable in most situations. Therefore, optimization to reduce the recovery time has been proposed. Birrell et al. store the abovementioned per page recovery information in the last page of a block when the block is fully written [8]. This design eliminates the need to read an entire block. Bjorling et al. take partial and full checkpoints of the L2P table and persist the images in a reserved area [9]. During recovery, these images are loaded as the initial L2P table, and pages written after the latest checkpoint are subsequently remapped.

3 OPTR SSD Design

We realize the following five components internal to an SSD to achieve *strong request-level crash guarantees* without changing the standard block interface: 1) tracking the completion of write requests to ensure request atomicity, 2) tracking the coalescing between write requests, 3) periodic mapping table checkpointing, 4) tracking the availability of blocks for GC, and 5) order-preserving recovery.

3.1 Write Completion Tracking

Request atomicity is one of OPTR's guarantees. To achieve this coarse-grained atomicity, OPTR determines the completion and incompletion of each individual write request using a simple strategy: a write request that involves N pages is completed if and only if those N pages do exist in flash after a crash.

More specifically, OPTR leaves the following three kinds of clues in the spare area of each written flash page to facilitate determining the completion of a write request afterward. The first is a unique sequence number of the write request (wid, an 8-byte integer) assigned by the FTL according to the order in which the request is received. The second is the size of the write request in number of pages ($size$, a 4-byte integer). The third is the logical page number (lpn, a 4-byte integer) of the written page.

To determine which writes are completed and which are not, the recovery procedure divides flash pages into groups according to their write request identifiers (wid), counts the appearance of each wid, and then compares this count with $size$ for each write request. The entire write request is completed if and only if the count matches the request size.

3.2 Write Coalescing Tracking

Two or more write requests may coalesce in the write cache of SSDs; we refer to the involved write requests as coalesced write requests. This situation reduces the in-flash appearance count of wid of the involved write requests.

OPTR allows write coalescing to happen instead of avoiding it. To this end, OPTR detects and records each coalesced page. Each page in the write cache is tagged with a dirty flag, a wid tag, and a $size$ tag. By doing so, whenever a dirty cache page is overwritten, OPTR detects that a coalesced page exists (and anticipates that the appearance of the corresponding wid in flash decrements). For each coalesced page, OPTR records (in a DRAM buffer) the request IDs of the two involved write requests and the size of the prior write request. For example, as shown in Figure 4, a coalescing record with

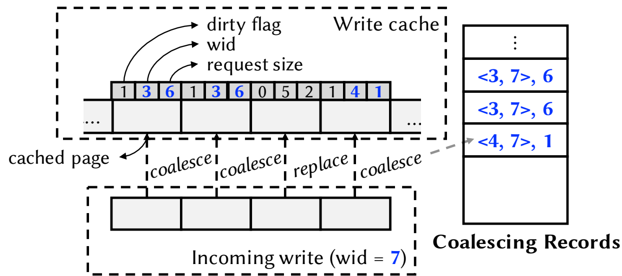

Figure 4: Write cache and generated coalescing records.

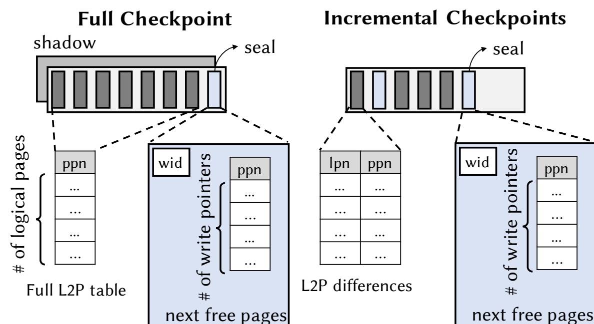

Figure 5: Full and incremental checkpoints.

"<3, 7>, 6" denotes that a prior write request whose ID is 3 coalesces with a later write request whose ID is 7, and the size of the prior write request is 6 pages. If a write involves multiple coalesced pages, multiple pieces of information are recorded. A batch of coalescing records are committed to flash when the buffer is full or when the SSD is requested to perform a flush (either issued externally by the host or internally by OPTR mechanisms).

It is hard to define the completion of each single write request that coalesces with other requests because the completion of multiple coalesced write requests needs to be atomic (which OPTR guarantees). In contrast, it is relatively simple to define incompletion as follows. Let P_i be the number of pages whose $wid = i$, D_i be the number of recorded $< x, y >$ pairs with $x = i$, and $Size_i$ be the size of the write request with $wid = i$. A coalesced write request with $wid = i$ is incomplete if $P_i + D_i < Size_i$.

3.3 Mapping Table Checkpointing

The L2P mapping table is checkpointed to flash to speed up recovery. More specifically, we reserve the first few flash blocks of each flash chip for checkpoints. OPTR keeps two types of checkpoints, a full checkpoint and several incremental checkpoints, as shown in Figure 5. The two types of checkpoints differ in that a full checkpoint snapshots the entire L2P table, while an incremental checkpoint records only the differences in the L2P table since the latest checkpoint (either full or incremental). In addition to the L2P table, both types of checkpoints record a seal page at the end of a checkpoint that includes 1) the latest wid at the time the checkpoint is made and 2) the PPNs of the next free flash pages at the time the checkpoint is made. OPTR employs incremental checkpoints by default. When the flash area for storing incremental checkpoints is full, OPTR creates a new full checkpoint and then clears the incremental checkpoints. OPTR employs a shadow for the full checkpoint to ensure its integrity, and the wid can be used to determine the recency between the full and incremental checkpoints after a crash. The PPNs of the next free flash pages allow L2P updates after the latest checkpoint to be retrievable. More specifically, for each PPN, subsequent written pages in the same block are available as pages within a block are sequentially written, and the summary page of the block can direct OPTR to the subsequent written block and so on. Then, the L2P updates can be derived from the LPN information in the spare area of these retrieved pages.

3.4 Garbage Collection

Flash pages that store outdated data are commonly considered invalid and useless, but it is these pages that OPTR leverages to rollback a disk from a crash to an order-preserved state. Thus, we enforce two constraints on the GC routine. The first constraint forbids GC from reclaiming pages programmed *after* the latest checkpoint. Since OPTR determines the completion of a write issued after the latest checkpoint by the number of pages owned by the write, reclaiming pages written prior to a flush but after the latest checkpoint would result in a flush semantics violation.

The second constraint forces an internal flush before performing GC. This flush ensures that every page being erased by GC has a stable counterpart that can always survive across a crash. To reduce the performance penalty of an internal flush, we amortize its cost by conducting GC to a batch of blocks (16 blocks in our case).

3.5 Order-Preserving Recovery

The recovery process is divided into the following phases: 1) recover the L2P table according to the latest full checkpoint, 2) sequentially incorporate the L2P differences recorded in the incremental checkpoints into the L2P table under recovery, 3) count the wid of flash pages written after the latest checkpoint according to the page pointers recorded in the latest checkpoint, and determine the completion/incompletion of each write request, 4) recover write requests after the latest checkpoint using a flow network, which we will describe shortly, and 5) sequentially incorporate the L2P changes of the write requests after the latest checkpoint.

The fourth phase above needs awareness of the order, completion, and coalescing of write requests to recover the disk to a state that satisfies our claimed guarantees. To this end, we formulate the task as a flow network problem as follows. As shown in Figure 6, write requests are represented by vertices. The order of immediately successive write requests is

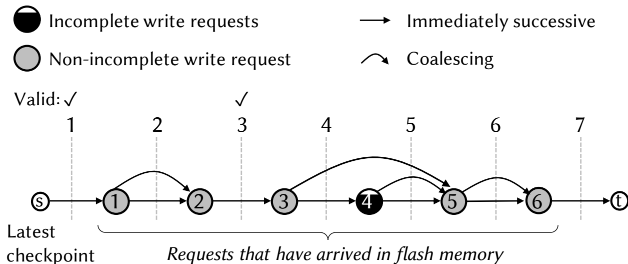

Figure 6: Determining the optimal recovery point by finding a cut in a flow network.

denoted by the straight directed edges pointing from request $wid = n$ to request wid=n+1, and coalescing between write requests is denoted by bent directed edges pointing from the earlier request to the later request. Each vertex is labeled by a wid and a Boolean value that denotes whether the write request is incomplete. Two additional vertices, s and t, are connected to the first and last vertices, respectively, to form a flow network from source (s) to sink (t), where s can be viewed as the latest checkpoint.

With such a formulation, finding a valid order-preserving recovery point is equivalent to finding an s-t cut such that 1) the cut size is equal to one (i.e., only a straight edge but not bent edges crosses the cut) and 2) the subgraph that contains vertex s (referred to as subgraph S for short) needs to contain no vertex denoting that the corresponding write request is incomplete. The rationales are as follows. The construction of the graph ensures that the write requests in subgraph S must preserve the order. A cut whose size is equal to one implies that coalesced write requests must be atomic. Since all write requests in subgraph S are not incomplete, it is valid for OPTR to recover them and drop others.

Let us take Figure 6 as an example. There are six write requests (1 to 6) present after the latest checkpoint, and some of their data pages have arrived in flash memory. The construction of the flow network reveals seven possible s-t cuts, 1 to 7, each representing a potential recovery point. Among the seven cuts, only 1 and 3 are valid. Cuts 5 to 7 are invalid recovery points because request 4 is incomplete, which breaks the order-preserving guarantee. Cuts 2 and 4 are invalid recovery points because they both cause coalesced requests to tear apart. Let us take Cut 4 as an example. Since some pages of request 3 are coalesced by request 5, request 3 cannot exist alone without request 5.

Note that OPTR can also handle multiple coalesces to the same page by creating multiple curved edges in the flow network. Again, take Figure 6 as an example. Consider a scenario where request 5 modifies a dirty cached page written by request 3, and then request 6 modifies the same page while this page is still dirty in the cache. This scenario would result in one curved edge from 3 to 5 and one from 5 to 6, as shown in Figure 6.

The optimal order-preserving recovery point should include as many write requests as possible. Therefore, finding this point is equivalent to finding the abovementioned s-t cut with the maximal subgraph S. A naive algorithm to find the optimal order-preserving recovery point is to start from a subgraph S containing only vertex s and gradually add vertices to subgraph S from left to right, one vertex at a time. Each time a vertex is added, the cut is checked to determine whether its size is equal to one and no request in S is incomplete. By doing so, the optimal recovery point is available.

In addition to the naive approach, we use a more efficient algorithm when implementing OPTR as follows. Let wid_{inc} be the wid of the earliest incomplete write and $\mathcal{C}$ be the set of all coalescing records generated after the latest checkpoint. As in Section 3.2, a coalescing record is in the form of an $< x, y >$ pair. The pseudocode is provided in Algorithm 1.

Algorithm 1 Find Optimal Recovery Point

Input: $wid_{inc}, \mathcal{C}$
Output: the optimal recovery point

1: $wid_{rec} \leftarrow wid_{inc}$;
2: Sort $\mathcal{C}$ by x in descending order;
3: **for** $c \in \mathcal{C}$ **do**
4:     **if** $c.x < wid_{rec} \wedge c.y >= wid_{rec}$ **then**
5:         $wid_{rec} \leftarrow c.x$;
6:     **end if**
7: **end for**
8: **return** wid_{rec};

4 Filesystem and Application Optimizations

We demonstrate Ext4 filesystem and SQLite database optimizations that exploit the benefits of OPTR SSDs as follows.

At the Ext4 level, we optimize an existing filesystem primitive, *fsync* (and its variant, *fdatasync*) and introduce a new filesystem primitive, *ffence* (and its variant, *fdatafence*). For brevity, we refer to *fdatasync* as *fsync* and *fdatafence* as *ffence* in this section. Conventional *fsync* issues two flush commands to a disk, one after *fsync* transfers a journal to the disk and the other after *fsync* transfers a commit record to the disk. Our optimized *fsync* uses the same order to transfer the journal and commit record to the disk but only issues the second flush request to the disk. Conventional *fsync* requires the first flush to prevent SSDs from persisting the commit record prior to the journal. With OPTR SSDs, which preserve order, the first flush becomes safely omissible. Note that the second flush of the optimized *fsync* still can guarantee the same durability semantics as the original *fsync* does.

The newly introduced *ffence* resembles the optimized *fsync*. This primitive also uses the same order to transfer the journal and commit record to the disk but omits both flush requests. Therefore, *ffence* is a pure barrier for applications to define

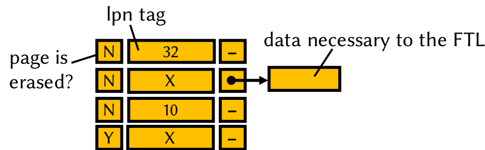

Figure 7: Emulated flash pages in VST.

the required partial order of transferring write requests to disks. With OPTR SSDs and the newly introduced *ffence*, applications can use *fsync* sparingly only when immediate durability is needed.

At the SQLite level, we modify SQLite to use *ffence* whenever a barrier alone is sufficient and to use the optimized *fsync* when immediate durability is required. To commit a single INSERT transaction, SQLite (version 3.19) calls *fsync* four times in its default configuration (journal_mode=DELETE and synchronous=FULL) [1]. Since the default configuration fails to guarantee durability on Ext4 (because unlink is not synchronous [3]), we set the configuration to the synchronous=EXTRA mode, which incurs one additional *fsync* on the parent directory after unlink to persist the deletion [4]. The objectives of the first four *fsync*s are as barriers instead of requesting immediate durability. The first *fsync* is a barrier after writing the content of a rollback journal file. The second *fsync* is a barrier to enforce that the rollback journal file exists in the directory before the db file is modified. The third *fsync* is a barrier after writing the header of the rollback journal. The fourth *fsync* is a barrier after writing the db file. Therefore, we change these four *fsync*s to *ffence*s. For the fifth *fsync*, we change it to the optimized *fsync*.

Some applications and filesystems, such as SQLite and OptFS, do not strictly demand immediate durability. For example, SQLite developers deliberately choose to avoid the fifth *fsync* by default and to allow loss of durability following a power loss event [3]. In this case, the *OPTR-enabled no-barrier mode* is the best solution.

5 OPTR Design Validation

Validating the functional correctness and crash guarantees of an FTL poses two challenges to FTL designers. First, the validation process is inherently time consuming since it requires extensive stress tests to create a large number of crash points. FTL operations such as GC, which are not invoked until a sufficient number of writes occur, make the issue even worse. Second, one may lack necessary hardware support during development of a new FTL. For example, the OpenSSD platform [2] on which we implement OPTR does not allow access to the spare area of flash, which OPTR demands during recovery.

To address this issue, we extend an FTL testing framework named Virtual Stress Testing (VST) [31] and use it to validate our OPTR implementation. Please note that we still evaluate

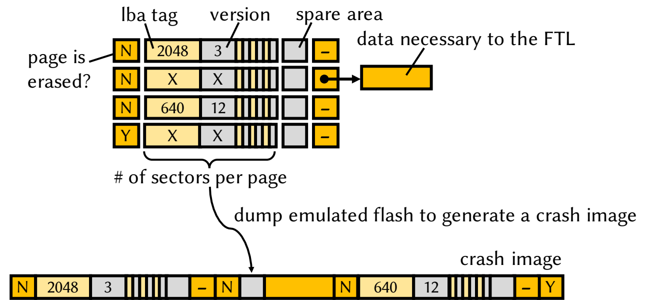

Figure 8: Extensions for crash-guarantee validation.

the performance on real OpenSSD hardware [2]. We use the same FTL code in the two experimental environments and make slight modifications to overcome hardware limitations (e.g., accessing the spare area).

5.1 VST Testing Framework

VST [31] is a simulation framework designed for validating the functional correctness of FTLs. This framework enables one to execute FTLs on PCs or servers that emulate the SRAM, DRAM and flash required by the FTLs. VST outperforms traditional FTL stress tests that use real SSDs by orders of magnitude. To validate an FTL, VST issues an extensive number of read and write requests to the FTL and reports a bug if the FTL violates any predefined rule such as incorrect page contents or a nonsequential program within a block.

The core data structure of VST is the emulated flash memory. As shown in Figure 7, an emulated flash page contains three fields: an $erased$ field that denotes whether a page has been erased, an lpn tag that records the LPN of the page, and a $data$ pointer that points to the FTL metadata stored in the page. The design of storing an lpn tag for host data rather than the actual contents dramatically decreases the memory requirement for simulation and speeds up the test. Thus, VST is particularly suitable for our validation purposes, as we want to generate a very large number of crash images.

5.2 Extending VST for Crash Recovery Tests

We largely extend VST to support crash recovery tests, which the original VST does not touch at all. For example, Figure 8 depicts the extensions we made to the emulated flash memory. We divide each emulated page into multiple 512-byte sectors to match the granularity of IO requests and further add a $version$ attribute to each emulated sector. The $version$ of a sector starts with 0 and increments by 1 when the sector is updated. For crash simulation, we fork a separate thread to periodically take snapshots of the emulated flash memory and store the snapshots as crash images.

The process of validating whether an FTL obeys prefix semantics and request atomicity is described as follows. First, we compile the FTL under test to a Linux shared object, execute the FTL on the extended VST, drive the FTL using

a trace file, and generate a number of crash images. Then, VST deserializes each crash image back into the form of the emulated flash memory and triggers the recovery procedure of the FTL. After recovery is done, VST queries the firmware for the last write it has recovered, which we call the *recovery point*, and replays the same trace separately until the recovery point to construct the *golden disk*, which represents the result of bug-free and crash-free execution. Finally, for each written sector in the golden disk, VST issues a read targeting the sector and checks if the LBA and version returned by the FTL match with those in the golden disk. If any inconsistency exists, our extended VST framework reports a violation.

We can also validate whether the FTL obeys flush semantics. We insert flushes into the request sequence and record the ID of the last flushed write in the header of a crash image. If the FTL fails to recover any write prior to the last flush, our VST framework also reports a violation.

5.3 Validation Results

We select 12 write-heavy traces from the MSRC I/O traces [35], which cover a variety of server-level access patterns [46], to drive the FTL tests. Our validation process consists of three runs. In the first run, we execute the firmware without crashes being simulated to validate its functional correctness. Similar to the validation approach in [31], we repeat each trace until the write amount reaches 1 TB. In the second run, we let the firmware recover from a total of 2,400 crash images created without any flush issued to validate whether the FTL correctly obeys prefix semantics and request atomicity. The final run is similar to the previous run, but we additionally insert a flush for every 1,000 writes to validate whether the FTL also obeys the flush semantics.

Table 1 shows the final validation results. Our implemented OPTR passes all three runs of tests. Please note that these results also suggest that our extended VST simulation framework passes the stress test, and this finding makes the simulator a much more reliable platform for future research.

Table 1: Validation results for our OPTR FTL.

	Functional Correctness	Prefix Semantics Preserved	Flush Semantics Obeyed
1-TB stress test	V		
2400 images w/o flushes		V	
2400 images w/ flushes		V	V

6 Evaluation

6.1 Experimental Setups

We implement the OPTR FTL on a real SSD (OpenSSD [2]) with an ARM7 core at 87.5 MHz, 96 KB on-chip SRAM, 64 MB DRAM, and 128 GB flash memory. We organize a total of 16 flash chips into four channels, each channel connects to four chips, each chip contains approximately 4,000 blocks, and each block contains 128 16-KB pages. The SSD adopts a static allocation strategy, which allocates a logical page to a certain flash chip based on modulo [22]. We allocate 8 MB of DRAM as the write cache of the SSD and adopt the LRU cache replacement policy. We adopt the greedy policy for GC [29, 42]. We store the per page recovery information (i.e., the wid, $size$ and lpn described in Section 3.1) in the last page of each flash block. For the OPTR-specific settings, we reserve 32 blocks for full checkpoints and 32 blocks for incremental checkpoints and coalescing records.

All the experiments are performed on a server with a 6-core Intel i7-8700 CPU and 32 GB DRAM running Ubuntu 16.04. We erase the entire SSD before conducting each experiment. More experimental setups are described in the captions of each experimental results figure.

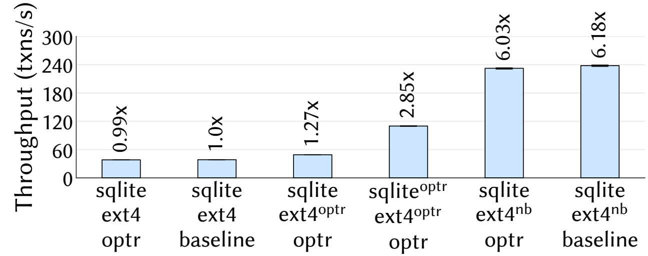

Figure 9: Performance of the three OPTR usage modes. In addition to the three usage modes and the baseline, we plot two additional bars: The leftmost bar represents running unmodified SQLite and Ext4 on OPTR to demonstrate OPTR's overhead for enforcing ordering. The rightmost bar represents running unmodified SQLite and Ext4 mounted with the no-barrier option; this configuration guarantees neither durability nor consistency and is for demonstrating the upper bound.

6.2 System-Level Performance

In this set of experiments, we evaluate three usage modes of OPTR as mentioned previously. The first mode (② in Figure 2) runs unmodified SQLite and the optimized version of Ext4; the second mode (③ in Figure 2) runs the optimized versions of SQLite and Ext4 (details of the optimizations are described in Section 4). The third mode is the OPTR-enabled no-barrier mode (④ in Figure 2). This mode guarantees consistency but achieves only eventual durability instead of immediate durability.

We use a microbenchmark that keeps generating transactions for a time interval of five minutes. Each transaction inserts a key-value pair into the SQLite database. Figure 9 shows the throughput performance of the three usage modes of OPTR. Removing the first flush of fdatasync (the third bar) improves the performance by 1.27×; invoking fdatafences (the fourth bar) for ordering constraints yields 2.85× im-

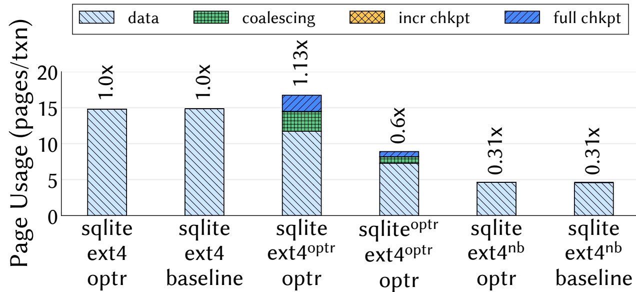

Figure 10: Endurance impact of the three OPTR usage modes.

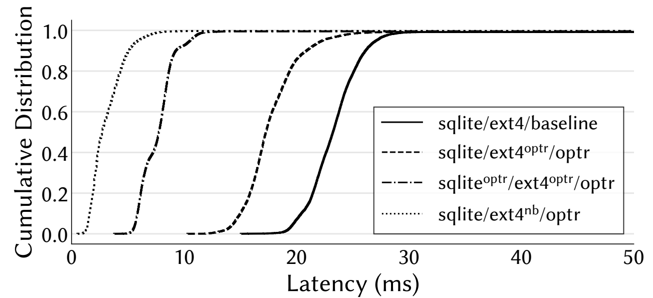

Figure 11: Latency of the three OPTR usage modes.

provement; finally, the OPTR-enabled no-barrier mode performs 6.03× better than the baseline, and this result is very close to the upper bound of 6.18×. We conduct the experiments ten times, and the errors are within ± 0.7%. To quantify the FTL overhead of enforcing the order, we compare unmodified SQLite and Ext4 atop OPTR SSDs (the first bar) with unmodified SQLite and Ext4 atop baseline SSDs (the second bar). The overhead is unnoticeable (hidden by the flushes of the workload). This result is consistent with our analysis in Section 7. However, we would like to emphasize that OPTR is not overhead-free (as shown in Section 7, OPTR can decrease the performance by up to 11.1% in some synthetic workloads).

In terms of SSD endurance impact, OPTR may improve endurance because removing flushes results in a greater chance of write coalescing; OPTR may also hurt endurance because OPTR stores checkpoints and coalescing records into flash memory for the sake of crash recovery. Figure 10 shows the overall endurance impact of the three OPTR usage modes. The y-axis denotes the average number of flash pages written per transaction. We break down written pages into user data (data) and OPTR-related data (i.e., incremental checkpoints, full checkpoints, and coalescing records).

The first usage mode of OPTR (the third bar) slightly increases the number of written pages per transaction (1.13×). The second usage mode (the fourth bar) lowers the frequency of flush operations and thereby decreases the number of written pages per transaction to 0.6×. The third usage mode does not incur any flush, and thus, the number of written pages is 0.31× that of the baseline.

Figure 11 shows the cumulative latency distribution of transactions. Flushes are slow in nature, and thus, partially or fully removing them is expected to achieve shorter latency. The experimental results show that the average latencies of OPTR in the first, second and third usage modes are 0.78×, 0.35× and 0.17× that of the baseline, respectively.

7 FTL Analyses

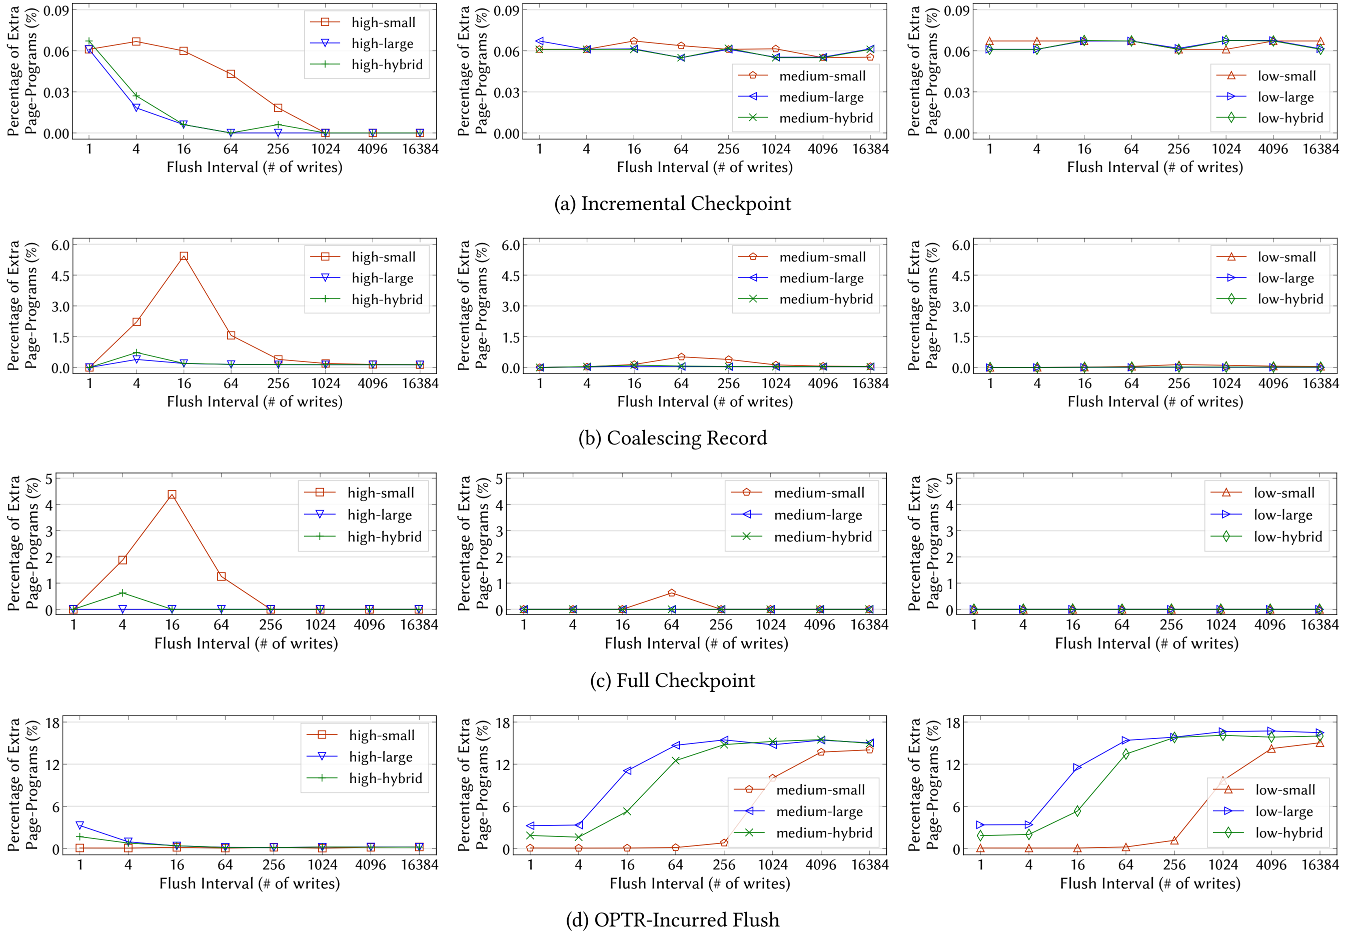
In this section, we analyze the FTL in more detail. We first report the extra flash page-programs caused by OPTR. Next, we analyze the extra GC constraints and report the overhead in terms of throughput performance. The above experiments are conducted using synthetic workloads that comprise random writes with different access localities (high: 1 MB footprint, medium: 80 MB footprint, and low: 1 GB footprint), different access granularities (large: 1 MB, small: 16 KB, and hybrid: half large and half small), and different flush intervals (1, 4, ..., to 16,384 writes). Note that these analyses are pessimistic because OPTR does not benefit from reducing flush requests in the synthetic workloads. Finally, we discuss the memory overhead (i.e., extra SRAM, DRAM, and flash space) caused by OPTR, and then, we estimate the recovery time.

7.1 Extra Flash Page-Programs

OPTR incurs extra flash page-programs because of incremental checkpoints, coalescing records, full checkpoints, and internally invoked flushes.

The overhead of **incremental checkpoints** is negligible (<0.075%), as shown in Figure 12a. The overhead is low because writing each user data page (e.g., 16 KB) incurs only an 8-byte L2P table change record, which constitutes incremental checkpoints. The overhead of incremental checkpoints is even low if write requests coalesce in the write cache. For example, the overhead is less than 0.01% for the workload with high access locality and a long flush interval (e.g., the *high-large* workload with a flush interval greater than 16 writes).

The overheads of **coalescing records** and **full checkpoints** are also negligible for most workloads. An exception is the workload with high locality and small access granularity (i.e., *high-small*) when the flush interval is between four and 64 writes (Figures 12b and 12c). High write locality tends to incur write coalescing. With more coalescing records, the checkpoint area is filled quickly, and OPTR invokes full checkpoints more frequently. If the flush interval is one write, flushes happen to suppress the occurrence of write coalescing. If the flush interval is long (e.g., >256 writes) or if the size of the write granularity is large, the overhead decreases because approximately 800 coalescing records result in an extra 16 KB page-program (each coalescing record is 20 bytes in our implementation).



(a) Incremental Checkpoint

(b) Coalescing Record

(c) Full Checkpoint

(d) OPTR-Incurred Flush

Figure 12: Page write overhead analysis using synthetic workloads. The prefix in the legends indicates the locality: *high*/*medium*/*low* access 1 MB/80 MB/1 GB of flash. The suffix indicates the access granularity: *small*/*large* write 16 KB/1 MB of data per request, and *hybrid* writes 16 KB or 1 MB of data per request, each with a 50% chance.

The percentages of page-programs caused by **internally invoked flushes** are shown in Figure 12d. In our OPTR implementation, the FTL internally flushes the write cache under the following four conditions: before an incremental checkpoint, before a full checkpoint, before GC, and every five seconds. The first three types of flushes are for correct recovery in case a crash happens, and the fourth type of flushes is for bounding the longest time duration for which dirty data can reside in the write cache. We observe a reasonable trend: if the flush interval is short (e.g., every four writes), the page-programs caused by internally invoked flushes only account for a small percentage (less than 4%). In comparison, if the flush interval is long (e.g., every 64 writes), the page-programs caused by internally invoked flushes account for a high percentage (up to 17%). Note that the page-programs analyzed here are for user data instead of OPTR's metadata, and baseline SSDs also need to flush their write caches at some points. Therefore, the above analysis is a conservative overestimation of overhead.

7.2 GC Constraints

Although OPTR constrains GC from selecting recently written flash blocks to guarantee recoverability, this constraint does not cause significantly adverse effects. The reasons are two-fold. First, OPTR constrains GC from selecting flash blocks written after the latest full or incremental checkpoint. According to our analysis, this type of blocks accounts for only 0.2% of the total blocks on average. Second, sophisticated GC policies such as age-aware GC policies avoid selecting recently written blocks in the expectation of data invalidation due to write locality.

7.3 Performance Overhead

Figures 13a, 13b, and 13c show the throughput performance (MB/s). Dotted lines denote the throughput of the baseline, and solid lines denote that of OPTR. Overall, OPTR incurs less than 2% performance overhead on average and up to 11.1% performance overhead for the synthetic workloads. Note that OPTR can slightly outperform the baseline for some workloads when OPTR's mechanisms happen to match the

workload characteristics. For example, for workloads with a high locality, age-aware GC is better than greedy GC. OPTR happens to achieve some effects of age-aware GC because OPTR constrains GC from selecting recently written flash blocks.

7.4 Memory Overhead

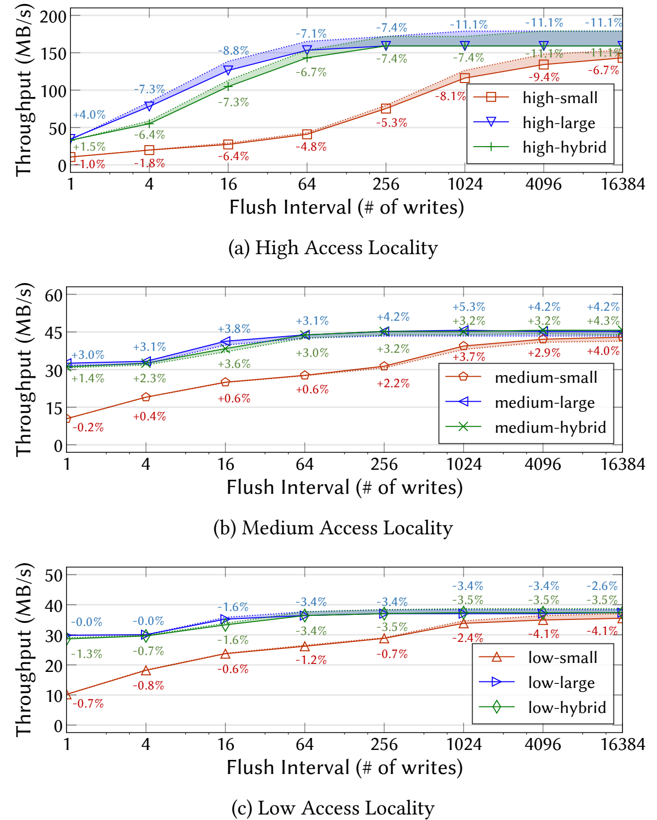
The DRAM and SRAM overheads for implementing OPTR are analyzed as follows. First, OPTR associates each entry in the write cache with two extra attributes, wid (8 bytes) and $size$ (4 bytes). In our implementation, the write cache is 8 MB (16 KB $\times$ 512 entries). Therefore, the space for storing wid is 8 $\times$ 512 = 4 KB (in DRAM in our implementation), and the space for storing $size$ is 4 $\times$ 512 = 2 KB (in SRAM in our implementation). Second, we employ a 256 KB DRAM area to buffer incremental checkpoints. Third, OPTR stores coalescing records in a DRAM buffer, whose size is equal to a flash page, e.g., 16 KB. Finally, the memory space for crash recovery can overlay that for regular FTL operation, so we do not consider this space as additional overhead.

The flash memory overhead for implementing OPTR is described as follows. First, OPTR additionally stores wid and $size$ (8 bytes and 4 bytes, respectively) in the spare area of flash memory. Modern flash memory with 16 KB page size equips each page with a 2,208-byte spare area (i.e., page size = 16,384 + 2,208 = 18,592 bytes) [6]. Since OPTR only consumes 12 bytes out of the 2,208 bytes, the overhead is only 12/2,208=0.5%, and the impact on the ratio of the error correction code rate is only 16,384/18,580 - 16,384/18,592 = 0.06%. Second, OPTR stores the lpn of each flash page in the spare area and summarizes the lpn of a block of pages in the last page of the block. We anticipate that baseline SSDs also do so. Third, OPTR keeps incremental checkpoints, coalescing records, and full checkpoints in flash memory. We set the area for storing incremental checkpoints and coalescing records to 64 MB. The size of a full checkpoint is equivalent to that of the L2P table. Given an SSD with 128 GB flash memory and 16 KB pages, the size of a full checkpoint and its shadow is at most 128 GB/16 KB $\times$ 4 B $\times$ 2 = 64 MB.

7.5 Recovery Time

OpenSSD does not provide an access approach to the spare area of flash pages, so we are not able to measure recovery time using OpenSSD. Instead, we conduct a worst-case estimation. We anticipate that accessing flash memory, which is slower than SRAM, DRAM, and computation, dominates the recovery time.

Recovery begins with reading the full checkpoint, whose size is approximately 32 MB (2,048 pages) for a 128 GB SSD. Second, OPTR sequentially scans the 64 MB area (4,096 pages) for storing incremental checkpoints and coalescing records. Third, OPTR scans the summary pages programmed after the latest checkpoint. Given a 256 KB buffer for incremental checkpoints, the number of summary pages after the latest checkpoint can be up to 256. Finally, each flash chip can



(a) High Access Locality

(b) Medium Access Locality

(c) Low Access Locality

Figure 13: Performance overhead for preserving write order.

have a partially written block, and OPTR needs to access these pages during recovery. We assume that the number of flash pages of partially written blocks is 4,096. Overall, there are 10,496 pages. We conservatively assume that reading each flash page costs 100 μs and no internal parallelism is available; then, the worse-case recovery time is 10,496 $\times$ 100 μs = 1 s, which is acceptable in general.

8 Related Work

OptFS [15], BarrierFS [45], and Featherstitch [23] are related filesystem and IO stack works that propose to decouple ordering from durability. Unlike this work, they do not focus on the FTL design and recovery process of SSDs. OptFS presents a filesystem that requires disks to support asynchronous durability notification, which notifies a host when certain blocks become persistent. BarrierFS presents a filesystem and an IO stack that require disks to support the cache barrier command, which is only available in a few eMMC (embedded multimedia card) products [45] but unavailable in the standard block device interfaces of off-the-shelf SATA, SAS, and NVMe SSDs. BarrierFS [45] implements an FTL to support the barrier write command in a commercial eMMC product. OPTR is complementary to both OptFS and BarrierFS and can simplify their designs. For instance, OptFS requires checksum encoding/decoding to enforce the ordering con-

straint between journal metadata and the commit record, and BarrierFS uses explicit cache barrier primitives to declare order; with OPTR, both can be simplified out because OPTR implicitly preserves the write order.

Mime [13], the Logical Disk [21], Stasis [43], TxFlash [40], Beyond Block IO [37], Mars [19], LightTx [32], X-FTL [28], and Isotope [44] propose transactional storage with full or partial supports to ACID at the disk level. The notion of transaction is stronger than OPTR's guarantees, but these works all propose changing the standard block device interface, which inevitably incurs significant software stack changes. Among these works, Mime [13] also advocates the benefits of request atomicity and ordering, which are in line with OPTR's design. Compared with OPTR, Mime [13] is fundamentally different because it is HDD design instead of SSD design. In addition, Mime does not allow write coalescing in a write cache, which OPTR can handle.

Increasing the disk-level crash guarantee not only can improve system performance but also, more importantly, helps to reduce crash vulnerabilities. In this sense, just replacing baseline SSDs with OPTR SSDs is beneficial. Crash vulnerabilities are serious problems. Pillai et al. [39] find 60 application-level crash vulnerabilities in widely used applications such as LevelDB and Git. Zheng et al. [47] also find ACID violations in many database systems. These vulnerabilities are mainly caused by the weak and vague crash guarantees provided by the underlying filesystems. Thus, Bornholt et al. present crash-consistency models [10], and Pillai et al. [39] specify a set of persistent properties. These approaches aim to confine and standardize the crash behaviors of filesystems, and OPTR can help to achieve these aims.

Several studies have attempted to reduce the usage or overhead of flush operations at the application or filesystem level. BarrierFS [45] and [5] replace *unnecessary flushes* with cache barrier commands. Our previous work-in-progress report [12] proposes to directly omit *unnecessary flushes* by considering *order-preserving SSDs* that achieve *strong request-level crash guarantees*. iJournaling [38] performs fine-grained journaling per file to mitigate the interference between fsync-intensive threads. NoFS [16] proposes backpointer-based consistency to fully eliminate ordering constraints but at the cost of not being able to implement atomic operations (e.g., rename). Xsyncfs [36] introduces external synchrony, in which a write is not immediately persisted (i.e., asynchronous writes) unless an external observer sees the write; thereby, this method provides the simplicity of synchronous writes and approaches the performance of asynchronous writes. Chen et al. identify the sync amplification issue in virtualized environments and propose solutions using journaling techniques at the virtual-disk level [14].

One can equip SSDs with supercapacitors, which may help to preserve write order. However, they are not widely adopted. In previous work [48], power interrupt tests are performed on 15 SSDs, and only four out of the 15 tested SSDs are equipped with supercaps. In addition, supercapacitors may be sufficient to protect an FTL from corruption, but they may not be sufficient to preserve write order. Among the four tested supercapped SSDs in [48], two still exhibit shorn or unserializable writes under power faults. Finally, capacitors are sensitive to temperature- and aging-related degradation and failures [25].

9 Conclusion

In common practice, consumer-grade SSDs (whose write cache is not battery-backed) cannot guarantee the order and atomicity of write requests upon a crash because SSD performance optimization strategies including write caching, write coalescing, request scheduling, and parallel flash programming all tend to break the guarantee. The lack of a strong crash guarantee at the disk level complicates the design of applications and filesystems and degrades the overall system performance. By exploiting the fact that SSDs adopt out-of-place updates, this work proposes order-preserving translation and recovery design (OPTR) that maintains SSD performance while preserving an illusion that write requests are completed in order and atomically. We realize the required address translation, garbage collection, and crash recovery techniques internal to a real SSD to achieve OPTR. We also develop a functional simulator to validate the correctness of OPTR.

Three usage modes of OPTR SSDs are identified and evaluated: 1) optimizing filesystems to remove the *unnecessary flushes* of *fdatasync*, 2) optimizing both applications and filesystems to further replace *fdatasync* with *fdatafence* primitives, and 3) combining the performance advantages of the no-barrier mode of filesystems and the *strong request-level crash guarantees* of OPTR SSDs. Real system experiments based on SQLite, Ext4, and a real SSD show that these three modes achieve 1.27×, 2.85×, and 6.03× performance improvement, respectively.

This work is the first SSD work with *strong request-level crash guarantees* and the standard block device interface. In comparison with previous works on transactional SSDs, we change the impression that increasing SSDs' crash guarantees is typically available at the cost of altering the standard block interface. We anticipate that OPTR can inspire more future application and filesystem designs.

Abstract

The popularity of Convolutional Neural Network (CNN) models and the ubiquity of CPUs imply that better performance of CNN model inference on CPUs can deliver significant gain to a large number of users. To improve the performance of CNN inference on CPUs, current approaches like MXNet and Intel OpenVINO usually treat the model as a graph and use the high-performance libraries such as Intel MKL-DNN to implement the operations of the graph. While achieving reasonable performance on individual operations from the off-the-shelf libraries, this solution makes it inflexible to conduct optimizations at the graph level, as the local operation-level optimizations are predefined. Therefore, it is restrictive and misses the opportunity to optimize the end-to-end inference pipeline as a whole. This paper presents *NeoCPU*, a comprehensive approach of CNN model inference on CPUs that employs a full-stack and systematic scheme of optimizations. *NeoCPU* optimizes the operations as templates without relying on third-parties libraries, which enables further improvement of the performance via operation- and graph-level joint optimization. Experiments show that *NeoCPU* achieves up to 3.45× lower latency for CNN model inference than the current state-of-the-art implementations on various kinds of popular CPUs.

1 Introduction

The growing use of Convolutional Neural Network (CNN) models in computer vision applications makes this model architecture a natural focus for performance optimization efforts. Similarly, the widespread deployment of CPUs in servers, clients, and edge devices makes this hardware platform an attractive target. Therefore, performing CNN model inference efficiently on CPUs is of critical interest to many users.

The performance of CNN model inference on CPUs leaves significant room for improvement. Performing a CNN model inference is essentially executing a computation graph consisting of operations. In practice, people normally use high-performance kernel libraries (e.g. Intel MKL-DNN [27] and OpenBlas [51]) to obtain high performance for CNN operations. While these libraries tune very carefully for common operations with normal input data shapes (e.g. 2D convolutions), they only focus on the (mostly, convolution) operations but miss the opportunities to further optimize the end-to-end model inference at the graph level. The graph-level optimization is often handled by the deep learning frameworks, e.g. TensorFlow [5] and MXNet [8].

However, the graph-level optimization such as operation fusion and data layout planing that a framework can do is limited because the operation implementation is already predefined in the third-party libraries. Therefore, the optimizations in the frameworks do not work in concert with the optimizations in the kernel library, which leaves significant performance gains unrealized in practice. Furthermore, different CPU architectures rely on different high-performance libraries and integrating a library into a deep learning framework requires error-prone and time-consuming engineering effort. Lastly, although those libraries are highly optimized, they present as third-party plug-ins, which may introduce contention issues with other libraries in the framework. As an example, TensorFlow originally used the Eigen library [4] to handle computation on CPUs. Later on, MKL-DNN was also introduced. As a consequence, at runtime MKL-DNN threads coexist with Eigen threads, resulting in resource contention. In summary, this kind of *framework-specific* approach for CNN model inference on CPUs is inflexible, cumbersome, and sub-optimal.

Because of the constraint imposed by the framework, optimizing the performance of CNN model inference end-to-end without involving a framework (i.e. a *framework-agnostic* method) is of obvious interest to many deep learning practitioners. Recently, Intel launched a universal CNN model inference engine called OpenVINO Toolkit [16]. This toolkit optimizes CNN models in the computer vision domain on Intel processors (mostly x86 CPUs) and claims to achieve better

[*]Equal contribution

performance than the deep learning frameworks alone. Yet, OpenVINO could only provide limited graph-level optimization (e.g. operation fusion as implemented in ngraph [15]) as it still relies upon MKL-DNN to deliver performance gains for the carefully-tuned operations. Therefore, the optimization done by OpenVINO is still not sufficient for most of the CNN models.

Based on the previous observation, we argue that in order to further improve the CNN model inference performance on CPUs, being able to do the *flexible end-to-end optimization* is the key. In this paper, we propose *NeoCPU*, a comprehensive approach to optimize CNN models for efficient inference on CPUs. *NeoCPU* is full-stack and systematic, which includes operation- and graph-level joint optimizations and does not rely on any third-party high-performance libraries. At the operation level, we follow the well-studied techniques to optimize the most computationally-intensive operations like convolution (*CONV*) in a *template*, which is applicable to different workloads on multiple CPU architectures and enables us for flexible graph-level optimization. At the graph level, in addition to the common techniques such as operation fusion and inference simplification, we coordinate the individual operation optimizations by manipulating the data layout flowing through the entire model for the best end-to-end performance. In summary, *NeoCPU* does the end-to-end optimization in a flexible and automatic fashion, while the existing works rely on third-party libraries and lack comprehensive performance tuning.

NeoCPU is built upon a deep learning compiler stack named TVM [9] with a number of enhancements. TVM enables the possibility of using own operation-level optimizations instead of third-party high-performance libraries, which make it flexible to apply our operation- and graph-level joint optimization. However, there was only one customized operation-level optimization on ARM CPUs for convolutions with specific data shapes and no operation- and graph-level joint optimization in the original TVM stack before our work. In addition, there exist other deep learning compilers such as Tensor Comprehensions [46] and Glow [40]. Unfortunately, they either do not target on CPUs or not optimize the CPU performance well, e.g. based on the paper description and our own experiments, Glow only optimizes the single-core performance for CPUs. Therefore we do not incorporate those works as the baseline. Table 1 summarizes the features of *NeoCPU* compared to others. To the best of our knowledge, *NeoCPU* achieves competitive performance for CNN model inference on various kinds of popular CPUs.

Specifically, this paper makes the following contributions:

- Provides an operation- and graph-level joint optimization scheme to obtain high CNN model inference performance on different popular CPUs including Intel, AMD and ARM, which outperforms the current state-of-the-art implementations;

	Op-level opt	**Graph-level opt**	**Joint opt**	**Open-source**
NeoCPU	✓	✓	✓	✓
MXNet [8]/TensorFlow [5]	3rd party	limited	✗	✓
OpenVINO [16]	3rd party	limited	?	✗
Original TVM [9]	incomplete	✓	✗	✓
Glow [40]	single core	✓	✗	✓

Table 1: Side-by-side comparison between *NeoCPU* and existing works on CNN model inference

- Constructs a template to achieve good performance of convolutions, which is flexible to apply to various convolution workloads on multiple CPU architectures (x86 and ARM) without relying on high-performance kernel libraries;
- Designs a global scheme to look for the best layout combination in different operations of a CNN model, which minimizes the data layout transformation overhead between operations while maintaining the high performance of individual operations.

It is worth noting that, this paper primarily deals with direct convolution computation, while *NeoCPU* is compatible to other optimziation works on the computationally-intensive kernels, e.g. *CONV*s via Winograd [7, 29] or FFT [52].

We evaluated *NeoCPU* on CPUs with both x86 and ARM architectures. In general, *NeoCPU* delivers the best performance for 13 out of 15 popular networks on Intel Skylake CPUs, 14 out of 15 on AMD EYPC CPUs, and all 15 models on ARM Cortex A72 CPUs. It is worthwhile noting that the baselines on x86 CPUs were more carefully tuned by the chip vendor (Intel MKL-DNN) but the ARM CPUs were less optimized. While the selected framework-specific (MXNet and TensorFlow) and framework-agnostic (OpenVINO) solutions may perform well on one case and less favorably on the other case, *NeoCPU* runs efficiently across models on different architectures.

In addition, *NeoCPU* produces a standalone module with minimal size that does not depend on either the frameworks or the high-performance kernel libraries, which enables easy deployment to multiple platforms. *NeoCPU* is used in Amazon SageMaker Neo Service [1], enabling model developers to optimize for inference on CPU-based servers in the cloud and devices at the edge. Using this service, a number of application developers have deployed CNN models optimized for inference in production on several types of platforms. All source code has been released to the open source TVM project[2].

The rest of this paper is organized as follows: Section 2 reviews the background of modern CPUs as well as the typical CNN models; Section 3 elaborates the optimization ideas that we propose and how we implement them, followed by evaluations in Section 4. We list the related works in Section 5 and summarize the paper in Section 6.

2 Background

2.1 Modern CPUs

Although accelerators like GPUs and TPUs demonstrate their outstanding performance on the deep learning workloads, in practice, there is still a significant number of deep learning computation, especially model inference, taking place on the general-purpose CPUs due to the high availability. Currently, most of the CPUs equipped on PCs and servers are manufactured by Intel or AMD with x86 architecture [1], while ARM CPUs with ARM architecture occupy the majority of embedded/mobile device market [2].

Modern CPUs use thread-level parallelism via multi-core [21] to improve the overall processor performance given the diminishing increasing of transistor budgets to build larger and more complex uniprocessor. It is critical to avoid the interference among threads running on the same processor and minimize their synchronization cost in order to have good scalability on multi-core processors. Within the processor, a single physical core achieves the peak performance via the SIMD (single-instruction-multiple-data) technique. SIMD loads multiple values into wide vector registers to process together. For example, Intel introduced the 512-bit Advanced Vector Extension instruction set (AVX-512), which handles up to 16 32-bit single precision floating point numbers (totally 512 bits) per CPU cycle. And the less advanced AVX2 processes data in 256-bit registers. In addition, these instruction sets utilize the Fused-Multiply-Add (FMA) technique which executes one vectorized multiplication and then accumulates the results to another vector register in the same CPU cycle. The similar SIMD technique is embodied in ARM CPUs as NEON [3]. As shown in the experiments, our proposed solution works on both x86 and ARM architectures.

In addition, it is worth noting that modern server-side CPUs normally supports hyper-threading [37] via the simultaneous multithreading (SMT) technique, in which the system could assign two virtual cores (i.e. two threads) to one physical core, aiming at improving the system throughput. However, the performance improvement of hyper-threading is application-dependent [35]. In our case, we do not use hyper-threading since one thread has fully utilized its physical core resource and adding one more thread to the same physical core will normally decrease the performance due to the additional context switch. We also restrict our optimization within processors using the shared-memory programming model as this is the typical system setting for CNN model inference. The Non-Uniformed Memory Access (NUMA) pattern occurred in the context of multiple processors on the same motherboard is beyond the scope of this paper.

2.2 Convolutional neural networks

Convolutional neural networks (CNNs) are commonly used in computer vision workloads [23, 26, 33, 36, 41–43]. A CNN model is normally abstracted as a computation graph, essentially, Directed Acyclic Graph (DAG), in which a node represents an operation and a directed edge pointing from node X to Y represents that the output of operation X serves as (a part of) the inputs of operation Y (i.e. Y cannot be executed before X). Executing a model inference is actually to flow the input data through the graph to get the output. Doing the optimization on the graph (e.g. prune unnecessary nodes and edges, pre-compute values independent to input data) could potentially boost the model inference performance.

Most of the computation in the CNN model inference attributes to *convolutions (CONVs)*. These operations are essentially a series of multiplication and accumulation, which by design can fully utilize the parallelization, vectorization and FMA features of modern CPUs. Existing works [19, 24, 27] have demonstrated that it is possible to achieve high performance of convolution operations on CPUs by arranging the data layout and consequently, the computation, in an architecture-friendly way. The remaining challenge is how to manage the data layout flowing through these operations efficiently to get the high performance out of the end-to-end CNN model inference.

The rest of the CNN workloads are mostly memory-bound operations associated to *CONV*s (e.g. batch normalization, pooling, activation, element-wise addition, etc.). The common practice [9] is fusing them to *CONV*s so as to increase the overall arithmetic intensity of the workload and consequently boost the performance.

The computation graph of CNN model training has no essential difference with inference, just being larger (adding in backwards operations) and with some more computationally-trivial operations (e.g. loss function). Therefore, the optimization work done for CNN model inference is applicable to training as well.

3 Optimizations

This section describes our optimization ideas and implementations in detail. The solution presented in this paper is end-to-end for doing the CNN model inference. Our proposed solution is generic enough to work for a wide range of common CNN models as we will show in the evaluation. The basic idea of our approach is to view the optimization as an end-to-end problem and search for a globally best optimization. That is, we are not biased towards a local performance optimal of a single operation as many previous works. In order to achieve this, we first present how we optimized the computationally intensive convolution operations at low-level using a configurable template (Section 3.1). This makes it flexible to search for the best implementation of a specific convolution workload on a particular CPU architecture, and to optimize the entire computation graph by choosing proper data layouts between operations to eliminate unnecessary data layout transformation overhead (presented in Section 3.2

and 3.3).

We implemented the optimization based on the TVM stack [9] by adding a number of new features to the compiling pass, operation scheduling and runtime components. The original TVM stack has done a couple of generic graph-level optimizations including operation fusion, pre-computing, simplifying inference for batch-norm and dropout [9], which are also inherited to this work but will not be covered in this paper.

3.1 Operation optimization

Optimizing convolution operations is critical to the overall performance of a CNN workload as it takes the majority of computation. This is a well-studied problem but the previous works normally go deep to the assembly code level for high performance [24,27]. In this subsection, we show how to take advantage of the latest CPU features (SIMD, FMA, parallelization, etc.) to optimize a single *CONV* without going into the tedious assembly code or C++ intrinsics. By managing the implementation in high-level instead, it is then easy to extend our optimization from a single operation to the entire computation graph.

3.1.1 Single thread optimization

We started from optimizing *CONV* within one thread. *CONV* is computationally-intensive which traverses its operands multiple times for computation. Therefore, it is critical to manage the layout of the data fed to the *CONV* to reduce the memory access overhead. We first revisit the computation of *CONV* to illustrate our memory management scheme. A 2D *CONV* in CNN takes a 3D feature map (height $\times$ width $\times$ channels) and a number of 3D convolution kernels (normally smaller height and width but the same number of channels) to convolve to output another 3D tensor. The calculation is illustrated in Figure 1, which implies loops of 6 dimensions: *in_channel*, *kernel_height*, *kernel_width*, *out_channel*, *out_height* and *out_width*. Each kernel slides over the input feature map along the height and width dimensions, does element-wise product and accumulates the values to produce the corresponding element in the output feature map, which can naturally leverage FMA. The number of kernels forms *out_channel*. Note that three of the dimensions (*in_channel*, *kernel_height* and *kernel_width*) are reduction axes that cannot be embarrassingly parallelized.

We use the conventional notation *NCHW* to describe the default data layout, which means the input and output are 4-D tensors with *batch size* N, *number of channels* C, *feature map height* H, *feature map width* W, where *N* is the outermost and *W* is the innermost dimension of the data. The related layout of kernel is *KCRS*, in which *K*, *C*, *R*, *S* stand for the output channel, input channel, kernel height and kernel width.

Following the common practice [27,45], we organized the feature map layout as *NCHW[x]c* for better memory access patterns i.e. better cache locality, in which *c* is a split sub-dimension of channel *C* in super-dimension, and the number *x* indicates the split size of the sub-dimension (i.e. $\#channels = sizeof(C) \times sizeof(c)$, where $sizeof(c) = x$). The output has the same layout *NCHW[y]c* as the input, while the split factor can be different. Correspondingly, the convolution kernel is organized in *KCRS[x]c[y]k*, in which *c* with split size *x* and *k* with split size *y* are the sub-dimensions of input channel *C* and output channel *K*, respectively. It is worth noting that a significant amount of data transformation overhead needs to be paid to get the desired layout.

In addition to the dimension reordering, for better utilizing the latest vectorization instructions (e.g. AVX-512, AVX2, NEON, etc.), we split *out_width* to *ow_outer* and *ow_inner* using a factor *reg_n* and move the loop of *ow_inner* inside for register blocking. For example, on a CPU featured AVX-512, we can utilize its 32 512-bit width registers $ZMM_0 - ZMM_{31}$ [28] as follows. We maintain the loop hierarchy to use one ZMM register to store the kernel data while others storing the feature map. The kernel values stored in one *ZMM* register (up to 512 bits, a.k.a, 16 output channels in float32) are used to multiply with a number of input feature map values continuously stored in the DRAM via AVX-512F instructions [28], whose results are then accumulated to other *ZMM* registers storing the output values. Figure 1 illustrates this idea. For other vectorized instructions, the same idea applies but the split factor of *out_width* (i.e. *reg_n*) may change.

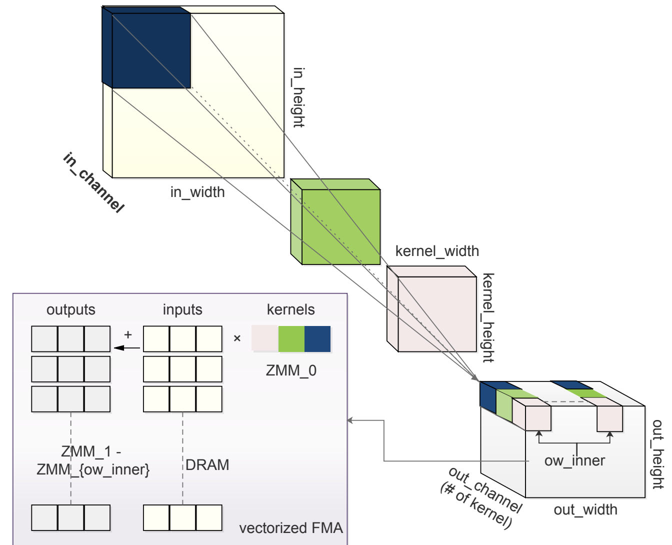

Figure 1: The illustration of *CONV* and the efficient implementation in AVX-512 instructions as an example. There are three kernels depicted in dark blue, green and light pink. To do efficient FMA, multiple kernel values are packed into one *ZMM* register and reused to multiply with different input values and accumulate to output values in different *ZMM* registers.

Algorithm 1 summarizes our optimization of *CONV* in single thread, which essentially is about 1) dimension ordering for friendly memory locality and 2) register blocking for good vectorization instruction utilization, as in previous works. However, unlike others, we made it a *template* in high-level language , in which the block size (x, y), the number of utilized registers (*reg_n*), and the loop-unroll strategy (*unroll_ker*) are easily configurable. Consequently, the computing logic can be adjusted according to different CPU architectures (cache size, registered vector width, etc.) as well as different workloads (feature map size, convolution kernel size, etc.). This is flexible and enables graph-level optimization we will discuss later.

Algorithm 1 CONV operation algorithm via FMA

```

23:         end for
24:     end for
25: end for
```

3.1.2 Thread-level parallelization

It is a common practice to partition *CONV* into disjoint pieces to parallelize among multiple cores of a modern CPU. Kernel libraries like Intel MKL-DNN usually uses off-the-shelf multi-threading solution such as OpenMP. However, we observe that the resulting scalability of the off-the-shelf parallelization solution is not desirable (Section 4.2.4).

Therefore, we implemented a customized thread pool to efficiently process this kind of embarrassing parallelization. Basically, in a system of N physical cores, we evenly divided the outermost loop of the operation into N pieces to assign to N threads. Then we used C++11 atomics to coordinate threads during fork-join and an single-producer-single-consumer lock-free queue between the scheduler and every working thread to assign tasks. Active threads are guaranteed to run on disjoint physical cores via thread binding to minimize the hardware contention, and no hyper-threading is used as discussed in Section 2.1. For the global data structure accessed by multiple threads such as the lock-free queues, we inserted cache line padding as needed to avoid false sharing between threads. In summary, this customized thread pool employs deliberate mechanism to prevent resource contention and reduce the thread launching overhead, which makes it outperform OpenMP according to our evaluation.

3.2 Layout transformation elimination

In this subsection, we extend the optimization scope from a single operation to the entire computation graph of the CNN model. The main idea here is to come up with a generic solution at the graph level to minimize the data layout transformation introduced by the optimization in Section 3.1. Previous works [19, 24, 27] which focus on individual operation optimization normally do not consider about the data layout transformation overhead between highly optimized operations.

Since *NCHW[x]c* is efficient for *CONV*s which takes the majority of the CNN model computation, we should make sure that every *CONV* is executed in this layout. However, other operations between *CONV*s may only be compatible with the default layout, which makes each *CONV* transform the input data layout from default (*NCHW* or *NHWC*) to *NCHW[x]c* before the computation and transform it back at the end. This transformation introduces significant overhead.

Fortunately, from the perspective of the graph level, we can take the layout transformation out of *CONV* to be an independent node, and insert it only when necessary. That is, we eliminate the transformation taking place in the *CONV* operation and maintain the transformed layout flow through the graph as far as possible.

In order to determine if a data transformation is necessary, we first classify operations into three categories according to how they interact with the data layout as follows:

1. *Layout-oblivious* operations. These operations process the data without the knowledge of its layout, i.e. it can handle data in any layout. Unary operations like *ReLU*, *Softmax*, etc., fall in this category.
2. *Layout-tolerant* operations. These operations need to know the data layout for processing, but can handle a number of layout options. For example, *CONV*, in our case, can deal with *NCHW*, *NHWC* and *NCHW[x]c* layouts. Other operations like *Batch_Norm*, *Pooling*, etc., fall in this category as well.
3. *Layout-dependent* operations. These operations process the data only in one specific layout, that is, they do not

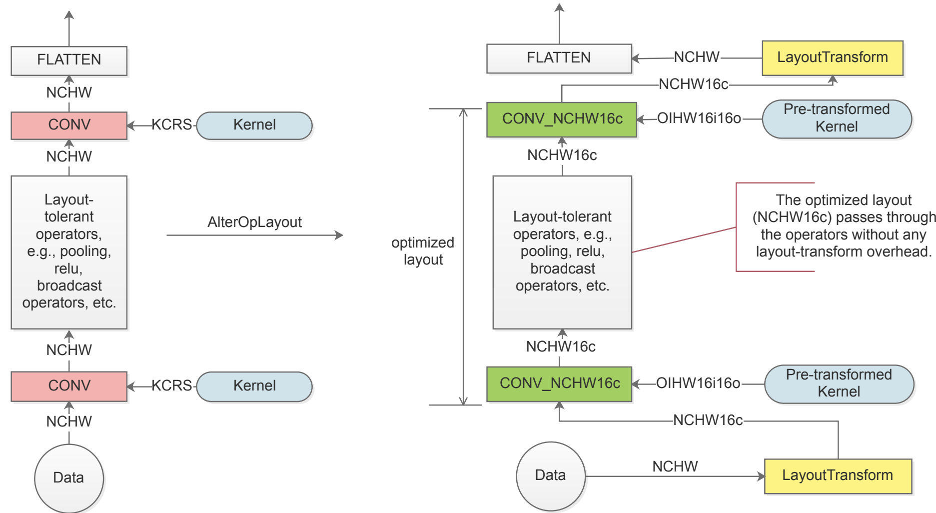

Figure 2: Layout optimization of a simple CNN model. The notation on an edge represents the layout of the data passing through this edge. The left side depicts the network with default data layout. Each *CONV* node in pink needs to pay additional overhead to transform the data into a favorable layout to achieve good performance and then transform back to default. The network in the right side is optimized at the graph level to minimize the data layout transformation during the runtime. The *CONV* nodes in green do not need to transform any data before and after computation.

tolerate any data transformation. Therefore, the layout has to be transformed to a certain format before passing to a layout-dependent operation. Transformation operations like *Flatten*, *Reshape*, etc, fall in this category.

Operations between *CONV*s in typical CNN models are either layout-oblivious (e.g. *ReLU*, *SoftMax*, *Concat*, and *ElemwiseAdd*) or layout-tolerant (e.g. *Batch_Norm*, *Pooling*), making it possible to keep the data layout being *NCHW[x]c* across convolution layers. Layout transformation from *NCHW* to *NCHW[x]c* happens before the first *CONV*. Data layout between *CONV*s can be maintained the same (i.e. *NCHW[x]c* sharing the same x value) without transformation. Only if getting to a layout-dependent operation, e.g. *Flatten*, the data layout is transformed back from *NCHW[x]c* to *NCHW*.

In practice, we first traverse the computation graph to infer the data layout of each node as illustrated in the left side of Figure 2, then we alter the layout of *CONV*s from default to *NCHW[x]c* for better performance. Note that in order to prevent further transformation, we make x a constant number (e.g. 16) across all *CONV*s. However, this value may vary across different *CONV*s in order to get the optimal performance, which requires layout transformation. We will explain more about this in Section 3.3. Finally, the *LayoutTransform* nodes are inserted to the graph accordingly. Thus, we still have *NCHW* input and output for the network, but the internal layouts between *CONV* layers are in optimized *NCHW[x]c*, as shown in the right part of Figure 2. It is worth noting that, the layout of the model parameters such as convolution kernel weights and the mean and variance of *Batch_Norm* are invariant so can be pre-transformed during the compilation. We also illustrate this in the right part of Figure 2.

We implemented the ideas by introducing multiple graph-level optimization *passes* to the TVM stack. By keeping transformed data layout invariant between *CONV* layers as much as possible and pre-transforming the layout of convolution kernel weights at compilation time, we further improve the end-to-end performance of CNN model inference.

3.3 Optimization scheme search

We came up with the aforementioned optimization schemes, especially, how to layout the data, based on our understanding of the hardware, e.g. cache size, vectorization unit width, memory access pattern, etc. However, it is tedious and impractical to exhaust all possible optimal cases by hand. As a trade-off, Section 3.2 assumes that the split factor of the channel, i.e. x in *NCHW[x]c*, stays the same during the entire network, while having various x values in different *CONV*s may lead to a better performance. In addition, the split factor of the output width, i.e. *reg_n*, also needs to adjust for different vectorization instruction sets.

Therefore, an automatic search for the best scheme is in demand to further improve the performance. Basically, we should build a system to allow the domain experts to construct the search space for the machine to explore for the best scheme resulting in the shortest execution time. The search is two-stage, first local to find optimization scheme candidates for the individual computationally-intensive operations, then global to select and combine the individual schemes for the optimal end-to-end results. It is feasible to conduct this

kind of search given the optimization template described in Section 3.1.

3.3.1 Local search

The first step is to find the optimal schedules for each computationally-intensive operations, i.e. *CONV*s in a CNN model. We used a tuple *(ic_bn, oc_bn, reg_n, unroll_ker)* to represent a convolution schedule, whose items are chosen to cover different CPU architectures and generations for different convolution workloads. The first two terms *ic_bn* and *oc_bn* stand for the split factors of input and output channels (i.e. *x* in the *NCHW[x]c* notation), which are relevant to the cache sizes of a specific CPU. The third term *reg_n* is the number of SIMD registers to be used at the inner loop, which varies among different CPU architectures and generations. Also, we observed that utilizing all SIMD registers in a single thread does not always return the best performance. The last term *unroll_ker* is a boolean deciding whether to unroll the *for* loop involving convolution kernel computation (line 12 of Algorithm 1), as in some scenarios unrolling this loop may increase the performance by reducing branch penalties and such. The local search uses the template discussed in 3.1.1 to find the best combination of these values to minimize the *CONV* execution time, similar to the kernel optimization step in [31].

Specifically, the local search works as follows:

1. Define the candidate lists of *ic_bn* and *oc_bn*. To exhaust the possible cases, we include all factors of the number of channels. For example, if the number of channels is 64, [32, 16, 8, 4, 2, 1] are listed as the candidates.
2. Define the candidate list of *reg_n*. In practice, we choose the *reg_n* value from [32, 16, 8, 4, 2].
3. Define the candidate list of *unroll_ker* to be [*True*, *False*].
4. Walk through the defined space to measure the execution time of all combinations, each of which will be run multiple times for averaging to cancel out the possible variance rooted from the unexpected interference from the operating system and/or other processes. This eventually generates a list of combinations ascendingly ordered by their execution time.

It is worth noting that we designed the above tuple in a configurable way, which means that we can always revise the tuple (e.g. adding or removing items, modifying the candidate values of an item) as needed.

Empirically, the local search of a CNN model takes a few hours using one machine, which is acceptable as it is one-time work. For example, it took about 6 hours to search for the 20 different *CONV* workloads of ResNet-50 on an 18-core Intel Skylake processor. In addition, we can maintain a database to store the results for every convolution workload (defined by the feature map and convolution kernel sizes) on every CPU type to prevent repeating search for the same convolution in different models.

Local search works well for each individual operation and indeed finds better optimization scheme than our manual work. However, greedily adopting the local optimal of every operation may not lead to the global optimal. Consider two consecutive *CONV* operations *conv_0* and *conv_1*, if the output split factor (*oc_bn*) of *conv_0* is different from the input split factor (*ic_bn*) of *conv_1*, a *LayoutTransform* node needs to be inserted to the graph as discussed in Section 3.2. This transformation overhead can be too expensive to take advantage of the benefit brought by the local optimal, especially when the data size of the network is large. On the other hand, if we maintain the same split factor throughout the entire network (as we did in Section 3.2), we may miss the opportunity to optimize some *CONV*s. Therefore, a trade-off should be made using a global search.

3.3.2 Global search

In this subsection, we extend the optimization search to the entire computation graph. The idea is to allow each *CONV* freely choosing the split factor *x* (i.e. *ic_bn* and *oc_bn*), and take the corresponding data layout transformation time into consideration. According to Section 3.2, the operations between *CONV*s are either *layout-oblivious* or *layout-tolerant*, so they can use whatever *x* decided by the *CONV* operation.

We extract a snippet of a typical CNN model in Figure 3 to illustrate the idea. From the figure we see that each *CONV* has a number of candidate schemes specified by different (*ic_bn* and *oc_bn*) pairs. The shortest execution time achieved by each pair can be obtained in the local search step. The number of pairs is bound to 100 since both *ic_bn* and *oc_bn* usually have choices less than 10. Choosing different schemes will introduce different data transformation overheads (denoted in dashed boxes between *CONV*s) or no transformation (if the *oc_bn* of the *CONV* equals the *ic_bn* of its successor). For simplicity, in the figure we omit the operations which do not impact the global search decision such as *ReLU*, *Batch_Norm* between two *CONV*s. However, operations like *Elementwise_Add* could not be omitted since it requires the layout of its two input operands (outputs of $CONV_j$ and $CONV_k$ in the figure) to be the same.

Naively speaking, if a CNN model consists of *n* *CONV*s, each of which has k_i candidate schemes, the total number of options of the global scheme will be $\prod_{i=1}^{n} k_i$, very easy to become intractable as the number of layers *n* grows. Fortunately, in practice, we can use a dynamic programming (DP) algorithm to efficiently solve this problem. Note that when choosing the scheme for a *CONV*, we only need to consider the data layout of it and its direct predecessor(s) but not any other ancestor *CONV*s as long as the so-far globally optimal schemes up to the predecessor(s) are memorized.

Therefore, a straightforward algorithm is constructed in

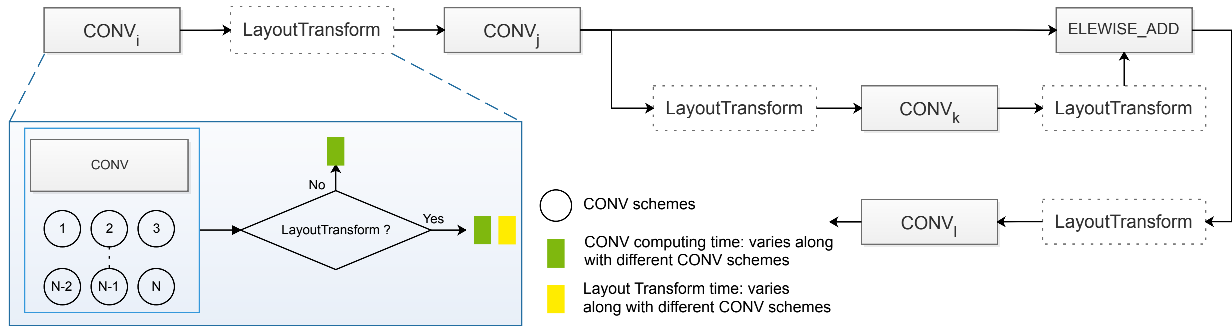

Figure 3: Global search for CNN model inference. *LayoutTransform* may or may not be in invoked according to the global decision. If invoked, an additional overhead of data transformation denoted in yellow needs to be paid.

Algorithm 2. In practice, a lot of CNN models has the structure as simple as a list, in which each *CONV* only has one predecessor [33, 41]. In this case, after a *CONV* is done, the intermediate states stored for its predecessor can be safely removed. For networks with more complex structure like using *Elementwise_Add* to add two *CONV* outputs to feed to the next *CONV* [23], it is trickier since the schemes of a *CONV* may need to be saved for a future use (e.g. in Figure 3 $CONV_l$ needs the schemes of $CONV_j$ via *Elementwise_Add*).

Algorithm 2 Global search algorithm

1: Sort the nodes of the graph in topological order
2: Initialize the optimal schemes of the *CONV*s without dependency using the execution time of their candidate schemes
3: **for** $CONV_i$ in topological order **do**
4:     **for** each candidate scheme CSI_j of $CONV_i$ **do** ▷ j is the jth scheme of $CONV_i$
5:         $t = execution_time(CSI_j)$
6:         $GSI_j = MAX$ ▷ initialize global optimal scheme of $CONV_i$ under scheme j
7:         **for** each so-far globally optimal scheme GSX_k of predecessor x **do** ▷ k is the kth scheme of $CONV_x$
8:             $cur_opt = t + transform_time(k, j) + GSX_k$
9:             **if** $cur_opt < GSI_j$ **then**
10:                 $GSI_j = cur_opt$
11:             **end if**
12:         **end for**
13:     **end for**
14: **end for**
15: **return** last node's shortest scheme

However, if the model structure becomes too complicated with many data dependency links between *CONV*s, the straightforward DP algorithm could go intractable, too. For example, in the object detection model SSD [36], the number of states can reach the order of trillions due to the occurrence of many concatenation blocks. In this case, we introduced an approximate solution to accelerate the search. Particularly, we reduced our global search problem to the register allocation problem in the canonical compiler domain with minor modification as follows. The register allocation problem is modeled as graph representation in which each node (variable) has a candidate list containing all possible register options, and each edge is associated with a cost matrix indicating the availability of registers between two nodes [20]. Similarly in our global search, each *CONV* has a list of candidate schemes and each edge is associated with the layout transformation cost matrix generated by the scheme lists of two *CONV*s. For other non-*CONV* nodes like *Elementwise_Add* which require all inputs in the same layout, we fixed the layout of one input and convert all other input layouts to it. Therefore, we defined the candidate list of a non-*CONV* node to be the same as the first input *CONV* and the cost matrix on the edge between these two nodes as all diagonal elements being 0 and all the other elements being infinite. For the edges between this non-*CONV* node and other input nodes, cost matrices are generated from the first input node and other input nodes. After such modification, all nodes and edges in our graph have the valid properties which are required by the register allocation modeling. This enables us to apply a heuristic solver based on partitioned boolean quadratic programming (PBQP) to our problem as it is done in register allocation [20].

In order to verify the result of this approximation algorithm, we compared it with the result of DP (the guaranteed best) on some simple networks where DP is tractable. It turns out that the approximation algorithm gets at least 88% of the best available result. Empirically, a typical DP search completes in 1 minute for most CNN models. In practice, we switch to the approximation algorithm if DP does not complete in 5 minutes. The approximation algorithm completes quickly, e.g. in 10 seconds. For the 15 popular networks we evaluated in Section 4, only SSD was done approximately.

4 Evaluation

This section evaluates the performance of our proposed solution, *NeoCPU*, by answering the following questions:

1. What is the overall performance of *NeoCPU* comparing

with the start-of-the-art alternatives on various kinds of CPUs?

2. What is the individual contribution of each optimization idea we proposed?

All experiments were done on Amazon EC2 instances. We evaluated *NeoCPU* on three kinds of CPUs, Intel Skylake (C5.9xlarge, 18 physical cores, featured with AVX-512), AMD EPYC (M5a.12xlarge, 24 physical cores, featured with AVX2) and ARM Cortex A72 (A1.4xlarge, 16 physical cores, featured with NEON). Although testing on the cloud, our results of ARM CPUs apply to the ones at the edge devices such as Raspberry Pi and Amazon Echo Dot due to the same architecture. All cores have uniformed memory access.

NeoCPU was built on top of the code base of the TVM stack 0.4.0. For CPUs with x86 architecture, we chose two framework-specific solutions and one framework-agnostic solution as baselines for comparison. For the framework-specific solution, we investigated a wide range of options and figured out that MXNet 1.3.1 with Intel MKL-DNN v0.15 enabled has the widest model coverage with the best inference performance compared to others (e.g. Intel Caffe). In addition, we chose TensorFlow 1.12.0 with ngraph v0.12.0-rc0 integration (empirically proved to be better than TensorFlow XLA on CPUs) due to its popularity. TensorFlow is known to have better performance on CPUs than another popular deep learning framework PyTorch [14]. The latest Intel OpenVINO Toolkit 2018 R5.445 served as the framework-agnostic solution. We used the official image-classification sample [3] and object-detection-ssd sample [4] for benchmarking. For ARM CPUs, we chose MXNet 1.3.1 with OpenBlas 0.2.18 and TensorFlow 1.12.0 with Eigen fd68453 [5] as the baselines. No framework-agnostic comparison was performed as on ARM CPUs there is no counterpart of OpenVINO to x86 CPUs. In addition, OpenMP 4.5 implemented in GCC 7.3 was used in the comparison with our own thread pool for multi-thread scalability. As a note, all implementations used direct convolution. Incorporating the advanced convolution algorithms to further improve the performance remains for future work.

We ran the model inference on a number of popular CNN models, including ResNet [23], VGG [41], DenseNet [26], Inception-v3 [43], and SSD [36] using ResNet-50 as the base network. Models consumed by MXNet and OpenVINO were from the Gluon Model Zoo [6]. Models consumed by TensorFlow were obtained mostly from TF-SLim [7] and for some missing ones (e.g. ResNet-34, DenseNet-169) we manually created them. The same model in different formats are semantically identical. As inherited from the TVM stack, *NeoCPU* is compatible to both Gluon and TF-slim formats, and in the evaluation we used the former one. The input data of the model inference are 224×224 images, except for the Inception Net (299×299) and SSD (512×512) by following the popular convention. Since the most important performance criterion of model inference is the *latency*, we did all experiments with batch size 1, i.e. each time only one image was fed to the model, to measure the inference time. Therefore, we fix the value N in $NCHW[x]c$ as 1. *NeoCPU* works for larger batch sizes as well, in which cases we just need to add the N value to our configuration tuple.

Since our optimization does not change the semantics of the model, we do not expect any change of the model output. As a sanity check, we compared the results generated by *NeoCPU* with other baselines (prediction accuracy for image classification models and mean accuracy prediction for object detection models) to validate the correctness.

4.1 Overall Performance

We first report the overall performance we got for 15 popular CNN models comparing with the baselines on different CPUs in Table 2. The results were obtained by averaging the execution times of 1000 samples, doing inference for one at a time. In general, *NeoCPU* is more efficient across different models on different CPU architectures than any of the baselines (up to 11× speedup without considering the suspicious OpenVINO outliers which will be explained later). Compared to the *best available* baseline result for each model, *NeoCPU* gets 0.94-1.15× performance on the Intel Skylake CPU, 0.92-1.72× performance on the AMD EYPC CPU, and 2.05-3.45× performance on the ARM Cortex A72 CPU.

As framework-specific solutions, MXNet and TensorFlow were suboptimal for CNN inference on CPUs because it is lacking of flexibility to perform sufficient graph level optimization (e.g. flexible data layout management). MXNet has active MKL-DNN support from Intel so it performed quite well on CPUs with the x86 architecture. MXNet performed worse than TensorFlow on ARM due to the scalability issue (demonstrated in Figure 4c). TensorFlow performs significantly worse on SSD as it introduces branches to this model, which requires dynamic decisions to be made during the runtime. Comparatively, the framework-agnostic solution provided by the OpenVINO tries to further boost the performance by removing the framework limitation. However, the performance of OpenVINO was unstable across models. Although it gets appealing results on some cases, OpenVINO sometimes performed extremely slowly on certain models (e.g. 45× slower than us for ResNet-152 on AMD) for unknown reasons. When summarizing the speedup results, we do not include these outliers. It is also worth noting that the

(c) Overall performance on a system with 16-core ARM Cortex A72 CPU

Table 2: Overall performance of *NeoCPU* and the selected baselines. Each entry contains the mean value of 1000 runs and the corresponding standard error. The best performance of each model is in **bold**. (*OpenVINO on Intel and AMD CPUs does not measure the entire SSD execution time)

OpenVINO measures the execution time of SSD without taking into account a significant amount of operations including *multibox detection*. Since OpenVINO is not open-sourced, we were not able to modify it for apples-to-apples comparison on the SSD model. OpenVINO does not work for ARM CPUs as it relies on MKL-DNN which optimizes only for CPUs with x86 architecture. *NeoCPU* outperforms the baselines mostly because of the advanced optimization techniques we presented in Section 3. In addition, all baselines largely rely on the third-party libraries (MKL-DNN, OpenBlas, Eigen) to achieve good performance. *NeoCPU*, on the other hand, is independent from those high-performance libraries, which gives us more room to optimize the model inference as a whole.

4.2 Optimization Implications

This subsection breaks up the end-to-end performance gain of *NeoCPU* by investigating the performance boost of each individual optimization technique we described in Section 3. For the sake of space, in each comparison we only pick one network from a network family, respectively. Other networks in the same family share the similar benefits. We only report the performance results on Intel CPUs in Section 4.2.1-4.2.3. The optimization effect applies to AMD and ARM CPUs, too. Basically, Section 4.2.1 is the operation-level optimization, and Section 4.2.2 and 4.2.3 cover the operation- and graph-level joint optimization.

4.2.1 Layout optimization of *CONV*

Firstly, we compare the performance with and without organizing the data in a memory access and vectorized instruction utilization friendly layout (*NCHW{x}c*) for the *CONV* operations at the second row of Table 3. This is the operation-level optimization that is commonly applied by the compared baselines in Section 4.1. We replicate it as a template using TVM scheduling schemes without touching the assembly code or

Speedup	ResNet-50	VGG-19	DenseNet-201	Inception-v3	SSD-ResNet-50
Baseline	1	1	1	1	1
Layout Opt.	5.34	8.33	4.08	7.41	6.34
Transform Elim.	8.22	9.33	5.51	9.11	9.32
Global Search	12.25	10.54	6.89	11.85	12.49

Table 3: The individual speedup brought by our optimization compared to the *NCHW* baseline. The speedup of row n was achieved by applying the optimization techniques till this row.

intrinsics, which enables the subsequent optimization for various CNN models on different CPU architectures. From row 2 of Table 3 we see significant improvement compared to the default data layout (*NCHW*), whose performance is normalized to baseline 1. Both implementations are with proper vectorization and thread-level parallelization, as well as basic graph-level optimizations introduced by the original TVM stack, e.g. operation fusion, pre-computing, inference simplification, etc.

4.2.2 Layout transformation elimination

Secondly, we evaluate the performance boost brought by eliminating the data layout transformation overhead as discussed in Section 3.2. The results were summarized at the third row of Table 3. Compared to the layout optimization of *CONV* (second row of Table 3), layout transformation elimination further accelerates the execution time by $1.1-1.5\times$. *NeoCPU* uses a systematic way to eliminate the unnecessary data layout transformation by inferring the data layout throughout the computation graph and inserting the layout transformation nodes only if needed, which is not seen in other works.

4.2.3 Optimization scheme search

Next, we compare the performance between the optimization schemes produced by our search algorithm and the ones carefully picked by us manually. By comparing the third and fourth row of Table 3, our algorithm (described in Section 3.3) is able to find the (approximately) best combination of data layouts which outperforms the manually picked results by $1.1-1.5\times$. ResNet-50 (and its variants) gains more speedup from global search because the network structure is more complicated, hence leaving more optimization room. In contrast, VGG-19 (and its variants) gains less since the structure of this model is relatively simple. SSD utilizes the approximation algorithm and gets significant speedup, too. The results also verify that, with automatic search, we can get rid of the tedious manual picking of parameters by producing even better results. To the best of our knowledge, *NeoCPU* is the only one that does this level of optimization.

4.2.4 Multi-thread parallelization

Lastly, we did a strong scalability experiment using the multi-threading implementations backed by our own thread pool described at Section 3.1.2 and the commonly used OpenMP API implemented in the GCC compiler. We also included the result of MXNet, TensorFlow and OpenVINO using Intel MKL-DNN, OpenBlas or Eigen (all realizing multi-threading via OpenMP) for comparison. We configured OpenMP via environment variables to make sure that the jobs are statically partitioned and each thread runs on a disjoint core, which resemble the behavior of our thread pool for apples-to-apples comparison. Figure 4 summarizes the number of images a model can inference one by one (i.e. *batch size* $=1$) in a second as a function of the number of threads the model inference uses. For the sake of space, we demonstrate one result for one CPU type. The figure shows that our thread pool achieves better scalability than OpenMP in *NeoCPU* as well as in the baselines. Although the tasks are embarrassingly parallelizable, each model inference consists of a number of parallelization regions. The overhead of OpenMP to launch and suppress threads before and after a region is larger than our thread pool, which attributes to the less scalability of OpenMP. Furthermore, sometimes we observed that the performance obtained by OpenMP jitters, or even drops, while adding threads. In addition, the performance of OpenMP may differ across different implementations. In summary, our evaluation suggests that in our use cases, it is preferable to have a self-customized thread pool with full control.

5 Related Works

As deep learning demonstrates more and more power in the real-world applications, there is a significant amount of effort being made to accelerate the deep learning workloads on all kinds of hardware ranging from CPUs [24, 27, 44, 53], GPUs [11, 13], FPGAs [18, 22, 49], to special-purpose accelerators [12, 32]. Modern deep learning frameworks normally leverage these optimized implementations to run deep learning training and inference on the corresponding hardware targets. There are also works tailored for inference to address the inference-specific requirement such as low latency and small binary size on different hardware targets (e.g. GPUs [38], ASICs [22]). *NeoCPU* is more flexible and combines the operation- and graph-level optimization intelligently. Although this paper focuses on CPUs, the ideas are applicable to other hardware targets.

NeoCPU is based on the TVM stack [9], an end-to-end framework inspired by Halide [39], which expresses a deep learning model into intermediate representations (IRs) and compiles to the machine code. There are several other similar deep learning compilers such as TensorFlow XLA [34], Tensor Comprehensions [46], Glow [40] and DLVM [47]. However, so far none of them has reported CPU inference results on par with what we did (e.g. Glow only optimized single-core performance on CPUs). We believe our proposed solution could be an integral part to these frameworks.

We follow the well-studied ideas implemented in other high-performance libraries [27, 51] to optimize the computationally-intensive *CONV* operations. In addition to the libraries, there are also highly customized optimization works for convolutions and matrix multiplications on Intel CPUs [19, 24]. These works are mostly about individual operation-level optimizations, which do not consider maintaining data layouts through the entire network. Specifically, they carefully investigate the computation nature of convolutions as well as the available CPU resources to fine tune the operations. This kind of optimization is able to maximize the convolution performance on the targeted CPUs but is not very flexible to extend to other platforms and to do joint optimization. Unlike others, we make the optimization as a configurable template so that it is flexible to fit to different CPU architectures and enable the opportunity to surpass manually tuned performance via operation- and graph-level joint optimization.

Our work utilizes auto search to look for optimal solutions. Similar *auto-tuning* ideas were used in other works as well [10, 46, 48]. However, they all focused on performance tuning for single operations, while ours extends the scope to the entire CNN model to search for optimal solutions globally. Recently, we also observed other work optimizing the DNN workloads at the graph level [30]. This work attempts to obtain better global performance using relaxed graph substitutions which may harm the local performance within a few operations. Its non-greedy search idea is conceptually similar to ours and potentially applicable to our solution. The approximation algorithm we employed to deal with the global search for the models with complicated structures (e.g. SSD) is inspired by the application of PBQP in the register allocation problem [6, 17, 20]. This paper leverages the previous idea and applies to a new domain by minor modification.

6 Conclusion

In this paper, we proposed an end-to-end solution to compile and optimize convolutional neural networks for efficient model inference on modern CPUs. The experiments show that we are able to achieve up to 3.45× speedup on 15 popular CNN models on the various kinds of CPUs (Intel Skylake, AMD EPYC and ARM Cortex A72) compared to the performance of the state-of-the-art solutions. The future work includes extending to other convolution computation algorithms such as Winograd and FFT, handling model inference in quantized values (e.g. INT8) and extending our operation- and graph-level joint optimization ideas to work on other hardware platforms (e.g. NVidia GPUs compared with TensorRT). Supporting the optimized model inference in dynamic shapes (e.g. RNNs [25, 50]) is another interesting direction to explore.

Acknowledgments

We would like to thank our shepherd Peter Pietzuch and the anonymous reviewers of the USENIX ATC program committee for their valuable comments which improved the paper a lot. We are also grateful to Tianqi Chen and Animesh Jain for helpful discussion and constructive suggestion.

Abstract

Infusing machine learning (ML) and deep learning (DL) into modern systems has driven a paradigm shift towards learning-augmented system design. This paper proposes the learned ranker as a system building block, and demonstrates its potential by using rule-matching systems as a concrete scenario. Specifically, checking rules can be time-consuming, especially complex regular expression (regex) conditions. The learned ranker prioritizes rules based on their likelihood of matching a given input. If the matching rule is successfully prioritized as a top candidate, the system effectively achieves early termination. We integrated the learned rule ranker as a component of popular regex matching engines: PCRE, PCRE-JIT, and RE2. Empirical results show that the rule ranker achieves a top-5 classification accuracy at least 96.16%, and reduces the rule-matching system latency by up to 78.81% on a 8-core CPU.

1 Introduction

Machine learning (ML) and deep learning (DL) bring new possibilities to modern system designs [9, 15, 17, 23, 24], which traditionally rely on human-written heuristics. Under the *learning-augmented design*, system logic is implemented with both heuristics and ML/DL to better address performance bottlenecks. Such design has the following advantages. First, compared to heuristics, ML/DL has been shown to excel in learning complex data patterns to enable classification, regression and prediction. Second, while traditional heuristics are designed to be general purpose and computation-efficient, systems such as web services can have a workload that is highly dynamic and scenario-specific. Adapting to workload characteristics can enable highly optimized algorithmic operations and system components.

This work was done when Zhao Lucis Li and Qiming Zheng were interns at Microsoft Research. Chieh-Jan Mike Liang is the corresponding author.

However, formulating ML/DL tasks into system building blocks is non-trivial. Given that ML/DL is stochastic in nature, inference uncertainties should not impact the system correctness. And, inference should not impose a significant resource overhead on the end-to-end system performance. Recently, the industry has had success in using learning-driven space exploration as a system building block, for scenarios such as system configuration tuning [9, 17, 23]. Building on this success, this paper explores the potential and feasibility of another building block for learning-augmented systems – the *learned ranker*.

Particularly, we use rule-matching systems as a concrete scenario for learned rankers. One common task of rule-matching systems is to match the given input to *one* rule in the ruleset as fast as possible, and the performance bottlenecks come from two observations. For rulesets that do not impose a mandatory ordering on rule checking, the naïve practice of sequentially going through rules can result in processing many unnecessary rules. The problem exacerbates when we consider that rules can have non-trivial conditions written in regular expressions (regex). Since regex matching engines typically rely on either deterministic finite automaton (DFA) or non-deterministic finite automaton (NFA), its overhead largely depends on the length and complexity of regex patterns and inputs. In the worst case, the backtracking problem can result in $O(2^n)$ time complexity for an input string of size n [13], rather than the expected $O(n)$.

To reduce the rule matching latency, common optimization techniques include string-matching pre-filters [7, 12], just-in-time compilation [4], and specialized hardware-based regex acceleration [20, 25]. The learned ranker enables a different but complementary technique – after the string-matching pre-filter removes unlikely inputs, it performs per-input rule prioritization for the regex matching engine, based on the likelihood of a given input to match each rule. Conceptually, if the matching rule can be prioritized as one of the top candidates, the rule-matching system effectively achieves early-termination, thus minimizing unnecessary rule checking.

Designing learning-augmented systems with the learned

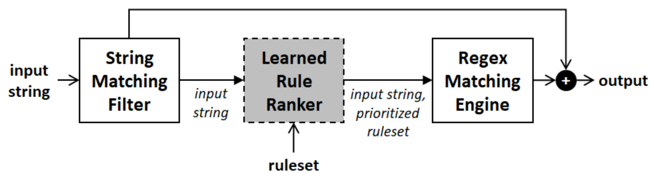

Figure 1: A learning-augmented design of rule-matching systems. Complementing existing acceleration techniques, we introduce a learned rule ranker to dynamically prioritize rules for each input. The goal is to minimize unnecessary rule processing and achieve early-termination.

ranker as a building block should go beyond simply selecting the most accurate ML/DL model – although the ranker helps to reduce the computation load for other system components, it is crucial to balance the trade off between inference accuracy and cost, with respect to the end-to-end system performance. To evaluate the benefits of the learned ranker as a building block for learning-augmented systems, we have integrated it into popular regex matching engines: PCRE [3], PCRE-JIT [4], and RE2 [5]. We benchmark with two publicly available rulesets: ModSecurity CRS [2] and Snort [6]. Empirical results show that the learning-augmented design reduces the rule-matching system latency by as much as 78.81%; in particular, the learned rule ranker can achieve a top-5 ranking accuracy at least 96.16%, and this reduces the average number of per-input regex matching invocations by as much as 98.54%.

2 System Overview

Figure 1 illustrates the learning-augmented design of rule-matching systems. The rule ranker exploits the fact that many rulesets do not fix a mandatory ordering of rules, and it dynamically re-orders rules according to how likely they would match the given input. If the ranker successfully prioritizes the matching rule among the top N candidates, then the regex matching engine can effectively early-terminate after checking at most N rules. The figure also illustrates that the learned rule ranker can complement many existing optimization solutions. First, there is a string-matching pre-filter that first removes inputs unlikely to match any rule [7, 12]. Second, there are efforts on reducing the regex matching engine latency, e.g., PCRE's just-in-time compilation [4] and hardware-based regex acceleration [20, 25].

The rule ranker can take different realizations and ML/DL models. While ranking accuracy is a primary consideration in designing the ranker, achieving high accuracy typically comes with the cost of computation overhead and latency. This trade-off is crucial, as each input incurs the inference cost. Therefore, it is possible that a ranker does not speed up the overall system performance – in the context of rule-matching systems, these worst cases happen when a given input triggers a large amount of rule processing. Possible reasons include ***(1)*** the string-matching pre-filter fails to first remove unlikely inputs, or ***(2)*** the ranker fails to optimally prioritize rules.

2.1 Strawman Solutions for Rule Ranker

Static and heuristics-based solutions. If the overall system workload exhibits a long tail in the rule hit distribution (e.g., some rules account for a majority of matches), then both static and heuristics-based solutions can be effective. In particular, for cases where system workloads are assumed to rarely exhibit temporal dynamics, system operators can sort rules by statistically counting the number of rule hits in historical logs. Otherwise, heuristics such as least recently used (LRU) and least frequently used (LFU) can be used to improve the adaptability to sporadically temporal dynamics.

While both strawman solutions are simple, they can be sub-optimal due to the following reasons. First, while inputs are independent, these solutions rank rules based on the historical hit distribution, rather than any features of the current input. Second, they are suitable only for scenarios with known or long-tailed rule hit distributions. For cases and systems where different inputs can match different rules, LRU and LFU might not work well if the principle of locality does not hold.

Classification-based solutions. The rule-matching problem can be formulated as a multi-class classification problem in the machine learning domain. Specifically, assuming each rule is one class, we aim to predictively classify an input and rank rules by the likelihood score of each class. One widely-used non-DL classification technique is the logistic regression (LR). While being used traditionally for single-class classification, LR can be extended for multi-class classification through the one-vs-rest strategy. Unlike linear regression and support vector machine (SVM), LR is able to output probabilistic values, rather than binary answers. Probabilistic values are useful in comparing the relative likelihood of rules in a ruleset.

As a strawman solution, LR can be sub-optimal due to the following reasons. First, since the one-vs-rest-strategy [11] requires one model for each rule, a ruleset with r rules would result in r LR models. In addition to the training cost, each input effectively forces inferences over all r models. Second, since LR commonly targets linearly separable datasets, it is inadequate to model the space of matching inputs for rules of complicated regex conditions. §5 compares LR with DL-based solutions.

3 Learned Rule Ranker

Recent advances from deep learning communities have driven the availability of off-the-shelf DL models such as the popular

fully connected Deep Neural Networks (DNN) and Recurrent Neural Networks (RNN). DL models have the following advantages in the context of realizing learned rankers for modern systems. First, DL models can model complex non-linear datasets (e.g., rules with complicated conditions in our case). Second, DL models have hyper-parameters (e.g., number of hidden layers and neurons) that can easily be tuned to optimize the trade off between model accuracy and inference latency. Third, although DL models have been known to require a large amount of training data, rule-matching system inputs can be randomly generated and cheaply labeled.

Deploying DL models for learned rule ranker involves the following considerations and customizations.

Model selection. Given that inputs are strings, we consider the use of both DNN models (for their simplicity) and RNN models (for their ability to handle an arbitrary length of texts). As §5 shows, DNN typically has a lower inference latency, and RNN typically has a higher accuracy in prioritizing the matching rule among the top-*N* candidates. However, we argue that model selection goes beyond simply selecting the most accurate model configuration. Being a system building block, the learned ranker design must consider how the inference accuracy and costs would impact the end-to-end system performance. We illustrate this consideration with Figure 1 – if the regex matching engine is fast, having a relatively inaccurate rule ranker might be a reasonable design, especially if the overhead of checking one unnecessary rule is lower than the inference overhead of more accurate rankers. At the same time, a relatively inaccurate rule ranker might hurt the overall system performance, especially if the reduction in the amount of unnecessary rule checking does not adequately compensate the inference overhead.

Model inputs and outputs. The input layer of a neural network takes in a vector of real numbers. Since inputs in our case are a string of characters, they go through the process of word embedding to convert individual characters into 8-bit numbers in ASCII encoding. Furthermore, we note that DNN needs to take the entire input string at once, which forces the DNN input layer size to be at least as large as the input string. While the maximum input string length needs to be decided beforehand, system operators usually have statistics on the typical system workload. If an input string is shorter than the maximum length, we pad "0" at the end of the vectorized input. On the other hand, since RNN can take the input string in chunks, it can handle inputs of arbitrary length.

The output layer has a set of neurons where each neuron corresponds to a particular rule. Each neuron outputs a number between 0 and 1 representing the classification probability. We use these outputs to rank rules.

Input Generator. In addition to real-world traces of rule-matching system inputs, ranker training can happen with artificially generated matching/unmatching inputs. One advantage that the input generator offers is the large quantity of training data necessary for training DL models. To generate training inputs for a rule, our input generator runs Xeger [21] and Exrex [22], which are popular Python libraries for generating random strings from a given regex. Then, we randomly repeatedly choose S random characters from each of these generated inputs, and replace them with random characters. These mutated strings are then classified as either the `matching` and `unmatching`, by running the regex matching engine. The value of S is a crucial parameter – a larger S produces a nearly random unmatching string, and a smaller S changes only a few characters to simulate "near-miss" cases in the real world.

Training. With training inputs collected in the real world or generated by the input generator, we follow the popular training method of backward propagation with gradient descent. Since training data are labeled, the training is effectively a supervised learning. We use batch training, and each batch contains one input for each rule and one unmatching input. In addition, we train the DL model with 1,000 epochs, we use ReLu as the activation function at hidden layers and we use softmax at the output layer for outputting classification probabilities.

4 Implementation

We implement our learned ranker in Python 3.6 and TensorFlow 1.10.0. Our current implementation consists of ∼1,400 lines of Python code. In order to optimize the performance of TensorFlow on a CPU, we recompile the library with SSE 4.2, AVX and FMA instructions. We also enable just-in-time compilation for TensorFlow graphs.

To expose the target rule-matching system for the purpose of labelling inputs, we write a client stub. The client stub receives input strings from our input generator, and calls the target system's API. The communication between the input generator and the client stub happens over HTTP with messages in the JSON format.

5 Evaluation

Our major results include – ***(1)*** a learned rule ranker can reduce the average number of per-input regex matching invocations by as much as 98.54%, with a top-5 ranking accuracy of at least 96.16%. ***(2)*** Factoring in the rule ranker inference overhead, the learning-augmented design reduces the rule matching latency by as much as 78.81%. ***(3)*** We demonstrate that the ranking model design should consider a global optimization strategy, as having the most accurate model does not necessarily benefit the end-to-end system performance.

5.1 Methodology

Rulesets. While a learned rule ranker is not limited to security-related scenarios, two popular rulesets that are publicly available are ModSecurity CRS v3.0 [2] and Snort v3.0 [6]. The former is a web application firewall module, and the latter is a network-based intrusion detection system. We are interested in rules with complicated regular expressions with metacharacters, rather than simple string matching – our RS_{CRS} ruleset consists of 69 regex rules ranging from 20 to 3447 characters, and RS_{Snort} ruleset consists of 196 regex rules ranging from 21 to 243 characters. We note that rules can have matching criteria on multiple input fields, e.g., `ARGS`, `ARGS_NAMES`, `REQUEST_COOKIES`, and `REQUEST_COOKIES_NAMES` in CRS, and `HTTP_header`, `HTTP_uri`, and `HTTP_method` in Snort.

Workload datasets. Our experiments are based on following rule-matching system workloads: ***(1)*** the public ECML data set, WL_{ECML} [1], and ***(2)*** artificial data sets generated from the CRS and Snort rulesets, WL_{CRS} and WL_{Snort}. The former is primarily used as testing dataset. The latter can drive training and testing, by separately generating multiple sets of inputs.

For the artificial data sets, an input generator (c.f. §3) outputs random matching and unmatching strings, with respect to the given regex pattern. Unmatching strings allow us to test rules that require only some of the specified fields to match. The tool can generate a balanced workload to simulate the worst case where all rules are likely to be hit.

Testbed environment. We run popular rule-matching engines including PCRE [3], PCRE-JIT [4], and RE2 [5]. PCRE is the most widely used open-source regex matching engine, and the JIT optimization minimizes unnecessary parsing of the internal bytecode representation, especially the matching engine can contain many unused code branches from `if` and `switch` statements. RE2 is a fast and thread-friendly regex matching engine. We use Python and carry out experiments on a Ubuntu-based Azure VM with access to 8 cores of Intel Xeon E5-2673 running at 2.4 GHz and 3 GB of RAM.

5.2 Rule Ranking Accuracy

The primary goal of the learned rule ranker is to minimize unnecessary regex rule matching, and the system performance gain depends on its effectiveness in correctly prioritizing the matching rule as a top candidate. We quantify the effectiveness by the top-N accuracy, or the probability that the rule ranker successfully prioritizes the matching rule to be one of the first N rules to check. This subsection evaluates the different factors of the top-N accuracy.

Impacts of model selection. One factor that can impact the rule ranker's top-N accuracy is the learning model, and we empirically evaluate rule rankers implemented by DNN models (with two hidden layers of 128, 256, and 512 neurons),

Model	Top-1	Top-3	Top-5	Latency (μs)
DNN(128)	81.85%	94.39%	97.05%	11.65
DNN(256)	83.37%	95.18%	97.45%	14.68
DNN(512)	83.72%	95.61%	97.52%	21.44
RNN(128)	89.44%	97.51%	98.82%	33.43
RNN(64)	92.98%	98.55%	99.30%	39.88
RNN(32)	95.02%	99.23%	99.71%	48.02
LR	67.69%	82.89%	88.18%	48.25

(a) RS_{CRS}

Model	Top-1	Top-3	Top-5	Latency (μs)
DNN(128)	80.08%	93.34%	96.16%	11.75
DNN(256)	83.14%	94.69%	97.27%	15.42
DNN(512)	84.45%	95.34%	97.41%	22.44
RNN(128)	85.59%	96.88%	98.26%	41.62
RNN(64)	91.33%	98.19%	99.18%	46.21
RNN(32)	94.45%	99.22%	99.63%	56.21
LR	83.83%	93.29%	95.65%	93.19

(b) RS_{Snort}

Table 1: One factor that impacts rule ranking accuracy is the learning model selection: DNN (with two hidden layers of 128, 256, and 512 neurons), RNN (with input chunk size of 32, 64, and 128 characters), and logistic regression (LR). Results illustrate the trade off between top-N accuracies and ranking latency.

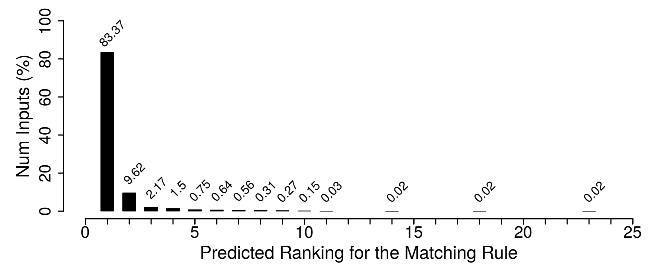

Figure 2: Distribution of the predicted ranking for matching rules. For 83.37% of inputs, the rule ranker is able to prioritize the matching rule as the first candidate.

RNN models (with input chunk size of 32, 64, and 128 characters), and logistic regression (LR). We train each model with 100,000 inputs from WL_{CRS} and WL_{Snort}. Table 1a and 1b show empirical measurements for WL_{CRS} and WL_{Snort}, respectively. We make the following observations. RNN and LR have the highest and lowest top-N accuracies, respectively. While DNN (512) exhibits a 2.19% lower top-5 accuracy than RNN (32), it is $\sim 2.24\times$ faster. This trade-off suggests that simply using top-N accuracies as the selection metric might not benefit the entire system, and we further discuss how the trade-off between top-N accuracies and inference costs impacts the end-to-end rule matching throughput in §5.3.

Next, we look at inputs where the rule ranker fails to properly prioritize rules. Since these inputs require the regex matching engine to process more rules, they have a higher rule matching latency. Figure 2 illustrates the distribution of the predicted ranking for matching rules in the case of

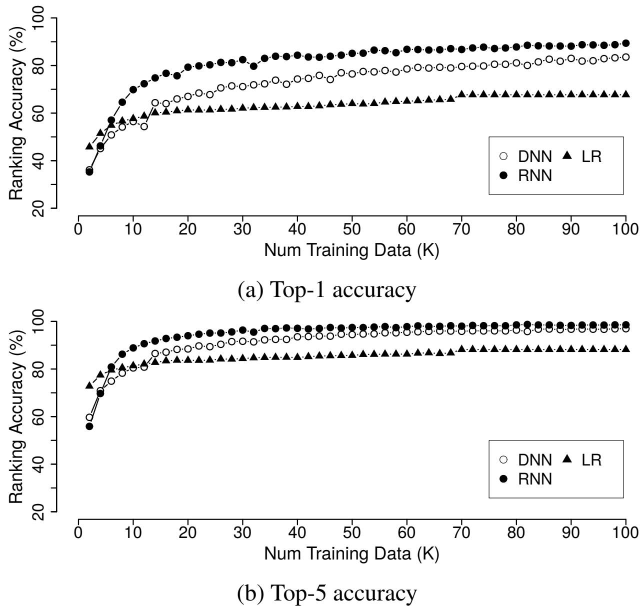

Figure 3: Increase in ranking accuracy in terms of training data size, in the case of RS_{CRS}.

DNN(256). For 83.37% of inputs, the rule ranker is able to prioritize the matching rule as the first candidate. For 2.55% of inputs, it fails to prioritize the matching rule as a top-5 candidate. Interestingly, most of these inputs are relatively short, and the excessive padding might cause the ranker to infer those inputs incorrectly.

Impacts of training dataset size. Another factor that can impact the rule ranker's top-*N* accuracy is the amount of training data. Figure 3 shows how the accuracy increases for different DL/ML models in the case of RS_{CRS}, and we evaluate the accuracy by testing 1,000 randomly generated inputs (after each training iteration with 2,000 generated inputs). We note that our models generally start to converge after being trained with ~90,000 inputs.

Impacts from imbalanced workload distributions. We acknowledge that, if the system operator has a complete prior knowledge of the workload distributions, it is possible to hardcode a static rule checking order. One case where this is particularly useful is the long-tailed rule hit distribution. In other words, the workload is imbalanced such that a majority of inputs match only a subset of the ruleset. Compared to WL_{CRS} and WL_{Snort}, the `ECML` dataset is relatively imbalanced. And, empirical results show that static order can significantly reduce the number of rules that the regex matching engine needs to process for WL_{ECML}.

However, given that the learned rule ranker is able to prioritize rules with each input's features, it can actually achieve a larger reduction – compared to static ordering, the DNN-based rule ranker reduces by 88.70% and 56.04% for RS_{CRS} and RS_{Snort} in the case of WL_{ECML}, respectively.

Regex engine	Without rule ranker	With rule ranker	Reduction
PCRE	1878.79 μsec	404.36 μsec	78.47%
PCRE-JIT	773.82 μsec	185.65 μsec	78.81%
RE2	206.01 μsec	55.15 μsec	73.22%

Table 2: Latency for matching one input with DNN(256)-based ranking model, on the RS_{CRS} ruleset.

Ruleset	No rule ranker	Rule ranker	Reduction
RS_{CRS}	22.38	1.68	92.49%
RS_{Snort}	91.56	1.34	98.54%

Table 3: Average number of regex rules that the regex matching engine needs to process for each input.

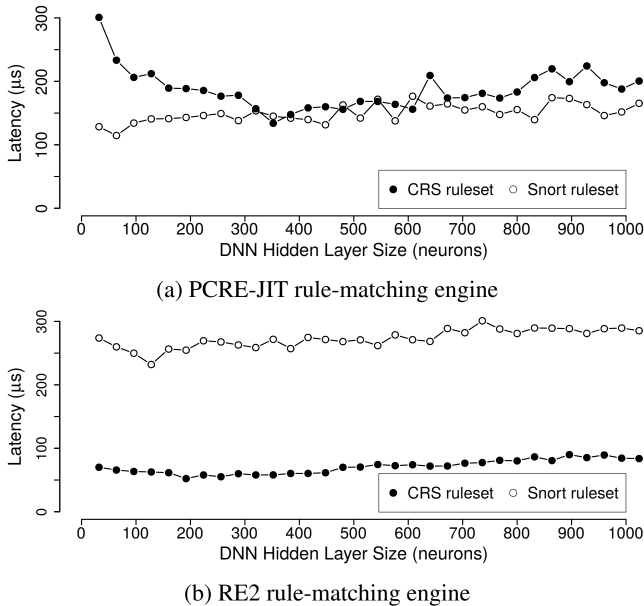
5.3 Rule Matching Latency Reduction

We next evaluate the rule matching latency reduction from the learned rule ranker, and we integrate the learned rule ranker into the PCRE, PCRE-JIT, and RE2 engines.

Table 2 shows the latency reduction for processing one input with different regex matching engines, on the RS_{CRS} ruleset. Each experiment runs 10,000 different inputs to avoid measurement noise. By fixing the ranking model, we observe that the reduction varies with different regex matching engines – the reduction ranges from 73.22% to 78.47%. This reduction in latency is correlated with the reduction in the number of rules that a regex matching engine needs to process. Table 3 shows that, for RS_{CRS}, the average number of regex matching invocations is 1.68, which is a 92.49% reduction from 22.38. The reduction in the case of RS_{Snort} is 98.54%. We note that, since both WL_{CRS} and WL_{Snort} are fairly balanced workloads (i.e., the number of matching inputs for each rule is roughly the same), per-input rule prioritization is key to reduction. And, the learned ranker exhibits a higher gain in cases where the overhead of processing an unnecessary rule is higher.

Finally, we highlight that the design of learning-augmented systems should consider the trade off between the learning's interference costs and the system's global performance gain. Figure 4 illustrates results from a DNN-based ruler ranker. Although having larger hidden layers improves DNN model accuracy, it does not necessarily benefit the end-to-end matching latency. This is due to the fact that, not only does an accurate model reduce unnecessary rule checking, but it also imposes higher inference costs to the end-to-end system performance. Unfortunately, the optimal model configuration depends on the execution environment and system configurations – in our case, the selection of regex matching engine and ruleset. For instance, Figure 4 shows that the optimal DNN hidden layer size is ~192 neurons for RE2 with RS_{CRS} ruleset, ~128 neurons for RE2 with RS_{Snort} ruleset, ~256 neurons for PCRE-JIT with RS_{CRS} ruleset, and ~64 neurons for PCRE with RS_{Snort} ruleset.

Discussion. We note that certain ruleset characteristics are also factors that potentially impact the overall rule matching



(a) PCRE-JIT rule-matching engine

(b) RE2 rule-matching engine

Figure 4: This figure illustrates that, although having larger hidden layers improves DNN model accuracy, it does not necessarily benefit the end-to-end matching latency. The reason behind this observation is the correlation between model accuracy and inference costs.

performance. One prominent example is the number of rules in the ruleset. Specifically, as the ruleset becomes larger, successfully prioritizing the matching rule means more rules can be skipped. On the other hand, a larger ruleset requires more complicated ML/DL models, which can impose additional overhead on the system performance. Given the lack of tools to automatically generate rulesets of different characteristics, our experiments in this section are based on two public rulesets, RS_{CRS} and RS_{Snort}. We leave the evaluation of ruleset characteristics as future work.

6 Related Work

Accelerating rule matching. The realization of regular expression patterns as finite state automata was first proposed by Kleene et al. [14] in the 1950s, and NFA and DFA have been widely used to formalize the description of regex patterns. Since most rule-based systems (such as traffic detection, data retrieving, and even DNA sequence matching) rely on regular expression patterns for condition matching, there have been efforts in speeding up regex pattern matching.

Some efforts focus on software optimizations for finite state automaton. PCRE-JIT [4] uses the just-in-time (JIT) library to minimize unnecessary parsing of the internal bytecode representation. Recently, Choi et al. proposed DFC [12], a memory-efficient and cache-friendly data structure that minimizes CPU stalls to maximize instruction-level parallelism. Kumar et al. [16] proposed a representation of regular expression patterns called Delayed Input DFA (D^2FA), which reduces the space requirement as compared to DFA. Further efforts build upon D^2FA [10, 18], and compress states and transitions. Finally, some efforts leverage hardware capabilities to speed up automaton – Mitra et al. [20] and Yuan et al. [26] explored the use of FPGAs and GPUs, respectively.

Being a system building block, the learned rule ranker should complement many existing optimizations.

Learning-augmented systems. Auto-tuning system parameters is a popular scenario for learning-augmented systems. OtterTune [8] is a database optimization tool. It uses a combination of supervised and unsupervised machine learning methods to reduce the parameter dimension, characterize observed workloads, and recommend configurations. CherryPick [9] demonstrates the potential of using Bayesian optimization and Gaussian process in predicting the best-performing cloud configuration for a given machine learning computation workload. Metis [17] addresses challenges that systems introduce to hinder the tuning robustness.

Furthermore, the networking community [24] has been applying ML and DL techniques to traffic prediction, traffic classification, resource management, network adaption, etc. To improve the QoS metric of video streaming, Mao et al. [19] used reinforcement learning in the rate adapting mechanism to continuously and adaptively adjust the streaming bit rate.

Finally, Kraska et al. [15] proposed the learned index to replace common indexes in databases. The learned index formulates the problem of database indexes as a DL predictive problem. It offers similar semantic guarantees, and a significant improvement in speed and memory efficiency.

Building on the success of these efforts, we explore whether the learned ranker can be a building block of learning-augmented systems.

7 Conclusion

This paper explores the potential and feasibility of learned ranker as a building block for learning-augmented systems. Particularly, we use rule-matching systems as a concrete scenario. To evaluate the benefits of the learned ranker, we have integrated it into popular regex matching engines. As future work, we plan to study challenges in training learned rankers, and apply learned rankers to other system scenarios.

Abstract

The advances of Machine Learning (ML) have sparked a growing demand of ML-as-a-Service: developers train ML models and publish them in the cloud as online services to provide low-latency inference at scale. The key challenge of ML model serving is to meet the response-time Service-Level Objectives (SLOs) of inference workloads while minimizing the serving cost. In this paper, we tackle the dual challenge of SLO compliance and cost effectiveness with MArk (Model Ark), a general-purpose inference serving system built in Amazon Web Services (AWS). MArk employs three design choices tailor-made for inference workload. First, MArk dynamically batches requests and opportunistically serves them using expensive hardware accelerators (e.g., GPU) for improved performance-cost ratio. Second, instead of relying on feedback control scaling or over-provisioning to serve dynamic workload, which can be too slow or too expensive for inference serving, MArk employs predictive autoscaling to hide the provisioning latency at low cost. Third, given the stateless nature of inference serving, MArk exploits the flexible, yet costly serverless instances to cover the occasional load spikes that are hard to predict. We evaluated the performance of MArk using several state-of-the-art ML models trained in popular frameworks including TensorFlow, MXNet, and Keras. Compared with the premier industrial ML serving platform SageMaker, MArk reduces the serving cost up to $7.8\times$ while achieving even better latency performance.

1 Introduction

Driven by the sustained advances of Machine Learning (ML), the past few years have seen a surging demand of ML-as-a-Service (MLaaS). A typical workflow of MLaaS covers the two phases of ML in the cloud: *training* and *inference*. In the training phase, developers build ML models from the training dataset using an array of ML frameworks. Efficient training in cloud environments has been well explored in the recent work [43, 56, 75]. In the inference phase, the trained models are published as *online services* in data center or cloud and can be queried by end users with new input. The service makes prediction decisions (inference) for a given input using the trained model [30] (e.g., recognizing human faces in a given photo), and returns the inference results to the querier.

Unlike training which runs offline and may take hours to days to complete, inference must be performed in *real-time* on dynamic queries with stringent latency requirements (e.g., tens to hundreds of milliseconds per query). These requirements are often specified as the *response-time Service-Level Objectives* (SLOs) [41], such as at least 98% of inference queries must be served in 200 ms. Failing to comply with the SLOs results in compromised quality of service or even financial loss, e.g., end users will not be charged for queries not responded in time. Therefore, an ML model serving system should strive to meet the target SLOs while minimizing the cost of provisioning the serving instances in the cloud.

However, achieving these two objectives can be challenging. Cloud providers like Amazon [11], Google [37], and Microsoft [52] offer a rich selection of service provisioning options, ranging from VMs and containers to the emerging serverless functions. For each provisioning option, there is a large configuration space (e.g., CPU, memory, and hardware accelerators) coupled with diverse pricing models offering tradeoffs between service guarantees and cost savings (e.g., on-demand and spot instances [17]). A key challenge of provisioning model serving in the cloud is: how should a serving system choose from a bewildering array of cloud services to provide low-latency, cost-effective inference at scale?

Unfortunately, there is no general guideline given by the cloud providers, nor has it been studied in the prior work [10, 25, 42, 45, 58, 59, 63, 70] which mainly targets at general workload. To bridge this gap, we perform extensive measurement studies of inference serving in AWS [11] and Google Cloud [37] by means of VMs (IaaS), containers (CaaS), and serverless functions (FaaS). We briefly summarize three key findings as follows.

First, our measurements suggest that among the three options, IaaS offers the best performance-cost ratio for inference serving, but it incurs long instance provisioning latency and is hence unable to quickly adapt to the changing workload. CaaS suffers from a similar problem as IaaS (though less

severe) with worse performance-cost ratio. Compared to IaaS and CaaS, FaaS scales much faster but is the most expensive.

Second, inference serving can gain significant benefits from *batching* when performed using costly hardware accelerators (e.g., GPU and TPU). Nevertheless, the benefits are not always guaranteed but critically depend on the batch size control knobs and their interactions with query arrivals: when there is not enough load, serving inference queries using GPUs is not economically justified. Therefore, a serving system should judiciously determine when to *scale up* from CPU to GPU instances and how to perform batching over GPUs.

Third, ML inference usually performs *stateless* computations. This opens up an opportunity of using serverless functions as a *handover service* when the system is provisioning new instances for scaling up/out. Also, many ML models, especially deep learning, have *deterministic inference time* [41, 74]—they take fixed-size input vectors and have input-independent control flows. This also brings an opportunity for better resource planing and latency control.

Motivated by these observations, in this paper, we propose MArk (Model Ark), a low-latency, cost-effective inference serving system in the public cloud. MArk takes use of the unique characteristics of ML model serving while also addressing the distinctive challenges posed by it. In particular, MArk allows developers to specify the target SLOs through common APIs. To attain high performance-cost ratio, it uses IaaS as the primary means of provisioning while employing FaaS to quickly fill the service gap when the system is undergoing horizontal/vertical scaling. MArk uses *predictive scaling* to hide the instance provisioning latency in IaaS. Unpredicted load spikes are covered by serverless functions to reduce over-provisioning. Based on the predicted workload, MArk opportunistically uses costly GPU instances to serve *batched queries* for improved performance-cost ratio. To further bring down the cost, MArk also supports the use of the discounted, yet *interruptible instances* (e.g., spot instances) with an interruption-tolerant mechanism that uses transient servers to handle instance interruptions at low cost.

We have prototyped MArk as a general-purpose serving platform in AWS [11] with pluggable backend model servers supporting a range of ML frameworks such as Tensorflow Serving [55], MXNet Model Server [24], and customized Keras [29] server with Theano [26] backend. We have evaluated MArk on AWS using several state-of-the-art ML models for image recognition, language modeling, and machine translation: Inception-V3 [67], NASNet [76], LSTM-ptb [51], and OpenNMT [47]. The results show that MArk yields up to 7.8× cost reduction while achieving comparable or even better latency compared to the state-of-the-practice solution SageMaker [13], and also comply with the predefined SLO requirements. MArk is open-sourced for public access.[1]

2 Background and Related Work

In this section, we survey related work on model serving systems and autoscaling techniques. We also provide background information on cloud services and their pricing models.

2.1 Machine Learning Model Serving

A wide array of ML inference serving systems have been proposed to facilitate model deployment [7, 8, 24, 30, 55, 72]. These systems place the trained models in *containers* and handle model inference requests through REST APIs. For example, systems like Clipper [30], Rafiki [72], and MXNet Model Server [24] host each model in a separate Docker [4] container to ensure process isolation; TensorFlow Serving [55] deploy models as *servables*, which are executed as black box containers and can also be used for version management. In order to provide low-latency inference, these systems employ a number of model-agnostic optimizations such as batching, buffering, and caching [30]. The recently proposed *white box* model serving [49] enables model-specific optimizations with fine-grained resource sharing and parameter re-use.

However, existing inference serving systems mainly focus on streamlining model deployment in server machines, without addressing the scalability and cost minimization issues for model serving on the public cloud. Microsoft's Swayam [41] is among a few inference serving systems that focus on infrastructure scalability and resource efficiency. Yet, Swayam is a proprietary system for model deployment in Microsoft's private MLaaS clusters, where the cloud provisioning options (e.g., IaaS, CaaS, FaaS) and their pricing models are not relevant. Amazon's SageMaker [13] offers scalable model serving over EC2 [1] instances. However, it only supports IaaS provisioning and requires manual specification of the provisioning instances. SageMaker is also *agnostic* to the response-time SLOs and serves inference queries in a best-effort manner. In contrast, MArk meets SLOs at low cost by choosing from a complex selection of provisioning services in AWS [11].

2.2 Autoscaling Dynamic Workload in Cloud

There is a large body of work on autoscaling dynamic workload for general web services hosted in the cloud. We refer to [59] for an extensive survey of this topic and compare some related work with MArk in Table 1. In general, there are two scaling approaches used to serve dynamic workload.

Feedback control scaling. This approach monitors hosted applications and *reactively* adjusts resource provisioning based on the monitored metrics (e.g., utilization, throughput, and latency). Feedback control scaling is adopted in many industrial serving platforms to autoscale dynamic workload, e.g., SageMaker in AWS [12, 13] and Kubernetes in Google Cloud [38, 39]. These systems perform scaling following some customized rules such as "adding 2 instances if CPU

Table 1: A comparison of MArk and existing work on autoscaling dynamic workload in the cloud.

Autoscaler	Scaling approach	Means of Provisioning	SLO-aware	Heterogeneous instances	Interruptible instances	Hardware accelerators
MBRP [33]	Feedback control	Private cluster	✓	✓	×	×
Ali-Eldin et al. [9]	Predictive	IaaS	×	×	×	×
Barrett et al. [25]	Predictive	IaaS	×	×	×	×
Urgaonkar et al. [70]	Predictive	IaaS	✓	×	×	×
Han et al. [42]	Predictive	IaaS	✓	×	×	×
Qu et al. [58]	Feedback control	IaaS	×	✓	✓	×
SpotCheck [63]	–	IaaS	×	✓	✓	×
He et al. [45]	–	IaaS	×	✓	✓	×
Swayam [41]	Predictive	Private cluster	✓	×	–	×
SageMaker [13]	Feedback control	IaaS	×	×	×	✓
MArk	Predictive	IaaS and FaaS	✓	✓	✓	✓

utilization reaches 70%," or tracking a target such as "maintaining 100 queries per minute per instance" [15].

Feedback control scaling makes no prediction about the future and is easy to implement. However, owing to its reactive nature, it incurs long instance provisioning delay when used to serve changing workload [59]. Over-provisioning is therefore needed in case of load spikes. For example, SageMaker recommends to start with 100% over-provisioning and adjust thereafter [16]. As ML model serving is often compute-intensive and requires costly CPU/GPU instances, solely relying on over-provisioning is economically not viable.

Predictive scaling. This approach makes predictions about the future workload, based on which it *proactively* autoscales the serving instances to reduce over-provisioning. Predictive scaling has been widely employed to serve general workload (e.g., web services and VM demands) using a number of time-series based prediction algorithms, such as linear regression [27], autoregressive models [34, 61], and neural networks [19, 53, 57, 65]. Predictive scaling is often complemented with feedback control scaling, where the two approaches operate at different time scales [42,70]. For example, predictive scaling can be used for resource planning at the time scale of hours or days, while reactive provisioning operates in minutes to respond to flash crowds or unexpected deviations from long-term behaviors [70].

However, due to the mismatch of target workload, existing predictive autoscalers do not work well for ML model serving. As summarized in Table 1, they only consider provisioning over homogeneous instances in IaaS [9, 25, 42, 70]. They also do not support hardware accelerators (e.g., GPUs) and cheaper, yet interruptible instances (e.g., spot servers), hence missing opportunities of cutting provisioning cost. In addition, many predictive autoscalers are unaware of the response-time SLOs and only provide best-effort services [9, 25].

2.3 Cloud Provisioning Services

Compared with private clusters, model serving in public clouds is more complex. Leading cloud platforms such as AWS [11], Google Cloud [37], and Microsoft Azure [52] offer a variety of provisioning services that can be used for model serving. We briefly review these services, with a main focus on AWS.

Infrastructure-as-a-Service (IaaS). With IaaS, cloud customers run virtual instances (VMs) of various configurations in terms of vCPUs, memory, storage, network, and accelerators (e.g., GPU, TPU, and FPGA). Customers can then configure and deploy ML model serving softwares [24,30,68] on running instances to serve model inference requests.

IaaS cloud provides flexible pricing options to allow customers to choose between service guarantees and cost savings. Taking Amazon EC2 [1] as an example, customers can run instances *on-demand* and pay for compute capacity by per hour or per second depending on the instance types. Alternatively, customers can run *spot instances* at steep discounts compared to the on-demand price, under the condition that a running spot instance can be *interrupted indefinitely* [17]. EC2 also allows customers to *reserve* an instance in a long term by making an upfront payment [21]. During the reservation period, the instance usage is subject to a heavy discount compared to the on-demand price. All three IaaS pricing options are also available in Google Cloud [37].

Container-as-a-Service (CaaS). With CaaS, customers encapsulate services and implementations in containers (e.g., Docker images [4]), and run containers with specified resource configurations in the cloud, e.g., Amazon ECS [2] and Google Kubernetes Engine [6]. Compared with IaaS, CaaS simplifies software configurations and deployment without the complexity of maintaining the server infrastructure. In Amazon ECS, users pay for the container capacity by per second, where the pricing is based on requested vCPU cores and memory.

Function-as-a-Service (FaaS). With FaaS, customers run applications as *serverless functions* in the cloud without provisioning or managing servers, e.g., AWS Lambda [3] and Google Cloud Functions [5]. In Lambda, customers can only specify the memory allocation for an instance, and pay for the total number of requests and the duration of compute time [3]. FaaS is particularly suitable for *stateless computations* and

Table 2: Cost ($) and average latency ($t$) of serving 1 million requests of three ML models in AWS. We choose c5.large EC2 instance (2 vCPUs and 4GB memory) as it is the most cost-effective. Each ECS container is allocated the same vCPUs and memory as c5.large; each Lambda instance has 3GB memory to achieve comparable latency with c5.large.

ML Model	EC2		ECS		Lambda	
	$	t (ms)	$	t (ms)	$	t (ms)
Inception-v3	5.0	210	9.17	217	19.0	380
Inception-ResNet	9.3	398	16.4	411	39.3	785
OpenNMT-ende	51.5	2180	96.3	2280	155	3100

has recently been used to provision ML model serving [69].

Given a complex selection of provisioning options in the public cloud, which one should be used for ML model serving? We answer this question in the next section.

3 Characterizing Model Serving in the Cloud

In this section, we characterize ML serving performance with IaaS, CaaS, and FaaS as well as their configuration space. Our characterizations are mainly based on AWS [11] (§3.1-3.4), a leading cloud platform offering the most diversified service options. We validate the major results in Google Cloud [37] where possible (§3.5).

3.1 What service to use: IaaS, CaaS, or FaaS?

We choose three representative ML models, Inception-v3 [67], Inception-ResNet [66], and OpenNMT-ende [47], for common prediction tasks such as image classification and machine translation, and evaluate their peak inference performance with TensorFlow Serving [55]. Table 2 summarizes the cost and average latency of serving 1 million requests using AWS EC2 (IaaS), ECS (CaaS), and Lambda (FaaS), respectively.[2]

IaaS vs. CaaS. In EC2 [1], customers can choose among predefined instance types with fixed vCPU and memory allocation. In Table 2, we choose the cheapest compute-optimized instance c5.large as the reference, since it is proven to be the most cost-effective one in §3.3. AWS's container service ECS [2], on the other hand, lets users choose the number of vCPUs they want. We allocate each container with 2 vCPUs to match the capacity of c5.large, and with the minimum memory allowed. Compared with c5.large, the ECS container has similar serving latency but is more expensive.

FaaS. As for the serverless computing service Lambda [3], the pricing is per-request based, and the cost per request depends on the resource allocation and runtime of the request. Customers specify memory allocation in Lambda, and CPU resource is allocated proportionally to memory [14]. For a fair comparison, we compare the Lambda cost of serving the same amount of requests c5.large can serve in an hour, with the maximum memory allocated for best performance. The cost is significantly higher, and the latency is longer, too.

Scalability. EC2 has long provisioning overhead (e.g., several minutes), because additional time is needed to load and set up large ML model serving atop standard overhead, as Microsoft suggests with their production traces [41]. The overhead makes it challenging to accommodate demand surge without high margin of over-provisioning. The high launching overhead also penalizes frequent provisioning and deprovisioning, since customers are billed during the instance launching period as well. Similar to EC2, ECS also needs dozens of seconds of provisioning overhead. Lambda, on the contrary, is able to spawn thousands of new ML inference instances in less than a few seconds, and once an instance is ready, it can continuously serve requests without incurring additional overhead [48]. The cold start overhead of Lambda can be amortized by warming up [48]. Compared with EC2 and Lambda, ECS shows no obvious advantage.

Summary. A natural question is that can we exploit the cost-effectiveness of IaaS service while also taking advantage of the high scalability of FaaS? Conventional cloud provisioning schemes have to over-provision because of the weak scalability of IaaS or CaaS. Now that ML serving is eligible for the highly scalable FaaS, we can reduce over-provisioning by combining IaaS and FaaS. IaaS is used as the primary serving option, while FaaS can provide transient service while new IaaS instances are launching. Moreover, FaaS can potentially handle the short lasting demand surges (short spikes), so that the overhead of frequent provisioning and deprovisioning can be eliminated. Although FaaS is costly, we believe the cost reduction from less over-provisioning can justify its price.

With IaaS as the primary serving option, we shall determine how to choose from a bewildering array of instance families and sizes, which we answer in the following subsections.

3.2 IaaS: Can we use burstable instances?

IaaS providers typically categorize instances into families. Within a family, instances share the similar physical hardware but may have various sizes in terms of vCPUs, memory, and network bandwidth. For CPU instances, EC2 offers four main instance families: the general-purpose m-family, the compute-optimized c-family, the burstable t-family, and the memory-optimized r-family.

Among all instance types, burstable instances (t-family) have the lowest hourly rate, but they are aggressively multiplexed on overbooked servers [71, 73]. Burstable instances provide a baseline level (10% in AWS) of CPU performance with the ability to burst when required by the workload, yet with limited timespan according to a throttle policy (a new t2 instance can sustain 100% utilization for 30 minutes) [22, 23].

We profiled t2 instances' performance for ML serving and show the results in Table 3. We see that the latency drops linearly with the CPU allocation but adding more memory does

[2]Costs of instances are all based on AWS us-east-1 region.

Table 3: The average latency (t) and cost ($) of serving 1 million model inferences with bursted `t2` instances.

AWS `t2` Instance Size		micro	small	medium	large
Inception-v3	t (ms)	268.6	268.3	140.37	142.5
	$	0.87	1.71	1.81	3.75
Inception-ResNet	t (ms)	603.0	593.2	311.8	309.8
	$	1.94	3.79	4.01	7.96

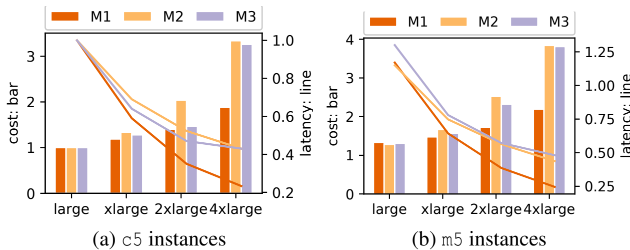
	$	13.85	24.83	28.36	56.71



(a) `c5` instances (b) `m5` instances

Figure 1: The latency (lines) and cost (bars) of serving 1 million model inference requests with `c5` and `m5` instances. M1, M2, and M3 respectively denote Inception-v3, Inception-ResNet, and OpenNMT-ende. The values are normalized by that of `c5.large` (182.5ms with $4.3 for M1; 389ms with $9.4 for M2; 2.18s with $51.5 for M3).

not benefit inference performance. Although it seems that `t2` instances are of low cost with viable latency for ML serving, these results are obtained in the bursted mode and do not sustain a long time. This fatal disadvantage means that burstable instances are not for compute-intensive services [50].

Summary. Burstable instances are plausible for transient ML serving usage, but not as the main long-running resources.

3.3 IaaS: Big instances or small instances?

We further investigate CPU instance families compute-optimized `c-family` and general-purpose `m-family`, where we focus on the latest generation `c5` and `m5`. We exclude memory-optimized instances (`r-family`) from consideration, as our measurements on `t2` instances indicate that 4GB of memory already does not bound the inference performance. In EC2, the configurations (vCPUs and memory) and prices of `m5` and `c5` instances are proportional to their sizes, so it is important to see how scaling up to larger instances would affect the ML serving performance.

Figs. 1a and 1b depict the measured latency (lines) and cost (bars) of serving 1 million inference requests of three ML models using `c5` and `m5` instances of different sizes. In general, `c5` instances are cheaper and have lower latency than `m5` instances because of more advanced CPU models, even though the latter have higher memory than the former. Our results also suggest that, for CPU instances of the same family, smaller instances are more cost-effective, as the serving throughput grows sub-linearly with the instance size. At the same time, by scaling from a smaller instance to a bigger one, the latency drops *sub-linearly* as well.

Summary. To sum up, smaller instances with advanced CPU models (`c5.large` in AWS) are preferable as they achieve higher performance-cost ratio. Moreover, owing to the finer provisioning granularity, using smaller instances to serve dynamic workload improves the resource utilization. Note that the cost analysis presented here is based in on-demand market. Once we switch to the spot market, the cost-effectiveness is variable w.r.t. the change of spot price.

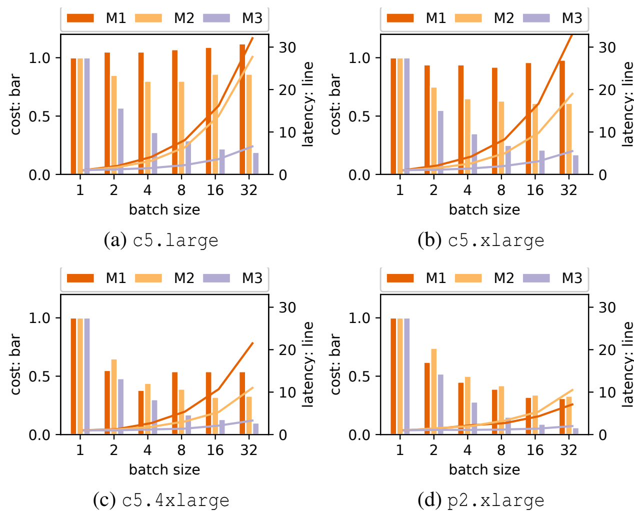
3.4 IaaS: How does GPU compare with CPU?

Many high-end IaaS instances are equipped with hardware accelerators, such as GPU and TPU (exclusive in Google Cloud), that can be used to speed up ML training and inference. The questions are: how would those hardware accelerators improve the latency of ML serving, and if such performance benefit can justify their high cost? In this subsection, we focus on GPU instances, as GPU is the most accessible and popular general-purpose ML accelerator. We will extend our study to TPUs in Google Cloud in §3.5.

A GPU instance is more expensive than a CPU instance, but it can achieve up to 40× speedup due to its massive parallel nature according to NVIDIA [54]. In order to unleash the full power of its computing capability, it is essential to *batch* multiple inference requests and serve them in one go [68]. Batching benefits the performance in two ways. First, it amortizes the overhead of operations such as RPC calls and inter-device memory copy. Second, it can take advantage of batch operation optimization from both software and hardware [30, 62].

To disclose the intriguing performance difference between CPU instances and GPU instances as well as batching, we compare the inference performance of three ML models on `c5` CPU instances and GPU instances `p2.xlarge`. We choose `p2.xlarge` as it is the smallest GPU instance in AWS (the next size available is `p2.8xlarge` which has 8 GPUs and is too expensive). Fig. 2 shows the cost and latency of serving 1 million inference requests with various batch sizes (# of requests served in one batch) on `c5` and `p2.xlarge` instances. For smaller CPU instances such as `c5.large` and `c5.xlarge`, the serving cost (bars) and latency improvement (lines) over batching is marginal (latency growing proportionally as the batch size), while bigger CPU instance (`c5.4xlarge`) displays certain improvement when batch size increases within a small range. GPU instances, on the other hand, benefit significantly from batching: the larger the batch, the lower the cost per request. This phenomenon suggests that batching can significantly improve the cost-effectiveness of larger CPU instances and GPU instances.

Summary. With an appropriate batch size, GPU instances can achieve lower per-request cost and shorter inference latency than CPU instances. However, batch size cannot be in-



(a) c5.large (b) c5.xlarge

(c) c5.4xlarge (d) p2.xlarge

Figure 2: The cost and batch latency of 1 million model inference with batching of various sizes. M1, M2, M3 represents inception-v3, inception-resnet, and OpenNMT-ende. The cost and batch latency are normalized by the values when batch size is set to 1.

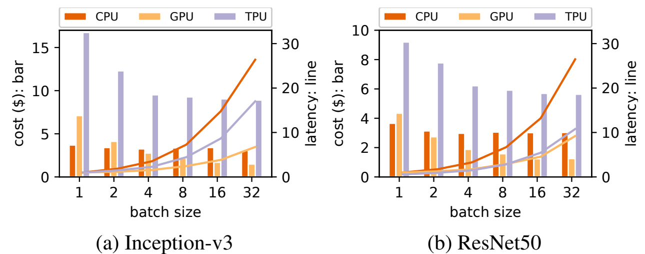
creased arbitrarily: increasing batch size leads to both longer queuing latency and batch inference latency [30]. We will further discuss the batching configuration in §4 and formulate the problem in a latency-aware context.

3.5 Characterization in Google Cloud

So far, all our profiling experiments are based on AWS. To validate whether our main observations also apply to ML serving in the other cloud platforms, we extend our characterization to Google Cloud [37] which offers similar service and pricing options as AWS, along with the Tensor Processing Unit (TPU), the state-of-the-art ML ASIC.

IaaS remains the best option. We first compare the cost and latency performance of ML serving using Google's IaaS, CaaS, and FaaS with the same workloads as in §3.1. All the experiments were run in `us-central1` region. Among the three provisioning options, IaaS remains the best with the lowest cost and shortest latency. For instance, the average latency and total cost of serving 1 million Inception-v3 requests on an customized IaaS instance with 1 vCPU and 2GB memory are 317ms and $3.70, respectively. In comparison, it takes 319ms and $4.17 using the cheapest CaaS instance `n1-standard-1` (1 vCPU and 3.75GB memory), and 527ms and $17.4 using Google Cloud Functions (FaaS) with 2GB memory.

Small instances win on performance-cost ratio. We then compare the cost and latency performance of CPU instances of various sizes within the same family. We made the similar observations as in AWS (§3.3): smaller instances offer higher performance-cost ratio than the bigger ones, though the latter leads to shorter latency. In particular, when serving 1 million Inception-v3 requests with `n1-standard-1`, `n1-standard-2`, and `n1-standard-4`, the cost (average latency) ends up with $4.16 (319ms), $7.82 (296ms), and $11.98 (227ms), respectively.



(a) Inception-v3 (b) ResNet50

Figure 3: The cost and batch latency of serving 1 million inference requests with various batch sizes. The batch latencies are normalized by the latency when there is no batching.

CPU, GPU, or TPU? Finally, we compare the cost and latency performance of using CPU, GPU, and TPU instances for ML serving with various batch sizes. We chose two popular image classification models, Inception-v3 and ResNet50 [44]. The results are shown in Fig. 3, where we used a customized CPU instance with 1 vCPU and 2 GB memory (`CPU`), the same instance with a K80 GPU attached to it (`GPU`), and a Cloud TPU-v2 instance (`TPU`). We observe the similar trend of cost and latency w.r.t. batch size for CPU and GPU instances as in AWS (§3.4). As for TPU, we find that its high price tag does not justify the performance benefit. In fact, TPU is a massively parallel accelerator optimized for training throughput rather than inference latency. Note that in Fig. 3, the batch size for TPU is calculated per core. As TPUv2 has 8 cores, the device batch size is actually 8 times the value. The design of TPU calls for large batch sizes to fully exploit its computing capacity [40]. However, the stringent latency requirement of real-time inference cannot wait for large batches to accumulate, leading to extremely low hardware utilization. In summary, TPUs are not suitable for real-time ML serving.

3.6 Characterization Summary

We summarize our key findings as follows: (1) IaaS achieves the best cost and latency performance for ML model serving, and combining it with FaaS can potentially reduce over-provisioning while remaining scalable to spiky workloads. (2) Burstable instances are viable to cover transient ML serving demand. (3) In on-demand CPU market, smaller instances have higher performance-cost ratio than the bigger ones, even though the latter provides shorter latency. (4) Only with appropriate batching can the use of GPU instances be justifiable to achieve lower cost and shorter latency than CPU instances.

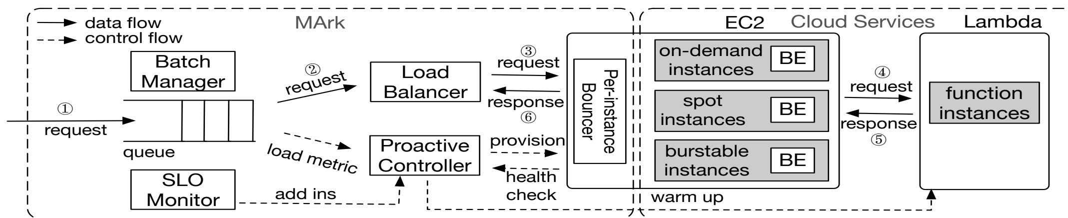


Figure 4: An overview of the MArk model serving system.

4 MArk

In this section, we present MArk (Model Ark), a scalable system that provides cost-effective, SLO-aware ML inference serving in AWS. While MArk is built in AWS, nothing prevents our design from being extended to the other cloud platforms with similar service offerings, such as Google Cloud.

4.1 Overview

Following our observations in §3, MArk uses EC2 as the primary means of provisioning ML serving. It also uses Lambda to quickly cover the service gap when there is a need to scale out/up. Fig. 4 illustrates the overall architecture of MArk. In particular, requests from clients are deposited to a request queue, and are grouped into batches by the *Batch Manager* (details in §4.3). MArk periodically measures the workload metrics, such as the request arrival rate, and sends them to a *Proactive Controller* which makes predictions and plans instances in advance to reduce over-provisioning (§2.2). The controller then sends the launching and destroying requests to EC2 instances, on which custom service backends such as Tensorflow Serving [55] are hosted. The controller also monitors the health status of all running instances. With predictive scaling, further actions are needed to handle prediction errors and unexpected load surges. On each running EC2 instance, there is a *Bouncer* monitoring serving metrics and performing request admission control. If an incoming request cannot be served within a specified time $RT_{\max}$, it will be handled by Lambda instances immediately. In addition, MArk employs an *SLO Monitor* that keeps track of and maintains the SLO compliance with the method described in §4.4.

SLO requirements. Following Swayam [41], we set two SLO requirements for MArk. (1) *Response Time Threshold*: A request is deemed fulfilled only if its response time is below $RT_{\max}$. (2) *Service Level*: The service is considered satisfactory only if at least $SL_{\min}$ percent of requests are fulfilled.

4.2 Workload Prediction

MArk employs predictive scaling to reduce over-provisioning. To expose the long-term cost trade-off between different instances and resource provisioning, we need to estimate the maximum request rate in the near future, which requires multi-step workload prediction. Existing works employ many well-established resource estimation methods, such as linear regression [27], autoregressive models [34, 61], and neural networks [19, 53, 57, 65]. As the accuracy of prediction depends on the underlying workload, there is no such a universal method that works perfectly in all cases. Therefore, MArk exposes an API through which users can implement their own workload prediction methods that best fit their applications. The challenge is how to gracefully handle unavoidable prediction errors and unexpected load surges.

We have implemented a vanilla version of long short-term memory (LSTM) network [36] for multi-step workload prediction, as it is reported to give the state-of-the-art performance [64]. In our implementation, the prediction unit (time interval) is P_u, and the prediction window is P_w, meaning MArk updates the predicted load for the next P_wP_u interval every P_u time units. During each unit, MArk keeps sampling the arrival rate in consecutive short sample windows of P_s. It keeps track of the maximum arrival rate of the unit, and gets the maximum arrival rate array for the next P_w units. In our evaluations, we set the $[P_u, P_w, P_s]$ to $[1\text{min}, 60, 5\text{s}]$. Prediction unit is set to 1 minute, as EC2 charges at least 1 minute for new instances. Prediction window is set to 60 steps, since 1 hour of future trend is good enough to expose the long term trade-offs. The sample size is set to 5 seconds, since the arrival rate can be treated as stable in short time slots [74]. MArk is designed to work for all ML serving workloads, so users can fine-tune this prediction algorithm or replace it with their own implementations for better prediction results.

4.3 Instance Provisioning and Batching

With workload prediction, we need to determine what and how many instances should be used to serve the requests. In general, this problem can be formulated as a compilation of queueing system [74], where instances of each type are modeled as an M/D/c queue with deterministic processing time and the predicted request arrival rate. However, as shown in [74], this problem has no closed-form solution even without considering request batching and instance pricing. Given this hardness result, we turn to a heuristic solution: instead of jointly considering batching and instance provisioning, we solve the two problems separately using heuristics.

Batching. Inspired by the adaptive batching in [30], we introduce two hyperparameters to control the batching behavior of an instance type: W_{batch} which is the maximum waiting

time window for request batching, and N_{batch} which is the maximum batch size. The Batch Manager fetches requests from the queue, and submits the batched requests if either of the two limits is reached (Fig. 4). We tune the two hyperparameters to meet the following two requirements: (1) No SLO requirements can be violated, meaning the waiting time window and the processing time of the batch together should be capped by response time threshold $RT_{\max}$; (2) the throughput with batching enabled must be greater than that of no batching. That is, the waiting time window and the batch processing time together should be less than the time needed to process all those requests sequentially without batching.

In practice, hyperparameter tuning requires light profiling for the target instance. We first profile the optimal processing rate of the target instance without batching, denoted by μ^*_{nb}. We then gradually increase the batch size from 1 until at least one of the following constraints no longer holds, where b is the batch size, and T_b is the time needed to process a batch:

$$W_{\text{batch}} + T_b \leq RT_{\max},$$
$$W_{\text{batch}} + T_b \leq \frac{b}{\mu^*_{nb}}.$$

Now that we have the optimal batch size $N_{batch} \leftarrow b$ and the maximum processing rate μ^* under this configuration, together with their corresponding W_{batch}, we can simply treat the target instance as a black box with processing rate μ^*.

Instance provisioning. We now solve the instance provisioning problem using an online heuristic algorithm that considers both long-term cost-effectiveness and the launch overhead, while at the same time attaining high utilization of running instances.

We first introduce the notations. Suppose there are n types of instances that can be used for serving. At a given time t_0, let $R = \{r_1, r_2, \cdots, r_n\}$ be the set of running instances and $F = (F_1, \cdots, F_m)$ the predicted maximum request arrival rate for the next m steps, where F_t is the predicted maximum rate in step t. For each instance type i, let C_i be the instance capacity, measured by the maximum throughput of a given model (requests per hour). Let P_i be its unit price, and O_i its launch overhead, i.e., cost due to the instance provisioning latency. Finally, let I be the set of available instance types. Given R, F, I and the target SLO, our problem is to determine what instances to launch and which instances to destroy at t_0, so as to minimize the cost while meeting the target SLO.

The challenge of finding the optimal solution in the long run is how to deal with the running instances at t_0. They may not be the most cost-effective in the next m steps, yet keeping using them avoids additional launch overhead. We propose a greedy solution in Algorithm 1. Our intuition is to greedily find the most cost-effective instance from time period t_0 to t_m considering both the pay-as-you-go fee and launch overhead. The running instances at t_0 can be treated as special ones without launch overhead.

Algorithm 1 Greedy Algorithm

```
procedure SCHEDULE(F, R, I, SLO)
    S ← S ∪ R    ▷ Running instances are treated as special ones with zero launch overhead
    for all instance i in S do
        if instance i cannot meet SLO requirement then
            S = S \ {i}                          ▷ Remove i from S
    if S = ∅ then
        Report error       ▷ No candidate instance can meet SLO
    instance_plan ← ∅               ▷ initialize provisioning plan
    FILL(F, S, instance_plan)
    Launch instances in instance_plan but not in R
    Destroy instances in R but not in instance_plan

procedure FILL(F, S, instance_plan)
    C^sum ← total capacity of all instance i in instance_plan
    for t = 1 to m do
        Λ_t = F_t − C^sum   ▷ Unfulfilled requests predicted at step t
    if Λ_τ ≤ 0 then          ▷ Planned capacity is enough at step τ
        return
    Find the largest e such that there are unfulfilled requests from steps τ to e, i.e., Λ_t ≤ 0 for all τ ≤ t ≤ e
    min_cost ← ∞ ▷ Greedily search the instance with the lowest per-request cost to cover unfilled requests from τ to e
    for all instance type i ∈ S do
        cost ← (O_i + (e − τ)P_i)/N, where N is the number of unfulfilled requests that will be served by an instance i in [τ, e]
        if cost < min_cost then
            min_cost ← cost
            j ← i
    instance_plan ← instance_plan ∪ {j}
    FILL(F, S, instance_plan)
```

In our algorithm, assuming most instances can get ready in τ time units after launching, we use the predicted load at $t_0 + \tau$ as the provisioning target, as it is safe to make instance provisioning decisions τ time units in advance. The values of τ can be easily adjusted based on the actual scenario. In our setup, τ is set to 5 minutes, and the scheduling time unit is set to 1 minute. In this case, the scheduling decisions are made every minute, targeting the load in 5 minutes. The launching requests should be sent right away once the *instance_plan* is ready, while destroying requests should be sent after a predefined cool-down period to ensure better service quality [59].

It is worth mentioning that Algorithm 1 trivially meets the SLO requirement by ensuring that the latency performance of each selected instance comply to the target SLO individually.

4.4 SLO tracking

The heuristic in Algorithm 1 plans instance capacity based on predictions. Yet not all demand surges are predictable, and such surges would result in SLO violations if solely relying on proactive provisioning [59]. To further improve the SLO compliance, MArk actively monitors request latency,

and *reactively scales* the cluster as soon as SLO violations are detected. MArk constantly checks if the last M requests satisfy the SLO requirements, if not, L instances of type T will be launched (`c5.large` by default). All those parameters can be tuned for specific models and SLO requirements.

4.5 Spot Instance and Lambda Cold Start

Use of spot instances. Note that Algorithm 1 does not differentiate between on-demand and spot instances, which allows MArk to exploit the price discount of spot instances. However, the adoption of spot instances poses the challenge of instance interruptions. Although the interruption of a spot instance will be notified 2 minutes in advance, such a grace period may not be long enough for a substitute spot instance to get ready. The question is how can we handle the outstanding requests in the presence of instance interruptions? Lambda seems to be a choice, but it would take a toll on the latency and cost.

Our answer to this challenge is the burstable instance. As shown in §3.2, burstable instances are cheap instances which can sustain full utilization for about 30 minutes. The low cost and high peak performance make them a perfect fit for transient backups in case of short-term interruptions. Moreover, burstable instances can be resumed from stopped state in less than 2 minutes thanks to their small sizes. Therefore, when we use spot instances with MArk, we reserve a few stopped burstable instances as cold standbys. Once MArk receives interruption notices, it resumes the corresponding amount of burstable instances to handle the transient requests until the regular spot instances capacity is back to normal, after which those burstable instances are stopped.

Lambda cold start. Another potential challenge MArk faces is the *cold starts* in Lambda [71]. Every time a new Lambda instance is launched, it needs to load the ML model, framework library and code in memory, which results in a much longer inference delay. Nevertheless, cold starts only occur when the request rate exceeds the concurrency, measured by the number of currently available lambda instances [32,73]. Existing benchmarking shows that a Lambda instance is recycled after it stays inactive for 45 to 60 minutes [31]. Our evaluations further confirm that, with more than 3 million requests, the cold start rate never exceeds 0.23%. Therefore, the latency impact of cold starts is limited. The cost impact is also negligible. Our profiling shows that $1 can spin up 7K inception-v3 Lambda instances, which is capable of serving more than 20K requests per second. Algorithm 1 hence does not consider the cost impact of Lambda cold starts.

Despite the negligible impacts of Lambda cold start, our implementation employs strategical concurrency warm-up to further amortize its impact. When a potential Lambda request surge is expected, such as spot interruptions and unexpected workload surges, MArk sends concurrent pings to Lambda to warm up more instances as described in [32].

Table 4: ML models and frameworks used in evaluation.

Model	Type	Framework	Size
Inception-v3	Image Classification	Tensorflow Serving	45MB
NASNet	Image Classification	Keras	343MB
LSTM-ptb	Language Modeling	MXNet Model Server	16MB
OpenNMT-ende	Machine Translation	Tensorflow Serving	330MB

5 Experimental Evaluation

We have prototyped the proposed MArk system and conducted extensive experimental evaluations on AWS to validate its effectiveness and robustness. We first compare the performance of MArk using on-demand instances and spot instances respectively with the premier industrial ML platform SageMaker against production traces from Twitter. To ensure MArk's performance does not mainly rely on prediction accuracy, we then examine whether MArk is able to maintain its advantage under unpredictable, highly bursty workload. After that, we run a few microbenchmarks to demonstrate the robustness of MArk in terms of handling spot interruptions, and the ability to handle unexpected demand surges.

5.1 Evaluation Setup

MArk. We have prototyped MArk on top of Amazon EC2 and Lambda services in two versions, *MArk-ondemand* which only uses on-demand instances, and *MArk-spot* which uses spot instances with interruption-tolerant mechanism, i.e., using burstable servers for smooth transition during unexpected instance interruption (§4.5).

Testbed. We use AWS as the testbed for conducting extensive experiments. The types of instance used in our evaluation include all the `c5` and `m5` instances as examples of CPU instances and `p2.xlarge` instances as an example of GPU accelerators. In our experiments, we used up to 42 `c5` instances, 10 `m5` instances, and 12 `p2.xlarge` instances.

ML models. We use four popular ML models that are of various sizes and cover diverse domains deployed in three popular ML serving software frameworks to evaluate MArk's performance, which are summarized in Table 4. To configure the batching of the ML models on EC2 instance, we performed lightweight profiling following the instructions detailed in §4.3. The optimal batching hyperparameters W_{batch} and N_{batch} for `p2.xlarge` instance found by our tuning algorithm outlined in §4.3 are 200ms and 8 for Inception-v3, 750ms and 16 for NASNet, 490ms and 16 for OpenNMT-ende. For LSTM-ptb, we only performed experiments on CPU as MXNet Model Server does not support batching at the time of writing. For OpenNMT-ende on CPU instance, the optimal batching hyperparameter N_{batch} is found to be 2, and W_{batch} is set accordingly. For the other models on CPU instance, we do not use batching as it does not bring benefits (see Fig. 2).

SLO. Recall that the SLO requirement is specified as at

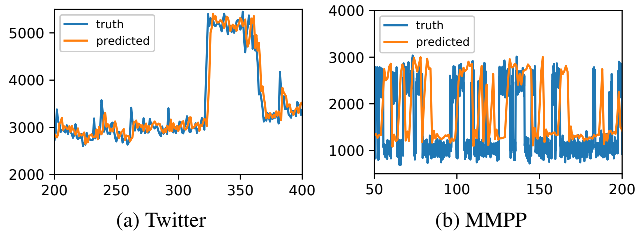

Figure 5: Snapshots of the arrival process using Twitter and MMPP with the prediction results of LSTM based algorithm.

least $SL_{\min}$ percent of requests must be served in $RT_{\max}$ time (§4.1). We set $SL_{\min}$ to 98% for all models, and set $RT_{\max}$ as 600ms, 1000ms, 100ms, and 1400ms for Inception-v3, NASNet, LSTM-ptb, and OpenNMT-ende respectively.

Workload. In our evaluation, we drive the arrival process of ML workloads in two different ways. First, as there is no publicly available traces for ML serving, we synthesize ML requests based on the tweets traces from Twitter [20]. We believe that the Twitter traces serve as a good benchmark, as it represents a popular web service with highly dynamic load. The trace exhibits typically characteristics of ML inference workloads, containing recurring patterns (e.g., hour of the day, day of the week) as well as unpredictable load spikes (e.g., breaking news). In particular, the peak request rate in the traces is 4 times higher than the valley, a result of transient demand surges commonly found in industrial-scale web applications. Fig. 5a(a) illustrates a snapshot of the trace.

Second, to further evaluate the performance sensitivity of MArk w.r.t the workload, we synthesize random and bursty ML request load using *Markov-Modulated Poisson process* (MMPP) [28,35,60]. The load generated by MMPP are highly unpredictable, as the occurrence and duration of demand surges are completely random, as shown in Fig. 5b.

In summary, we use the Twitter traces to evaluate how well MArk performs against synthesized real workload that can be largely predicted. Using MMPP-generated workload, we stress test MArk's performance in the presence of frequent, unpredictable load spikes.

Baseline. We use SageMaker [13] as the baseline for the evaluation. SageMaker is AWS's leading ML training and hosting system. SageMaker hosting employs AWS's new target tracking autoscaling policy [16,18]. Given the dynamics in request arrival rate (i.e., the arrival rate can increase more than double in just a few minutes), to ensure service quality, we follow the AWS guidelines [16] and set the over-provisioning factor to 2 for SageMaker. We will show in Fig. 7 that even so the over-provisioning is still incapable of handling the volatile workload of the Twitter traces.

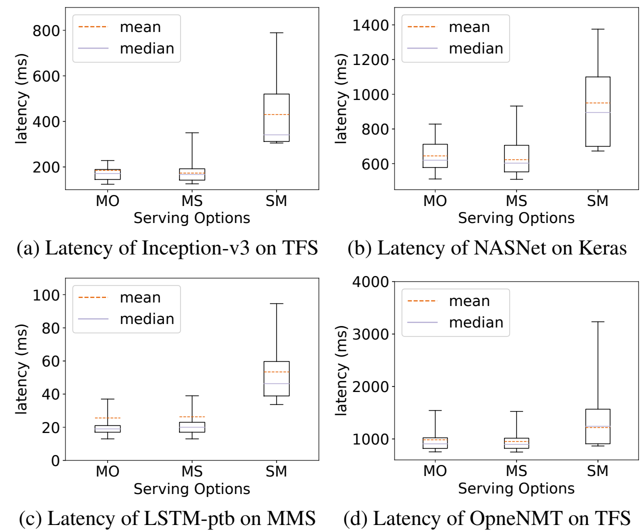

Figure 6: Latency comparison of MArk-ondemand (MO), MArk-spot (MS), and SageMaker (SM) on 4 ML models using Twitter workload.

5.2 Macrobenchmarks

Workload prediction. For Twitter traces, we use the data of the first 5 months to train the workload prediction model. For MMPP-generated arrival process, we use a period of 24-hour data for training. Fig. 5b demonstrates snapshots of the prediction results. We see that the prediction accuracy is in general good for the Twitter traces, yet very poor for the MMPP case. Since striving for the best workload prediction is NOT the focus of this paper, and we mainly use the LSTM based algorithm as an example of the pluggable workload prediction component, we do not provide detailed evaluation of the prediction algorithm in the interest of space.

Experimental results using Twitter traces. We first compare MArk-ondemand, MArk-spot, and SageMaker on the ML models described in §5.1 by feeding the arrival rate extracted from Twitter traces. The experiments were performed on AWS spanning more than 8 hours each. We report two metrics: request latency in Fig. 6, and cost breakdown in Table 5. The request latency is measured as the time between request arriving at the serving system and getting response back, while the cost is the charge billed by AWS. The comparison results suggest that MArk can significantly reduce both the cost and latency compared with SageMaker. For cost reduction, compared with SageMaker, MArk-ondemand respectively achieves 3.63×, 2.79×, 2.41×, and 3.15× for the four ML models; MArk-spot achieves 6.21×, 5.91×, 6.64×, and 7.83×, respectively. For latency, MArk-ondemand achieves up to 57% reduction and MArk-spot achieves up to 60% reduction compared with SageMaker.

The latency advantage of MArk over SageMaker comes in three-fold. First, with appropriate batching configuration,

Table 5: Cost ($) comparison of MArk-ondemand (MO), MArk-spot (MS), and SageMaker (SM) on 4 ML models using Twitter workload.

Setting	Inception-v3			NASNet		
	MO	MS	SM	MO	MS	SM
EC2	20.94	9.83	80.98	24.21	10.71	68.1
Lambda	1.34	3.2	NA	0.19	0.81	NA
Total	22.28	13.03	80.98	24.40	11.52	68.1

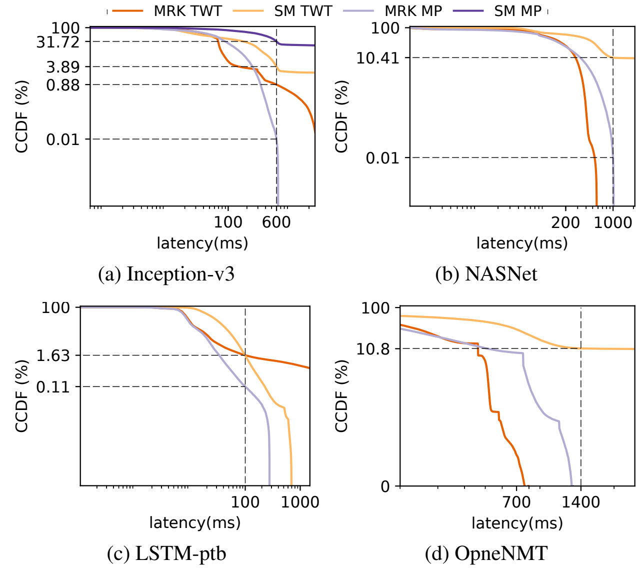
Setting	LSTM-ptb			OpenNMT-ende		
	MO	MS	SM	MO	MS	SM
EC2	6.17	2.24	14.9	27.54	10.79	87.1
Lambda	0	0.04	NA	0.12	0.33	NA
Total	6.17	2.28	14.9	27.66	11.12	87.1

GPU instances can reduce the overall latency by performing more efficient parallel computation. Second, the SLO-aware design of MArk helps reduce the queuing delay. In addition, the predictive scaling and SLO-awareness together form an efficient hybrid approach that enjoys the benefits in both proactive and reactive designs. It is worth pointing out the different performance behaviors between MArk-ondemand and MArk-spot. As shown in the latency box plots in Fig. 6, MArk-spot has longer latency tails, since more requests are handled by Lambda compared with MArk-ondemand, in case of interruptions. However, the average and median latencies of MArk-spot are usually the same or even better than MArk-ondemand. This is because in spot market, the performance-cost ratio is highly dynamic, which allows MArk-spot to opportunistically use large instances and GPU instances at cheaper price than on-demand, leading to better latency performance.

MArk's cost reduction comes from the following aspects. First, predictive scaling together with Lambda services brings a more judicious over-provisioning design that can reduce the cost. The 2× cost reduction over SageMaker in MArk-ondemand using only CPU instances for LSTM-ptb is a good example. Second, GPU instances can further reduce the cost during high arrival rate as batching increases the efficiency of computing. The cost reduction is more significant for OpenNMT as it benefits the most from batching as shown in Fig. 2d. MArk-spot further brings down the cost by enjoying the spot market discounts. Note that although Lambda service used by MArk is expensive in price, but the cost of Lambda can be well justified by enabling more judicious over-provisioning.

We have also performed a case study of SLO compliance and report the *Complementary Cumulative Distribution Function* (CCDF) of request latency in Fig. 7. As expected, MArk managed to maintain its compliance with SLO requirements, thanks to the SLO-aware design. SageMaker, on the other hand, is SLO-oblivious, so the queuing delay adds up during high arrival periods, and the SLO is violated.

Experimental results using MMPP-generated load. Next we evaluate MArk using the more challenging, less predictable MMPP workload. We still use the same four ML models, and each experiment lasts about 4 hours on AWS. In the interest of space, we only demonstrate the SLO compliance results in Fig. 7. Fig. 7a shows that the SLO compliance of SageMaker is significantly degraded from Twitter case to MMPP case due to the much more dynamic and bursty behaviors in MMPP. However, MArk can still meet the SLO requirements even when the workload is highly dynamic and unpredictable, thanks to the SLO Monitor that can detect the failure of proactive prediction and timely add backup machines based on the feedback control algorithm. Note that we only evaluated SageMaker with MMPP-driven arrival process on Inception-v3 model as it is too expensive for us to run all of them. However, given the SLO-oblivious nature of SageMaker, we expect the behavior would be similar.



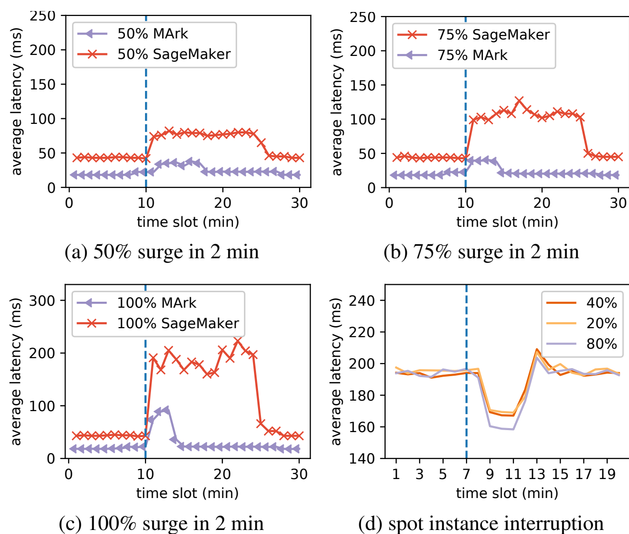
(a) Inception-v3 (b) NASNet (c) LSTM-ptb (d) OpneNMT

Figure 7: CCDF of latency comparison between MArk and SageMaker. RT_{max} is drawn as a black dashed vertical line (the black dashed horizontal line shows the corresponding CCDF value of RT_{max}). MRK and SM represents MArk and SageMaker, while TWT and MP represents Twitter and MMPP workload respectively.

5.3 Microbenchmarks

In this section, we evaluate the robustness of MArk by taking a closer look at how MArk handles unexpected demand surges and spot interruptions.

Robustness against unexpected surge. MArk harvests performance and cost benefits by using a judicious over-provisioning scheme. One important question is whether MArk can handle unexpected demand surges well in the presence of unforeseeable flash crowds or poor workload prediction accuracy. To answer this question, we increase the request rate for LSTM-ptb serving by 50%, 75%, and 100% in 2 minutes and compare the latency over time between MArk



(a) 50% surge in 2 min (b) 75% surge in 2 min (c) 100% surge in 2 min (d) spot instance interruption

Figure 8: Microbenchmark results. (a), (b), (c): The latency change comparison during unexpected demand surge between MArk and SageMaker, where the surge starts at the 11th min shown by the dashed line. (d): The latency change when different percentages of spot instances are interrupted in MArk-spot, where the interruption notice is received at the 7th min.

and SageMaker in Figs. 8a, 8b, and 8c. [3] Since the surge is unpredictable, both MArk and SageMaker handle it reactively. The results suggest that MArk acts faster and effectively than SageMaker during the unforeseeable surge, i.e., the increased latency period and amount are much smaller, thanks to the Lambda-based fallback mechanism, which can immediately take over and cap the latency to prevent queue building up like in SageMaker. In addition, MArk's SLO Monitor can detect the SLO violations and issue backup instance requests right away to adapt to the new arrival rate, while SageMaker is only able to react in the next scaling cycle.

Robustness against spot interruption. MArk-spot utilizes spot instances to reduce the cost. However, the interruption of spot instance can cause performance degradation if not handled properly. We evaluate MArk-spot by zooming in the interruption handling periods under different interruption ratio of instances. We launched a 20-instance Inception-v3 cluster, and manually interrupted 20%, 40%, and 80% of the instances respectively. Fig. 8d illustrates the latency change during the interruption. The interruption happens at the 7th minute (vertical dashed line), and MArk resumes `t2` instances as transient resources upon receiving interruption notice. The proactive controller then adjusts the provisioning plan and requests new instances. At the 13th minute new spot instances are ready, and the latency goes back to normal. The average latency drops during transient period because burstable `t2` instances can have temporal boosted performance as discussed in §3.2. The short latency bump at the 13th minute is due to the switching overhead (i.e., warm up of new instances).

To sum up, the results above confirm that MArk can handle unexpected surge and spot interruption robustly.

[3] Given that we only compare latency here, we show the results of MArk-spot as the latency results of MArk-ondemand can only be better.

6 Discussion

Cloud platform. The measurements and evaluations in this paper are mainly based on AWS. However, the main design of MArk can be generally extended to other major cloud platforms, as they offer both IaaS and FaaS services, as well as flexible pricing models. Nevertheless, some hyperparameters used in the algorithm are platform-dependent, and must be re-tuned. Also, we have not considered reserved instances, as they require a long-term usage commitment. We believe they will bring down the cost of serving stable inference demands in a long run, and will leave it as a future work.

Large models. Deep learning models are becoming increasingly large and may not fit into the memory of Lambda (or even IaaS) instances. A possible solution goes to distributed inference under the model parallel scheme, which is not supported in our current design. We will leave it as a future work.

Hardware accelerator. We used the most common ML accelerator GPU as an example of utilizing hardware accelerators. The same batching formulation can be applied to other accelerators (e.g., FPGA) as they benefit from batching similarly.

MArk's architecture requires a master machine to make provisioning decisions. While such design has limitations on scalability and is vulnerable to the single point of failure, these problems can be easily addressed with mature industrial solutions such as Zookeeper [46].

7 Concluding Remark

In this paper, we conducted a systematic study of serving ML models on cloud and concluded that combining FaaS and IaaS can achieve scalable ML serving with low over-provisioning cost. Driven by the unique characteristics of ML model serving, we proposed MArk, a cost-effective and SLO-aware ML serving system. We prototyped MArk on AWS and showed that compared with the premier autoscaling ML platform SageMaker, MArk yields significant cost reduction (up to 7.8×) while complying with the SLO requirements with even better latency performance.

Abstract

In recent years, software applications are increasingly deployed as online services on cloud computing platforms. It is important to detect anomalies in cloud systems in order to maintain high service availability. However, given the velocity, volume, and diversified nature of cloud monitoring data, it is difficult to obtain sufficient labelled data to build an accurate anomaly detection model. In this paper, we propose cross-dataset anomaly detection: detect anomalies in a new unlabelled dataset (the target) by training an anomaly detection model on existing labelled datasets (the source). Our approach, called ATAD (Active Transfer Anomaly Detection), integrates both transfer learning and active learning techniques. Transfer learning is applied to transfer knowledge from the source dataset to the target dataset, and active learning is applied to determine informative labels of a small part of samples from unlabelled datasets. Through experiments, we show that ATAD is effective in cross-dataset time series anomaly detection. Furthermore, we only need to label about 1%-5% of unlabelled data and can still achieve significant performance improvement.

1 Introduction

In recent years, we have witnessed increasing adoption of cloud service systems. Many software applications are now deployed on cloud computing platforms such as Microsoft Azure, Google Cloud Platform, and Amazon Web Services (AWS). As the cloud systems could be used by millions of users around the world on a 24/7 basis, high service reliability and availability are critical.

However, cloud systems, like other software systems, may exhibit some anomalous behaviors. These anomalies could seriously affect service availability and reliability and could even lead to huge financial loss. The anomalies could be caused by a variety of factors (such as software bugs, disk failures, memory leaks, network outage, etc.) and reflected by a variety of cloud monitoring data (such as KPI, performance counters, usage statistics, system metrics, logs, etc.). The cloud monitoring data are usually time series data, which have high velocity and enormous volume because of the scale and complexity of cloud systems. To maintain high service reliability and availability, it is important yet challenging to detect anomalies from a large amount of cloud monitoring data precisely and timely.

Specifically, anomaly detection in practice encounters several challenges due to the characteristics of cloud systems. A large cloud system is composed of a variety of services and each service is associated with some monitoring data. For some types of data, the characteristics of anomalies are common across many services. While for some other types of data, the characteristics of anomalies could differ from service to service. For example, 90% CPU utilization is normal for computation intensive services but anomalous for other services. Therefore, simple threshold-based anomaly detectors can hardly perform well for a variety of services.

Over the years, many machine-learning based anomaly detection methods have been proposed, including supervised [22, 25] and unsupervised methods [2, 41, 38]. However, it is not trivial to detect anomalies in a large and diversified set of time series data in real cloud environment where labelled data is scarce but a high detection performance is demanded. Unsupervised learning methods can deal with a large amount of data as they do not require labelled data. However, the performance achieved by these methods is rather low [13]. Although supervised learning methods can achieve higher accuracy than the unsupervised counterparts, it is time-consuming and tedious to manually label the anomalies due to the volume and diversity of cloud monitoring data. Therefore, supervised-learning based methods are difficult to be applied to anomaly detection in practice.

Facing the above challenges, to build an accurate and efficient anomaly detection model, we propose ATAD, which enables cross-dataset anomaly detection for cloud systems. The main idea of cross-dataset is to perform anomaly detection on an unlabelled dataset (the target dataset) by learning

from existing, labelled datasets (the source datasets). For example, a detector can be learned from a public dataset such as NAB [23], and then applied to an unlabelled dataset collected from a real-world system.

ATAD consists of two major components: 1) Transfer Learning, which transfers the common anomalous behavior learned from a labelled time series data to a large volume of target unlabelled dataset. Through transfer learning, the commonalities across datasets could be leveraged and the labelling effort for the target dataset could be reduced. 2) Active Learning, which improves the detection performance by labelling only a small number of selected samples in the target dataset. Through active learning, the diversified data with specific characteristics can be addressed with a small amount of labelling effort.

In particular, in the Transfer Learning component, we identify multiple features of cloud monitoring data and perform clustering to select an appropriate subset of existing labelled data as the sub source domain. Then the CORAL algorithm [37] is applied to narrow the feature difference between the source and target domain. In the Active Learning component, we utilize the UCD (Uncertainty-Context-Diversity) method to recommend informative data points to be labelled. The labelled points are used to retrain the classifier trained from the Transfer Learning component. In this way, we aim at minimizing the labelling effort and improving the performance of the detector as much as possible.

We have conducted experiments on public datasets to verify the effectiveness of our method. The experimental results show that using ATAD we can achieve cross-dataset anomaly detection with good accuracy. We test the effectiveness on both public datasets and real-world cloud monitoring data. On public datasets, ATAD shows higher accuracy than existing methods when performing anomaly detection on a target dataset (i.e. Yahoo) by the detector learned from a source dataset (Non-Yahoo, like AWS, Twitter and Artificial datasets). Furthermore, labelling about 1%-5% of unlabelled data could achieve much higher F1-score than the related methods. We also train an ATAD model using public datasets and apply the trained model to detect anomalies in real-world cloud monitoring data of Microsoft. ATAD achieves the best F1-Score, which is much higher than those achieved by other methods.

The contributions of this paper are as follows:

- We propose a new anomaly detection method called ATAD, which enables cross-dataset anomaly detection for cloud systems.
- To the best of our knowledge, we are among the first to detect anomalies in time series cloud data using a combination of transfer learning and active learning techniques.
- We have performed an extensive evaluation of the proposed approach using public and real-world datasets.

This paper is organized as follows: we first elaborate the background and motivation of our work in Section 2. In Section 3, the details of ATAD are described. Section 4 reports the experiments and corresponding results. Next, we discuss threats to validity in Section 5. We introduce the related work in Section 6, before concluding the paper in Section 7.

2 Background and Motivation

For cloud service vendors like Microsoft Azure, Google Cloud Platform, and Amazon Web Services (AWS), there are millions of servers and virtual machines providing a variety of services to users. Despite many quality assurance methods, it is difficult to avoid system failures in reality. A severe system failure can cause damage to user's operation and vendor's reputation. Recovering system from failures in time is of great importance. In order to do that, quick and accurate anomaly detection is essential.

Anomaly detection is the identification of rare items, events or observations which raise suspicions by differing significantly from the majority of the data [43]. Anomaly detection in cloud is usually performed on Cloud Monitoring Data (such as KPI, performance counters, CPU utilization, VM downtime, system workload, etc.). The cloud monitoring data is often presented in time series, that is a series of numerical data points recorded in time order.

Unlike a general anomaly detection problem, it is much more difficult to detect anomalies in a large-scale cloud service system. We identify the following challenges:

- Diverse characteristics of anomalies: in a large-scale cloud service system, different usage scenarios and components have different levels of tolerance to anomalies. For example, a minor system deviation occurring in a certain key component, like storage cluster, may become an anomaly and lead to the failure of the whole system [11, 21]. However, such a deviation may not cause serious problems in other components. It is difficult to set accurate thresholds of anomalies for each usage scenario and system component [11]. Therefore simple threshold-based anomaly detection methods are not suitable for cloud service systems.

- Anomaly detection in time series data: cloud monitoring data is large-scale time series data that has temporal property. Many commonly-used machine learning algorithms cannot be directly applied because the time series data does not satisfy the independent and identically distributed (i.i.d) assumption. Although some deep learning models, like LSTM [17], could capture the temporal property, they require enormous labelled data to train an accurate model. Thus, an appropriate approach to incorporate the temporal property of time series data is important.

- Unsatisfactory performance of unsupervised learning: unsupervised machine learning techniques such as Isolation Forest [26] or Seasonal Hybrid ESD [16] can be applied to anomaly detection. These methods detect anomalies by checking outliers/deviations from the normal data distribution. However, the effectiveness of unsupervised anomaly detection algorithms is often unsatisfactory [13]. The false alarm rate of unsupervised models is higher, which requires much more effort for engineers to check the status of the cloud system.

- Lacking labels for supervised learning: As mentioned above, if the temporal property of time series data can be well incorporated into the labelled data, supervised machine learning methods such as SVM or Random Forest are good to be used to learn and predict anomaly patterns [29]. However, due to the scale and complexity of a cloud service system, labelling the whole dataset requires enormous human effort and is an almost impossible task. The problem of lacking labelled data limits the application of supervised anomaly detection methods to cloud service systems.

3 Proposed Approach

In order to address the challenges mentioned above, in this paper, we propose a novel time series anomaly detection method called ATAD (Active Transfer Anomaly Detection), which combines transfer learning and active learning technologies for anomaly detection in cloud monitoring data. Fig. 1 shows the overall workflow of ATAD.

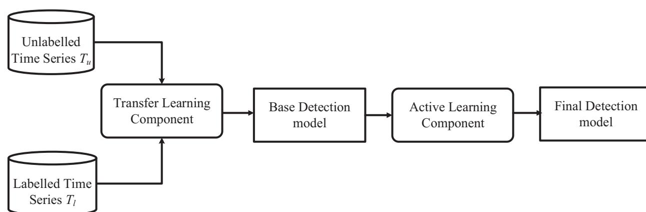

Figure 1: The overall workflow of ATAD

There are two sets of input data, one is the unlabelled time series data T_u on which anomaly detection will be conducted, the other is labelled time series data T_l collected from the public domains or the other components of the cloud system. In T_l, each point in the time series has been manually labelled as either anomaly or normal.

Our approach consists of two main components, namely *Transfer Learning component* and *Active Learning component*. In transfer learning, to incorporate temporal property of time series data, multiple general features are extracted from the raw dataset T_l and form the feature dataset F_l. Feature-based and instance-based transfer learning methods are then applied on F_l to learn a base detection model. After that, the unlabelled time series T_u goes through the same feature extraction process and forms the feature dataset F_u. The active learning component recommends a small number of informative samples from F_u for labelling through *Uncertainty and Context Diversity* (UCD) strategy. Then the labelled data is used to retrain the base detection model. After T rounds of active learning, we obtain the final anomaly detector.

We will describe more details about ATAD in the following sections.

3.1 Transfer Learning Component

Many machine learning methods assume that the distributions of labelled and unlabelled data are the same. However, transfer learning, in contrast, allows the domains, tasks, and distributions used in training and testing to be different [30]. In order to achieve knowledge transfer among different time series datasets, we utilize an efficient and effective transfer method for large-scale cloud monitoring data. For the anomaly detection problem in cloud systems, it is non-trivial to perform transfer learning directly. We need to consider the following factors when we design our transfer learning component.

- Cloud monitoring data is usually presented in the form of time series. Time series is not independent data, but a set of data points with temporal dependence. Thus the anomaly patterns of time series have contextual relevance. How to incorporate this relevance into anomaly detection is a challenge. In our work, we extract time series related features at each data point. Each data point is transformed from the original single-dimensional scalar into a high-dimensional feature vector, and the contextual information is preserved by these features. In ATAD, we not only take account of the simple descriptive features (statistical values), but also the order-aware features (forecasting error features and temporal features).

- For a time series, it is a problem what granularity transfer learning should be performed at. We can conduct transfer learning on entire time series, subseries, or discrete time points. If transfer learning is performed at a coarse-granularity (e.g. the entire time series or subseries) that contains several different anomalous patterns, it is not conducive to distinguish them. Further, coarse-granularity anomaly detection leads to the difficulty of locating and retrieving the cause of anomalies. In this work, we aim to conduct anomaly detection at a fine granularity (i.e. for each data point), and so we perform transfer learning at the level of data point.

- Transfer learning requires that the source domain and

the target domain have the underlying similarity. However, the time series generated from various components in a large-scale cloud system could be very different. We should guarantee that the source domain and the target domain come from similar services or have similar characteristics. Thus, during the transfer learning process, we need to filter out those source-domain samples that are not similar to the counterpart in the target domain.

Fig. 2 shows the workflow of the Transfer Learning Component. The following subsections describe our algorithm in detail.

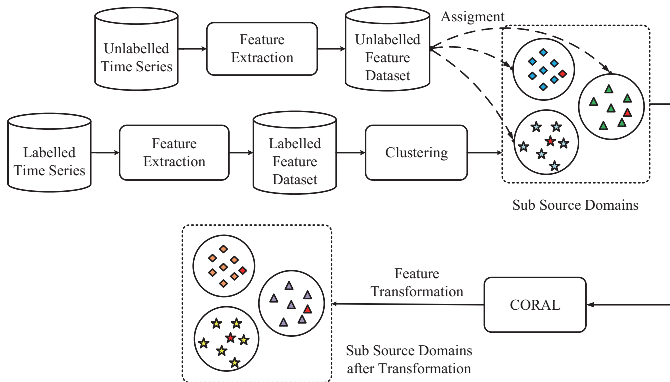

Figure 2: Transfer Learning Component

3.1.1 Feature Identification

The feature engineering process of ATAD converts each data point in a time series (T_l) into a set of features (F_l), which can capture both contextual and temporal information around the point. These features can be categorized into three groups: statistical features, forecasting error features, and temporal features.

Before computing the value of these features, we use Discrete Fourier Transform (DFT) to estimate the period p of the most dominant frequency. Different periods determine different sizes of the sliding window used in the following process.

Statistical features: Statistical features describe some basic characteristics around each data point in time series. We hold a view that the statistical features are able to describe the basic characteristics of different time series generated from various sources in cloud systems, and it is conducive to detecting anomalies that violate the basic characteristics. For example, in an active-running computation intensive service, if the average CPU utilization over a time window tends to be low, it may be an indicator that part of the computation process on it halts unexpectedly.

We identify features for depicting statistical characteristics of time series data (as listed in Table 1). These descriptive features are all calculated in a rolling window derived from the period p. They can represent short-period aspects of time series data such as mean, variance, autocorrelation, trend, remainder, and stationary test.

Table 1: Statistical Features

Feature	Description
Mean	Mean.
Var	Variance.
Crossingpoint[18]	The number of crossing points.
ACF1	First order of autocorrelation.
ACFremainder	Autocorrelation of remainder.
Trend	Strength of trend.
Linearity [18]	Strength of linearity computed on trend of STL [5] decomposition.
Curvature [18]	Strength of curvature computed on trend of STL [5] decomposition.
Entropy [18]	Spectral entropy [12].
ARCHtest.p [9]	P value of Lagrange Multiplier (LM) test for ARCH model [8].
GARCHtest.p [24]	P value of Lagrange Multiplier (LM) test for GARCH model [8].

Forecasting error features: Following the prior work [22], we use a set of error metrics resulted from time series forecasting as features. The intuition is that if the value of current point deviates from the forecasting result, there is more likely to be an anomaly. We use ensemble models to carry out forecasting and apply different models based on the seasonality of the time series. The models leverage classical forecasting techniques, namely SARIMA [27], Holt [19], Holt-Winters [19], and STL [5] for seasonal data, and SARIMA, Holt, Holt-Winters, and Polynomial Regression [15] for non-seasonal data, respectively. The metric *RMSE* (Root Mean Squared Error) is used to endow different forecasting methods with different weights at a fixed time. More weight should be assigned to more precise forecasting model. The weighted prediction result of the ensemble model from M models at time t is calculated by:

$$\hat{Y}_t = \sum_{m=1}^{M} \frac{\hat{Y}_{m,t}}{M-1} \cdot \left(1 - \frac{RMSE_{m,t}}{\sum_{n=1}^{M} RMSE_{n,t}}\right) \tag{1}$$

where $\hat{Y}_{m,t}$ is the prediction by model m at time t, $RMSE_{m,t}$ is the prediction error of model m at time t, $\hat{Y}_t$ is the ensemble prediction at time t.

After gaining the ensemble prediction $\hat{Y}_t$, we calculate 5 metrics on 3 rolling time windows to measure the bias between predicted and actual values. The metrics are shown

in Table 2, where $\hat{Y}$ is the predicted value, Y represents the actual value, and N is the size of the time window.

Table 2: Metrics used as forecasting error features

Features	Formula	Description
ME	$\frac{\sum(Y_i-\hat{Y}_i)}{N}$	Mean Error.
$RMSE$	$\sqrt{\frac{\sum(Y_i-\hat{Y}_i)^2}{N}}$	Root Mean Squared Error.
MAE	$\frac{\sum\lvert Y_i-\hat{Y}_i\rvert}{N}$	Mean Absolute Error.
MPE	$\frac{1}{N}\cdot\sum\frac{Y_i-\hat{Y}_i}{Y}$	Mean Percentage Error.
$MAPE$	$\frac{1}{N}\cdot\sum\frac{\lvert Y_i-\hat{Y}_i\rvert}{Y}$	Mean Average Percentage Error.

Temporal features: Generally speaking, the drastic changes of system metrics are likely to be anomalies. For example, the sharp decline of disk I/O traffic rate may be caused by the hardware failure in the disk array. To understand the changes of time series data over time, we identify temporal features (as shown in Table 3) by comparing data in two consecutive windows. We also compute the difference between current values and previous w values (e.g., the difference between x_{n-w} and x_n). In our implementation, we set $w = p/2, p, 2p, w_{pr}, w_{pr}/2$, respectively to get the corresponding different values (Diff-w). w_{pr} is selected according to some prior knowledge. For example, if a time series is recorded by hours, we can set $w_{pr} = 24$.

Table 3: Temporal Features

Features	Description
Max_level_shift	Max trimmed mean between two consecutive windows.
Max_var_shift	Max variance shift between two consecutive windows.
Max_KL_shift	Max shift in Kullback-Leibler divergence between two consecutive windows.
Lumpiness	Changing variance in remainder.
Flatspots	Discretize time series values into ten equal-sized intervals. Find maximum run length within the same bucket. [18].
Diff-w	The differences between the current value and the w-th previous value.

In summary, with original time series value, we extract total 37 features used to capture the characteristics of time series data. It is also worth mentioning that all those features are normalized in order to make them comparable among different time series.

3.1.2 The Transfer between Source Domain and Target Domain

In order to transfer knowledge between the source and target domains, it is necessary to narrow the difference between the two domains. Considering the effectiveness and efficiency requirements in the anomaly detection task, we propose a transfer method combining the instance-based transfer learning and feature-based transfer learning.

In transfer learning, we should guarantee that the source domain and the target domain come from similar fields (such as similar monitoring data) or own similar characteristics (such as trend or period). However, the source domain may consist of various time series data. Thus, the first step of transfer learning is to collect the time series data from the source domain that are similar to the data in the target domain. In ATAD, we use instance-based method to filter out those source-domain samples which are not similar to the counterpart in the target domain.

The idea of instance-based transfer learning is to select the source-domain samples which are similar to samples in the target domain so that the difference between two domains can be reduced. For source domain, after identifying features and converting T_l into F_l, we perform *K-means* [29] algorithm on F_l to build K clusters. Each cluster F_l^i $i \in [1,K]$ is a subset of F_l without overlap, which can be regarded as a sub source domain. To select the similar samples, firstly, the same feature extraction process is applied to the unlabelled time series data T_u to form feature dataset F_u. Then we calculate the Euclidean distance between each unlabelled sample and the central point of each cluster. Each target-domain sample will be assigned to the nearest sub source domain F_l^i. We denote the testing samples which are assigned into the same cluster as F_u^i $i \in [1,K]$.

After the instance-based transfer, we need to further narrow the difference between target domains and corresponding sub source domains from the perspective of feature space, because the distribution of features may still remain different. In ATAD, we conduct CORrelation ALignment (CORAL) [37] on each cluster, which is the idea of the feature-based transfer learning process. CORAL is a domain adaption algorithm, which can align the second-order statistics, namely, the co-variance of the source and target features in an unsupervised manner. Specifically, CORAL aims to minimize the Frobenius norm between co-variance matrices of the target and source domains, as shown in Eq. 2.

$$\min_A \left\| A^T C_l^i A - C_u^i \right\|_F^2 \tag{2}$$

where A is a linear transformation matrix, C_l^i is the co-variance matrix of labelled data in cluster i, and C_u^i is the co-variance matrix of unlabelled data in cluster i. We can get the optimal solution of A by whitening source data and re-coloring with target co-variance method, i.e. CORAL. More

details can be referred in [37]. Finally, we can get the new sub source domain features data $\hat{F}_l^i$ after transformation.

In the last step, we train a base supervised model, like Random Forest (RF) or Support Vector Machine (SVM), on each sub source domain $\hat{F}_l^i$. In the end, we can get K independent base models.

Some notes about the proposed transfer learning component:

- Base model: we use Random Forest as the supervised machine learning model (i.e. the base model) in our implementation. Random Forest can be implemented in a parallel way thus it owns high efficiency.
- Computational framework: we emphasize that this component can be regarded as a computational framework. In fact, the choices of distance measurement, clustering method, and base model are flexible.
- Assignment complexity analysis: when assigning unlabelled samples, we need to calculate the distance between each sample in the unlabelled set and the center points of all clusters (sub source domains). This time complexity is $\mathcal{O}(m \cdot K)$, where K is the number of clusters and m is the size of F_u. K is generally much less than m and can be regarded as a constant, so $\mathcal{O}(m \cdot K) \approx \mathcal{O}(m)$. Therefore, our assignment process has linear complexity.
- Parallel processing: it is worth noting that the sub source domains are completely independent to each other, which means that the follow-up processes for each sub source domain could be conducted in a parallel manner. This can help improve the efficiency of anomaly detection.

3.2 Active Learning Component

Due to the high complexity of the cloud service systems, the time series generated from different components are characterized by great diversity. Thus, transfer learning technique is not enough to achieve satisfactory results on various time series in cloud. In ATAD, leveraging active learning method, the diversified data with specific characteristics can be addressed with a small amount of labelling effort.

Active learning focuses on minimizing the labeling effort of users and improving the accuracy of the prediction model. In this work, we utilize an active learning method that considers *Uncertainty* and *Context Diversity* of samples during sampling. We call it UCD for short.

3.2.1 Uncertainty

Most active learning methods use *uncertainty* as the principle to select samples for labelling [33] because it is believed that if a model is less certain about the classification results of some samples, labelling such samples would be more helpful to the base model. In our approach, we use the base model (Random Forest) to estimate the probability of an unlabelled data to be normal or anomalous. We then use the following formula to calculate the uncertainty for unlabelled samples:

$$Uncertainty = -\left|Prob(Normal) - Prob(Anomaly)\right| \quad (3)$$

where *Prob* represents the probability given by the base model.

We calculate the uncertainty according to Eq. 3 and sort them in descending order. The larger the uncertainty, the more it needs to be labelled.

3.2.2 Context Diversity

To recommend samples to be labelled, *diversity* is also an important factor to be considered. Sometimes, two samples are very similar or may belong to the same anomaly pattern. It is unnecessary to label both of them.

Traditional diversity methods are generally based on clustering [7], which do not consider the context of samples in time series scenario. In cloud systems, time series of system metrics, such as CPU utilization or traffic load, are continuous without drastic breakpoints. Thus, samples that are adjacent in time series tend to be similar. Our active learning algorithm makes full use of this property in time series.

Specifically, we sort all samples by uncertainty and scan them sequentially. If a new sample we scanned is in the context of another sample in the candidate set, i.e. these two samples are adjacent to each other, we hold a view that the information embedded in them could also be similar. We thus ignore the new sample because it may contain redundant information. If the new sample does not appear in the context of all samples in the candidate set, it is added to the candidate set. In our work, the context of sample x_t is controlled by a parameter α, which represents a range from $x_{t-\alpha}$ to $x_{t+\alpha}$ in a time series. Fig. 3 illustrates the concept of context diversity in a time series. More details can be found in Algorithm 1.

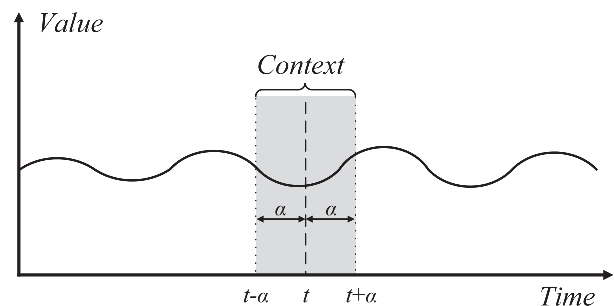

Figure 3: Context in time series

For each source domain, we perform active learning on its own testing data F_u^i. We recommend d diverse and uncertain samples to be labelled, and add the labelled samples into the training set to retrain the base model. After repeating T rounds of this process, we obtain the final detection model.

Algorithm 1: Active Learning Component

Input:
labelled feature data from source domain F_l;
unlabelled feature data from target domain F_u;
base model M_{base} obtained from F_l;
the number of samples at each round d;
context parameter α;
the number of rounds T;

Output: Final model M_{final};

```
1  M = M_base
2  for i = 1 to T do
3      Candidate Set, S = ∅
4      Prob(Normal), Prob(Anomaly) = M(F_u)
5      Uncertainty =
         −|Prob(Normal) − Prob(Anomaly)|
6      Uncertainty_Candidate = argsort(Uncertainty)
7      for j = 1 to S.size() do
8          if S == ∅ then
9              S = S ∪ Uncertainty_Candidate[j]
10             continue
11         end
12         if S.size() > d then
13             break
14         end
15         if Uncertainty_Candidate[j] ∉
             [x_{t−α}, x_{t+α}], ∀x_t ∈ S then
16             S = S ∪ Uncertainty_Candidate[j]
17         end
18     end
19     label the S as F_fed
20     F_l = F_l ∪ F_fed
21     M = M.train(F_l)
22 end
23 return M as M_final
```

3.3 Usage of ATAD

Transfer learning and active learning are only conducted in the training process. Once the training of ATAD finished, a classifier will be generated and further applied to anomaly detection task in practice. The detection process of ATAD is as follows: Firstly, we feed the time series data to be detected into the feature extraction component and extract features as the training process does. After that, the features are input to the trained classifier to get the anomaly probabilities. Finally, the points whose probabilities are higher than a pre-specified threshold are predicted as anomalies. This pre-specified threshold can be treated as the sensitivity parameter for adapting to different requirements of various users and scenarios.

4 Experiments

In this section, we evaluate the effectiveness of our approach ATAD through a series of experiments. We aim to answer the following research questions in evaluation:

RQ1: How effective is the proposed ATAD approach?

RQ2: How effective is the Transfer Learning component?

RQ3: How effective is the Active Learning component?

RQ4: How effective is ATAD in detecting anomalies in a company's local dataset based on public datasets?

4.1 Dataset and Setup

We use two public time series anomaly detection datasets, NAB [23] and Yahoo [22], to evaluate our proposed method. NAB is a novel benchmark for evaluating anomaly detection algorithms in streaming, real-time applications. It contains datasets collected from different fields, including AWS, Twitter, and Artificial, etc. Each dataset contains several time series of variable length. The AWS dataset contains different server metrics, such as CPU utilization, network traffic, disk write bytes, etc, collected by the Amazon CloudWatch service. The Artificial dataset contains artificially generated time series data with various types of anomalies, while the anomaly patterns are much simpler. The Twitter dataset is the collection of Twitter mentions of large publicly-traded companies such as Google and IBM. The Yahoo dataset consists of metrics of various Yahoo services, which reflects the status of Yahoo system. All datasets are given in time series form and every data point is manually labelled. These time series range in length from hundreds to thousands. The proportion of anomaly is about 1% $\sim$ 5%.

In the experiments, we use Yahoo, AWS, Artificial and Twitter datasets as the testing set (target domain). There are two reasons for this choice. First, these datasets are related to cloud monitoring data. Second, the scale of these datasets are relatively large, or the anomalous points are also much more than other datasets. More details about datasets are shown in Table 4. The first column is the average length of time series. The second and third columns are the total number of data points and the number of anomalies, respectively. We also show the percentage of anomaly data points in the last column.

We perform cross-dataset anomaly detection according to our setup. The experiments are conducted on four pairs of datasets, including non-Yahoo→Yahoo, non-AWS→AWS, non-Twitter→Twitter, and non-Artificial→Artificial. The right side of the arrow represents the unlabelled testing

Table 4: Summary of datasets

Dataset	time series mean length	#data points	#anomaly points	%anomaly
Yahoo	1415	92016	1617	1.76%
AWS	3985	67740	3097	4.57%
Artificial	4032	16128	624	3.87%
Twitter	15862	142765	217	0.15%

dataset, i.e. target domain and the left side of the arrow represents the labelled dataset from other fields. The labels of the target domain are not used during the training and transfer learning process. They are only used during active learning and evaluation.

4.2 Evaluation Metric

We evaluate the accuracy of anomaly detection methods using F1-Score, which is defined as follows:

$$F1 = \frac{2 \cdot P \cdot R}{P + R}, \quad P = \frac{TP}{TP + FP}, \quad R = \frac{TP}{TP + FN} \tag{4}$$

where P and R denote the precision and recall, respectively. In addition, TP, FP, FN, and TN are referred to as true positive, false positive, false negative, and true negative, respectively. We might fail to detect potential anomalies if only focus on the precision. On the other hand, a couple of false positives might be received when we solely pay attention to the recall. F1-Score builds up the balance of the precision and recall, is therefore used as the main evaluation metric in our experiments.

Under an acceptable recall, we expect the anomaly detector to achieve as high precision as possible. The more precise the detector is, the less amount of false alarms will be reported, and thus less human effort is required to investigate. Therefore, precision can be regarded as an important metric, which reflects the automation degree of anomaly detection systems.

4.3 Results

4.3.1 RQ1: How effective is ATAD?

In this section, we evaluate the effectiveness of our proposed approach, ATAD. First, we compare ATAD with some commonly-used anomaly detection algorithms to examine the superior performance of the proposed approach. Second, we present the advantages of ATAD in saving labelling cost, as a comparison with supervised learning based anomaly detectors.

The comparative anomaly detection algorithms are developed based on Isolation Forest (iForest) [26], K-Sigma [14], Seasonal Hybrid ESD (S-H-ESD) [16] and Random Forest (RF). The iForest model ensembles random split tree models to identify which points are isolated. K-Sigma is a common statistics-based method, in which the samples are taken as anomalies whose values deviate more than k times of the variance of samples from the corresponding mean. S-H-ESD builds upon the Generalized ESD test [32], and is able to detect both global and local anomalies. This algorithm is incorporated in the well-known *AnomalyDetection* R package [39] and thus is widely used. Because the RF is used in ATAD as the based learning classifier, we exploit a classical RF based supervised model as a comparison to demonstrate the superior performance of ATAD. The RF and iForest models use the same features as the ATAD. The K-Sigma and S-H-ESD are performed on the raw time series.

In the experiments, we evaluate the metrics under different settings and present the best results in terms of F1-Score in the following. Towards this end, the proportion of anomalies in iForest is set to 0.01, 0.05, 0.10 and 0.20, respectively, and the integer k varies from 1 to 3 in K-Sigma. In addition, the maximum proportion of anomalies in S-H-ESD is set to 0.01 and 0.05, respectively. We labelled the same proportion of samples for RF as the counterpart in ATAD used in the target domain. In ATAD, the K in the Transfer Learning component changes from 3 to 5, whereas the number of rounds T and the labelling ratio are fixed to 3 and 1%, respectively, in the Active Learning component. The probability threshold is set to $0.6 \sim 0.8$.

The results are shown in Table 5. It is clear that the ATAD can achieve much higher F1-Scores than other approaches on all datasets. Particularly, though the supervised learning method (RF) achieves better performance than those unsupervised methods, the ATAD outperforms the RF when given the same number of labels.

In order to demonstrate the advantages of ATAD in saving labelling efforts, we compare the number of labelled samples of ATAD and RF under the similar F1-Scores. The relevant results are presented in Table 6, whose first and third column depicted the F1-Scores of the supervised model (RF) and the ATAD, respectively. Their corresponding quantities of labelled data are included in the second and fourth column of Table 6. It is evident that the supervised model generally takes $3 \sim 10$ times more labels than the ATAD to achieve comparable results. The superior performance benefits the transferred knowledge from the source domain in the Transfer Learning component. As a consequence, a small number of labels is required in the target domain. Moreover, the UCD method helps to further reduce the number of labels because the performance can be improved rapidly and significantly by the extraordinary informative recommendations in the Active Learning component.

Table 5: Results of Comparative Methods

Dataset	Method	Precision	Recall	F1-Score
Non-Yahoo → Yahoo	iForest	0.3832	0.2183	0.2781
	K-Sigma	0.6499	0.3364	0.4433
	S-H-ESD	0.2779	0.6215	0.3840
	RF	0.8668	0.2075	0.3348
	ATAD	0.8847	0.4040	**0.5547**
Non-AWS → AWS	iForest	0.1523	0.0491	0.0743
	K-Sigma	0.6899	0.1992	0.3091
	S-H-ESD	0.5382	0.7100	0.6123
	RF	0.9999	0.6226	0.7674
	ATAD	0.9195	0.8142	**0.8637**
Non-Artificial → Artificial	iForest	0.3477	0.9006	0.5017
	K-Sigma	1.000	0.1730	0.2950
	S-H-ESD	0.7888	0.4568	0.5785

Non-Twitter → Twitter	iForest	0.4685	0.3087	0.3722
	K-Sigma	0.2608	1.0000	0.2608
	S-H-ESD	0.7481	0.4654	0.5739
	RF	0.7285	0.4811	0.5795
	ATAD	0.8769	0.6951	**0.7755**

Table 6: Supervised Model (Random Forest) vs. ATAD

	RF	#labels	ATAD	#labels
Non-Yahoo → Yahoo	0.5440	4600	0.5547	920
Non-AWS → AWS	0.8403	763	0.8637	254
Non-Artificial → Artificial	0.9755	1612	0.9924	161
Non-Twitter → Twitter	0.7126	17131	0.7755	1427

4.3.2 RQ2: How effective is the Transfer Learning Component?

We evaluate the effectiveness of our Transfer Learning Component from the following two aspects:

- The effectiveness of identified features, including forecasting error, statistical, and temporal features.
- The effectiveness of our proposed transfer method.

Effectiveness of the identified features Our proposed transfer learning is based on many time series features including forecasting error, statistical, and temporal features. The conventional transfer learning is only based on statistical features such as averages and variances [30]. The statistical features are simple descriptive values that are independent of the context of time series.

In order to evaluate the validity of features used in ATAD, we perform an experiment on four dataset pairs. We compare ATAD using statistical features alone and ATAD using order-aware features (forecasting error features and temporal features).

Experimental results are shown in Table 7. It can be seen that using statistical features alone for ATAD leads to poor results, and when order-aware features are added, the performance becomes better. The reason is that the transfer learning needs to narrow the differences between the source domain and the target domain. If only statistical features are extracted and the characteristics of time series are ignored, the features do not reflect the context property in time series. Thus the resulting performance is less satisfactory.

Table 7: The effectiveness of features (F1-Score)

Features	Yahoo	AWS	Artifical	Twitter
Statistical	0.2956	0.7387	0.7441	0.6937
Order-aware	0.4200	0.8441	0.7569	0.6622
All features	**0.5781**	**0.8637**	**0.9924**	**0.7755**

Random Forest also provides a popular approach to feature ranking. Here we use the Random Forest classifier to evaluate the importance of the features used in ATAD. The importance of a feature can be ranked according to the mean decrease impurity [3]. In Table 8, we show the top-10 most important features of the RF models in ATAD. The definitions of these features can be found in Table 1, Table 2 and Table 3. We can see that the forecasting error features and the original time series are much more informative for anomaly detection. In addition, some temporal features, such as Diff-*w* and Flatspots, also play an important role in the model. It is also worth noting that the important features of each dataset are different. It implies that we should consider all the features comprehensively when conducting transfer learning between different datasets.

Effectiveness of the proposed transfer method In our transfer learning, we create multiple independent sub source domains through clustering and conduct the CORAL algorithm to transform the features of sub source domains. We expect the transfer learning can reduce the labelling effort for users, because we can activate the Active Learning component directly based on the transfer model, without any manual labels in the testing set. We validate the effectiveness of our Transfer Learning component by comparing with

Table 8: Feature Importance Evaluation

Dataset	Important Features
Yahoo	Original_data, RMSE, MAE, ME, Mean, MPE, Diff-p, Diff-$w_{pr/2}$, Diff-2p, MAPE
AWS	Original_data, RMSE, MAE, ME, Mean, ACF1, Diff-2p, Curvature, Flatspots, Diff-p
Artificial	Original_data, Mean, Diff-p, MPE, Flatspots, RMSE, MAE, Diff-2p, Diff-w_{pr}, Lumpiness.
Twitter	Var, RMSE, MAE, ARCHtest.p, Mean, Flatspots, Original_data, Max_level_shift, MPE, Original Data

naive active learning applied directly on target domain without transfer methods.

Specifically, in the naive method, we pre-fetch a part of samples in the testing dataset to train a base model. After that, we use this base model to conduct the active learning process. This naive active learning approach needs no auxiliary public labelled data as source domain and transfer learning technique, but it needs more labelling effort for building the base model, as illustrated in Table. 9.

Table 9: Comparative Experiment of ATAD and Naive Active Learning without Transfer Learning (F1-Score)

	Naive		ATAD	
	F1-Score	#labels	F1-Score	#labels
Yahoo	0.5691	1380	0.5697	920
AWS	0.8589	381	0.8637	254
Artificial	0.9815	322	0.9924	161
Twitter	0.6164	2855	0.7755	1427

In Table 9, we fix the labelling ratio of the active learning process to 1% in both Naive method and ATAD. For fairness, in the naive method, we pre-fetch samples from the testing set in stratified style to train the base model. From the table, it can be seen that the number of samples required for the naive method without transfer learning component is, in average, 1.56 times than that of ATAD, but its results are still slightly lower than those achieved by ATAD. We also illustrate the number of labels required by the supervised model, naive active learning model without transfer methods, and ATAD in Fig 4. It is clear that active learning can significantly save labelling effort and ATAD can further reduce the labelling cost by introducing the transfer learning component.

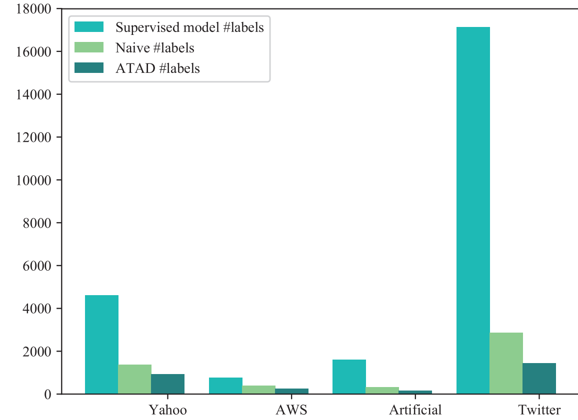

Figure 4: The number of labels required by Supervised Model, Naive Active Learning without transfer learning and ATAD

Table 10: The experimental result with active learning alone (F1-Score)

Dataset	Method	Base	Round1	Round2	Round3
Yahoo	U	0.2090	0.2437	0.2839	0.2695
	UCD	0.2090	0.2383	0.3032	**0.3814**
	random	0.2090	0.2275	0.2256	0.2196
AWS	U	0.0443	0.1932	0.6838	0.6799

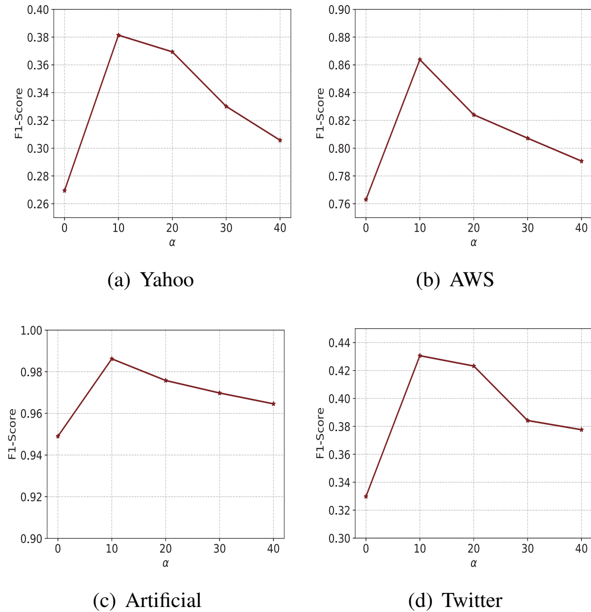
	random	0.0443	0.3227	0.5164	0.6604
Artificial	U	0.6239	0.7272	0.8737	0.9006
	UCD	0.6239	0.7340	0.8780	**0.9715**
	random	0.6239	0.6446	0.6275	0.5000
Twitter	U	0.1647	0.2916	0.2959	0.3298
	UCD	0.1999	0.3070	0.3703	**0.4232**
	random	0.1647	0.1798	0.1944	0.1689

4.3.3 RQ3: How effective is the Active Learning component?

To evaluate the effectiveness of the Active Learning component, we use total labelled datasets F_l to train the base model and do not apply transfer learning on them. We compare the UCD method with the conventional Uncertainty method (U) and the random selecting method (random). In all experiments, we conduct 3 rounds of active learning and select 60 samples for labelling at each round. In order to avoid the data leakage problem [20], all samples labelled by the active learning component are removed from the testing set. The experimental results are shown in Table 10.

From Table 10, it can be seen that the UCD method achieves the best results on all datasets, confirming the usefulness of incorporating time series context diversity. We

also find that as the number of rounds increases, the F1-Scores achieved by UCD are also steadily improved. However, the random selection method cannot guarantee such trend. The results confirm the validity of the active learning method.



(a) Yahoo (b) AWS

(c) Artificial (d) Twitter

Figure 5: Experimental results with different α

The hyper-parameters in the Active Learning component include the number of samples to be labelled per round d, the number of rounds T, and the context parameter α. Obviously, if T and d are much larger, the entire algorithm will be closer to supervised learning. Therefore the accuracy will be improved gradually.

We conduct an experiment to explore the impact of different α values on the final results. In Fig. 5, we can see that as the α value increases, the F1-Score rises rapidly first and then falls gradually. The larger α means the wider range of context and more attention to Context Diversity because the wider context will cause more uncertain candidate samples to be discarded. The smaller α means the narrower range of context and more attention to Uncertainty. If $\alpha = 1$, UCD becomes purely U. Therefore, α can be treated as a parameter which trades off between Context Diversity and Uncertainty. Too large or too small α value will result in loss of accuracy. In conclusion, choosing an appropriate α can make full use of both kinds of information. Through our practice on all experimental datasets, we empirically set $\alpha = 10$.

4.3.4 RQ4: How effective is ATAD in detecting anomalies in a company's local dataset based on public datasets?

In RQ1, we examined the performance of ATAD on public datasets. In this RQ, we evaluate its effectiveness by using practical industrial data from the large-scale cloud system in Microsoft. More specifically, we hourly record IOPS (I/O Operations Per Seconds) of the storage service in a cluster and collect the corresponding time series data in the past few months. The data is labelled by domain experts in the operation team. All public datasets are utilized as the source domain, and then the ATAD is applied to the target domain dataset, i.e., the IOPS data, for anomaly detection. The experiment is conducted as the similar process in RQ1.

Table 11: Experimental result on IOPS dataset of Microsoft

	Precision	Recall	F1-Score
iForest	0.2886	0.3988	0.3349
K-Sigma	0.8170	0.1882	0.3059
S-H-ESD	0.9117	0.1741	0.2924
RF	0.5213	0.6724	0.5873
ATAD	0.8082	0.6188	**0.7009**

The results are shown in Table 11. It is noted that the traditional unsupervised methods cannot work well due to the low recalls and the resulting F1-Scores. The extremely low recalls exhibit a high probability in failing to detect potential anomalies, which might cause a huge customer and financial loss. RF can achieve a higher recall but lower precision, which means lots of false alarms. In contrast, ATAD can achieve a higher F1-Score, which is beneficial to improving the service availability and detection automation.

5 Threats to Validity

- Data quality: in this work, we use public datasets in evaluation. The labels about anomalies are provided with the datasets. Although these dataset are of high quality and are used by several other studies [23, 22], it is possible that they contain a small degree of noise. Furthermore, their data volume is also limited. We will experiment with larger scale datasets in our future work.

- Correctness of labelling: the Active Learning component in ATAD requires users to manually label a few percentages of data and assumes that the labels are correct. However, in reality, the quality of labeling may vary (i.e., users may incorrectly label a data point).

- Data leakage: in order to avoid the data leakage problem, we remove the samples labelled in the active learning process from the testing set. Since active learning

may recommend different samples to be labelled at different rounds, the resulting testing set could be slightly different in each experiment, which may cause bias in comparisons. However, the proportion of samples to be labelled is very small, so we can ignore this influence on the final results.

6 Related Work

In recent years, there have been many studies on anomaly detection problem for time series data. The proposed methods can be largely divided into supervised methods, semi-supervised methods, unsupervised methods and statistical-based methods [4].

Unsupervised methods do not require manual labelling. These methods assume that normal instances are far more frequent than anomalies and anomalies deviate from the normal data distribution. For example, Ahmad, et al. proposed an unsupervised online sequence memory algorithm called Hierarchical Temporal Memory to detect anomaly in streaming data [2]. Xu, et al. proposed Donut, an unsupervised anomaly detection algorithm based on Variational Auto Encoder (VAE) [41].

Supervised methods aim to build a classification model for normal and anomaly classes. General supervised machine learning models can be applied to this problem. Steinwart, et al. interpreted anomaly detection problem as a binary classification task and proposed a supervised framework [36]. The most famous is the anomaly detection system of Yahoo, called EGADS [22], which used a collection of anomaly detection and forecasting models with an anomaly filtering layer for accurate and scalable anomaly detection on time series. Opperentice [25] used operators' periodical labels on anomalies to train a random forest classifier and automatically select parameters and thresholds.

Semi-supervised methods assume that the training data has labelled instances for only the normal class. Malhotra, et al. used stacked LSTM networks trained on non-anomalous data as a predictor to detect anomaly [28]. Erfani, et al. used a combination of one-class SVM model and deep learning model to detect anomaly [10]. Daneshpazhouh, et al. presented an entropy-based method that consists of two phases, including reliable negative examples extraction and entropy-based outlier detection [6].

Statistical-based methods are built up based on the statistical theory. The most famous method is K-Sigma method [14], in which the samples are taken as anomalies whose values deviate more than k times of the variance of samples from the corresponding average. Recently, more advanced methods using Extreme Value Theory [34, 42] were proposed. Compared with K-Sigma method, these methods do not require prior assumption on the data distribution.

From the view of effectiveness, supervised and semi-supervised methods generally perform better than unsupervised methods and statistical-based methods. However, due to the high labelling cost, they are difficult to be applied in the real world when the scale of dataset is very large. More recently, transfer learning and active learning techniques are applied to deal with this important problem. Transfer learning has been widely applied in many fields like classification, regression, and forecasting [30]. For example, Spiegel, et al. embeds a given set of labelled data into dissimilarity space, leading to enriched feature representations that facilitate statistical learning procedures [35]. Vercruyssen, et al. transferred labelled examples from a source domain to a target domain where no labels are available and constructed a nearest-neighbor classifier in the target domain with DTW measure [40]. Another technique to reduce the labelling effort is active learning. For example, Abe, et al. used a selective sampling mechanism based on active learning to the reduced classification problem of outlier detection [1]. Pelleg, et al. proposed a novel active learning method to identify rare category records in an unlabelled noisy set with a small budget of data points that they are prepared to categorize [31].

In our work, we combine transfer learning and active learning methods so that we could achieve a balance between labelling effort and performance. On the one hand, unlike unsupervised models, ATAD could achieve a high F1-Score. On the other hand, we only need to label a few number of samples from the unlabelled dataset. These advantages are not possessed by the existing methods mentioned above.

7 Conclusion

In this paper, we propose a novel anomaly detection method ATAD for cloud service systems. ATAD combines transfer learning and active learning techniques. In transfer learning, we use an existing labelled dataset as the source dataset. We extract multiple features, construct source domains, and use the labelled data in each source domain to train base models for a target, unlabelled dataset. In active learning, we use the UCD method to recommend informative samples in the target dataset to label and retrain the base models. Our experiments on cross-dataset anomaly detection show that we can achieve satisfactory detection accuracy by labeling only a small number of samples in the target dataset. We have also evaluated the effectiveness of ATAD using real-world data collected from a production cloud system in Microsoft.
