- **BigBand:** [21] leverages sparse Fourier transform and uses co-prime sampling to acquire sparse spectrum. It achieves 6× sub-sampling below the Nyquist rate, but only works when the spectrum is sparse.
- **D-BigBand:** [43] extends BigBand to sense dense spectrum by considering the differential changes in occupancy. It also achieves 6× sub-sampling, but assumes the changes in the spectrum occupancy over time are sparse.
- **SweepSense:** [20] enhances USRP software-defined radio's ability to quickly scan and sense wideband spectrum. It is able to scan 5 GHz bandwidth in 5 ms with 2×25 MS/s ADC sampling rate.

Table 1: Sum of false positives and negatives for S^3 and State-of-the-Art prior work: The table compares the sum of FPR and FNR of S^3, BigBand, D-BigBand, and SweepSense at different spectrum occupancies.

	BigBand	D-BigBand	SweepSense	S^3
10%	0.38% + 14% (unresolved)	$\sim$ 0.95%	4.88%	0.00%
50%	N/A	$\sim$ 1.75%	13.09%	1.29%
90%	N/A	$\sim$ 3%	13.76%	2.47%

Table 1 shows the sum of FPR and FNR when the total spectrum occupancy is 10%, 50%, and 90%. We compare S^3 directly to the results reported in [21] and [43], because they used custom hardware but were evaluated using the same metrics as ours. One can see that in sparse spectrum (<10% occupied) where BigBand works, BigBand has a total error rate of 0.38% but still cannot recover the status of 14% of the spectrum. In contrast, S^3 accomplishes a 0% error rate at such low spectrum occupancy and samples 8.5× below the Nyquist rate, which exhibits a 1.4× gain over BigBand.

D-BigBand is able to work in densely occupied spectrum. It has a total error rate of 0.95% and 3% when the spectrum is 50% and 90% occupied respectively. However, S^3 is able to outperform D-BigBand at all occupancy levels with a 1.2× to 1.35× gain in accuracy. Moreover, S^3 also achieves 1.4× gain in sampling rate reduction and makes no assumptions on the changes in spectrum occupancy. Therefore, unlike D-BigBand, S^3 can monitor highly dynamic spectrum, which we will demonstrate later in this section.

To compare S^3 to SweepSense, we reproduce SweepSense on a N210 USRP with a CBX daughterboard using the codes and FPGA images released by the authors. We use SweepSense to sense the spectrum generated by our testbed along with S^3. In Fig. 10, we show SweepSense's error rate in detecting occupied bands as we vary the spectrum occupancy between 10% and 90%, and when the modulation scheme is randomly picked by the transmitters. This result shows that SweepSense can work in densely occupied spectrum. When

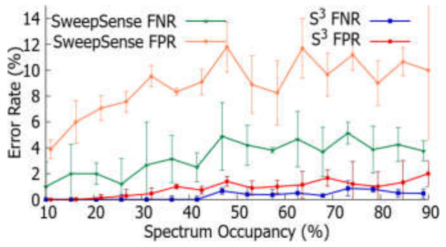

Figure 10: False positives and negatives comparison between S^3 and SweepSense.

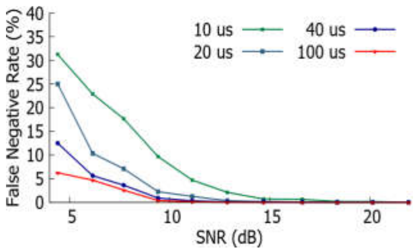

Figure 11: FNR vs SNR and sampling time.

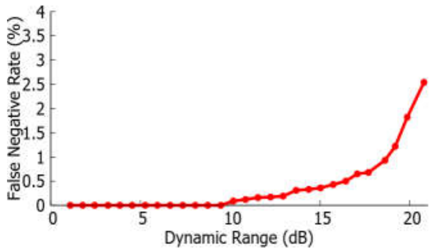

Figure 12: FNR vs dynamic range.

the spectrum is 10% occupied, SweepSense achieves an FPR of 3.88% and an FNR of 1%. As the spectrum becomes more crowded, the FPR and FNR of SweepSense increase, but they remain below 10% and 3.76% respectively even if the spectrum is 90% occupied. SweepSense's higher error rates are likely due to the fact that fast LO sweeping can smear nonempty frequency components, resulting in more leakage from the occupied bands to the adjacent bands, which increases its false positive rates. We also note that, SweepSense requires accurate phase information for the digital chirp demodulation, so it is sensitive to the IQ imbalance in the hardware, which is likely why it underperforms S^3. However, SweepSense is highly valuable as we can combine it with S^3 to capture the power spectral density as we show later in this section.

Next, we present some microbenchmarks that provide more insights into the working of S^3 and its performance.

C. Microbenchmark - Sensitivity:
To understand the ability of S^3 to detect low signal-to-noise ratio (SNR) signals, we examine the FNR of bands with different SNRs. The SNR we show is the average signal power per Hz of RX signal / noise floor. We compare four different sampling duration: 10, 20, 40, and 100 μs. The FNR is high when the SNR is low, however, this can be addressed by increasing the sampling duration. In fact, we can reduce the FNR by $5\times$ at 3dB SNR. As the SNR gets higher, the FNR goes down and down, and eventually even for shoft sampling windows, the FNR is very low ($\approx 0\%$). Note that $40 \sim 100$ μs is a short enough window to detect short transient packets and fleeting signals, as it is comparable to the DIFS duration for Wi-Fi carrier sensing (e.g. 34 or 50 μs).

D. Microbenchmark - Dynamic Range:
Here we evaluate the dynamic range of S^3, which is the ratio between the strongest and weakest signal powers S^3 can accurately detect at the same time. It reflects the ability of S^3 to detect low-power signals with the presence of much higher power signals, that would cause interference and lower the signal-to-noise-pluse-interference ratio (SINR), making low-power signals harder to be detected. In Figure 12, we compare the FNRs in experiments with different dynamic ranges. One can see that S^3 achieves very low FNR ($< 0.63\%$) when the power difference between the occupied bands is up to 15 dB. As the signal power difference becomes even larger, the FNR of S^3 increases. When the spectrum dynamic range reaches ~ 21 dB, the FNR of S^3 is 2.54%. This result shows that S^3 can accurately detect (FPN<1%) the relatively weak signals under interference from signals 19 dB stronger.[5]

E. Microbenchmark - Resolving Collisions with Voting:
We want to verify that through voting using two different sampling rates, S^3 can effectively resolve frequency collisions. To this end, we compare S^3 to baselines where we detect the spectrum occupancy using only one ADC. In Fig. 13(a), we qualitatively compare the correctness of occupancy detection on each band in 20 randomly selected experiments. It shows that when using either ADC alone, we have many false positives due to frequency collisions. However, the two ADCs exhibit false positives in different bands, because they experience frequency collisions between different spikes. As a result, through voting S^3 is able to distinguish and resolve false positives where the two sampling rates disagree with each other. Furthermore, we also quantitatively show the FPR of S^3 and baselines. As can be seen from Fig. 13(b), the FPR of S^3 is much lower than those of baselines, which suggests that our voting scheme can effectively leverage the different sampling rates to resolve frequency collisions. Note that ADC1 outperforms ADC2. This is expected because, as we discussed in section 6, 45.5 MHz is an optimized sampling rate that can spread out the spikes and minimize the frequency collisions. In contrast, the second sampling rate of 52.74 MHz is optimized to avoid having the same collisions as ADC1, so it does not work as well by itself.

F. Monitoring Dynamic Spectrum:
S^3 senses all bands in the spectrum in real-time and makes no assumptions on the changes of spectrum occupancy, so it can monitor highly dynamic spectrum with rapidly-changing occupancied bands. To evaluate this ability of S^3 we create a rapidly-changing spectrum in our testbed whose occupied bands change every 327 μs, and as a result, the total spectrum occupancy varies between 0% and 63%. We use S^3 to continuously monitor the occupancy changes in the spectrum, and output a signal power estimation and occupancy detection for every 76 μs-long frame. We show a spectrogram captured by S^3 consisting the signal power detected in every band per

[5]After wire-bonding, the spike-train filter experiences degradation in the out-of-band suppression due to the direct leakage from the input port to the output port of the PCB. Hence, the sensitivity and dynamic range of S^3 also degrade, but this issue can be resolved by better isolation in the PCB design.

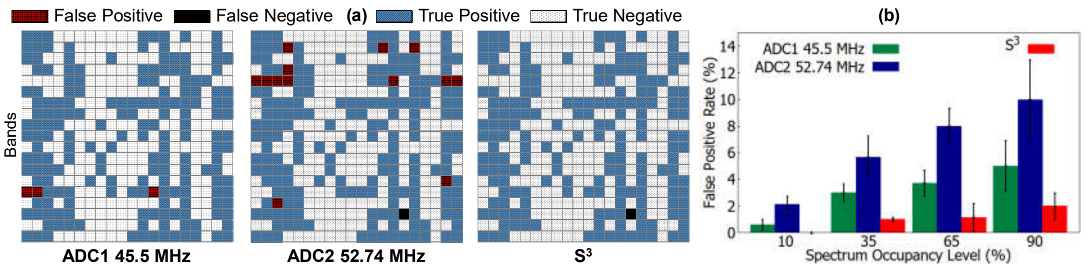

Figure 13: False positives comparison between S^3 and baselines that use single sampling rate: (a) shows the spectrum occupancy detected by S^3 and the baselines in 20 randomly selected experiments. (b) shows the false positive rate comparison as the spectrum occupancy increases.

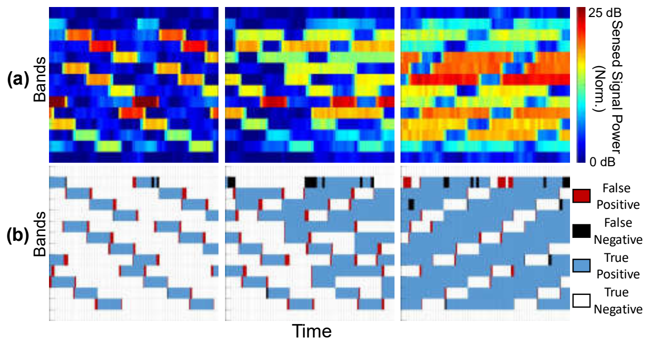

Figure 14: Monitoring rapidly-changing spectrum: The figure shows (a) spectrogram (b) spectrum occupancy captured by S^3 in real time.

frame in Fig. 14(a). Furthermore, we show the accuracy of the corresponding occupancy detection per frame in Fig. 14(b). It shows that S^3 is able to capture the occupancy of rapidly-changing spectrum with great accuracy and time precision.

G. Capturing Wideband Power Spectral Density: As we mentioned in section 7, we can sweep the LO frequency of S^3 over the 22 MHz spacing between spikes to sense all the frequencies in the spectrum. This enables S^3 to capture the power spectral density (PSD) of the entire wideband spectrum. At every LO frequency, S^3 captures signal power in the spike train and identifies the occupancy of each spike. For the occupied spikes, S^3 uses the signal power estimates in them to reconstruct the PSD at the corresponding RF frequencies. When LO sweeping finishes, all frequencies on the wideband spectrum will be reconstructed. Comparing to conventional spectrum scanners, this extended S^3 prototype only needs to sweep a much narrower frequency range. Therefore, the scanning time is much shorter.

Figure 15(a-c) shows the PSD captured by the extended S^3 prototype of spectra generated by our testbed, along with the detected spike occupancy. We use S^3 and an HP 8563E Spectrum Analyzer to monitor the 1.8 to 2.4 GHz spectrum simultaneously. As one can see, the PSDs captured by S^3 match the ground truth from the spectrum analyzer very well. Besides, we also measure PSDs of real-world spectra, both outdoors and indoors, which are shown in Figure 15(d-f). Figure 15(d) shows the spectrum between 1.8 and 2.4 GHz measured outdoor at our geographical location. It shows that S^3 is able to capture the PSD of 4G LTE signals in Band 2 and 66. In Fig. 15(e) and (f), we show the PSD of 2.4 GHz and 5 GHz Wi-Fi signals captured by S^3 respectively. One can see that Channel 1 and 11 in the 2.4 GHz band as well as four non-overlapping 20 MHz channels (Channel 116, 120, 124, and 128) from 5.57 to 5.65 GHz in the 5 GHz band are being used. Figure 15(d-f) demonstrate that the real-world PSDs captured by S^3 also closely match the spectrum analyzer ground truth. On some frequencies that S^3 classifies as empty, the spectrum analyzer shows some non-zero spectral components. However, this is expected because in our experiments, the spectrum analyzer takes the maximum over a lot more scans than S^3.

9 Related Work

In this section, we provide more related work. For further background, we refer the reader to section 2.

Spectrum sensing has been extensively studied in the past two decades [3, 5, 49]. However, most of this work focuses on narrowband sensing [6, 7, 9, 23, 25, 35, 38, 62]. In contrast, this paper focuses on wideband spectrum sensing to enable dynamic spectrum sharing of many channels. Several systems attempt to sense wideband spectrum using narrowband sensors without sequentially scanning each band [42, 46, 61]. QuickSense [61] leverages analog filters and energy detectors to hierarchically sense wide bandwidth by detecting the total signal power in groups of consecutive channels. However, when the spectrum is densely occupied, QuickSense's approach reduces to sequentially scanning the spectrum. SpecInsight [42] leverages machine learning to predict spectrum occupancy based on learned utilization patterns and optimize which channels to sense. Similarly, [46] uses time-series analysis to predict which bands are occupied. However, these systems are sensitive to training data and assume that transmissions follow predictable patterns. Spectrum sharing is based on opportunistic access and as a result is highly dynamic and unpredictable [50].

Recent work aims to enhance USRP software-defined radio's ability to sense wideband spectrum [20, 26]. SweepSense [20] enables sensing wideband spectrum by quickly sweeping the center frequency of the USRP. It is able to sweep 5 GHz bandwidth in 5 ms, which offers great potential for sensing an extremely wideband spectrum on commercial software radios. However, SweepSense requires

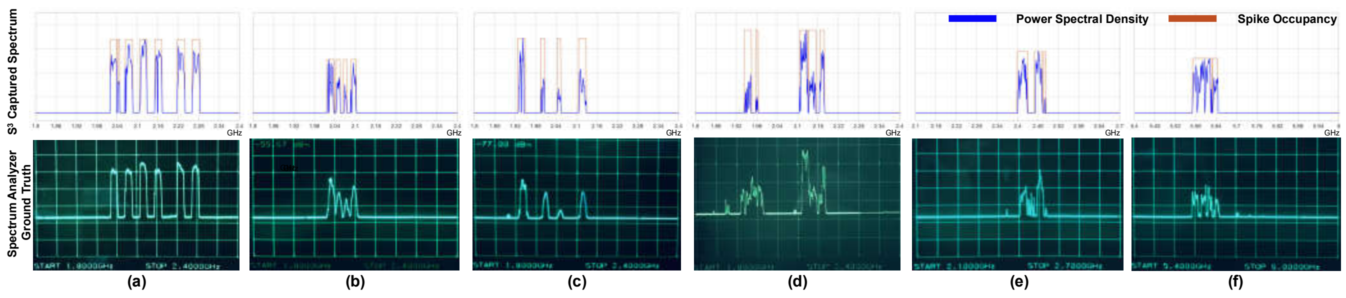

Figure 15: Wideband Power Spectral Density Capture: The figure shows the wideband power spectral density captured by the extended S^3 prototype. Spectrum (a-c) are generated by our evaluation testbed. Spectrum (d-f) are real-world spectra captured both outdoor and indoor.

accurate phase information for the digital chirp demodulation and is sensitive to the IQ imbalance. As a result, our comparison with SweepSense in section 8 shows that it can suffer from a high error rate especially when the spectrum is not sparse. SparSDR [26] reduces the backhaul and computation requirements for sensing sparse spectrum on USRPs, which offers great utility for continuously monitoring underutilized spectra but cannot scale to densely occupied spectrum.

The use of single passband MEMS filters in spectrum sensing has been studied [33, 36]. However, these techniques require an array of channel-select MEMS filters to form a reconfigurable filter bank. In contrast, S^3 only uses a single MEMS spike-train filter that consists of overtone resonators.

Our work is also related to theoretical work on co-prime sampling [54, 56, 57] and multicoset sampling [22, 55] of sparse wideband spectrum. These approaches also do not work for densely occupied spectrum. Moreover, [56, 57] require using k ADCs where k is the number of occupied frequencies. [22, 55] aim to recover the signals in each occupied band and must assume prior knowledge of which bands are occupied. In contrast, S^3 aims to recover the occupancy of each band and uses 2 ADCs irrespective of the number of occupied frequencies. S^3 is further implemented and shown to work in practice.

Sub-Nyquist sampling has been used for test equipment to reconstruct wideband periodic signals [44, 52]. However, these techniques require the signal to be periodic and repeat for a long time in order to take on samples during each period until all samples are recovered. Hence, these techniques are not applicable to real communication signals where the signal is constantly changing and carries different modulated bits.

Finally, some works aim to capture spectrum usage at large geographical and time scales through crowdsourcing [10, 37, 63]. S^3 is complementary to these works, as it enables real-time wideband occupancy detection of every single sensor with minimum data size and computational complexity.

10 Limitations

In this section, we discuss some limitations of S^3.

- The frequency-domain sampling rate and maximum sensing bandwidth is limited by the filter design trade-offs. As a result, narrowband signals (< 20 MHz) and over GHz-wide spectrum cannot be sensed using a single spike-train filter. This can be resolved by hopping the LO frequency as shown in Section 8. Alternatively, we can also use the extended architectures proposed in appendix A that combines multiple spike-train filters in parallel to break the fixed filter-level design trade-offs.
- Sub-Nyquist sampling leads to aliasing of both signals and noise, which typically lowers the signal SNR and degrades the spectrum sensor's sensitivity. To minimize the loss of SINR, we design the spike-train filters to have low insertion loss and high out-of-band suppression i.e., most of the noise is filtered out before it aliases. Moreover, instead of detecting signal power, known signals like the preambles can be leveraged to improve the sensitivity [48]. However, directly applying this technique to S^3 would require further research as the preambles might become corrupted after applying the filter.
- While S^3 can detect the occupancy of the different bands and reconstruct the power spectral density of the spectrum, it cannot recover complex I and Q samples of the signal. As results, S^3 cannot reconstruct the signal itself or decode the data in the signal.

11 Conclusion

This paper presents S^3, a new efficient real-time wideband spectrum sensing mechanism that can work in densely occupied spectrum. S^3 monitors only a small fraction of bandwidth in each band to accomplish significantly below-Nyquist sampling and hence great energy efficiency. It leverages recent advances in RF MEMS filtering solution that enables sampling the spectrum along the frequency axis. Empirical evaluation demonstrates that S^3 can accurately sense densely occupied spectrum and rapidly-changing spectrum; we also show that S^3 can be extended to capture the power spectral density of the entire spectrum. We believe S^3 can enable dynamic spectrum access and very high spectrum utilization.

Appendix A Alternative S^3 Architectures

As we mentioned in section 7, we can extend S^3 to use two or more MEMS filters in parallel to enlarge the sensing bandwidth or enable S^3 to sense different channel allocations including narrower bands and even non-uniformly allocated

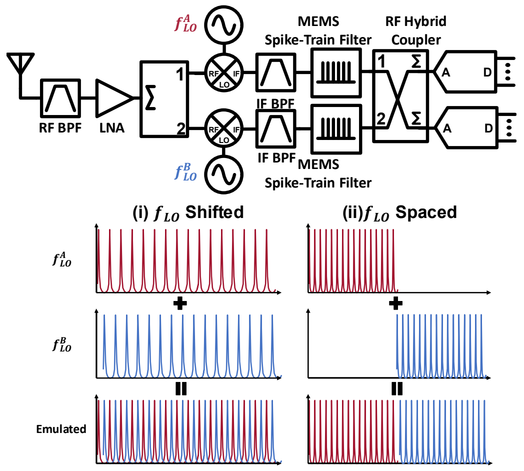

Figure 16: Circuit diagram and emulated spike-train filter for alternative S^3 architecture leveraging LO center frequency difference.

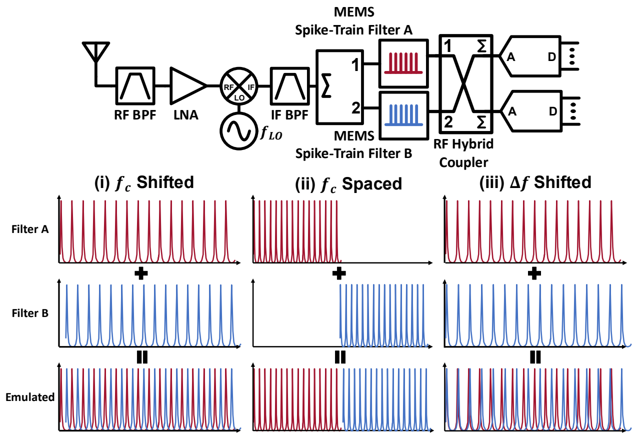

Figure 17: Circuit diagram and emulated spike-train filter for alternative S^3 architecture leveraging different MEMS spike-train filters.

bands. This system level parallelism introduces another degree of freedom and allows us to break the fixed design tradeoffs at the filter level. Here, we present some alternative architectures of S^3 that combine two spike-trains filters.

(1) Changing LO Center Frequencies: First, we can combine two identical spike-train filters that are fabricated using the same process. Hence, these two filters will have almost identical frequency responses with the same center frequency f_c and spacing between spikes Δf. In order to cover different frequencies in the RF spectrum, we use the two filters on separate receiver RF chains with different LO frequencies. We demonstrate the circuit diagram and the emulated spike trains in the RF spectrum in Fig. 16.

After bandpass filtering and amplifying the received signal, we split the RF signal into two channels, and use two LOs with center frequencies f_{LO}^A and f_{LO}^B to down-convert the signal to the IF frequencies. Then we pass each IF signal into a spike-train filter to sampling the spectrum along the frequency axis. Based on the LO frequency difference $df_{LO} = f_{LO}^B - f_{LO}^A$, we can emulate two types of spike trains, as shown in Fig. 16(i) and (ii). When $\Delta f_{LO} < \Delta f$, the two spike trains are slightly shifted on the frequency axis as shown in Fig. 16(i). As a result, we can emulate a spike-train filter with narrower spacing between the spikes. This increases the frequency domain sampling rate of the filter and enables S^3 to sense narrower channel bandwidths. On the other hand, when $df_{LO} = K\Delta f$, the two spike trains are concatenated along the frequency axis as shown in Fig. 16(ii). In this way, a longer spike train with more spikes covering wider bandwidth is emulated.

Although it is straight forward to sample the two IF signals separately, the number of ADCs required will increase linearly with the number of spike-train filters. Instead, after passing IF signals on the two channels through the spike-train filters, we combine the filtered signals and sample the combined signal using two low-speed ADCs. The analog combination and splitting can be achieved using an RF power combiner in series with an RF power splitter, but it can also be done using a RF hybrid coupler. Note that with more spikes in the emulated filter, there will be more aliasing in the subsampled spectrum. Therefore, a higher ADC sampling rate might be needed, but the sampling rate should be able to scale sublinearly with respect to the number of spikes. Besides, the ADC input cutoff frequency needs to be higher than the spike-train bandwidth.

The advantage of this architecture is that we can use the same MEMS spike-train filter on the two channels without needing to redesign a new filter. However, it requires two LOs and mixers which increases the cost and power consumption of the system. [6]

(2) Changing Spike-Train Filter Structure: Instead of introducing a second local oscillator, we can use only one LO and two different spike-train filters to emulate spike trains with wider bandwidth as well as narrower or nonuniform spike spacing. As we mentioned in section 3, we can modify the width of the piezoelectric film and the position of the electrodes to obtain different Δf and f_c. When two spike-train filters with different Δf and/or f_c are combined in parallel, we can emulate a spike train with more sophisticated sparsity structures. We show the circuit diagram for this type of alternative architectures in Fig. 17, along with three emulated spike-train filter frequency responses.

In this architecture, the down-converted IF signal is split and filtered by two different MEMS spike-train filters, whose center frequencies and spike spacing are f_c^A, f_c^B, and Δf^A, Δf^B. The output spectra of the two filters are then combined and sampled by two low-speed ADCs. Using this architecture, we can emulate the same spike trains as the first alternative architecture. For instance, when the difference between the filter center frequencies $df_c = f_c^B - f_c^A < \Delta f$, as shown in Fig. 17(i), the two spike trains are slightly shifted on the

[6]Since the power consumption of spectrum sensors is dictated by the ADC [58], the additional power consumption of the second LO is not the primary concern.

frequency axis and emulate a spike-train filter with narrower spacing between the spikes. Besides, when $df_c = K\Delta f$, the two spike trains are spaced by the bandwidth of the spike train and emulate a wider bandwidth spike train as shown in Fig. 17(ii). However, in additional to enlarging the filter bandwidth and narrowing the spike spacing, we can even emulate a non-uniformly spike train as as shown in Fig. 17(iii). This is achieved by combining two spike-train filters with different Δf^A and Δf^B. Such spike train profile provides us with all sorts of frequency resolutions across the spectrum to accommodate the different channel bandwidth required by the secondary users in TV Whitespace and CBRS bands.

WiForce: Wireless Sensing and Localization of Contact Forces on a Space Continuum

Abstract

Contact force is a natural way for humans to interact with the physical world around us. However, most of our interactions with the digital world are largely based on a simple binary sense of touch (contact or no contact). Similarly, when interacting with robots to perform complex tasks, such as surgery, richer force information that includes both magnitude and contact location is important for task performance. To address these challenges, we present the design and fabrication of WiForce which is a 'wireless' sensor, sentient to contact force magnitude and location. WiForce achieves this by transducing force magnitude and location, to phase changes of an incident RF signal of a backscattering tag. The phase changes are thus modulated into the backscattered RF signal, which enables measurement of force magnitude and contact location by inferring the phases of the reflected RF signal. WiForce's sensor is designed to support wide-band frequencies all the way up to 3 GHz. We evaluate the force sensing wirelessly in different environments, including through phantom tissue, and achieve force accuracy of 0.3 N and contact location accuracy of 0.6 mm.

1 Introduction

Our sense of touch is critical for understanding and interacting with the world around us. While interacting with the physical world, force-sensitive mechanoreceptors in the skin respond to various vibrations, motions, pressures, and stretching of the skin to provide us with critical information on the location and magnitude of the stimuli [1]. Thus, if we want the next generation of tactile sensors to emulate how our skin reacts to stimuli, we need to both sense the magnitude and location of contact forces acting on the sensing surface.

Current skin-like continuum tactile sensors enable numerous critical applications. These applications mostly involve dexterous tasks to be performed via mechanical tools or robotic manipulators, rather than via human hands. For example, in order to grasp and manipulate an object, a robot must be able to sense where and how firmly it is pressing the object [2, 3]. Another example can be seen during minimally invasive surgery, where a surgeon must operate inside the body with a surgical tool that naturally contacts numerous tissues throughout the procedure. A sensing layer which acts like a skin covering the entire surgical tool could enable safer surgeries [4–6], since the surgeon would know exactly where the tool is in contact with the tissues and with how much force. In addition to these robotics applications, tactile sensing can supplement our interactions with the digital world. Most of our current interactions with digital technologies occur with aid of a touchscreen, which binarizes human contact into simply touch/no-touch, and the richer information on contact force is typically lost. Augmenting our digital interfaces with the capability to sense the magnitude of the forces with which we interact with them could lead to more natural, intuitive, and realistic interactions, creating new possibilities for the evolving AR/VR settings [7–9].

Driven by these applications, design of such continuum sensor skins has been an active area of research over the past decade [10–20]. The common approach has been to create a sensing surface consisting of an array of discrete force sensitive resistors or electrodes, whose measurements are interpolated to reconstruct a continuum force profile. However, this approach has prohibitive wiring costs [10–16], since it requires a wired link to obtain data from each individual sensor, as well as wires for satisfying the power requirements. In scenarios where space is a premium, including surgical robotic applications, this wiring challenge is exacerbated, and force sensing for the surgical robotics has been acknowledged as a 'Grand-Challenge' [21]. One way to address the wiring requirements is to reduce the density of sensors in the surface and improve the interpolating algorithms [10–12]. A more drastic solution is to eliminate the wiring problem completely by creating new sensing modalities with modest power requirements such that both the sensor feedback and power can be delivered wirelessly [13, 14, 16].

Motivated by these challenges, we present WiForce, which makes progress in this direction by sensing force magnitude and location over a 1-D continuum by leveraging backscattering techniques. Rather than generating a wireless signal to feed back the sensor readings, which would require power-hungry electronics, WiForce's sensor transduces force magnitude and location directly onto the reflections of the incident RF signals. The design has very minimal power requirements, and consists of only one antenna, a small identification unit, and a force continuum surface. Thus, WiForce presents a new tactile sensing modality, which makes headway towards batteryless wire-free sensor skins.

The key enabler for such a low-powered design is the

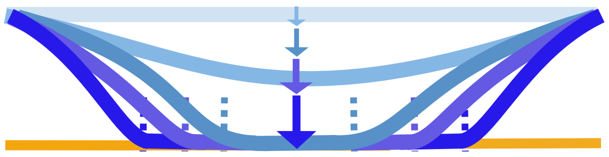

Figure 1: Beam bending in effect of contact force: As contact force increases (shown via increasing arrow lengths), the top beam bends and collapses more and more onto the bottom beam

transduction mechanism, which modulates the reflected signal with information on the contact force and its location, by altering the RF signal parameters as applied force on the sensor changes. To achieve this, WiForce links contact force, a mechanical entity, to RF signal parameters by combining classical beam bending models and RF transmission line concepts, using a novel sensor surface. This sensor surface consists of two parallel conductive traces, similar to a microstrip line, augmented with a soft specialized polymer beam. As a force is applied at a specific location on the sensor surface, the beam bends, causing the traces to connect (Fig. 1). From the RF perspective, this beam bending leads to shorting of the traces, which causes reflection of signals. From the mechanical perspective, the soft beam allows us to use beam bending models to characterize how the shorting phenomenon changes as the applied force increases.

Essentially, the shorting points shift towards the ends of the sensor, as the applied force increases and the soft layer of the beam bends and flattens on the bottom trace (Fig. 1). By estimating the shorting lengths from both ends of the sensor, we can determine the magnitude and location of the applied force. The shorting lengths are related to the signal phases measured on both the ends of the sensor. Basically, the longer the signal travels on the sensor surface, the more phase change it will accumulate. The goal at the wireless reader is to measure the accumulated phases due to signal propagation on the sensor surface from both the ends, in order to use the transduction mechanism to sense and localize the forces.

To enable sensing of these phases by the wireless reader, the phases from both ends have to be disambiguated, and thus each end has to be given an identity. To do so, a naive solution would be to have RF switches toggling on-off with different frequencies on either ends (f_{s_1}, f_{s_2}, Fig. 2), with the toggling frequency providing the unique identity to each of the ends. However, this naive solution does not work out of the box, because the two ends are electrically connected to each other via the transmission line, causing signals to leak from one end to the other, which would in turn cause intermodulation effects. To resolve this issue, WiForce comes up with a creative RF switch toggling strategy, which not only provides electrical isolation to combat intermodulation, but also provides different identities to these ends in terms of different frequency shifts. Thus, the external wireless

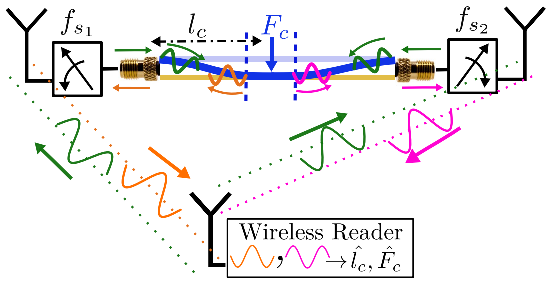

Figure 2: The key insight of WiForce is to view the parallel beams as a microstrip line. Force F_c and it's location l_c gets transduced onto changes in the reflections due to the line shorting caused by beam bending. The wireless reader uses the reflected signals to estimate l_c, F_c

reader is able to view the sensor ends as having different identities in frequency domain, as envisioned by the intuitive scheme in Fig. 2, with the intermodulation problem abstracted out via the intelligent toggling scheme.

The final piece in WiForce is designing the wireless reader, such that it can use any wireless device (like WiFi (OFDM) or LoRa (FMCW)) with wide-band transmission to read the WiForce's force and location. The task of the wireless reader is two-fold, first identify and isolate the signals coming from the sensor and second, accurately track the phase of the sensor signal. Since the wireless phase observed by the reader can also be altered by various entities in the environment, the task of reading phase changes stemming only from the sensor is non-trivial. Hence, WiForce designs a novel signal processing algorithm which utilizes periodic wide-band channel estimates to pick up the reflection signatures from the sensor to isolate the signal, as well as to read the phase changes at multiple frequencies, providing robustness to the phase sensing requirements for the proposed force transduction mechanism.

We designed and fabricated the sensor with a soft-polymer augmented microstrip line, which is 'force-sensitive'. That is, the microstrip line sensing surface has bending properties which maximize the phase changes transduced by contact forces. This sensing surface was retrofitted with RF-switches and antenna to enable backscattered feedback. The fabricated sensor works for the entire sub-3 GHz verified with the test equipment (vector network analyzer). We evaluated the WiForce sensor abilities to report force magnitude and location in multiple settings, both indoors and inside a body-like environment using gelatin. We used USRP radios as the readers, and tested the sensor at 900 MHz and 2.4 GHz, which are the two most popular ISM bands. We show that the sensor can be read up to 5 meters of range over the air, and show the algorithm working even with propagation through the gelatin-based muscle/fat/skin tissue layers composition similar to the human body to demonstrate the surgical applications. We achieved phase sensing with an accuracy as low as 0.5^o, giving us a force resolution of 0.3 N, and location accuracy of 0.3 mm. We also showcase the ability to read from multiple sensors, by sensing forces from 2 sensors simultaneously. Finally, we even evaluated our force sensor with a user pressing with his hand, and we achieved force resolution of 0.3 N, and location accuracy of 0.3 mm. In fact, recent interfaces for Human-Computer Interactions (HCI) work shows that similar resolution (0.2 N) is required to support force enabled gestures on smartphones and desktop computers [22]. We believe this is the first step towards enabling numerous force sensing applications.

2 Background and Motivation

The problem of sensing tactile phenomenon over a surface continuum has attracted considerable research interest [10–12, 15, 18, 20]. The usual approach has been to densely populate the surface with either force sensitive resistors [15], electrodes [10–12, 20], or force sensitive yarns [18]. The continuum sensing is performed by interpolating over the sensor readings of these discrete sensors. Numerous papers in the past decade have raised the issues stemming from the wiring requirements of the developed sensor skin modalities [13, 14, 16].

Researchers have tried addressing these issues by considering sparser deployments, such as considering sensors only on the boundaries [20], or populating the sensors in a minimal way across the surface [10, 23]. Although these efforts have reduced the wiring requirements for sensing considerably, these surfaces still lack a solution to both feedback the sensor readings wirelessly, as well as get rid of wired battery connections required for these sensing efforts. Recent review papers have advocated the need of powering up these sensing surfaces with energy harvesting methods to alleviate the battery requirements [14, 16], and a backscatter-enabled sensor is a promising approach to address the battery concerns.

Before re-designing the sensing modalities to be compatible with low-powered backscatter communications, a key question to answer is whether a hybrid solution would work. That is, can we take one of the sensing solutions requiring the least number of wired connections across the surface [10, 20] and feedback the sensor readings via currently developed backscattering RFICs[1] [24, 25]. However, this solution won't suffice since these backscatter links typically work with a RF energy harvestor, which generates small voltages capable of powering a small RFID chip, and not a large continuum sensing surface. Further we would need to sense multiple voltages from these electrodes via an array of ADCs (Fig. 3), managed by a micro-controller, which

[1]This fusion of sensor skin + backscatter RFIC has not been yet demonstrated, however we consider it as an hypothetical scenario

(b) WiForce transduces the continuum force information directly onto analog backscattered phase changes without discretization

Figure 3: Force feedback design, WiForce in comparison with a possible wireless extension to existing sensing modalities

would then digitize and buffer the data for transmission through the low capacity backscatter link.

Hence, WiForce attempts a RF-only analog approach, where the sensing modality directly transduces force and its location into wireless signal phase changes, which can be read by a radio over the air. The argument here is that, if analog phase readings can be fed back accurately, it would require much less power than procuring the analog readings, digitizing/buffering them, and then sending them over the backscatter link. Thus, the novel force to phase transduction mechanism, coupled with the analog phase feedback, fulfills both the key requirements for low powered tactile sensing – the ability to sense over a continuum and low-powered battery-free operation.

3 Design of WiForce

In this section, we present the design principles of WiForce. First, we describe WiForce's force transduction mechanism, which translates the force and its application location to changes in the RF signal phase. Next, we present novel algorithms to measure changes in the RF properties to deduce the force and its application location wirelessly. Finally, we conclude with a robust channel measurement technique that uses a wireless waveform to read the sensors while rejecting multi-path.

3.1 Force Transduction Mechanism

As a first step towards a backscattered force sensor, WiForce has to formulate a transduction mechanism which relates force magnitude and application location, to parameters like RF signal amplitude and phase, which can then be used to modulate the sensor readings onto the

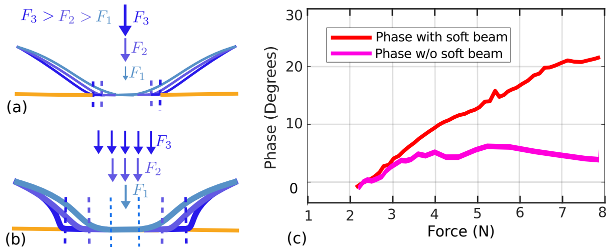

Figure 4: Bending of (a) Thin, (b) Soft beam augmented thick trace, as forces increase ($F_1 < F_2 < F_3$). The soft beam distributes forces along the length, which leads to profound phase changes (c) as compared to thin traces w/o soft beam

reflected signals. The challenge here is to take an object (like transmission lines) which supports RF signal propagation, and make it force-sensitive. That is, RF propagation in this object should give significant changes in its signal parameters as we press the object at different locations with varying force magnitudes. In this section, we will elaborate on how WiForce makes microstrip lines 'force-sensitive'.

A microstrip line traditionally consists of two parallel conducting traces– the signal trace and the ground trace. A force applied to the microstrip line would cause the traces to bend and come in contact with each other, which shorts the line and leads to signal reflections. The reflections produced by this shorting have different phase accumulation based on the location of pressing. However, this reflected phase is not sensitive to force magnitude at all. That is, irrespective of the contact force applied, the traces will short each other only in the vicinity of a single point (Fig. 4a). The contact point invariance leads to a near invariant phase response as force is changed (Fig. 4c), therefore preventing the measurement of force through phase changes.

WiForce modifies the traditional microstrip line by augmenting a new soft, flexible beam on top of the signal trace to address this problem and make the microstrip line force-sensitive. The key insight here is that the soft beam distributes the force along the length of the trace (Please refer to [26] for details on the mechanical implementation of the sensor). The distributed force leads to a finite length of the signal trace to come in contact with the ground trace, creating two distinct shorting points, as shown in Fig. 4b. Further, these shorting points shift towards the ends as the applied force magnitude increases. Varying shifts induce different phase changes since the signals travel less distance on the microstrip line before getting reflected at the shorting points. Hence, the reflections caused by higher magnitude forces accumulate less phase relative to the reflected phases when lower force was applied. Thus, the soft beam augmented microstrip line allows phase to force transduction (Fig. 4c).

This beam bending effect manifests itself in the form of a varying phase-force relationship depending on the con-

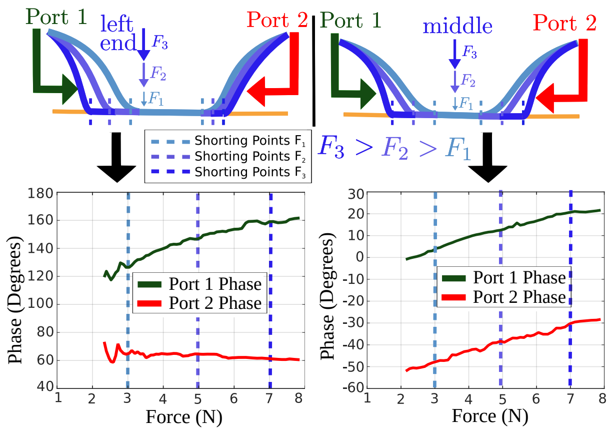

Figure 5: The shorting points shift due to increased force because of bending of the soft beam, changing the reflected phase. When the force is applied at the middle, we observe symmetric phase change across the two ports, whereas when force is applied towards the ends, we see asymmetric phase changes, due to the beam bending mechanism illustrated in the top row

tact force's point of application (Fig. 5, top images). A force applied in the middle of the sensor compresses it symmetrically, and therefore the reflected signals from both the ends show similar phase changes. In contrast, a force that acts asymmetrically will disproportionately compress the smaller length of the beam. Therefore, the end near the smaller length shows a higher phase shift than the end near the longer one. The longer length collapses onto the bottom trace, leading to an almost stationary shorting point as the force increases (Fig. 5, bottom images). These varying phase changes that depend on the location of a contact force also allow WiForce to localize the force application point. Thus, the double-ended measurement allows us to estimate the applied force's magnitude and its application location along the sensor length. However, at the same time, this asymmetric behavior of phase change with force contact location necessitates sensing phases from both ends of the sensor.

3.2 Two-ended backscatter modulation

As described in the previous section, sensing phases from both ends of the sensor forms the cornerstone of the phase to force transduction mechanism. This is because it allows to disambiguate the different force profiles observed as the sensor is pressed at different locations, which basically allows us to both locate and then measure how much force was being applied. In this section, we will go over how to attempt this double ended phase sensing via wireless backscatter sensing.

The first and foremost thing which any backscatter sensing solution needs, is an ability to give an identification to the reflections occurring at the sensor. This identification helps the wireless reader isolate the sensor reflections from the environmental clutter. A popular technique to do so has been to use RF switches toggling at

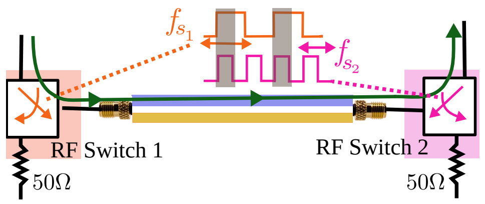

Figure 6: RF switches toggle between sensor (on) and 50 Ω (off) depending on the control input. Different freq. clocks as control inputs introduce intermodulation due to both switches being toggled on at the same time (grey shaded time instants)

different frequencies as identification unit [27–29]. This technique basically multiplies the incident signal with an on-off modulation of certain switching frequency.

In frequency domain, this operation leads to frequency shifts corresponding to the switching frequency. Putting this mathematically, say the sensor receives the excitation signal $s(t)$ and reflects $s(t)m(t)$ where $m(t)$ is a square wave, with time period T. Expanding $m(t)$'s Fourier series, we get odd harmonics, $m(t) = \sum_{k\in(2i+1),i\in\mathbb{Z}} \frac{1}{|k|} e^{(j2\pi k f_s t)}$ where $f_s = \frac{1}{T}$. Ignoring the high order harmonics, we get reflected signal as $r(t) = s(t)m(t) \approx s(t)e^{j2\pi f_s t}$. Hence the reflected signal will be shifted by the switching frequency $\pm f_s$, which allows the reflected signal, $r(t)$, to be isolated from the excitation signal, $s(t)$ in the frequency domain.

A naive extension of this idea to the double ended sensing problem at hand, would be to have switches at both ends of the sensor and make them switch at different frequencies (f_{s_1}/f_{s_2}). Theoretically, this solution should give separate identities to reflections emanating from both the ends. However, the problem at hand is inherently coupled to allow for such naive de-coupled solutions, because both the ends are physically connected to each other via a microstrip line. When both the switches are toggled-on, the signals will propagate through the sensor and leak out from the other end (Fig. 6). This causes intermodulated reflections, where the reflected signal would be partially modulated by both toggling frequencies, leading to muddled up identities.

The challenge in avoiding the intermodulation effects is that the sensor has to reflect signals from the opposite end when a switch is toggled on. Using reflective RF switches in the off state allows us to make either of the ends reflective, under the restriction that the other should be off when one switch is on. Said differently, we want to design a coupled two-ended switching scheme, which gives separation in frequency domain, under the constraint that both switches are not 'on' at the same time. The unique insight which allows WiForce to have such an switching scheme, is the use of duty cycle properties of square wave Fourier series.

In a standard square wave, with 50% duty cycle, all the even harmonics (i.e. every second harmonic) are absent. Similarly, in a wave with 25% duty cycle, ev-

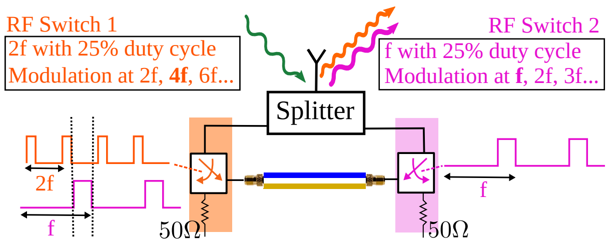

Figure 7: The duty-cycled modulation ensures that switches aren't toggled on at once, as well as providing freq. separation

ery fourth harmonic would be absent. Hence, a frequency f_s, 25% duty cycle square wave will give modulation at $\underline{\mathbf{f_s}}, 2f_s, 3f_s, \cancel{4f_s} 5f_s, \ldots$ Similarly, a frequency $2f_s$, 25% duty cycle square wave will give modulation at $2f_s, \underline{\mathbf{4f_s}}, 6f_s, \cancel{8f_s}, 10f_s \ldots$ Observe that a combination of these 2 clocks will cause interference at $2f_s$, but can be read up individually at f_s for the former clock, and $4f_s$ for the latter clock. Hence, a combination of these 2 clocks can provide separation in the frequency domain. Also, by controlling the initial phases of these two clocks, we can suppress the intermodulation problem as well. This is possible because when one clock is high, the other clock will be guaranteed to be low and vice versa (Fig. 7). Hence, at any given time, only one port will be on, and other port will be reflective open.

Further, this clocking design allows us to reduce the form factor requirements, instead of having 2 antennas, one for each end of the sensor, we can just have just a one antenna design using a splitter. Since the clocking strategy provides separation in the frequency domain, we can add the modulated signals from the either ends via a splitter. Thus, the wireless reader can identify the two ends by reading at $f_s, 4f_s$ frequency shifts.

3.3 Sensing Forces at the Wireless Reader

Till now, we have described the phase-force transduction mechanism, and delineated a method to give disambiguated identities to both ends of the sensor. Now, in this section, we move on to the description of how the wireless reader is designed. We design our wireless reader to detect the separate identities stemming from frequency shifts, and then extract the valuable phase information which allows us to sense and localize forces. The key insight of WiForce here is to view the frequency shifts from the sensor as 'artificial-doppler' and use wide-band channel estimates in order to estimate the doppler and thus isolate the signal coming from the sensor. This approach to view the backscatter tag's frequency shift as an artificial doppler has been also utilized in some of the recent past work [28]. Finally, to obtain the required analog phase estimates required to sense and localize the forces, we utilize that fact that force, a mechanical quantity, changes slowly (at about 1 kHz rate [30–32]), as compared to MHz's of RF bandwidth. This allows us to group the channel estimates and perform a 'short-time phase transform', which enables us to track the phase shifts at the two artificial doppler bins corresponding to the two ends of the sensor.

The algorithm WiForce uses to extract the backscattered phases embedded inside the wideband channel estimates is visually illustrated in Fig. 8. Say we are estimating the channel periodically after every T seconds, with frequency steps of F. If we use OFDM channel sounding strategy, T will be the time of the OFDM frame, and F will be the subcarrier spacing. We denote $H(kF, nT) = H[k,n]$ where k is subcarrier index and n is time index. If there are M multipaths in addition to the signal coming from the sensor, we can write the channel estimates from geometric channel model as

$$H[k,n] = \sum_{i=1}^{M} \alpha_i e^{-j2\pi kF\frac{d_i}{c}} + (s_1(nT)e^{-j\phi_n^1} + s_2(nT)e^{-j\phi_n^2})\alpha_s e^{-j2\pi kF\frac{d_s}{c}} \quad (1)$$

Here, α_i is the attenuation factor for the i-th path, d_i is the distance separation between the TX-reflector and reflector-RX, and ϕ_n^1, ϕ_n^2 is the phase accumulated from the RF propagation in the microstrip line sensor at time index n from sensor end 1 and sensor end 2. $s_1(t), s_2(t)$ are the duty-cycle square wave modulations to give intermodulation free frequency identities at $f_s, 4f_s$ as discussed in Section 3.2. Ignoring the higher harmonics terms in $s_1(t), s_2(t)$, we get

$$H[k,n] \approx \sum_{i=1}^{M} \alpha_i e^{-j2\pi kF\frac{d_i}{c}} + (e^{j2\pi(f_s)nT}e^{-j\phi_n^1} + e^{j2\pi(4f_s)nT}e^{-j\phi_n^2})\alpha_s e^{-j2\pi kF\frac{d_s}{c}} \quad (2)$$

Now, to isolate the signal from the sensor, we take FFT over the n index, to obtain $\tilde{H}[k,f]$. We observe N channel snapshots to calculate, $\tilde{H}[k,f] = \sum_{n=1}^{N} H[k,n]e^{-j2\pi fnT}$. Assuming ϕ_n^1, ϕ_n^2 stay constant over the period of N snapshots, at f_s, $4f_s$, we have,

$$\tilde{H}[k,\{f_s,4f_s\}] = \sum_{n=1}^{N} H[k,n]e^{-j2\pi\{f_s,4f_s\}nT} = \alpha_s e^{-j2\pi kF\frac{d_s}{c}} e^{j\phi_n^{\{1,2\}}} \quad (3)$$

Observe that for this transform, the nyquist frequency would be $\frac{1}{2T}$, and hence, f_s has to be chosen such that $4f_s \leq \frac{1}{2T}$. The switching frequency f_s can be related to an equivalent Doppler, $f_s = \frac{f_c v}{c}$, and thus an object in the environment moving at velocity $v = \frac{cf_s}{f_c}$ would create interference with the sensor signal. However, the chosen f_s is large enough so that this equivalent speed is so high to guarantee that, the signal observed in the frequency bins corresponding to $f_s, 4f_s$ are free from multipath clutter.

However, recall that while writing Eqn. (3), we assumed ϕ_n^1, ϕ_n^2 stay constant as n goes from 1 to N. That is, the transform is only valid when the phases from the sensor ends do not change much over the period of taking

Figure 8: WiForce's reader utilizes wideband channel estimates to isolate sensor signal from multipath in doppler domain. Arranging the channels into 'groups' allows to read phase changes across subcarriers to give robust measurements

the transform. This is a reasonable assumption to make, since the sampling is occurring in MHz rate, whereas force will at max change in rate of kHz, since it is a mechanical quantity. However, we can not obviously assume the phase to stay constant forever, and, the phase will change as we apply force on the sensor which would move the shorting points. More importantly, we need to not only tweak the standard doppler transform to respect phase change, we also need to estimate the phase changes in order to estimate the forces. Thus, WiForce designs an algorithm similar to the familiar short-time transforms. The algorithm divides the channel estimates into groups of N_g, referred to as 'phase-groups'. For each phase-group we first take the harmonics FFT as described earlier and obtain two $K \times 1$ vectors from Eqn.3 for FFT frequency f_s, $4f_s$. Assume that there are G such phase groups, i.e. $N = GN_g$. For all the N_g samples of g-th group, $\phi_n^1, \phi_n^2 \approx \phi_g^1 \phi_g^2 \forall n \in \{1,2,\ldots N_g\}$ from the choice of N_g to respect the time it takes for the force to become effective. The output at g-th phase group, k-th subcarrier, after harmonics FFT at $f_s, 4f_s$, is denoted as $P_1[k,g], P_2[k,g]$.

$$P_{\{1,2\}}[k,g] = \tilde{H}[k,\{f_s,4f_s\}] = \alpha_s e^{-j2\pi kF\frac{d_s}{c}} e^{j\phi_g^{\{1,2\}}} \quad (4)$$

To get rid of the air phases, we can obtain the phase change between 2 groups by conjugate multiplication:

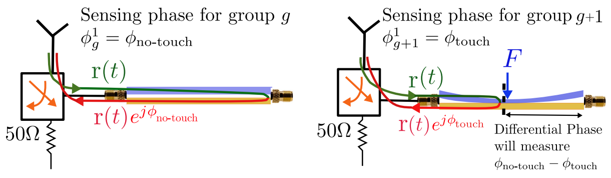
$$\tilde{P}_{\{1,2\}}[k,g] = P_{\{1,2\}}[k,g+1] * \text{conj}(P_{\{1,2\}}[k,g]) = \alpha_s^2 e^{j(\phi_{g+1}^{\{1,2\}} - \phi_g^{\{1,2\}})} \quad (5)$$

Hence, we have

$$\angle\tilde{P}_1[k,g] = \phi_{g+1}^1 - \phi_g^1, \angle\tilde{P}_2[k,g] = \phi_{g+1}^2 - \phi_g^2 \quad (6)$$

for each subcarrier k. Observe that the right side of the equation is the phase change independent of k, which entails that we have K independent estimates of the phase change from the K subcarriers. Thus, we can estimate very precise phase changes by averaging over these K independent estimates, allowing WiForce to calculate very precisely the analog phase changes.

The last piece in the puzzle to conclude the design section, is to internalize how can we use differential phase



Sensing phase for group g

Figure 9: Differential Phase measurements can be compensated with fixed quantity $\phi_{\text{no-touch}}$ procured via calibration, to obtain the quantity of interest ϕ_{touch}, which varies with force magnitude and location

to sense and localize the contact forces. In fact, since force is an event based quantity, that is, unlike quantities like temperature, moisture, which sense the ambient quantity, tactile sensors have to sense the force from an 'touch-event' which exerts certain force on the sensor at a given location. When we measure the differential phase between the 'no-touch' and 'touch' events, we can measure differential phase and obtain the absolute phase by simply subtracting the phase which the waves accumulate when the sensor is at rest (Fig. 9). Since this no-touch phase is a fixed quantity and depends only on the length of the trace, we measure it beforehand via a VNA setup and compensate. Hence, compensating the differential phase with the VNA calibrated no-touch phase allows us to recover phases from both the ends, which can then used by the transduction mechanism in order for estimation of force magnitude and location at the reader.

4 Implementation

4.1 Microstrip line RF Interfacing

To support the two broad applications targeted by WiForce, the sensor must give good RF propagation performances at 900 MHz (for in-body sensing applications) and at 2.4 GHz (to be compatible with Wi-Fi/Bluetooth standards). From our simulations (Section 10.2), we expect that by having the ratio between trace width and sensor height to be around 4 : 1, we should get good impedance matching. Hence, we design an air substrate microstrip line with trace width of 2.5 mm, ground trace width of 6 mm and height of 0.63 mm, for a sensor length of 80 mm. To verify the impedance matching, we assess the RF design performance of the sensor in terms of insertion/thru losses. For this, we perform a 2 port amplitude/phase analysis using VNA. As visible in Fig. 10, this leads to a S11/S22 ratio below -10 dB over the entire frequency range from 0 to 3 GHz, along with linear S12 phase, which justifies the broadband nature of the sensor.

4.2 Forming the sensor model with soft beam microstrip line

After having verified the RF properties of the microstrip line, we fabricate the soft layer using Ecoflex 00-30 (a commonly used elastic material [33–35]). The Ecoflex layer is placed onto the top trace to create the WiForce

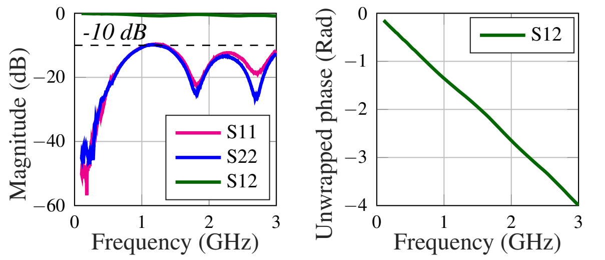

Figure 10: 2 port RF profiling of the sensor. S11 stays below -10 dB across 0-3 GHz, with S12 around 0 dB with linear phase.

sensing surface with thick traces, endowed with the novel phase to force transduction mechanism.

To verify if the sensor is following the transduction mechanism, we exert forces on the sensor at 5 locations, namely 20, 30, 40, 50 and 60 mm (20, 40, 60 marked in Fig. 11). We expect the beam to show a symmetric phase changes on both the ends when tested at the center point, and asymmetric phase changes for the end points, as described in Section 3.1. When pressed on the end points, the port near the pressing location would show more phase change, whereas the other end essentially shows a constant phase as force increases. For this testing, we use the setup visible Fig. 11, where an indenter allows us to apply a force at a given location on the sensor, and a load cell on which the sensor is attached, allows us to collect the values of force magnitudes applied. As seen clearly in the 20/40/60 mm figures in Table 1, the phases do follow the beam bending model as discussed above, since 40 mm testing shows symmetric behaviour, whereas for 20/40 mm, one of the ends show a constant phase as force magnitude is increased.

We now use the data obtained by applying forces at all 5 locations, and compute a cubic-fit to make a sensor model that allows us to compute the force magnitude and force location based on the measured phase changes. To confirm the validity of the model, we asses it at an intermediate point (55 mm), and plot the phase-force profile

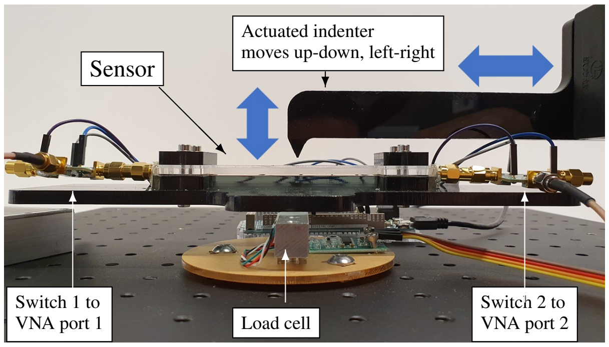

Figure 11: Sensor on the load cell platform, The actuated indenter which can move up-down to exert force on the sensor, as well as left-right, to do so at a particular location, shown via blue arrows . A load cell below the platform and VNA (not shown here) provide force, phase ground truth measurements.

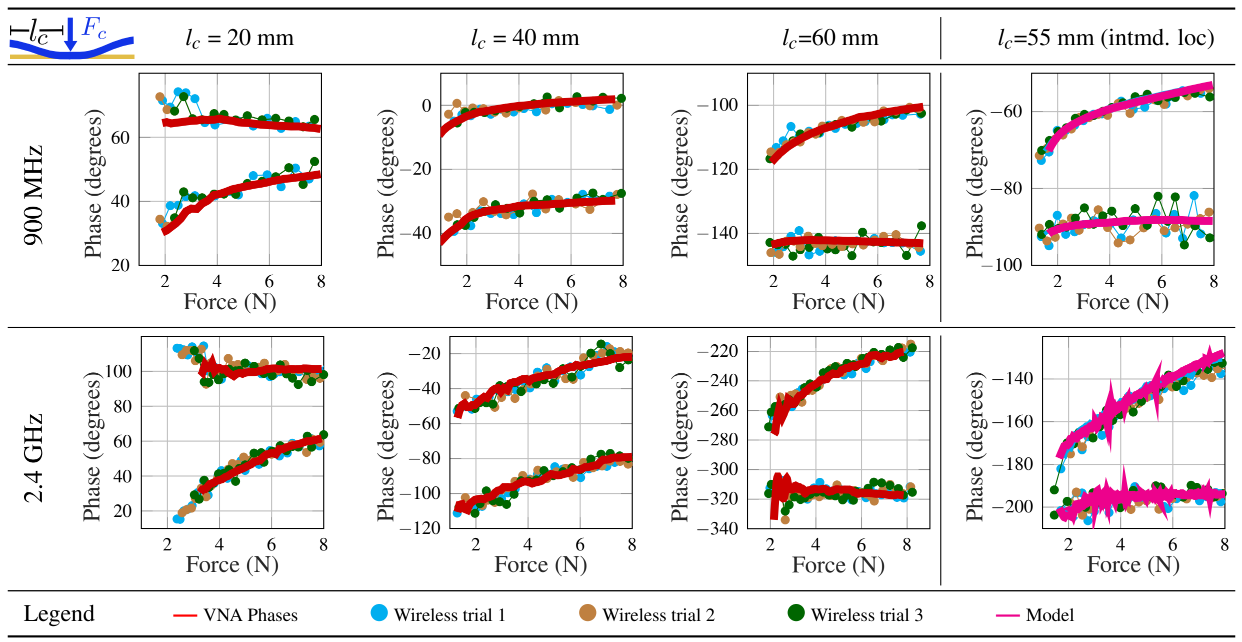

Table 1: Ground truth phase-force profiles (red) measured via the VNA and load cell setup show symmetric phase changes when pressed at center ($l_c = 40$mm, total length is 80mm), and asymmetric phases when pressed at $l_c = 20, 60$mm, as discussed in Section 3.1. We collect VNA data at $l_c = 20, 30, 40, 50, 60$mm, and perform a cubic fit to get the sensor model, which is evaluated by testing at intmd. $l_c = 55$mm. The wireless phase measurements, as well as the model predictions at 55mm consistently overlap with ground truth, warranting the performance of WiForce's design .

as predicted by the model alongside the ground-truth profile we collect from the VNA. As visible in Table 1, all graphs for force applied at 55 mm overlay on each other, which confirms the reliability of the sensor model.

4.3 Clock Design and RF Switches

To encode the phase changes caused by different shorting positions on the microstrip line due to application of a force, we utilize 2 RF-switches with the duty cycled clocking strategy described in Section 3.2. We use the HMC544AE from Analog Devices in our prototype, which is a reflective-open switch consistent with our duty cycling requirements discussed in Section 3.2.

The final component in our prototype design is the clock source. We use the timer channels in Arduino Due with an Atmel SAM3X8E ARM Cortex-M3 processor [36] to generate the duty cycled clock source as described in Section 2. We generate a 25% duty cycled 1 kHz square wave, and a 75% duty cycled 2 kHz square wave to modulate the two RF switches. This gives us interference-free modulation at $1, 4$ kHz.

Hence our sensor prototype consists of five components, shown in Fig. 12b, the microstrip line sensor, 2 RF switches, 2 clock sources, a splitter to combine outputs of the 2 switches and one antenna to communicate the backscaterred phases to the wireless reader. The elements in our design which require power thus are the 2 RF switches and the 2 clock sources. For switching at kHz frequencies, we observed that the power consumed by the 2 HMC544AE switches was almost similar to the static power consumption of 3.3 μW (the static current for switch at 3.3V voltage level is 0.5 μA [37]). Although in our design we use a microcontroller to provide the clocks, by using low-powered oscillators, we can meet the clocking requirements with about 2 μW power budget [38]. Overall, the requirements are lesser than 10μW which are modest enough to be supported by a RF energy harvesting circuit. In recent works, papers have even shown more than 50 μW power being harvested via RF signals, across 1cm of tissue [39].

4.4 Wireless Reader Implementation

The main task of the wireless reader is to transmit the OFDM waveform and periodically estimate the channel, so that phase changes at the shifted frequencies from the sensor can be read wirelessly. To perform the channel estimation, we utilize a 64 subcarrier, 12.5 MHz OFDM waveform. We test this for both center frequency of 900 MHz and 2.4 GHz. We use separate antennas for transmission and reception, and use the same USRP N210 SDR [40][2] for both functions. Since the transmit and receive chains are on the same device, they are synchronized and will not show frequency/phase offsets. We emphasize here that the arduino clock is not synchronized with the other elements of the system since the force sensor is deployed as a separate entity.

We use a 320 sample long OFDM preamble padded with 400 zeros for the channel estimate. At the sam-

[2]We can potentially use a COTS device as well as the wireless reader. Refer to Section 10.1 for a brief discussion on the same

pling rate used, this translates to fresh channel estimates every $T = \frac{720}{12.5\times10^6} = 60\ \mu$s. Recall that to sense harmonics, the maximum harmonic frequency which can be sensed would be $|f_{\max}| = \frac{1}{2T} \approx 8.7$ kHz due to the Nyquist Limit. We therefore chose our sensor clock frequencies to be 1,2 kHz, which would give modulation at 1,4 kHz, and falls comfortably within measurable limits.

5 Experimental Evaluation

Armed with a sensor model to get from phases to force magnitude/location, as well as wireless reader and sensor implementation to enable backscatter sensing capabilities, we now evaluate the wireless performance of our sensor in different indoor environments. The developed sensor model is first used to estimate the force magnitude and location exerted on the sensor, and this predicted force magnitude/location is compared to ground truth readings from the load cell and actuator position, as shown in Fig. 12a. In addition, we plot empirical CDFs, which allow us to understand the accuracy of our sensing solution. Not restricting to over the air evaluations, we even evaluate our sensor when the wireless propagation occurs through tissue phantoms made to emulate human tissues. We also show the capability of reading forces from two sensors simultaneously. Finally, we show that the force sensing works not only with the precision touches of the actuator, but can also detect the force and contact location when a human interacts with the sensor via finger touches.

5.1 Wireless Performance Evaluation

The first step in the wireless performance evaluation is to verify if the estimated force magnitudes and locations agree with the ground truth force-phase curves obtained via the load cell and the VNA setup. For this purpose, the setup illustrated in Fig. 12a is used[3], with the sensor on top of a platform having load cell to give ground truth readings for the experiment, similar to the VNA experiment in Section 4.2. Forces are applied between 0 and 8 N at 20, 40, 55 and 60 mm positions on the sensor. From Table 1, we can clearly see that wireless sensing is able to follow the VNA force-phase curves. Hence, this allows to validate the wireless implementation.

Using the estimated values of force magnitudes and force location to the ground truth, i.e. load cell readings and indenter location, we plot empirical CDFs to evaluate the wireless performance metrics. In Fig. 13a, Fig. 13b, we see that median error of force magnitude estimation of WiForce is 0.56 N when being read at 900 MHz, and 0.34 N when being read at 2.4 GHz. These results are satisfactory, since the errors are a fraction of the operating range of the sensor, which is approximately 8 N. One can observe that the error is lower at high frequency. Since higher frequency signals accumulate more phases for the same travelled distance, the required granularity for phase sensing is more relaxed, leading to lower error than sensing at low frequencies. Another observation from Fig. 13a, Fig. 13b, is that the sensor works uniformly across its length, i.e. error CDFs are similar when plotted for touching at individual locations with increasing magnitude of forces.

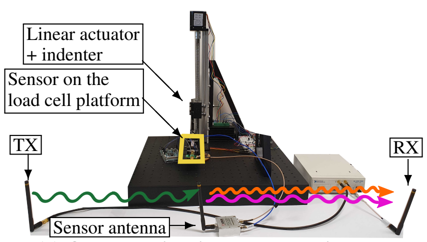
Proceeding similarly, the median errors on the estimated force location is 0.86 mm at 900 MHz, and 0.59 mm at 2.4 GHz, as visible in Fig. 13c. Similar to force magnitude CDFs, performance is better at a higher frequency, since more phase change is accumulated per unit length at higher frequencies, enabling finer location estimation. These location results are satisfactory, with about 5 times higher accuracy than reported in recent work [41,42], where errors are in the order of magnitude of centimeters. The reasons for this improved performance are two-fold. To localize the contact location, WiForce correlates the extra separation between the shorting points caused by sensor bending in the action of a certain contact force. This correlation is enabled by the novel two-ended sensing strategy of WiForce. This is fundamentally very different from the past contact location sensing approaches [41,42]. Furthermore, this is supported by a wideband phase sensing algorithm (Section 3.3), which is capable of sensing these phases very accurately and robustly, unlike the previous works which used a narrowband RFID reader for the evaluations [41].

5.2 Testing with Tissue Phantoms

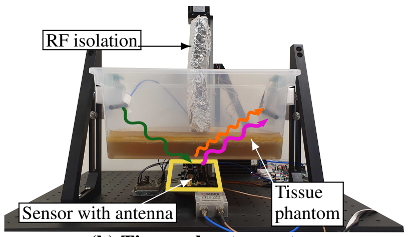
We now assess the performance of our backscatter sensing strategy through human tissue. Propagation through human tissues necessitates using 900 MHz over 2.4GHz, as frequencies higher than 1 GHz are severely attenuated in such environments [43,44]. Wireless signals undergo huge losses when they propagate through human tissue, since these tissues are typically materials with high dielectric constants (with $\varepsilon_r > 10$) [45]. Further, the propagation is hampered via refraction and total internal propagation effects, which exacerbate the losses. Thus, to sense the robustness of our strategy with these impairments, we use the setup visible in Fig. 13d. It consists of a tissue phantom composed of three layers (muscle, fat and skin, and thickness of 25, 10 and 2 mm, respectively), with dielectric properties selected to mimic human tissue properties, as in [46].

During these experiments, we observe that there was around 110 dB two-way backscatter loss from the TX-sensor and sensor-RX, for center frequency 900 MHz, when communicating through the tissue phantom. However, the direct path TX to RX signal had about 10-15 dB loss. The dynamic range of the USRP SDR we use was around 60 dB, because of which we can't decode

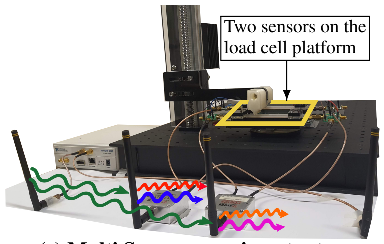
[3]We also evaluate the performance of the sensing algorithm over a range of distances till 2m. The results are presented in Section 10.3



(a) Over the air wireless evaluation setup

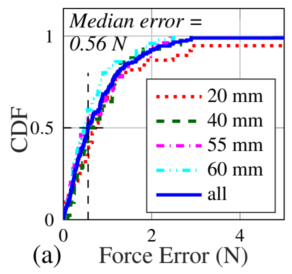


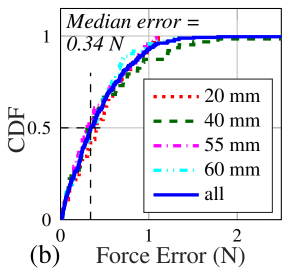
(b) Tissue phantom setup

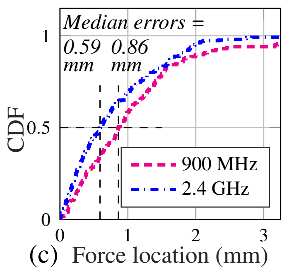


(c) Multi Sensor experiment setup

Figure 12: Different evaluation settings for WiForce's sensor prototype. In (a), the distance between TX-sensor antenna is 50cm, sensor antenna-RX is 50cm. In (b), the antenna and sensor placement ensures that propagation happens through the tissue phantom. In both (a), (b), green: excitation signal, orange,pink: freq. shifted backscattered signal. We also show capability to read from multiple sensors via the setup in (c), here, the red/blue waves represent a different set of frequency shifts for the second sensor







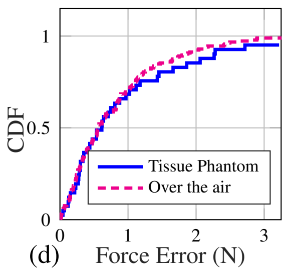


Figure 13: Force CDF Plots, 900 MHz (a), 2.4 GHz (b). For testing at individual points, the error is comparable to the combined CDF for which readings across the length are collected. Hence, the performance of the sensing strategy remains good throughout the sensor length. (c) shows the localization CDF for both the frequencies and (d) compares over the air performance with the tissue phantom setup. Similar CDF plots for both the setups show the sensing robustness when tested with the tissue phantoms

the weak backscattered signal under the presence of the much stronger direct path signal. Hence, for these experiments, we isolated the TX and RX with a metal plate for this experiment. Because of the metal plate, the direct path loss increased to about 60 dB, which allowed us to decode the 50 dB lower backscattered signal at the receiver using the 60 dB dynamic range ADC of the USRP. For this experiment, we apply contact force at 60 mm on the sensor. We obtain similar performance as with the over-the-air tests, with the median force error increasing slightly from 0.56 N to 0.62 N (Fig. 13d). These results demonstrate the robustness of WiForce's wireless capabilities, since the sensing algorithm was able to decode force readings from a weaker signal trough the tissue phantom. In future works, the metal blockage can be replaced by self-interference canceling strategies, however, this is beyond the scope of this paper.

5.3 Multi-sensor experiments

We also evaluate the capability of WiForce to sense from multiple sensors simultaneously. The setup here consists of two sensors placed on a platform, and we use a custom designed indenture with the actuator in order to press on the two sensors simultaneously (Fig. 12c). A load cell is attached below the platform to measure the combined forces acting on the platform (Fig. 14), whereas via wireless sensing from the two sensors we can estimate F_1, F_2 individually. In order to have separate identities for the two ends of the other sensor, we modulate via 1400, 2800 Hz duty cycled waves (visually illustrated via red, blue waves Fig. 12c, Fig 14).

By reading at these frequencies, we can wirelessly obtain estimates $\hat{F_1}, \hat{F_2}$ of F_1, F_2. Because the load cell measures $F_1 + F_2$, we expect that adding these two estimates should allow us to compare against the ground truth load cell readings. The added estimates are expected to give a median error of $1.12N$, since one estimate from the sensor comes with a median error of $0.56N$ at 900 MHz, as profiled by the CDF plots (Fig. 13). Thus, we plot $F_1 + F_2 \pm 1.12N$ as the blue shaded region as the expected median performance of the sensor to sense the added force. Indeed, we see the added up estimates respecting the median error by being confined inside the median error region (Fig. 14).

5.4 Getting More Than Finger Touch: Measuring Fingertip Forces

We now motivate a UI use case, which has the potential to improve and change the way users interact with digital devices. For this purpose, we select a center frequency of 2.4 GHz for our sensor, which is well-adapted to Wi-Fi and Bluetooth devices. To assess the relevance of our sensor for such applications, we use the fingertip, instead of the actuated indenture, to press the sensor with varying force levels. An operator presses the sensor at the 60 mm location. We plot the force readings from the load cell in real time, and use this real-time plot to give the user visual cues to settle in to some force level. Then, we

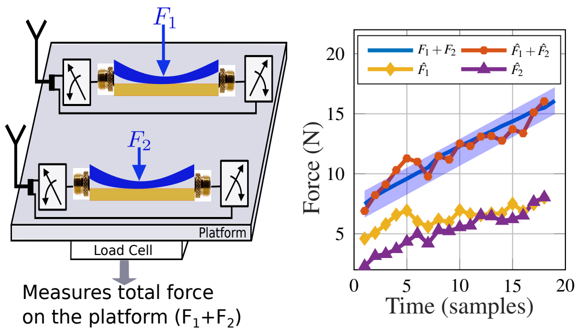

Figure 14: Sensing forces simultaneously from two sensors

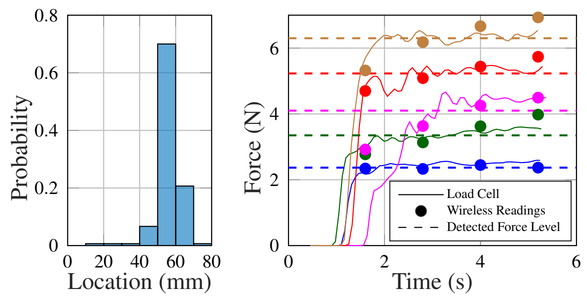

(a) Finger touch location histogram.

(b) Finger force level readings vs time.

Figure 15: Wireless Sensing results for pressing at 60 mm with increasing force levels via a fingertip. From (a) we see that all the touch interactions at 60 mm ±20mm were classified correctly, as the sensor was pressed with a finite-width fingertip (about 15-20 mm [47, 48]). From (b), it can be seen that WiForce was able to estimate increasing force levels accurately

estimate these force levels using WiForce to evaluate if it can support these sensing capabilities.

Fig. 15 shows the evaluation results of WiForce's experiments. From Fig. 15a one can see that the sensor could accurately detect the pressing location, which was 60 mm, with sufficient accuracy, considering the fact that a typical human fingertip has a width and thickness of approximately 15-20 mm [47, 48]. That is, even though WiForce's location sensing had sub-mm location sensing accuracy, now the error source will most likely be coming from the uncertainty of how operators press the sensor with their finite width fingertips, instead of the precise point-pressing feature of the actuator before. Since most of the readings are clustered ±20mm near the visual cue of 60mm given to the operators, WiForce does operate under the practical limit of the experimental setting due to finite width of the operators.

Further, in Fig. 15b, we see how WiForce is able to get more than just binary touch sensing results. Not only can WiForce detect the point where a finger touched the sensor, going one step ahead, WiForce is able to detect the force profiles of the touch interactions as well, which motivates much improved UI use cases by getting more than just touch/no touch information.

6 Discussions and Applications

The most natural usecase for such wireless haptic feedback lies in surgical robots and tools. Human hands are extremely dexterous, and provide unparalleled sensory feedback which enable very precise operations required for surgery. However, we need tools and robots to emulate the human hands when direct operation is not possible, such as during minimally invasive surgical operations. Ideally surgeons should receive haptic feedback from the tools/robots they are operating, which would require information of both force magnitude and contact location. However, such haptic feedback is generally not available in practice, and one reason has been that force sensing modalities are still not evolved enough to support these applications [5, 49–52]. Loss of haptic feedback increases the training time for surgeons, increases risk of surgical errors, and hinders the closed-loop operation for robot assisted surgeries [53–56].

The current form factor and sensor interface hinders direct use of WiForce's sensor in more complex surgical tasks requiring force feedback, such as cardiac ablation [55] or pre-retinal membrane peeling [57]. However, the sensor can help solve a major problem in laparoscopy known as the fulcrum effect [58]. The fulcrum effect is caused due to lever effect caused by contact forces between the body and surgical tool, at the entry point of the surgical incision. Due to lack of feedback on both the magnitude of force and location, the tool tend to slip, which causes risks of tissue damage. A laparoscopic surgical tool augmented with a WiForce sensor to determine and localize the contact force can prevent this fulcrum effect since the surgeon can do a closed loop correction based on this haptic feedback.

Apart from surgical applications, sensing contact force and location can be extremely useful for robotic tasks which require a manipulator/gripper. Robotic manipulators need this haptic feedback to determine how firmly they have grasped a particular object [2, 3]. People have attempted doing this via vision induced haptics [59, 60], however, these methods typically require computationally intensive algorithms and fail to meet the required temporal rate of feedback required to determine if the grasp of the object is loosening and slipping [61]. However, since wireless sensing is not bound to such issues, and can be made near real-time. Thus, such sensors can be used for direct and low-latency haptic feedback to improve robotic manipulation operations.

Alongside the robotics centered applications, force sensing can have many latent applications in the next generation interfaces for HCI/AR-VR. Smart surfaces have been an active area of research, with touch sensing touted to a game changer for ubiquitous computing [62–64]. Force sensing will add more depth to these touch sensing solutions, and can lead to some unforeseen applications.

7 Future Work

Extending to 2-D continuum: The current sensor prototype of WiForce consists of sensing on a 1-D continuum. To extend this sensing to a 2-D continuum, we can deploy multiple WiForce sensors placed next to each other. Hence, by reading phase changes from multiple WiForce sensors, we can infer the location and contact force magnitude on the 2-D continuum spanned by these multiple sensors. A hindering factor to this 2-D extension is how to address multiple touch points simultaneously, which will be explored in future works.

Reducing the form factor: WiForce is the first work which presents such a low-powered sensor, and thus naturally leads the way to realize a battery-free haptic feedback. The current sensor prototype of WiForce is 80 mm long, and about 10 mm thick. With the current form factor, the sensor is not directly applicable for some of the medical applications which need smaller sensors. The sensors can get to the correct form-factor requirements by designing integrated circuits, antenna and the sensor fabrication. To make the sensor prototype more flexible, we will explore new fabrication strategies like flexible PCB printing and creating custom RF connectors.

8 Related Work

Force sensors have been developed using a variety of transduction mechanisms, such as capacitive, piezoresistive, piezoelectric, optical, magnetic, and inductive [65]. There are a number of tradeoffs among the various mechanisms, including, for example, sensitivity, spatial resolution, accuracy, power consumption, and size. To meet the requirements of many emerging systems, particularly those where it may be difficult to have a physical wired connection to the sensors, many researchers have been investigating the creation of wireless sensors.

Wireless force sensors: A number of wireless capacitive force sensors that leverage a change in capacitance due to deformation have been recently developed. For example, a flexible capacitive sensor was created for wirelessly measuring strain in tires [66], and a capacitive textile sensor was developed for wireless respiratory monitoring [67]. While the capacitive sensing paradigm can work well for a number of force sensing applications, it is not naturally compatible with wireless sensing. In order to wirelessly transmit force information obtained through capacitive sensing, additional hardware and circuits are needed, complicating the design.

Inductor-capacitor (LC) wireless sensors are passive devices that can remotely sense a number of parameters, including pressure. The working principle of these sensors is based on changes in the capacitance that causes a shift in the LC resonant frequency, which can be wirelessly measured [68, 69]. A number of these LC sensors have been developed for applications like monitoring of pressures during arterial blood flow [70], and the measure of finger tip forces during athletic activities [71]. However, the resonance frequency of these sensors is in the range of a few hundred kHz to a few MHz [69], which makes wireless sensing difficult. As a consequence, these sensors suffer from short interrogation distances in the range of a few centimeters [69, 72].

There has also been a large body of research on strain sensors [35, 73–76]. In strain sensing, instead of sensing the normal transversal force, the longitudinal force is sensed. Longitudinal force has a tendency to stretch and elongate the object it is acting upon, hence these sensors estimate the change in the length to infer strain. Thus, most of the wireless strain sensors exploit the shifts in resonant frequencies to sense strain. Thhat is, to infer strain, a wireless reader evaluates signal strength at multiple frequencies, to estimate the resonant frequency, where a notch will form in the signal strength measurements. It is well known that signal strength is a fickle quantity easily corrupted by multipath. Indeed, most of these works show evaluations in a controlled, anechoic environment, and the technology has not been found to be robust to static multipath [74].

Backscatter sensing systems: Recent advancements in 'backscatter sensing' has enabled the creation of passive, battery-free touch interfaces. Touch sensing has been a well explored use case of RFID-based sensing [41, 42, 77–82]. IDSense [82] utilized the fact that reflected RSS and phase change in a unique way when the RFID chip is touched, and following up on this PaperId [81] even gave a simple manufacturing method by which one could simply use an inkjet printer to manufacture these RFID tags and augment everyday objects with touch interactions. RIO [41] further explored the touch to reflected signal phase mapping to extend touch sensing to multiple RFID tags by utilizing mutual coupling effects, and extended the design further to use custom designed, application specific RFID tags. Livetag [42] presented a similar touch sensing system showing how to sense these touch interactions using Wi-Fi based readers, instead of relying on expensive, dedicated RFID readers used by earlier works. However, none of these systems could sense force magnitude and were limited to sensing just the position where the tag was being touched in order to sense simple gestures/sliding movements etc.

10.1 Replacing SDR with COTS

We can read the sensor using a COTS-WiFi implementation which can provide CSI, like Quantenna [83]. With COTS devices, periodic channel estimates can be obtained with similar time latency as compared to our implementation using SDRs. In our implementation, $T = 60\mu s$ (Section 4.4), which is reasonably higher than packet sizes of $12\mu s$ achievable by 1 Gbps WiFi systems [84]. A potential issue could be MAC overheads, as also cited in [84], however, we can alter the packet structure slightly to avoid backoffs which can mitigate against the MAC overheads. However, with COTS devices, we will have to deal with CFO effects in the measured channel response.

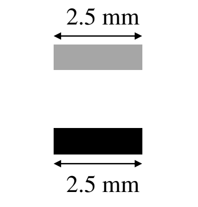
In our implementation on USRP, we had TX and RX sharing the same RF chain. With COTS devices like quantenna, we will have TX and RX as separate devices which might not be able to share a clock, thus leading to frequency and phase offsets. Although WiForce design is robust to phase offsets due to our differential phase sensing approach, we would need to counter CFO. To counter the CFO effects, we can use the fact that CFO will remain same for both the direct path between TX and RX, and the reflected signal from the sensor. To do so, we can consider a differential sensing approach by calculating phase relative to the direct path, and similar approaches have been explored to do so in past work [85, 86]

10.2 HFSS Simulations

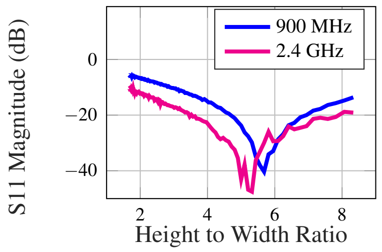
For an air substrate microstrip transmission line, we have the following equation which governs the impedance matching, $Z = 60 \ln \left[\frac{6h}{w} + \sqrt{1 + \left(\frac{2h}{w} \right)^2} \right]$, where h is the vertical separation between signal and ground trace, and w is the width of the signal trace [87].

Setting $Z = 50\,\Omega$ in the above equation, gives us the operating $\frac{h}{w}$ ratio to be approximately $5:1$. In order to interface SMA connectors to the air-substrate microstrip line designed, we have to increase the width of the ground trace so that the bottom legs of the SMA connector can be soldered directly to the ground trace.

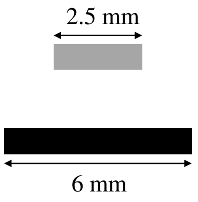
However, we notice some deviation from this ratio when the width of ground trace is increased to allow for easier interfacing with SMA connectors. We simulate the sensor in Ansys HFSS (Fig. 16) to determine this deviation, and observe that the ideal operating ratio shifts to about 4:1 instead of 5:1 when the width of ground trace is increased.



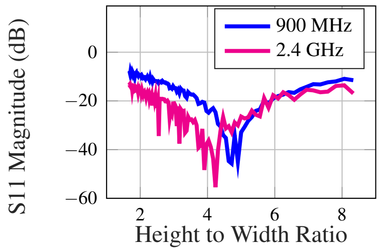
(a) Signal (gray) and Ground (black) traces



(b) Insertion Loss optimal near 5:1 ratio



(c) Signal (gray) and Ground (black) traces



(d) Insertion Loss optimal near 4:1 ratio

Figure 16: HFSS simulation results: as the ground layer width is increased to allow for easier interfacing with the SMA connector, the ideal height:width ratio decreases from 5:1 to 4:1.

10.3 Performance with distance

We also evaluate our sensor and wireless reader design over a range of distances. For this experiment, we place the TX antenna, sensor antenna and RX antenna along a straight line. The TX antenna is placed 4 m away from the RX antenna, and the sensor is moved from the midpoint, which is 2 m away from both to distances, closer to the RX antenna, and farther away from the TX antenna. The TX power is set to 10 dBm, and the center frequency for this experiment was 900 MHz. We can observe that the sensor gives accurate and satisfying phase stability of less than 1^o even at a distance of 1 m, 3 m from the RX/TX, and acceptable within 5^o performance even at the worst 2 m, 2 m distance from the TX/RX. These operating distances are comparable with previously shown evaluations with RFID based backscatter at 900 MHZ [41], which tested sensing at a maximum distance of 2 m from the RFID reader.

MAVL: Multiresolution Analysis of Voice Localization

Mei Wang[*], Wei Sun[*], Lili Qiu
The University of Texas at Austin

Abstract

The ability for a smart speaker to localize a user based on his/her voice opens the door to many new applications. In this paper, we present a novel system, MAVL, to localize human voice. It consists of three major components: (i) We first develop a novel multi-resolution analysis to estimate the AoA of time-varying low-frequency coherent voice signals coming from multiple propagation paths; (ii) We then automatically estimate the room structure by emitting acoustic signals and developing an improved 3D MUSIC algorithm; (iii) We finally re-trace the paths using the estimated AoA and room structure to localize the voice. We implement a prototype system using a single speaker and a uniform circular microphone array. Our results show that it achieves median errors of 1.49^o and 3.33^o for the top two AoAs estimation and achieves median localization errors of $0.31m$ in line-of-sight (LoS) cases and $0.47m$ in non-line-of-sight (NLoS) cases.

1 Introduction

Motivation: The popularity of smart speakers has grown exponentially over the past few years due to the increasing penetration of IoT devices, voice commerce, and improved Internet connectivity. The global smart speaker market is estimated to grow at a rate of 21.12% annually and reach 19.91 billion US dollars in 2024.

The ability to localize human voice benefits smart speakers in many ways. First, knowing the user's location allows the smart speaker to beamform its transmission to the user so that it can both hear from and transmit to a faraway user. Second, the user location gives context information, which can help us better interpret the user's intent. For example, as shown in Figure 1, when the user issues the command to turn on the light, the smart speaker can resolve the ambiguity and tell which light to turn on depending on the user's location. In addition, knowing the location also enables location based services. For instance, a smart speaker can automatically adjust the temperature and lighting condition near the user. Moreover, location information can also help with speech recognition and natural language processing by providing important context information. For example, when a user says "orange" in the kitchen, it knows that refers to a fruit; when the same user says "orange" elsewhere, it may interpret that as a color.

[*]Both authors contributed equally to this work

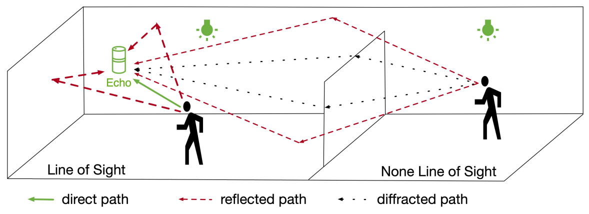

Figure 1: Illustration of application for MAVL under multiple coherent incoming paths in LoS and NLoS scenarios.

There have been a number of interesting works on motion tracking and localization using audio [23, 25, 29, 32, 41, 44, 50, 52], RF [43, 45, 48] and vision-based schemes [8, 53], etc. Cameras cannot be deployed everywhere at home for privacy concerns. Device-based tracking requires carrying a device, which is not convenient for people at home. Device-free RF is interesting, but requires large bandwidth, many antennas, or mmWave chips to achieve high accuracy, which is not easy to deploy at home. Meanwhile, acoustic-based tracking has also been shown to achieve high accuracy. In the past few years, acoustic tracking accuracy has improved from centimeter level [50] to millimeter level [23, 29, 41, 44]. These works focus on tracking users by emitting specially designed acoustic signals. These signals are mostly in inaudible frequency range $16kHz$-$22kHz$.

Challenges: Despite significant acoustic based tracking works, localizing human voice poses new challenges:

- Many of the existing systems require transmission of known signals (*e.g.*, chirps, OFDM symbols, sine waves).

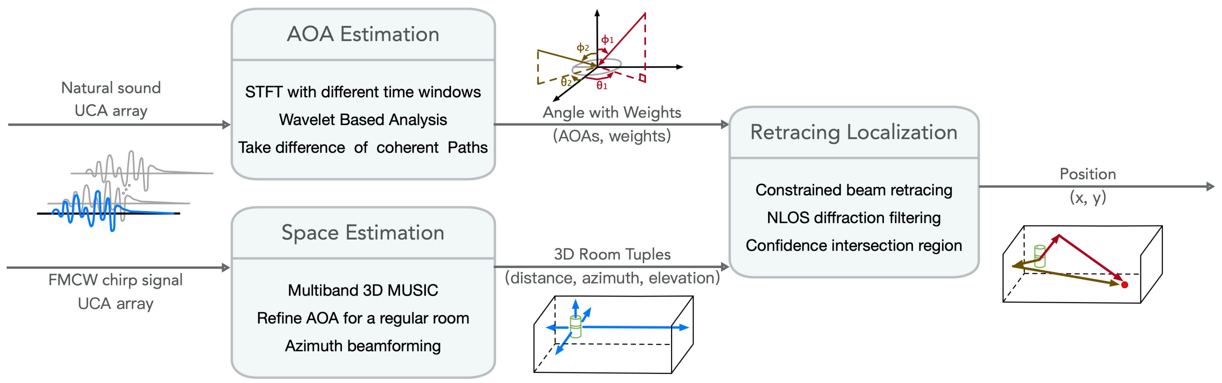

Figure 2: MAVL system involves a three-step process. (1) estimate AoA from multiple paths, (2) recover room structure by actively emitting wideband chirps, (3) localize the voice by retracing back the estimated AoA based on room structure.

In comparison, we can neither control nor predict users' voice signals, including their timing, frequency, and content. This makes it challenging to apply traditional channel estimation and distance estimation based methods.

- In order to localize a user, we need to estimate angle of arrival (AoA) of multiple propagation paths so that we can trace back these paths to localize the user. The signals traversing via multipath are coherent, which significantly degrades the accuracy of AoA estimation methods (*e.g.*, MUSIC requires all signals be independent).

- To enable retracing the location using multiple AoAs, we also need to estimate the indoor environment first. However, depth sensors are not widely deployed at home and vision-based approaches raise privacy concerns.

- The user may not be in line of sight (LoS) from the smart speaker (*e.g.*, the user is behind a wall or in a different room). Localizing the user in NLoS using acoustic signals remains an open problem due to low SNR and detoured propagation paths.

Our approach: In this paper, we build a novel indoor voice localization system, MAVL, by retracing multiple propagation paths that the user's sound traverses, as shown in Figure 2. First, we estimate AoAs of the multiple paths traversed by the voice signals from the user to the microphone array on the smart speaker. The multipath may include the direct path (if available) and the reflected paths. Second, we estimate the indoor space structure (*e.g.*, walls, ceilings) by emitting wideband chirps to estimate the AoA and distance to the reflectors in the room (*e.g.*, walls). Third, we re-trace the propagation paths based on the estimated AoA of the voice signals and the room structure to localize the voice.

We choose AoA since it eliminates the need of distance estimation, which is challenging when we do not know the transmission signals. We use a microphone array widely available on a smart speaker to collect the received signals. While there have been many AoA algorithms proposed, the low frequency of voice signals and the presence of coherent paths pose significant new challenges. To reduce coherence and separate paths, we capture the voice signal that finishes fast so that the signal traversing via the shortest path has small or no overlap with those traversing via the longer paths. We cannot control how many words a user speaks. Instead, we could select the voice signals that occupy some frequencies for a short time period. This requires good time and good frequency resolution. Since there is no single method that can simultaneously achieve good time and good frequency resolutions, we perform wavelet and STFT analyses over different time windows to benefit from both transient signals with low coherence and long signals with high cumulative energy. We further use differencing to cancel the signals in the time-frequency domain to reduce coherence, thereby improving the AoA accuracy.

Next we need to estimate the room contour, *i.e.*, the distances and direction of the walls. Researchers have used depth sensors [2, 15, 31], cameras [9, 18, 21] or multiple sensors [7, 12, 49] to estimate the indoor room contour. However, these systems require extra sensors and some need significant computation cost. It also raises significant privacy concerns. Acoustic has been applied to image the shape of objects [20, 24, 47]. It is promising to use acoustic signals to capture the room contour. Our system emits wide-band Frequency Modulated Continuous Waves (FMCW) chirps and propose the wide-band 3D MUSIC to estimate multiple propagation paths simultaneously. The wide bandwidth not only improves distance resolution, but also allows us to leverage the frequency diversity to estimate AoAs of coherent signals. We improve the AoA estimation by leveraging the assumption of a rectangle room (which is common in real world scenarios), and improve the distance estimation to the wall by using beamforming.

Finally, we develop a constrained beam retracing algorithm based on the estimated AoA candidates and room structure.

We localize the user at the intersection between the propagation paths with only one-time reflection. Our retracing can effectively identify the plausible user location.

We implement and evaluate our AoA and localization approaches in an anechoic chamber, conference room, bedroom and living room. Our results show that our AoA estimation yields median errors of 1.49^o and 3.33^o for the top two paths in LoS, and 2.75^o and 6.49^o in NLoS. Moreover, our retracing algorithm can localize the user with a median error of $0.31m$ in LoS and $0.47m$ in NLoS.

The contributions can be described as follows:

1. We develop a multi-resolution analysis to estimate the AoA of multipath. It combines STFS over different window sizes and wavelet to reduce coherence between signals.
2. We develop an effective method to estimate room structure and retrace the user based on the estimated AoA and room structure.
3. We implement a system to actively map indoor rooms and localize voice sources using only a smartspeaker without additional hardware. Our prototype system can localize voice in both LoS and NLoS. To our knowledge, this is the first indoor sound source localization system that works for None-Line-of-Sight (NLoS) scenarios.

2 Primer on AoA Estimation

In this section, we introduce AoA estimation problem, existing approaches, and challenges.

2.1 Antenna Array Model

We can estimate the AoA using an antenna array. The antenna array can take different forms, such as uniform circular array (UCA), uniform linear array (ULA), or even non-uniform array. This paper uses a uniform circular array consisting of N microphones as shown in Figure 3. The circle has a radius of r. The azimuth and elevation angles of signal arrival are θ and ϕ, respectively.

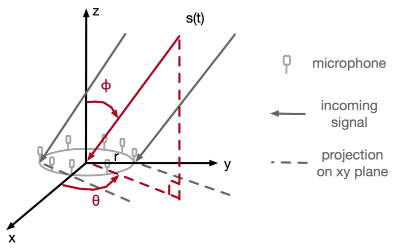

Figure 3: UCA Array model and angle notations.

A general model for the received signal of a single source is

$$x(t) = a(\theta,\phi)s(t) + n(t), \qquad (1)$$

where a is the array steering vector and $n(t)$ is the noise vector. The steering vector for UCA is as follows:

$$a(\theta,\phi) = [1, e^{j2\pi\frac{f}{c}rcos(\theta)sin(\phi)}, \ldots, e^{j2\pi\frac{f}{c}r(N-1)cos(\theta)sin(\phi)}]^T. \qquad (2)$$

where f is center frequency and c is sound propagation speed. For M independent source signals $S(t) = [s_1(t), \ldots, s_M(t)]^T$, we can extend the steering vector to a steering matrix, $A(\theta,\phi) = [a(\theta_1,\phi_1), \ldots, a(\theta_M,\phi_M)]$, where the i_{th} column is the steering vector associated with the i_{th} signal.

2.2 AoA Estimation Algorithms

There are several AoA estimation algorithms, including phase [43], MUSIC [35], ESPIRIT [17], and beamforming. The subspace based MUSIC algorithm is the most accurate. To apply MUSIC, we calculate the auto-correlation matrix R for the received signals x as $x^H x$, where x^H is conjugate transpose of x and R has the size $N \times N$. Following that, we apply eigenvalue decomposition to R, and sort the eigenvectors in a descending order in terms of the magnitude of corresponding eigenvalues. The space spanned by the first M eigenvectors is called *signal space*, and the space spanned by the other eigenvectors is called *noise space*. Let R_N denote the noise space matrix, whose the i_{th} column is the i_{th} eigenvector in the noise space. It can be shown that

$$R_N^H \cdot a(\theta_0,\phi_0) = 0, \qquad (3)$$

when θ_0 and ϕ_0 are the incoming azimuth and elevation angles [35]. Based on this property, we can define a pseudo-spectrum of the mixed signals as

$$p(\theta,\phi) = \frac{1}{a(\theta,\phi)^H R_N R_N^H a(\theta,\phi)}. \qquad (4)$$

Then we can estimate the AoA by locating peaks in the pseudo-spectrum.

2.3 Modeling Multipath Propagation

Now we consider signals under multipath propagation. Most traditional AoA estimation algorithms have the assumption that the signal sources should be independent. In contrast, our system requires estimating the AoA of multipath and have to handle coherent signals. To capture multipath effects, we introduce a channel matrix $H(\alpha,d) = [h(\alpha_1,d_1), \ldots, h(\alpha_M,d_M)]^T$, where α_i, d_i, and $h(\alpha_i,d_i) = \alpha_i\frac{d_0}{d_i}e^{j2\pi\frac{f}{c}d_i}$ are the attenuation, propagation delay, and channel of the $i-th$ path, respectively. The received signal $x(t)$ under multipath is as follows:

$$x(t) = A(\theta,\phi)H(\alpha,d)s(t) + n(t), \qquad (5)$$

For the array model under multipath in Equation 5, we define a transformation matrix $T = A * H$ to capture the array manifold matrix A and propagation paths H. The transformation matrix T is

$$T_{i,j,k} = \alpha_j \frac{d_0}{d_j} e^{j2\pi \frac{d_j}{\lambda_k}} e^{j2\pi \frac{r}{\lambda_k}(i-1)cos(\theta_j)sin(\phi_j)} \tag{6}$$

where $1 \leq i \leq N$ denotes the microphone index, $1 \leq j \leq M$ denotes the j_{th} arrival path, and k denotes the frequency bin index. The transformation matrix T takes three dimensions: spatial dimension i, path delay in time dimension j, and frequency dimension k, which allows us to perform cancellation in the time-frequency domain.

The received signal from all incoming paths to microphone m_i on frequency f_k is

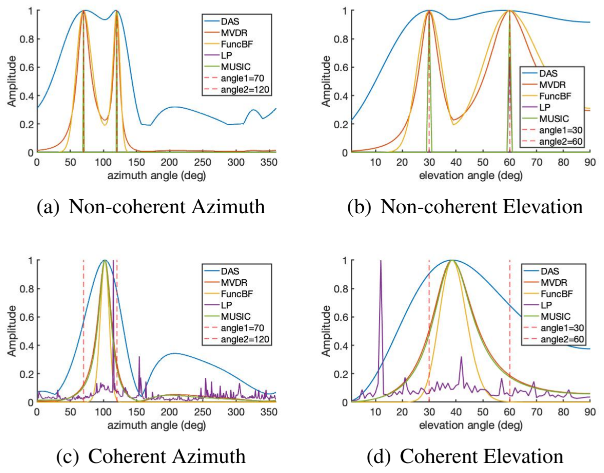
$$x(t)_{i,k} = \hat{T}_{i,k} * s(t) + n(t). \tag{7}$$

where $\hat{T}_{i,k} = \sum_{1 \leq j \leq M} T_{i,j,k}$. In order to estimate the AoA of multipath, we need to deconvolve $\hat{T}_{i,k}$ to each propagation path $T_{i,j,k}$.

2.4 Challenges

Coherent signals: A major source of AoA error comes from the coherence in the incoming signals. In our context, the received signals come from the same voice source and only differ in their propagation paths. Such strong correlation can significantly degrade the AoA estimation accuracy. We quantify the impact of coherent signals on several well-known AoA estimation schemes in the frequency range of human voice. We use a UCA with radius of $9.6cm$, which is approximately the half wavelength of $2kHz$. The two signals are $(70, 120)$ and $(30, 60)$ in the azimuth and elevation angles. Figure 4(a) and (b) are the azimuth and elevation power profiles of five AoA algorithms for two non-coherent signals and Figure 4(c) and (d) are profiles of two coherent multipath signals coming from the same source. MUSIC performs the best in all scenarios. However, when coherence occurs, the estimation errors increase in all algorithms. For example, the two peaks in MUSIC merge into one peak in this case and LP even gives incorrect results.

Impact of frequency: The low frequency of the voice also accounts for part of the error. Existing acoustic tracking schemes (*e.g.*, [23,25,44]) use frequency at $16kHz$ or higher. In comparison, human voice is typically below $6kHz$ [27, 33] and most energy is concentrated in $100Hz$-$3kHz$. The corresponding wavelength ranges between $11cm$ and $3.4m$. The resolution of angle of arrival is determined by the antenna separation distance normalized by the wavelength. Therefore, with centimeter level separation between the microphones and dm-level wavelength, the AoA resolution is very coarse.



(a) Non-coherent Azimuth (b) Non-coherent Elevation

(c) Coherent Azimuth (d) Coherent Elevation

Figure 4: Comparison of power profiles for different AoA algorithms in non-coherent (a,b) and coherent (c,d) scenarios. Coherence makes peaks merged and introduces error.

Summary: The above evaluation shows that MUSIC is competitive for AoA estimation accuracy. However, the accuracy is still insufficient to support coherent low-frequency voice signals. Motivated by these observations, next we will design approaches to explicitly address these major challenges.

3 Multipath Voice Localization

We decompose our approach into the following three steps: (i) estimate the AoA of coherent low-frequency voice signals, (ii) estimate the room structure, (iii) retrace the paths to localize the user. Below we describe each step in turn.

3.1 AoA Estimation of Voice Signals

As shown in Section 2, we should address two major challenges in AoA estimation of human voices: (i) received signals are strongly correlated and (ii) limited resolution due to the low frequency of human voice. Below we describe our sections in turn.

Limitation of existing work: Recently, Voloc [37] proposed an iterative-delay-and-cancellation algorithm to align and cancel the correlated paths to separate multipath signals in the time domain. Their first step, called ICA, is to estimate the AoA of the first reflection by using the initial recording samples before mixing with the second reflection. However, this method introduces two major problems. First, in order to cancel in the time domain, we need to use a small enough time window during which only samples from the direct path are included, usually only tens of samples. A small number of samples limits the AoA estimation accuracy. Moreover, hu-

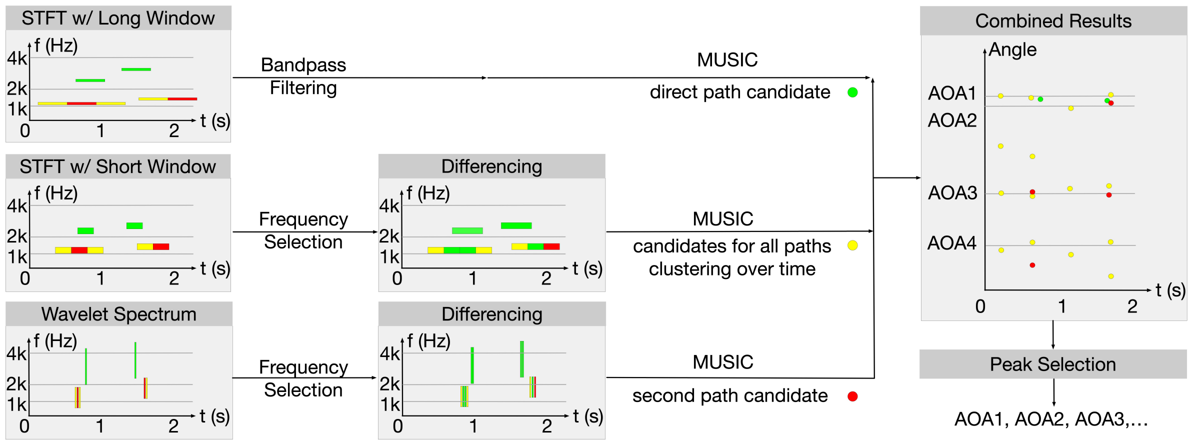


Figure 5: Illustration for multi-resolution analysis algorithm. We perform wavelet and STFT analyses over different time windows followed by the differencing component for small windows. We synthesize the combined results to select the final AoA results.

man voice ramps up slowly. This means the beginning cleaner audio samples for AoA estimation have low SNR, which also limits the accuracy. In addition, the cyclic autocorrelation property of human voice is large, which indicates small alignment error introduces large cancellation error. Therefore, Voloc reports over 10 degrees error for the first path AoA and relies on their second step, which uses joint optimization based on wall geometry to refine the estimation result. This has several limitations: (i) its standalone AoA estimation has limited accuracy, and (ii) the second step requires exploring a large search space, which is very time consuming (*e.g.*, hours to estimate wall parameters and 5 seconds to localize voice).

Overview: Different from [37], we use time-frequency analysis to reduce coherence in voice signals since signals that differ in either time or frequency will be separated out. As the transformation matrix $T_{i,j,k}$ shown in Equation 6, the IAC algorithm in Voloc aligns phases for each microphone i to cancel path delays d_j and get the second reflected path. We first separate coherence in across different frequency bins, and then cancel the paths in each frequency bin by taking the difference between the two consecutive time windows. This is especially useful for voice signals since different pitches may occur at different time. An important decision in time-frequency analysis is to select the sizes of time window and frequency bin to perform the analysis.

On one hand, aggregating the signals over a larger time window and larger frequency bin improves SNR and in turn improves the AoA estimation accuracy according to the Cramer-Rao bound [38]. On the other hand, a larger time window and larger frequency bin also mean more coherent signals. Moreover, the frequency of voice signals varies unpredictably over time, which makes it challenging to determine a fixed time window and frequency bin.

To separate paths with different delay, we desire good time resolution. Small time windows have good time resolution, but poor frequency resolution. To separate paths with different frequencies, we desire good frequency resolution. Small frequency bins have good frequency resolution, but poor time resolution. Therefore, there is no single time window or frequency bin that works well in all cases.

To address this challenge, we use multi-resolution analysis as illustrated in Figure 5. Specifically, we use Short Term Fourier Transform (STFT) with different window sizes and wavelet as they are complementary to each other. Our first method performs STFT using a large time window and feeds the spectrogram to MUSIC. While STFT results with large window have more coherent signals, which results in more outliers, their peaks also include points that are close to the ground truth, likely due to the stronger cumulative energy. Our second method is to perform frequency analysis using smaller windows and take difference between adjacent windows to reduce the coherent signals and improve AoA estimation under coherent multipath. Our third method uses wavelet. It has higher time resolution for relatively high frequency signals. This allows us to capture the transient voice signals that has low or no coherence, thereby reducing outliers in MUSIC AoA estimation. However, since transient signals have low cumulative energy and cause non-negligible AoA estimation errors, we combine Wavelet with STFT with different window sizes. Below we elaborate these three methods.

STFT using a large window size: We perform STFT using a larger time window. A larger window yields higher SNR and hence higher accuracy according to the Cramer-Rao bound [38]. On the other hand, a larger window tends to have more coherent multipath, which may degrade the accuracy. This is shown in Figure 4(c), where we see a merged peak near the ground truth. So this approach can provide information about the AoA of the direct path, but not sufficient on its own.

STFT using a short window: Using a smaller time window gives good time resolution and helps separate paths with different delays. We choose to use a smaller time window and select the evanescent pitches in the time-frequency domain to reduce error from coherence. The next step is to further reduce coherent signals by taking difference between two consecutive time windows for each antenna. This cancels the paths with different delay in the time-frequency domain, and is more effective than cancelling in the time-domain alone. If the difference between two adjacent windows is greater than the delay difference of any two paths, this process can remove the old paths. This cancellation is not perfect since the amplitude may vary over time and each window may contain different sets of paths. Nevertheless it reduces coherence in a short time window.

Wavelet based analysis: Wavelet is a multi-resolution analysis. We can use both short basis functions to isolate signal discontinuities and long basis functions to perform detailed frequency analysis. It has super resolution for relatively high frequency signals. Transient signals in small time window have less energy and may yield large errors. To improve the accuracy, we also take difference of wavelet spectrum in the two consecutive time windows to further reduce the coherence.

Comparison: We compare the AoA derived from applying MUSIC to STFT and wavelet. Figure 6 shows the result for the case where a woman speaks at $2.4m$ away from the microphone array. The dashed red lines are ground truth AoAs of different paths. The STFT results without taking difference, shown in the blue circles, deviate from the right angles due to coherence even after using different window sizes. The wavelet results without taking difference are plot as yellow circles, which also deviates a lot from red dashed lines because of low energy. The stared orange and purple points are the AoA estimates derived from MUSIC when we apply differencing to STFT and wavelet, called STFT Diff and Wavelet Diff methods. Compared with the original results (shown in blue and yellow circles), differencing brings the estimation closer to the ground truth angles (shown as dashed lines). It is interesting to observe that there are false peaks in STFT Diff but the peaks in the Wavelet Diff are all close to the ground truth though STFT Diff may have peaks closer to the ground truth than the wavelet. This suggests that it is beneficial to combine STFT Diff and wavelet Diff results.

Final algorithm: Figure 5 shows our final algorithm. For each algorithm, we derive the results using different time windows. Then we compute weighted cluster of these points where the weight is set according to the magnitude of the MUSIC peak. We select the top K clusters from each algorithm. Our evaluation uses $K = 6$. To combine the results across different algorithms, we use nearest neighbors. Since STFT with a large window provides more stable results without significant outliers, we use them to form the base. For each point in the base, we search for the nearest neighbor in the results of the other two methods as they contain both more accurate real peaks and outlier peaks. Finally, we pick the top P peaks from the selected nearest neighbors as the final AoA estimates. Our evaluation uses $P = 5$.

3.2 Room Structure Estimation

In order to localize the user, we need not only the AoAs of the propagation paths of the voice signals, but also the room structure information so as to retrace back the paths. In this section, we estimate the room contour using wideband 3D MUSIC algorithms. We improve the accuracy by leveraging constraints of the azimuth AoA and applying beamforming.

3.2.1 3D MUSIC

The smart speaker estimates the room structure once unless it is moved to a new position. The smart speaker estimates room structure by sending FMCW chirps. Let f_c, B and T denote the center frequency, bandwith, duration of the chirp. Upon receiving the reflected signals, it applies the 3D MUSIC algorithm.

We generalize 2D Range-Azimuth MUSIC algorithm [5,6,22] to 3D joint estimation of distance, azimuth AoA and elevation AoA. 3D MUSIC has better resolution than 2D MUSIC since the peaks that differ in any of the three dimensions are separated out. Our basic idea is to transform the received signals into a 3D sinusoid whose frequencies are proportional to the distance and a function of the two angles. We extend the steering vector to have three input parameters: distance R, azimuth angle θ, and elevation angle ϕ.

$$\hat{a}(R,\theta,\phi) = e^{j2\pi \frac{r}{c} f_c \sin\phi \cos(\theta - \frac{2\pi i}{N}) + j4\pi \frac{RB}{cT} N_s M_s T_s}, \qquad (8)$$

where i is the array index, N is the number of microphones, r is the radius of the microphone array, c is sound speed, N_s is the subsampling rate, M_s is the temporal smoothing window and T_s is the time interval.

3.2.2 Our Enhancements

However, there are several challenges in applying the 3D MUSIC algorithm to indoor environments. First, the number of microphones and their sizes are both limited, which limits the resolution of 3D MUSIC. Second, there is significant reverberation in indoor scenarios. Third, large bandwidth is required to get accurate distance estimation, but MUSIC requires narrowband signals for AoA estimation. Therefore, we develop three techniques to improve the 3D MUSIC algorithm: (i) leveraging frequency diversity, (ii) incorporating the fact that rooms are typically rectangular shaped, and (iii) using beamforming to improve distance estimation.

Multiband 3D MUSIC: We use FMCW signals from $1kHz$ to $3kHz$ for AoA estimation. To satisfy the narrowband requirement in the MUSIC algorithm [35], we divide the 2 KHz bandwidth into 20 subbands each with $100Hz$. Since the frequency of FMCW signal increases linearly over time, we can divide the FMCW signal into multiple subbands in the time domain, run 3D MUSIC in each subband, and then sum up the MUSIC profiles from all subbands.

In order to use the $100Hz$ subband for 3D MUSIC, we should properly align the transmission signal with the received signal so that they span the same subband. The alignment is determined by the distance. Therefore, we search over the azimuth and distance for a peak in the 3D MUSIC profile obtained by mixing the received signal with the transmitted signal that is sent δT ago, where δT is the propagation delay and determined based on the distance.

We use the azimuth AoA and distance output from the 3D MUSIC. Figure 7 shows an example of azimuth-distance profile. Note that we adjust the elevation angle to the horizontal AoA since the elevation AoA estimation from the UCA (which has all antennas on the same horizontal plane) is not very accurate. However, despite a larger error in elevation AoA, the 3D MUSIC is more effective in separating the paths than the 2D MUSIC.

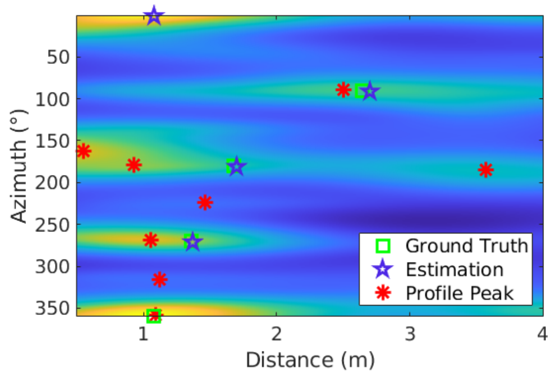

Figure 7: An example of azimuth-distance profile from real trace. Azimuths are accurate and distances requires further the fine granularity search.

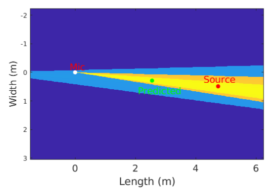
Refine AoA for a regular room: Due to multipath, the MUSIC profile can be noisy, which makes it hard to determine the right peaks to use for distance and AoA estimation of walls. Since most rooms take rectangular shapes, we leverage this information to improve peak selection. Specifically, we select the peaks such that the difference in the azimuth AoA of two consecutive peaks are as close to 90^o as possible. That is, we search for the 4 peaks $\{\theta_0, \theta_1, \theta_2, \theta_3\}$ from the 3D MUSIC profile that minimizes the fitting error with a rectangular room (*i.e.*, $min \sum_i |PhaseDiff(\theta_i - \theta_{i+1}) - \pi/2|$, where $PhaseDiff(.)$ is the difference between the two angles by taking into account of the phase wraps every 2π. After finding these peaks, we further adjust the solutions so that the difference between the adjacent AoA is exactly $\pi/2$. This can be done by find θ_1' that minimizes $\sum_i |PhaseDiff(\theta_1' + \pi/2(i-1) - \theta_i)|$ and the final AoA is set to $(\theta_1', \theta_1' + \pi/2, \theta_1' + \pi, \theta_1' + 3/2\pi)$.

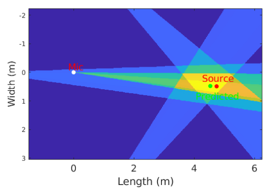
Improve distance estimation by beamforming: Accurate distance estimation requires a large bandwidth and high SNR. Therefore, to improve distance estimation, we send $1kHz$-$10kHz$ FMCW chirps. Among them, we only use $1KHz - 3KHz$ for AoA estimation to reduce computational cost since MUSIC requires expensive eigenvalue decomposition, but use the entire FMCW for distance estimation. We increase the SNR using beamforming. We use delay-and-sum (DAS) beamforming algorithm towards the estimated azimuth AoAs. Then we search a peak in the beamformed FMCW profile. We find that the peak magnitude increases significantly and get more accurate distance estimation after beamforming.

3.3 Constrained Beam Retracing

We can localize the user by retracing the paths using the estimated AoA of the voice signals and room structure. As shown in left figure of Figure 8, we can first find the reflection points on the walls by the propagation path derived from the estimated AoA. Then we trace back the incoming path of voice signals before the wall reflection based on the reflection property. If we have at least two paths, the user is localized at the intersection between the incoming paths. However, the above method is not robust against AoA estimation error. When simulating the retracing algorithm, we find that even when the AoA estimation errors of 2 paths are only 0.5 degrees, it can cause a localization error of more than 60 cm at a distance of 4 meters. A small AoA error can result in a large localization error at a large distance. Moreover, an AoA error in the outgoing path can result in an error in the incoming path, thereby further amplifying this effect. To enhance robustness



(a) Two near parallel paths



(b) More paths

Figure 8: Retracing using ray or cone.

against AoA estimation, we employ two strategies. First, instead of treating each propagation path as a ray defined by the estimated AoA, we treat it as a cone where the cone center is determined by the estimated AoA and the cone width is determined by the MUSIC peak width. This allows us to capture the uncertainty in the AoA estimation.

Second, while theoretically two paths are sufficient to perform triangulation, it is challenging to select the right paths for triangulation. Therefore, instead of prematurely selecting incorrect paths, we let the AoA estimation procedure return more paths so that we can incorporate the room structure to make informed decision on which paths to use for localization. Specifically, for each of the K paths returned by our AoA estimation, we trace back using the cone structure as shown in Figure 8. We observe that the azimuth AoA is reliable for the strongest path, which is the direct path in LoS or the path from the user to the ceiling and then to the microphone in NLoS. Therefore, within the cone corresponding to the strongest path we search for a point O such that the circle centered at the point with radius of 0.5m overlaps with the maximum number of cones corresponding to the other $K-1$ paths. We localize the user at the point O. Our evaluation sets $K = 4$.

4 Implementation

Setups: We implement our system on a Bela platform [4]. It is connected with a JBL Clip 3 or an echo dot speaker and a circular microphone array with 8 microphones. Figure 9 shows an example setup in a conference room. Each microphone uses a sampling rate of 22.05kHz. Many commercial smart speakers have similar numbers of speakers and microphones. We test our system using two microphone arrays: a larger array has radius of 9.6cm and a smaller one has radius of 5.0cm. We use the smaller array to compare with VoLoc [37] since its size is similar to their setup. The Bela board uses a 1 GHz ARM Cortex-A8 single-core processor. The Bela is connected to a laptop with Intel I5 processor and 8GB memory. We use javaosc protocol to listen and continuously transmit the audio signals in WAV format encapsulated in OSC packets to the laptop through USB in real time and run the processing program in MATLAB on the laptop to derive the AoAs and localize the user. In MAVL , AoA estimation takes 2.35 seconds, room estimation takes 87 seconds, and retracing takes 0.16 seconds. In comparison, VoLoc spends hours in estimating wall parameters and 5 seconds in AoA estimation.

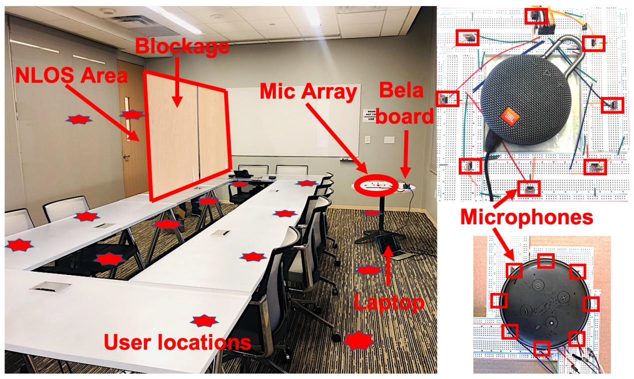


Figure 9: System setups in conference room and mic arrays.

Evaluation environments: We evaluate our system in different environments, including an anechoic chamber, conference room, bedroom and living room. These rooms take different sizes: 2.5m×3.5m, 3.5m×4.0m, and 5.1m×7.5m. We use a wooden board as a blockage in NLoS cases as shown in Figure 9. We let a person speak at $1-6$ meters away from the microphone array in the room. We also vary the distance, users, type of voices (*e.g.*, man, women, child and applause), smartspeaker positions, clutter and noise levels to assess their impacts.

Ground truth: We measure the relative locations of the smartspeaker, user and walls using a measuring tap. We derive the ground truth AoAs of the direct path and 5 reflected paths (*i.e.*, the paths from 4 side walls and ceiling) in LoS scenarios. In NLoS scenarios, we derive the AoAs of the 4 reflected paths and 1 diffraction path.

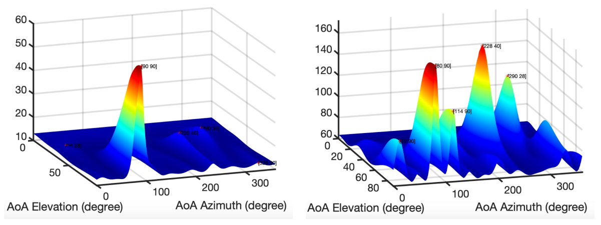
Metrics: We quantify the errors using both AoA estimation error and localization error. The localization error is computed based on the Euclidean distance between the ground truth and estimated positions.

5 Evaluation

In this section, we evaluate our AoA estimation, room contour estimation, and voice localization accuracy.

5.1 Performance of AoA Estimation

Two paths in anechoic chamber. We start from testing our AoA estimation algorithm in the anechoic chamber, where there is no reflection in the room. We put our microphone array on the ground and place an acrylic board to act as a wall to introduce a reflection path. The ground truth of two angles are 81.95^o and 112.68^o. Figure 10 shows the MUSIC power profile. It has a single merged peak around 90^o, which results in 8^o and 22.68^o errors for the two paths. In comparison, our algorithm accurately estimates these two paths within the error of 1.5^o. We can clearly see there are two separate peaks in our MUSIC profile Figure 10. We also change the acrylic board reflector to other places, and find that MUSIC can separate the two paths only when the difference between two ground truth angles is greater than 90^o. This resolution is not sufficient for voice localization since it is quite likely to have reflected paths within 90^o. In comparison, our approach can separate the two paths as long as they are 30^o apart.



(a) MUSIC with merged peak. (b) MAVL with separated peaks.

Figure 10: Comparison of power profiles in anechoic chamber.

AoA accuracy for LoS and NLoS: Next we conduct experiments in three rooms. Figure 11 shows the CDF of LoS AoA estimation error of six methods for the top 3 angles across all experiments. We use a large UCA of radius $9.6cm$, comparable to Amazon Echo Studio, Google Home Max and Apple HomePod. The median error of our approach for the top two paths are 1.49^o and 3.33^o, respectively. This accuracy is sufficient for retracing. In comparison, the corresponding numbers for MUSIC are 2.55^o and 14.54^o , which are significantly worse.

Figure 12 shows the CDF of NLoS AoA estimation error for the top 3 angles across all experiments. The median errors of the top two paths are 2.75^o and 6.49^o. We also plot the CDF for the third angle estimation. In theory, one can retrace the user's location using two paths. However, a median error around 10^o for the third path is too large to be used directly for triangulation. Nevertheless our cone-based retracing algorithm can still leverage the AoA of the paths beyond the top two paths to improve the localization accuracy despite their relatively high errors.

We also evaluate MAVL using a smaller UCA with a radius of $5cm$, comparable to the size of Echo Dot, Amazon Echo and Google home. Figure 13 compares the AoA accuracy of the first path with MAVL using small UCA, VoLoc using ICA algorithm only and VoLoc using joint estimation. Using our approach, the median AoA error of the first path is 1.98^o and the second path is 4.08^o, both of which are larger than the errors from the larger UCA, which are 1.49^o and 3.33^o, respectively. In comparison, Voloc yields median errors of 18.04^o and 5.28^o before and after joint optimization, respectively, much larger than the errors of MAVL.

AoA performance to distance: Figure 14 plots the AoA error versus the distance between the user and smart speaker in a $7.5m \times 5.1m$ conference room. Overall, the accuracy degrades slightly as the user moves away from the microphone array. The SNR of voice is not a serious problem because its frequency is low and it attenuates slowly in the air.

Interestingly, the AoA error of our approach at $4m$ is better than many other distances. This could be due to the specific room structure and user's distance to the nearby wall. Measurements at the distance around $4m$ were collected when the user is near the middle of the room, which makes the propagation delay from the reflected path well separated from the direct path and alleviates the coherence effects. The measurements at a larger distance (*e.g.*, $5m$) were collected when the user was close to the wall and the difference between the direct path and reflect path is smaller, which makes it more challenging to separate in the MUSIC profile.

Performance to different voices: We classify our measurements into four groups: *i.e.*man, woman, child, and applause. Figure 15 shows the sensitivity to different users' voices. The bars are centered at the mean error and their two ends denote the minimum and maximum values across all traces. Our system is fairly robust across the users and the voice they produced. We also evaluate the applause sound, and find the AoA errors of the two paths are about 1.4^o and 3.0^o. The applause sound has smaller AoA error because it is shorter than the human voice, which reduces coherence and improves AoA estimation accuracy.

Impact of smartspeaker positions: The relative positions between the microphone array and walls have direct influence on multiple propagation paths. VoLoc requires the microphone array to be close to a wall to ensure that the first two

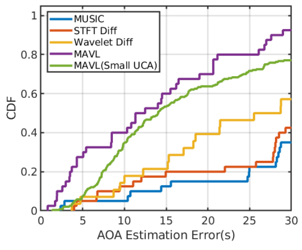
(b) AoA 2 CDF.



(c) AoA 3 CDF.

Figure 11: Comparison of LoS CDF of AoA estimation.

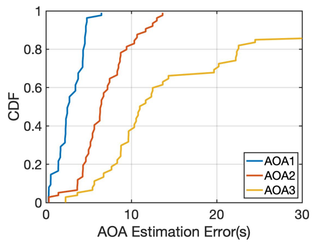


Figure 12: CDF of AoAs error for NLoS.

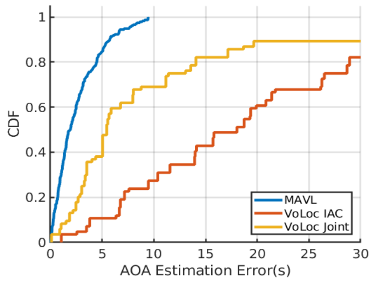

Figure 13: Comparison of AoA estimation for the small UCA.

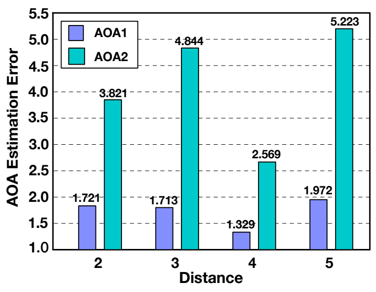

Figure 14: AoA accuracy vs distance.

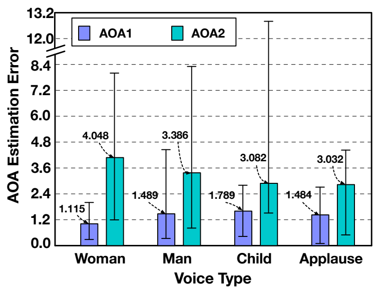

Figure 15: AoA accuracy to voices.

paths come much earlier than other paths. We evaluate the robustness of MAVL against smartspeaker positions. We evaluate UCA setup at three positions:

(1) *center*: 2.35m and 2.92m to the two closest walls;
(2) *close to one wall*: 0.3m and 2.4m to the two closest walls;
(3) *corner*: 0.26m and 0.39m to the two closest walls.

The median AoA errors of MAVL are 1.80^o, 1.97^o, 2.08^o for the direct path, when the smartspeaker is at *center*, *close to one wall* and *corner*, respectively; the corresponding AoA errors are 3.07^o, 4.51^o, 4.37^o for the second path AoA, respectively. MAVL performs best at the *center* and worst near the *corner*. The latter is because the second and third paths have comparable SNR and closer AoAs to the direct path, which increases coherence. But overall it is fairly robust to different placement. In comparison, the median AoA error of VoLoc before its joint optimization is 18.04^o for direct path, when the UCA is placed *close to one wall*. It does not work at the *center* or *corner*. VoLoc only works when the UCA is *close to one wall* and users are not close to any wall.

5.2 Performance of Room Estimation

Next we evaluate our room structure estimation algorithm using different room sizes and microphone placements.

Overall Room estimation Performance: We use room sizes of 2.5m×3.5m, 3.5m×4.0m, and 5.1m×7.5m. The median distance error for all walls is 2.8cm and azimuth error is 1.8^o. We can reduce the azimuth error to 1.4^o by leveraging the knowledge of room shape (*i.e.*, the azimuth angles of walls differ by 90 degrees for rectangular rooms). VoLoc jointly estimates the wall parameters. We follow the VoLoc's setup that the UCA is close to one wall. We speak 5 commands to find the best parameters. The distance error is 2.5cm and azimuth error is 12^o. Its performance is sensitive to the selection of the beginning samples and window size for cancellation.

Impact of smart speaker positions: We also vary the positions of the smart speaker in the rooms to evaluate its impact. We plot the median AoA and distance errors in Figure 16 as we vary the distance between the smart speaker and the wall from 5cm to 20cm. We find an interesting trade-off between the distance error and azimuth error. For the shortest distance range ($< 0.5m$), it has a small distance error of 1.5cm and a larger azimuth error 5.1^o. For the longest distance range ($> 2m$), it has an azimuth error of 1.1^o and a distance error of 5.4cm. The worse distance error for the far away wall has little impact on the final localization error, because the reflected signals from this wall always have a much lower SNR and these results are rarely used for retracing.

5.3 Overall localization results

Localization accuracy: Figure 17 shows the CDF of MAVL localization errors in LoS (blue line) and NLoS (or-

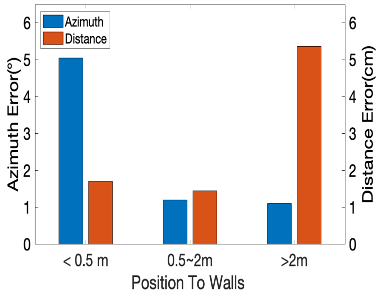

Figure 16: Wall estimation performance over distance.

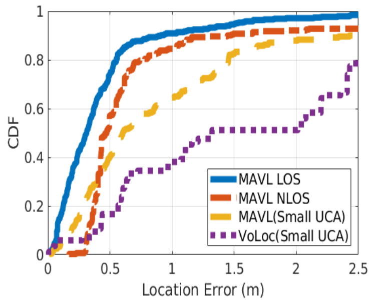

Figure 17: CDF of Localization error for LoS and NLoS, small UCA and Voloc.

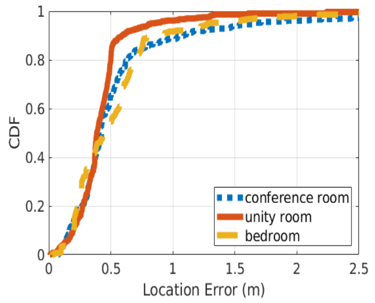

Figure 18: CDF of MAVL Localization error in different rooms.

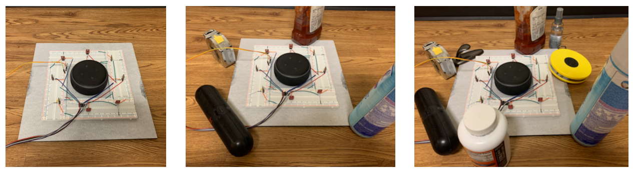
ange line) scenarios. The median error is 0.31m for LoS and 0.47m for NLoS across all ranges and environments in our evaluation. The accuracy decreases slightly in the NLoS scenario compared to LoS because the diffraction path has lower SNR. The overall localization error for smaller UCA is 0.56m in MAVL . VoLoc [37] reports an overall median error of 0.44m in LoS and a median error of 1.7 m at a large distance (>4m). In our setup, we put the smart speaker *close to one wall*, which is the only setup that VoLoc can work, and find the median error of 1.32 m. This error is larger than the one reported in [37] likely due to different distances and environments.

Performance in different rooms: Figure 18 presents the CDF of localization errors in different rooms. We select three representative environments: a 7.5m x 5.1m conference room with a large desk and many chairs, a 4m x 3.5m bedroom with strong reflectors, such as monitors and wooden furniture, a 3.5m x 2.5m utility room with soft reflectors. We can see that localization error increases with the increasing room size and the number of strong reflectors. A larger room size reduces SNR. For many locations in a large room, the directions of reflected paths are close to each other, which makes it more difficult to separate difference paths. Strong reflection from walls and large furniture may produce merged peaks in the MUSIC profiles. Nevertheless, MAVL still achieves 0.45m median error for the complex bedroom .

Impact of UCA size: As discussed earlier, a smaller UCA size degrades the accuracy of AoAs. The overall localization error for smaller UCA is 0.56m. The yellow line in Figure 17 shows how small UCA works in our system. Although it is worse than that of the larger UCA size, the error can still support many indoor localization applications (*e.g.*, providing useful context information for speech recognition and beamforming to strengthen SNR).

Impact of different positions of UCA: Position of the microphone array have impact on both room contour estimation and source AoA estimation. We place the UCA at three predefined locations, *center*, *close to one wall* and *corner* and evaluate our system. The median localization errors are 0.41m, 0.59m, 0.76m at *center*, *close to one wall*, and *corner*, respectively. Our system works the best when the UCA is placed at the *center*. The accuracy degrades significantly if the UCA is placed at the corner due to increased coherence. VoLoc reports 0.44m overall error and 1.7m error beyond 4m when UCA is placed *close to one wall*. But in our settings with a larger room size and larger distance, VoLoc yields a median error of 1.32 m. VoLoc relies on direct path and reflection path from the close wall in the back. When one retrace using these two paths, a small AoA error may lead to a large localization error. Note that what matters is not the absolute distance to the wall but the ratio between the distance to the wall and the room size. For instance, 0.5m to a wall is considered close for a 5.1$m \times$ 7.5m room and large for a 2$m \times$ 3m room. Our system works best in the center position, but also works well for the other setups. Therefore it can support more flexible placement.

Performance to clutter levels: Nearby objects introduce multipath, which makes the AoA estimation more challenging. Figure 20 shows how the clutter level affects the final localization errors across different types of voice. Increasing the clutter level increases the localization errors as we would expect.



(a) Sparse (b) Moderate (c) Dense

Figure 19: Clutter Setups.

Performance to noise level: MAVL is robust to different background noise. Figure 21 shows the influence of various background noise and noise levels. White noise just degrades the accuracy slightly even when SNR is as low as -10dB,

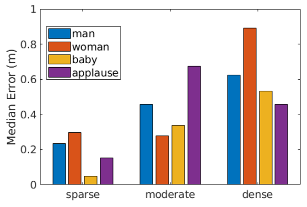


Figure 20: Localization accuracy across clutter levels.

and background music has larger impact than white noise as there are human voices in songs. Our approach is fairly robust against background music unless the SNR is too low (*e.g.*,< -10dB SNR), in which case the error increases to 1.4*m*.

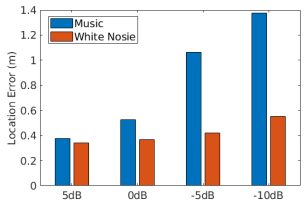

Figure 21: Localization accuracy vs noise levels.

6 Related Work

Acoustic Sensing: A number of systems have been proposed to track a mobile device using acoustic signals [19, 23, 32, 50, 52]. Several recent systems [25, 28, 29, 51] enable device-free tracking using acoustic signals. Many systems generate inaudible acoustic sound for motion tracking. Some use Doppler shift (*e.g.*, AAMouse [50]), time of flight (*e.g.*, BeepBeep [32], or combination (*e.g.*, CAT [23]). Covertband [30] actively sends out OFDM based inaudible signals and builds on top of MUSIC to improve sensing energy. BreathJunior [42] encodes FMCW into white noise to detect motion and breathing of infants. These systems require controlling transmitted acoustic signals and are not suitable for tracking human voice. The most relevant work to ours is VoLoc [37]. Our work advances VoLoc in several important aspects. First, we improve the AoA accuracy from 10 degrees to 1.5 degrees by leveraging multi-resolution analysis in the time-frequency domain. Second, we develop a novel method to automatically estimate the room contour. This significantly eases the deployment effort. Third, we can localize users in both LoS and NLoS whereas they only support LoS.

RF Based Localization: The accuracy of RF based localization approaches are mostly limited by its large wavelength and fast propagation speed for commodity WiFi infrastructure. Chronos [40] can achieve decimeter level localization accuracy by inverting the NDFT. Spotfi [16] incorporates novel filtering and estimation techniques to identify AoA of direct path. Arraytrack [48] designs a novel multipath suppression algorithm to remove reflection between clients and APs. However, they use more than three APs with 16 antennas and require controlling the transmitted signals. Moreover, their approach is focused on eliminating multipath rather than separately estimating each multipath.

Sound Source Localization: There has been a few sound source localization work [26, 34, 46]. [14] builds a real-time system to detect the AoAs of different sound sources. [2] requires a Kinect depth sensor to build a 3D mesh model of an empty room. It estimates multipath AoAs using a cubic microphone array and perform 3D reverse ray-tracing to localize the voice. Its localization error is around 1.12*m*. [1] considers the diffraction path and applies Uniform Theory of Diffraction for voice localization. Its error is 0.82*m*. These works either require multiple specialized sensors to get indoor environment or only estimate AoAs instead of localization. They do not address the coherence arising from multipath, so their AoAs are not reliable. MAVL can localize a user using a single smart speaker without extra hardware and explicitly addresses the coherence of multipath.

Audio-Visual Indoor Representation Learning: Recent work combines sound and vision in multimodal learning frameworks to better understand the environment so that they can track audio-visual targets [3, 11, 13], localize pixels relevant to sound in videos [36, 39], and navigate indoor environments [10]. VisualEchoes [12] emits 3*ms* chirps to combine multipaths and images at different location and learn spatial representation without manual supervision. Soundspaces [7] applies multi-modal deep reinforcement learning on a stream of egocentric audio-visual observations. Our work uses a stand-alone smart speaker, and does not require vision data or pre-training.

7 Conclusion

In this paper, we develop a system, MAVL, to localize users based on their voice using a smartspeaker like device. Our design consists of a novel multi-resolution based AoA estimation algorithm, an easy-to-use acoustic-based room structure estimation approach and a robust retracing to localize the user based on the estimated AoA and room structure. We evaluate MAVL using different sound sources, room sizes, smart speaker setups, noise and clutter levels to demonstrate its effectiveness.

Abstract

We report a 3-year city-wide study of an operational indoor sensing system based on Bluetooth Low Energy (BLE) called `aBeacon` (short for alibaba Beacon). `aBeacon` is pilot-studied, A/B tested, deployed, and operated in Shanghai, China to infer the indoor status of Alibaba couriers, e.g., arrival and departure at the merchants participating in the Alibaba Local Services platform. In its full operation stage (2018/01-2020/04), `aBeacon` consists of customized BLE devices at 12,109 merchants, interacting with 109,378 couriers to infer their status to assist the scheduling of 64 million delivery orders for 7.3 million customers with a total amount of $600 million USD order values. Although in an academic setting, using BLE devices to detect arrival and departure looks straightforward, it is non-trivial to design, build, deploy, and operate `aBeacon` from its conception to its retirement at city scale in a metric-based approach by considering the tradeoffs between various practical factors (e.g., cost and performance) during a long-term system evolution. We report our study in two phases, i.e., an 8-month iterative pilot study and a 28-month deployment and operation in the wild. We focus on an in-depth reporting on the five lessons learned and provide their implications in other systems with long-term operation and large geospatial coverage, e.g., Edge Computing.

1 Introduction

Instant delivery is an emerging business where online orders (e.g., groceries or foods) are delivered within a short time (e.g., 30 mins) from merchants (e.g. grocery stores and restaurants) to customers. This business grows rapidly in recent years with the emergence of several online platforms, e.g., Prime Now [6], Uber Eats [50], Instacart [26], DoorDash [16], Deliveroo [14], and Alibaba Local Services [17]. In an instant delivery service, a customer uses an APP on a platform to place an order at a merchant; the platform assigns a courier to pick up this order at the merchant and then deliver it to the customer. It is essential for the platform to know its couriers' real-time arrival status at merchants, which is used to assign new orders to the most suitable couriers based on their locations to avoid an order delivery overdue given short delivery window [57]. While the outdoor status of couriers can be obtained by smartphone GPS, inferring the indoor status is always challenging due to a lack of infrastructure at scale.

In this paper, we report a 3-year study for a system named `aBeacon` developed by Alibaba Inc. [5] in Shanghai to infer its couriers' indoor status, i.e., arriving and departing at merchants. The indoor status inference is of great significance for Alibaba Local Services (a subsidiary of Alibaba Inc. for instant delivery), since couriers spend almost one third of total working time indoor based on our data. The goal of `aBeacon` is to provide a city-wide indoor sensing solution with practical cost/performance tradeoffs when deploying in the wild. *We share one-month data of `aBeacon` for future research*[1] [1].

Admittedly, indoor arrival and departure status detection is not technically challenging and has been widely investigated in controlled environments, e.g., labs, museums, and airports. However, it is still an open question for city-wide detection in the wild. In industry, current solutions mainly rely on either courier's smartphone GPS (which is inaccurate in indoor environments) [29] or manual reporting (which suffers from intentional or unintentional human errors). In academia, the solutions are based on Wi-Fi [11,13,23,31,39], LED fixtures [32,49,52,54], and RFID [2,51]. However, each of them has limitations for a city-wide deployment with more than 12,000 merchants and 109,000 couriers with only commodity smartphones. Wi-Fi based solutions are limited because continuous scanning is required to keep the Wi-Fi list updated, which brings much extra power consumption for courier's smartphones, and more importantly, for merchants without Wi-Fi Access Point devices, it is costly to deploy new ones [9,30,33,41]. LED solutions do not scale up due to hardware modification costs [49]. RFID solutions require additional equipment on both receivers and transmitters.

In this work, we argue the Bluetooth Low Energy (BLE) device [15,19,24,56] is a promising solution to achieve our goal. BLE is not a new technology, and BLE-based iBeacon was introduced by Apple [25] in 2013. However, the new features provided in BLE 5.0 [45] in 2016 (e.g., longer range and faster speeds) offer us the opportunity to build `aBeacon` starting from 2017/05. We deploy 12,109 customized `aBeacon` devices to 12,109 merchants on Alibaba platform in Shanghai. An `aBeacon` device is a low-cost ($8 USD) broadcast-only BLE device, and does not have GPS or cellular/ Wi-Fi connections, so it cannot receive any update, and it also cannot directly communicate with back-end servers. An `aBeacon` device deployed in a merchant constantly broadcasts its ID tuple (UUID, major, minor) following the BLE protocol, which will be received by couriers' smartphone APP if in proximity

[1] https://tianchi.aliyun.com/dataset/dataDetail?dataId=76359

and then uploaded to a server by APP using smartphones' Internet connection. Based on the uploaded ID tuple, the server is aware of the couriers' arrival to this merchant given previously-mapped device-merchant pairs in the deployment.

BLE devices have several advantages. Continuous scanning in BLE only introduces less than 2% extra power consumption on couriers' smartphones based on our experiments, which is much less than Wi-Fi [7]; compared to RFID-based solutions, no hardware modification is needed on the courier end, since `aBeacon` only requires a courier to have a smartphone; compared to LED, battery-powered BLE devices can be installed in many places due to their small size and portability. We note that a key limitation of `aBeacon` is we need to deploy an `aBeacon` device at every merchant, which introduces both hardware and deployment costs. However, our deployment has a low cost since we utilize an Alibaba in-house team and its members visit merchants periodically for business development; the hardware cost of `aBeacon` can be managed if we only remain core functions, e.g., no GPS, no cellular/Wi-Fi, and no Over-The-Air (OTA) updates.

In a control environment, using BLE devices to detect arrival and departure is straightforward. However, it is nontrivial to build, deploy, and operate `aBeacon` from the ground up, considering the tradeoffs between various practical factors, e.g., cost and performance, in a **metric-based approach**. BLE devices are already applied in real-world applications, e.g., interaction in museums [34] and indoor localization in airports [47]. However, we argue that these indoor environments are normally under the control of BLE system operators. Still, the indoor environments for instant delivery (e.g., shopping mall) are not under the company's control, i.e., in the wild. To our knowledge, there are few studies, if any, on a practical city-wide BLE device deployment in the wild. We introduce `aBeacon` based on Alibaba Local Services for courier indoor status monitoring (i.e., arrival and departure) in a 36 month two-phase study from 2017/5 to 2020/4.

- **Phase I: 8-Month Iterative Pilot Study (2017/5-12)**. We deployed three types of commodity BLE devices in 18 merchants and built an APP to test the feasibility of BLE. Based on the promising results, we customized `aBeacon` devices for lower cost and new functions. We deployed one customized `aBeacon` device and one commodity device in 200 merchants to A/B test their performance.
- **Phase II: 28-Month Deployment and Operation in the Wild (2018/1-2020/4)**. We deploy and operate 12,109 `aBeacon` devices in Shanghai with one device in each merchant. In this phase, `aBeacon` interacts with 109,378 couriers to provide their status to assist the scheduling of 64 million delivery orders for unique 7.3 million customers with a total amount of $600 million USD order values.

As of 2020/4, `aBeacon` is being retired and replacing by a new system `aBeacon+` (introduced in the Discussion section). In this Operational Systems track submission, we focus on 5 lessons we learned in our 3 year study of `aBeacon` from its conception to retirement to provide new insights for the existing design assumptions based on our successes and failures.

Lesson learned 1: Explicitly Quantifying the System Gain. During our interaction with the Alibaba executives team who makes the decision to fund `aBeacon`, we utilize a metric-based approach to quantify `aBeacon`'s monetary gain (i.e., benefit minus cost) to justify `aBeacon`. In particular, we explore the fundamental tradeoff between cost and benefit (proportional to its performance) to optimize the gain of `aBeacon` by (i) reducing the cost by customizing new devices and utilizing our in-house team without technical expertise for configuration-free deployment, and (ii) increasing the benefit by improving lifetime, reliability, and utility. We study the system gain in an evolving cumulative fashion at the fine-grained device level. `aBeacon` achieves the break-even point where its benefit is equal to its cost after 12 months of the deployment, and then generate 14 months of benefits. In retrospect, a batch deployment, instead of an "one-shot" deployment, could make `aBeacon` break even earlier.

Lesson learned 2: System Scale Evolution in the Wild. Even though a device has an expected lifetime of 24 months, `aBeacon`'s scale (i.e., number of live devices) has been constantly shrinking, immediately after fully deployed in the wild, for the entire 26 months of the operation. In particular, the decrease is steady in the first 20 months due to various factors (e.g., deployment, hardware, and merchants closed) yet with a stable citywide spatial coverage; whereas the decrease is dramatic in the last 6 months due to clustered device battery run-outs. This observation has the potential to provide some guidance on the re-deployment strategies (e.g., timing and priority) to keep the system scale and a positive gain (as suggested in the Lesson Learned 1), e.g., large-scale re-deployment much earlier than expected battery lifetime. In retrospect, `aBeacon`'s scale shrinking is much worse than our expectation, making us rethink the initial rationale of deploying physical devices in the wild. It motivated us to virtualize the next generation of `aBeacon`, i.e., `aBeacon+`.

Lesson learned 3: Lifetime in the Wild. During the `aBeacon` operation, the lifetime of 42% devices is longer than deployment environment (e.g., a device is live but the merchant it was deployed is closed). However, once deployed in the wild, large-scale recycling of low-cost ($8 USD) devices from these short-lifetime environments is not practical due to significant labor. In retrospect, `aBeacon` devices could be designed with different energy modules for different environment lifetime (e.g., predicted based on our order data) to minimize the hardware cost.

Lesson learned 4: Reliability in the Wild. Many existing sensing systems (e.g., proximity [36], gesture [58], and breath [55]) are mainly tested in control environments with high reliability [22]. However, we found that even for simple arrival detection in `aBeacon` the reliability is heavily affected by many real-world factors including smartphone diversity (e.g., 52 phone brands and 672 phone models in our platform), device placement (e.g., non-expert installation), and courier mobility behaviors. In retrospect, we could add an OTA update function to some devices (but not all devices) deployed in uncertain environments, and utilize couriers' phones to update them, e.g., increasing their transmission powers.

Lesson learned 5: Utility in the Wild. Unlike other infrastructures, e.g., Wi-Fi, we found that in our aBeacon operation, the locations with more interactions between couriers and devices may not have higher device deployment utility (quantified by the order delivery rate improvement based on courier detection). In contrast, the locations with higher uncertainty of courier mobility behaviors (e.g., higher floors) lead to a higher utility. In retrospect, we could change our deployment strategies to prioritize more uncertain environment.

Based on the above lessons learned, we discuss our limitations and potential applications of aBeacon and then discuss their implications to other systems with long-term broad geospatial coverage (e.g., Edge Computing), and finally share the direction of our ongoing work aBeacon+.

2 aBeacon Design Goal

In aBeacon, a generic workflow is as follows: (1) devices deployed in indoor merchants to continually broadcast their ID tuples; (2) an embedded BLE scanning module in the Alibaba couriers' smartphone APP (mandatory for all couriers) to receive these ID tuples from devices when in proximity and to upload them to a back-end server using the smartphone Internet connectivity; (3) The server updates couriers' arrival and uses them for various functions, e.g., new order scheduling. Based on this workflow, we introduce our metrics as follows.

2.1 Cost and Performance Metrics

Cost C_{Dev}: The costs of a device in aBeacon mainly consist of the hardware cost and the deployment cost (i.e., the shipping and labor cost to deploy a device at a merchant).

Lifetime P^i_{Life}: In our design, we envisioned a lifetime of a device for two years, and then redeploy new devices after two years if (i) aBeacon was successful (Yes); (ii) the deployment cost was still low (Yes); and (3) aBeacon was still the best solution (No since we have aBeacon+). The lifetime of a device i is affected by the design (e.g., battery) and the environment (e.g., the deployed merchant is closed).

Reliability P^i_{Reli}: We quantify a device i's reliability by the percentage of couriers we detected among all arrived couriers. The ground truth of the courier arrival is obtained by the delivery order accounting data. P^i_{Reli} is affected by device deployment, smartphone diversity, and courier mobility.

Utility P^i_{Util}: We quantify the utility of a device i by *overdue delivery rates reduction* for the merchant after i was deployed in it. After a merchant was deployed with a device, the platform can better detect and predict the status of couriers around this merchant, which are used to schedule new orders for this merchant by finding nearby couriers (e.g., a courier just left), thus reducing the overdue rate for this merchant. P^i_{Util} is affected by a merchant's features where i was deployed (e.g., merchant locations, floors).

Table 1: Metric Summary

C_{Dev}:	cost of a device, i.e., hardware & deployment
C_{Over}:	cost of overdue penalty per order, e.g., \$1.
P^i_{Life}:	lifetime of a device i
P^i_{Reli}:	reliability of i
P^i_{Util}:	utility of i
t^i_0:	day of i was deployed
T:	# of days since aBeacon deployed
N_t:	# of deployed devices until the tth day
O^i_t:	# of orders at tth day in the merchant with i

2.2 Metric-based Approach for Trade-offs

We utilize a metric-based approach to explore the trade-off between costs and performance by Eq. (1). Assuming it has been T days since aBeacon was deployed, the cumulative aBeacon gain G_T is given by the difference of (i) the cost C_T of deploying aBeacon until the Tth day; and (ii) the benefit (i.e., monetary saving) brought by performance improvement, i.e., overdue reduction due to better detection by aBeacon.

$$G_T = \sum_{t=1}^{T} \sum_{i=1}^{N_t} B^i_t - \underline{C_T} \tag{1}$$

where N_t is the number of devices deployed until the tth day ($t \leq T$) including live and dead devices. $\underline{C_T} = N_T \cdot C_{\text{Dev}}$ is the cost of all devices until Tth day where C_{Dev} is a device cost. B^i_t is the **Benefit** of a device i in the tth day as

$$B^i_t \;=\; \underline{F_1(\,P^i_{\text{Life}},\, t,\, t^i_0\,)} \;\cdot\; \underline{F_2(\,O^i_t,\, P^i_{\text{Reli}},\, P^i_{\text{Util}},\, C_{\text{Over}}\,)}. \tag{2}$$

$\underline{F_1(P^i_{\text{Life}},t,t^i_0)}$ indicates whether or not a device i reached its lifetime limit by the tth day. It was calculated by remaining lifetime $P^i_{\text{Life}} - (t - t^i_0)$, where P^i_{Life} is the lifetime of i; t^i_0 is number of days that device i has been deployed. $F_1(P^i_{\text{Life}},t,t^i_0) = 1$ if $P^i_{\text{Life}} - (t - t^i_0) \geq 0$; $F_1(\cdot) = 0$ otherwise, i.e., no remaining lifetime, so we do not have to consider F_2. $\underline{F_2(O^i_t,P^i_{\text{Reli}},P^i_{\text{Util}},C_{\text{Over}})}$ indicates the monetary saving by reduced overdue penalty of the orders detected by i. O^i_t is the number of orders at the tth day in a merchant with i, e.g., 100; P^i_{Reli} is the percentage of the orders whose couriers can be detected by i, e.g., 80%; P^i_{Util} is the reduced overdue rate (compared to the overdue rate before the device was deployed) for all orders whose couriers are detected by i, e.g., 20%; C_{Over} is the overdue penalty per order, e.g., \$1. An example of F_2 is the product of all these terms, i.e., $O^i_t \cdot P^i_{\text{Reli}} \cdot P^i_{\text{Util}} \cdot C_{\text{Over}}$ (e.g., saving is $100 \cdot 80\% \cdot 20\% \cdot \$1 = \$16$).

3 aBeacon Life Cycle Overview

Unlike the wireless systems (e.g., Smart Home IoT) that can be updated by OTA, an aBeacon device was not designed to be updated after customization to save the hardware cost. Thus, separated by the time we finished the customization

Table 2: Overview of Two Phases

Phase / Stage & Scale / Goal		Phase I: 8-month Pilot Study (2017/5 – 2017/12)		Phase II: 28-month Operation in the Wild (2018/1 – 2020/4)	
		Conception Stage (2017/5-8) 18 merchants,54 devices	**Customization Stage** (2017/8-12) 200 merchants, 400 devices	**Deployment Stage** (2018/1-3) 12,109 merchants & devices	**Operation Stage** (2018/3-2020/4) Evolving
Cost	Hardware	Commodity (Fig.1)	Commodity ($11, Fig.1, T4) Customized ($8, Fig.2)	Customized	—
	Deployment	Our Team (Fig.1)	Our Team	302 Business Managers	—
Performance	Lifetime	Fig. 1	Commodity (2-3 yrs. advertised) Customized (2 yrs. designed)	*In retrospect, we should have selected the merchants with longer lifetime*	Fig. 4 & 5
	Reliability	98%	Both are Close to 98%	Installation Handbook Provided	Fig. 6-8 & Table 5
	Utility	—	—	Highly Profitable Merchants Selected	Fig. 9-12

Size Comparison	Device 1 (T15)	Device 2 (T4)	Device 3 (T11)
Tx Power	-59 dB	-65 dB	-65 dB
Advertised Lifetime	≤ 3 yr	$2 \sim 3$ yr	≤ 3 yr
Cost	$11 each	$10 each	$10 each
Encapsulation	—	Water, Dust, Shock Proof	Dust Proof Only

Fig 1: Deployment for Conception Stage

(i.e., 2018/01), we divide the entire 3-year study of `aBeacon` into two phases, i.e., Phase I: 8-Month Pilot Study; and Phase II: 28-month Deployment and Operation.

As in Table 2, we carefully designed the stage, scale, cost, and performance to serve each phase's purposes.

3.1 Phase I: 8-Month Pilot Study (2017/5-12)

In this phase, we performed two studies in a conception stage to investigate three commodity devices, and a customization stage to design and evaluate new devices with A/B testing.

(i) Conception Stage (2017/5-8): As shown in Table 2, we aim to understand whether a BLE device system can detect the couriers' indoor arrival and departure with reliability higher than 95%. We bought 54 commodity devices in three brands and deployed them in 18 merchants of a shopping mall in Shanghai. Each merchant was equipped with three commodity devices of different brands, as shown in Fig.1 with technical specifications. We set some key configurations of couriers' mobile APP when interacting with commodity devices as parameters for further developing, e.g., scanning duration and intervals, data upload cycle, and working hours. Note that the couriers' APP and the back-end server developing were also the major works in this stage, but we omit them in this paper since they are standard. After this study, we had average reliability of 98%, so we concluded that a beacon-based solution could achieve high reliability.

Table 3: BLE Chip Comparison

BLE Chip	Link Budget	Tx Power Consump. (curr. at 0dB)	Sleep Power Consump. (curr.)	Price $/unit
CC2540 [27]	97 dB	21 mA	0.9 ua	~1.1
DA14580 [43]	93 dB	12.4 mA	0.5 ua	~1.1
CSR1010 [40]	93 dB	18 mA	5 ua	~1.1
nRF51822 [44]	**96 dB**	**8.06 mA**	**2.6 ua**	**~1.1**

(ii) Customization Stage (2017/8-12): Instead of using commodity devices, we customized our `aBeacon` device for low cost ($8 per device) and longer lifetime. We performed a middle-scale A/B testing between the best one among three commodity devices and our customized device. As in Table 2, after the reliability had been proved in the previous stage, our customization was focused on the hardware cost and lifetime since the large-scale city-wide deployment cost in Phase II is marginal when we utilize our in-house business team. In our customization, three components, i.e., BLE chip, battery, and casing, were carefully customized to achieve overall lower cost and longer lifetime. (1) For the BLE chip, we compared the mainstream BLE chips as in Table 3. Since our BLE devices in `aBeacon` were expected to broadcast for at least two years without external power continuously, we chose the nRF51822 from Nordic Semiconductor as the BLE chip since it has both the minimum Tx power and acceptable other configurations. (2) For the battery, we considered both the lithium battery and the alkaline battery since we expected an `aBeacon` device could operate for at least two years without maintenance. The lithium battery usually has a smaller size, but the alkaline battery has a much better unit capacity (mAh/$), so we used two alkaline AA batteries in cascade . (3) For the casing, we considered dust, water, and shockproof for transportation and operation in various indoor (or potential future outdoor) operations. Finally, we built 200 `aBeacon` devices, as shown in Fig.2. We A/B tested our 200 customized

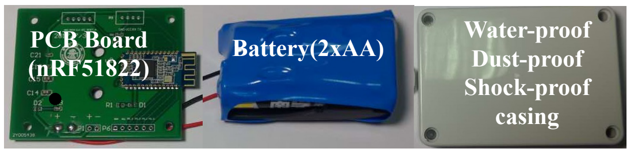

Fig 2: Customized Hardware for `aBeacon`

devices with 200 commodity devices (i.e., Device 2 (T4) [10] in Fig.1). We selected 200 merchants in two malls and placed one customized device and one commodity device side by side to compare their performance. After 2-month testing, we concluded our customized devices are ready for deployment and operation because they have similar reliability with the commodity devices, but have a lower hardware cost and potentially longer lifetime.

3.2 Phase II: 28-month Operation (18/1–20/4)

We introduce a 3-month deployment and a 25-month operation stage of 12,109 devices in Shanghai (visualized in Fig.3.)

(i) Deployment Stage (2018/1-3). After we received all `aBeacon` devices from a manufacturer, we aim to deploy them in 12,109 chosen merchants among 57,223 merchants in Shanghai after consulting with our accounting department to understand these merchants' profitability, potentially decides our `aBeacon`'s utility. We decided to deploy around 12 thousand devices for `aBeacon` because of the approved $100,000 budget, i.e., the system cost. Assuming no benefit at all, based on Eq. (1), our system gain G_T is $-\$100,000$ (i.e., the trivial lower bound in Fig.3 (iii)). In Phase I, our team deployed 200 devices by ourselves, but 12,109 devices were out of our team's capability. As a result, we utilize our in-house regional business development managers who periodically visit all merchants for regular business meetings to install our `aBeacon` device. We mailed our `aBeacon` devices and guided them for `aBeacon` device deployment and mapping between `aBeacon` devices and merchants by a detailed handbook, which shows "Where to attach the device?" (e.g., main entrance), "How to attach the device?" (e.g., double-sided tape) and "How to map the device?". The mapping was achieved by scanning a QR code on an `aBeacon` device and then choosing its merchant from a given merchant list in a business manager APP. 302 managers participated in our deployment process, and it took us around two months to deploy all the devices after one month of shipping and logistics. Since our business managers deploy our devices for free, the main deployment cost is the shipping cost, which is around $1 per device.

(ii) Operation Stage (2018/3-2020/4). After the deployment, `aBeacon` is fully operational, and we have been monitoring its status and utilizing it to detect couriers remotely based on the data we collected from couriers' APPs. We embed the device monitoring function in the official smartphone APP of 109,378 Alibaba couriers in Shanghai. When we first receive an `aBeacon` device ID tuple from a courier's phone,

Table 4: Operation Data Collected

(a) aBeacon monitoring data

Attribute	Example	Attribute	Example
Courier ID	C_000001	RSSI	-80dB
Timestamp	2019/08/15 12:30:23	Phone ID	D_000001
Device ID Tuple	(UUID, Major, Minor)	Phone Brand/OS	Apple/iOS
Merchant ID	M_000001	Phone Model	iPhone X

(b) Courier GPS data

Attribute	Example
Courier ID	C_000001
Timestamp	2019/08/15 12:30:23
Latitude	31.243715
Longitude	121.245847
Speed	3.7 km/h
Altitude	40.2 meters

(c) Courier order report data

Attribute	Example
Courier ID	C_000001
Timestamp	2019/08/15 12:30:23
Merchant ID	M_000001
Order ID	O_000001
Report Type	Acceptance/Arrival/ Departure/Delivery

we need to make sure this live device is correctly deployed and works properly. For all devices, their initial status on our server end is "Not Deployed"; once a manager completes the mapping operation on her APP, a "Not Deployed"device becomes "Online". For all "Online", we use order accounting data to validate if the deployment is correct or not indirectly: (1) if a device is heard by more than three couriers whose current orders or GPS would not let them pass the merchant mapped to this device, this "Online" device would be changed to "Wrongly Deployed"; (2) if no ID tuples were received from a device for 24 hours, and if the mapped merchant still has orders during these 24 hours (e.g., more than ten orders), then this "Deployed" device would be considered as "Offline" or "Retired" based on its expected lifetime is reached or not since deployment; (3) if ID tuples were received from a device, but the merchant was closed (based on our accounting data), it would be considered "Closed".

(iii) Operation Data Collected. During our operation, we collected three kinds of data sets to monitor and validate `aBeacon`. **(a) `aBeacon` Monitoring Data**. As in Table 4(a), every time an `aBeacon` broadcast was received by a courier's phone, we recorded the information of the `aBeacon` device, phone, and the Received Signal Strength Index (RSSI) of the broadcast. **(b) Courier GPS data**. As in Table 4(b), GPS data were collected under courier consent since customers also like to know where his/her order is, and the platform needs to know couriers' locations for order assignment. **(c) Courier Order Report Data**. As in Table 4(c), for each delivery order, the courier needs to report when he/she arrives at or leaves from the merchants manually for real-time order status updates. These report data are used as the ground truth for `aBeacon` detection. However, in our previous study, we found couriers often forgot to report their status and exaggerate their status (e.g., early reporting) to game the scheduling system for better order assignment. That is why these report data can only be used as post-hoc ground truth, i.e., we know that a courier arrived at a merchant after an order was delivered since a courier often forgets or falsely reports their arrival. Please

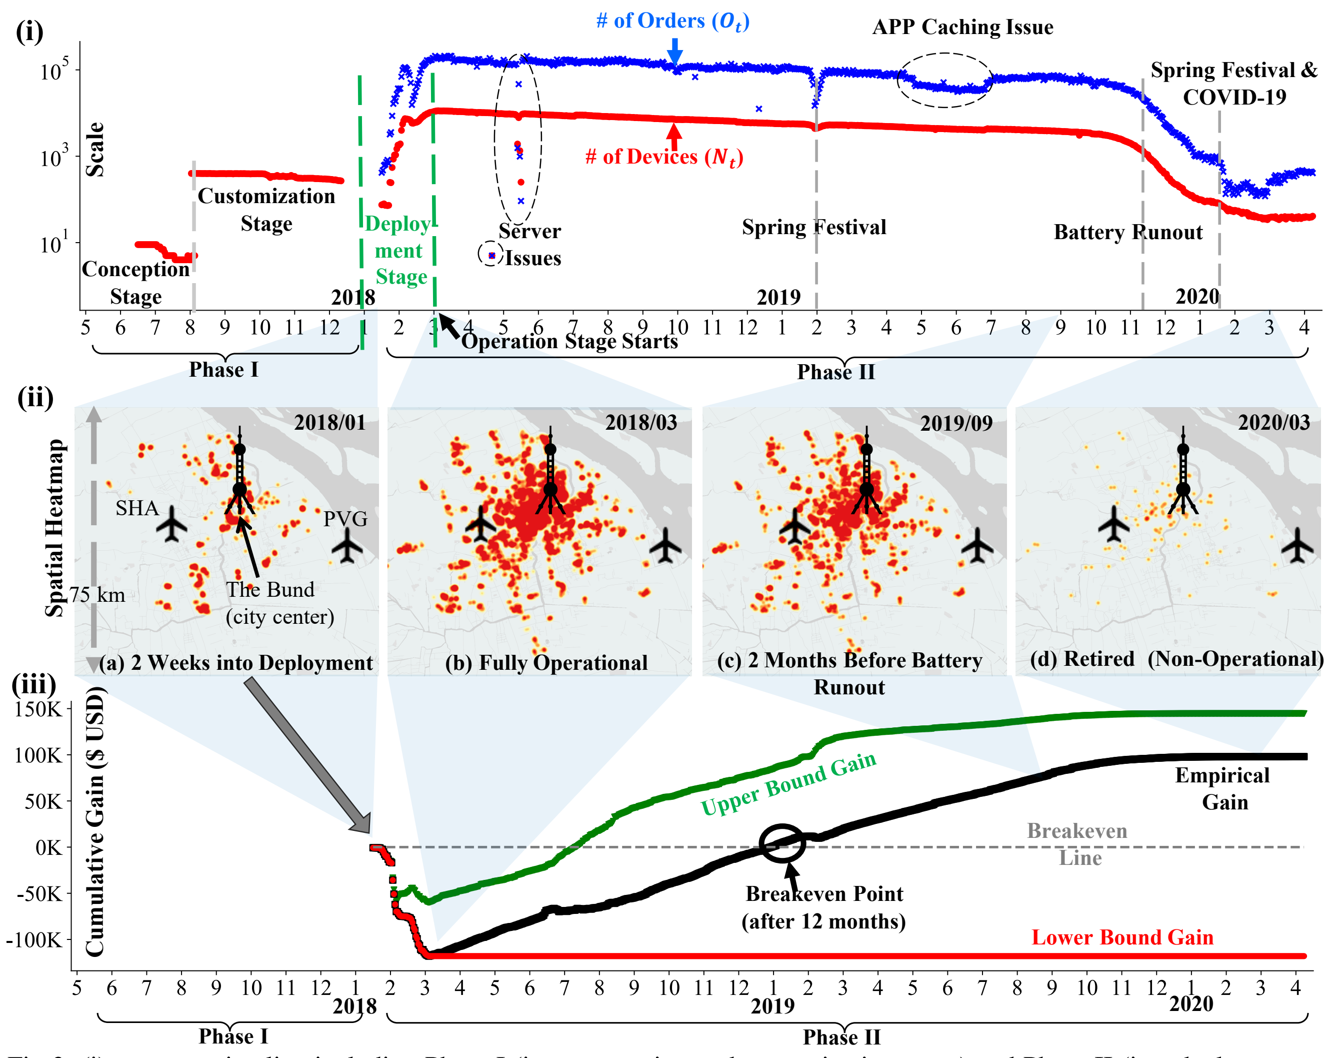

Fig 3: (i) aBeacon timeline including Phase I (i.e., conception and customization stage) and Phase II (i.e., deployment and operation stage); (ii) aBeacon device heatmaps in Shanghai for four key stages; the background shapes are expended to the corresponding time in (i) and the system gains (iii); (iii) Three aBeacon gains with three kinds of utility.

see our Discussion section for details on using aBeacon for Anomaly Detection.

4 aBeacon Operation Results

4.1 Result Overview

In Fig.3, we show a panorama of aBeacon life cycle with our two phases from 2017/5 to 2020/4.

Quantitative System Evolution Overview: In Fig.3 (i), given a day t, we show both the number of aBeacon devices N_t with "Deployed" status in t and the number of delivery orders O_t whose couriers are detected by aBeacon in t. We omit the number of couriers detected since it is highly correlated with the number of delivery orders. The detailed analysis on N_t and O_t in Sec.4.3, but we would like to highlight two technical incidents affecting both N_t and O_t as indicated by three circles in Fig.3 (i). On May 16th and 21st, 2018, a configuration exception occurred on the APP server and led to data loss, and our team diagnosed and fixed it quickly. In May 2019, we found an unusual decrease in detected orders, which took our team around two months to diagnose the root cause, i.e., a caching problem in the courier APP of some phone brands. In particular, since the courier APP is not always connected to the server, it would cache some received aBeacon device data if the network connection is unavailable. But when the local cache was full, received data got lost without exceptions raised in some smartphones brands. By the end of June, the problem was fixed, and the detected orders increased.

Qualitative Spatial Coverage Evolution: In Fig.3 (ii), we visualize the aBeacon spatial evolution in Shanghai at four critical periods. (a) 2018/01: 2 weeks into the deployment stage where aBeacon has not been uniformly deployed; (b) 2018/03: aBeacon is fully operational, reaches its spatial scale peak, and covers all the central business districts in Shanghai; (c) 2019/09: aBeacon has been operating for 20 months, and the spatial cover remains relatively similar, and it is two months away from the starting of clustered battery run-out; (d) 2020/03: aBeacon drops below a critical level and is being retired and replaced by aBeacon+ (see the Discussion section). We found even the scale of aBeacon has been shrinking right after the full deployment due to various real-world issues, the spatial coverage has been relatively stable for 20 months. Based on our field study, we found the most of the dead devices are related to merchants closed, deployment imperfection, hardware malfunction, and vandalism. It provides some practical guidelines for our current project of the next generation of aBeacon, i.e., aBeacon+.

4.2 System Gain Evolution

System Gain Overview: In Fig.3 (iii), we utilize Eq. (1) to show the system gain, i.e., the monetary saving minus the system cost. All metrics in Eq.(1) can be directly measured by our aBeacon data except the system utility P^i_{Util}. We show three cumulative gains (defined in Sec.2.2) based on the empirical value of system utility P^i_{Util} (overdue rates reduction after device i was deployed, discussed in Sec.4.6), along with its lower bound $\underline{P}^i_{\text{Util}}$ (no overdue reduction at all) and its upper bound $\overline{P}^i_{\text{Util}}$ (complete overdue reduction), respectively. We found aBeacon achieved a break-even point after 12 months , which provides empirical guidance for our aBeacon+. Some additional applications of aBeacon for the Alibaba group are shared in the Discussion section.

Lesson Learned 1: **Explicitly Quantifying the System Gain.** Even though the cost of a real-world system can be often explicitly quantified, the benefit of a system is often hard to be, which makes the justification of deploying a system challenging when convincing the decision-makers. Based on our interactions with the Alibaba executive team, who made decisions to initiate and fund aBeacon, we utilized a metric-based approach to quantify the cumulative system gain to justify aBeacon development. In particular, we explore the cumulative system gain by (i) reducing the cost by customizing new devices (e.g., 20% less than commodity devices yet with more functionality) and utilizing our Alibaba in-house business development team without technical expertise for large-scale deployment due to our configuration-free setting, and (ii) increasing the performance by extending device lifetime, improving reliability, and enhancing utility. As shown in Fig.3 (iii), aBeacon achieves a break-even point after 12 months. In retrospect, a few approaches could be used to make sure aBeacon achieves break-even earlier. The most promising one is a batch deployment instead of a “one-shot" deployment in a short time, which have been used in our other physical device deployment projects.

In-depth System Gain Investigation Overview: To provide an in-depth investigation on the cumulative system gain, we analyze seven metrics in Eq.(1) and (2) individually: (i) C_{Dev} and C_{Over} are the individual device cost and the order overdue penalty, which are almost fixed in our setting; (ii) N_t and O_t are related to the system scale and we study them in Sec. 4.3; (iii) P^i_{Life}, P^i_{Reli}, P^i_{Util} are related to the system performance in terms of lifetime, reliability, and utility, which are studied in Sec. 4.4, 4.5, and 4.6, respectively. The correlation between different metrics is introduced in Sec. 4.7.

4.3 Scale Metric: Number of Device & Order

Scale Metric 1: Number of Devices N_t. In Fig.3 (i), starting from our deployment stage in Phase II, the number of aBeacon devices increased significantly until the end of our deployment stage in 2019/3. However, after aBeacon scale peaked in 2019/3, two decreasing trends are observed. (1) The first one is a slow decrease throughout the major part of Phase II from 2018/3 to 2019/10, where we lost some devices every day. In addition to vandalism, deployment, and hardware issues, the primary reason is that some merchants terminate their business with Alibaba every day. The merchant turnover rate in China online platforms is high, and almost 70% of new merchants were closed within one year of the opening in 2017 [20]. We report our empirical merchant lifetime data in Fig.4 and analyze it in detail later. (2) The second one is the sharp decrease from 2019/11 to 2020/2, due to the clustered battery running out after 20 months of operations since 2018/3. Such an observation provided some insights about our potential re-deployment strategies, which we will discuss in the Lesson Learned 2.

Scale Metric 2: Number of Orders O_t. As shown in the Cumulative System Gain Eq.(1), the number of orders O_t whose couriers were detected by aBeacon is the central part of deciding the gain of aBeacon. In Fig.3 (i), we found in the full operation stage of Phase II (from 2018/3 to 2019/11), the number of orders detected is around ten times the number of aBeacon devices, which implies each device serves ten orders on average every day. This ratio remains similar throughout Phase II except for the mid-February, during which the overall number of orders decreases sharply. Mid-February is typically the Chinese Spring Festival, i.e., the biggest holiday where the number of total orders reduced since many merchants closed during this time. We observed sharp decreases and recoveries during February of 2018, 2019, and 2020 in Fig.3 (i), and the corresponding impact on the system gain in Fig.3 (iii). In 2020, the impact of COVID-19 lasts after February, so we do not see an apparent recovery at the end of February.

Lesson Learned 2: **System Scale Evolution in the Wild.** The scale of aBeacon (quantified by the number of devices N_t and the number of associated orders O_t) is essential to ensure the cumulative system gain. As in Fig.3 (i), after fully deployed in the wild (2018/3), aBeacon scale has been continuously shrinking for 26 months until 2020/4, even though devices have an expected lifetime of 24 months. In particular, the decrease is steady in the first 20 months (from 2018/3 to 2019/10) due to various factors (e.g., vandalism, hardware malfunction) yet with a stable city-wide spatial coverage in Shanghai (Fig.3 (ii)). In contrast, the decrease is quite sharp in the last six months (from 2019/10 to 2020/4) due to clustered battery run-out. It suggests that if we want to keep the system scale, we should start a full-scale re-deployment much earlier than expected, or perform batch-based small re-deployment continuously if we want to keep `aBeacon` at scale. However, we did neither of them in practice since we move on to a new system `aBeacon+` without deployed devices as introduced in future work. Further, by using the number of orders as a bridging factor, our results also provided some insights on how to link the traditional system scale (i.e., number of devices) to the business revenue (i.e., reduced order overdue penalty) to justify their potential correlation. The insights help us communicate with the Alibaba executive team when reporting the impact of `aBeacon` on the overall Alibaba ecosystem.

4.4 Performance Metric 1: Lifetime P^i_{Life}

Lifetime Overview: The lifetime of an `aBeacon` device is decided by two primary factors: (i) the battery size, which was considered in the customization stage of Phase I when we design our hardware; (ii) the merchant lifetime, which unfortunately was not considered in the deployment stage of Phase II as shown in Table 2 since we mainly consider the profitability of merchants. In our defense, there should be a strong correlation between the profitability and lifetime of a merchant, but we found that the profitability of many merchants has been rapidly changing, especially on the online platform. Further, given the high real estate rental fees in Shanghai, many merchants move their physical stores frequently. If a merchant deployed with an `aBeacon` device is closed or moved, there is a high chance that the deployed device would be thrown away. The CDF of devices' and merchants' lifetime are given in Fig.4. Around 23% and 40% of merchants closed within 1 or 2 years, respectively; whereas more than 50% of devices died within one year, much less than the expected lifetime based on battery alone.

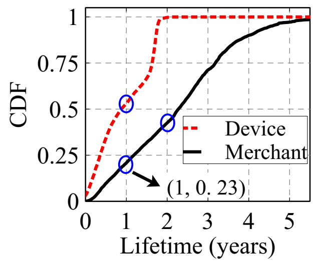

Fig 4: CDF of Device Lifetime and Merchant Lifetime

Lifetime Correlation: An in-depth visualization of the correlation between these two factors is scatter-plotted in Fig.5 where we record the last day a device i was heard as X-axis; the last day the corresponding merchant had orders on our platform as Y-axis. We have three observations: (1) points (15%) around the diagonal ($|x-y| \leq 14$, i.e., 14 days) suggest devices died within two weeks of the closure of the corresponding merchants on our platform; (2) another cluster of points (17%) is around $x = 640$, which means a device is dead after 21 months of operation, as observed in Fig.3 (i). (3) for the points above the diagonal (26%, $x < y$), it indicates the merchant has active orders from our platform, but the `aBeacon` device is dead; for the points below the diagonal (42%, $x > y$), it indicates the merchant closes on our platform (i.e., no orders) but the device can still be heard by couriers, i.e., the device may be in the original locations or nearby, and can be heard when our couriers in proximity. We note that a merchant has no orders on our platform does not necessarily mean the merchant is closed, but it can be used to approximate the merchant's lifetime on our platform. For a closed merchant, an intuitive idea is to recycle the device for re-deployment, but in practice, we did not do it due to two reasons: (1) the platform is not generally informed in advance when the merchant is closing so we cannot prepare in advance to recycle the device; (2) the device recycling introduces significant labor and shipping costs, and the recycled devices may be damaged or with low battery, which makes purchasing a new device a better choice overall. As a result, we did not perform large-scale device recycling in practice.

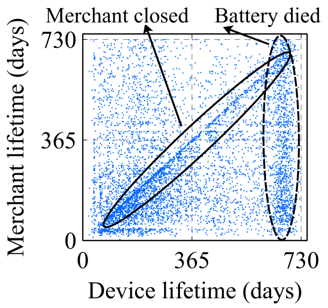

Fig 5: Last day a Device was Heard and Last day the Corresponding Merchant has Orders

$\boxed{\textbf{Lesson Learned 3:}}$ **Lifetime in the Wild.** The lifetime of 42% devices is longer than the lifetime of their deployed environment (e.g., merchants). It provides new insights on our design assumption on mobile device energy since a longer battery life may not increase the device lifetime due to uncertainty of the deployed environment but introduce higher costs. This lesson is especially true when the large-scale device recycling and re-deployment are not practical due to higher labor cost. It motivated us to design devices with different battery capacity and then deploy devices in batches to accommodate the environment's lifetime, which can be predicted by our platform data. We apply this lesson in our `aBeacon+` where we use merchant phones as our *virtual devices* (instead of deploying physical devices) to broadcast their ID so that the couriers can receive them in proximity. In `aBeacon+`, embedded in merchants' smartphone APPs, the virtual device broadcasting module has different versions, whose parameters were set differently for different merchants.

4.5 Performance Metric 2: Reliability P^i_{Reli}

We quantify the reliability P^i_{Reli} of an `aBeacon` device i with a percentage indicating among all the orders from a merchant deployed with the device i, how many orders we detect. There are three major factors impacting P^i_{Reli}: Stay Duration, Device Deployment, and Smartphone Hardware.

Impact of Stay Duration on P^i_{Reli}. The stay duration is the time between a courier arrives at and departs from a merchant. The stay duration varies due to multiple factors such as the layout of a merchant, the courier's walking speed, and whether an order is ready when the courier arrived, i.e., waiting for the order or not. In Fig.6, we found that the longer that a courier stays, the higher the P^i_{Reli}. The stay duration is computed as the differences of departure and arrival time from the couriers' order report data in Table 4(c) Even though there were inaccurate report data due to human errors, our results are based on 76 million orders for two years, ensuring our results are statistically significant. Two observations can be made from Fig.6: (1) The reliability increases with the staying duration, but does not change much after 7 mins; (2) iOS has a much better performance than Android.

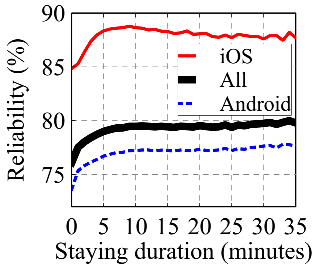

Fig 6: Impact of Stay Duration

Impact of Deployment Position on P^i_{Reli}. The deployment position is an essential factor for reliability, as we found some merchants with an exceptionally low detection ratio. Although our deployment handbook suggested that "Beacons should be attached around the order pickup area", some business managers put devices somewhere else due to various reasons. For example, some merchants do not have a fixed "meal/groceries pickup area"; some merchants prefer the device to be placed somewhere else, e.g., under the counter. We performed some field study, and our findings can be clearly explained with Fig.7 that depicts the layout of a real-world restaurant. In this merchant, there are two entrances with a horizontal wall in the center. Two couriers may pick up orders from both entrances, which leads to the different indoor pickup traces. Unfortunately, because the wall obstructs the device broadcast, only the Courier 1's arrival was detected, which results in a reliability P^i_{Reli} of 46% in our observed period. If the aBeacon device were placed in the pickup area, we could have better reliability since both courier traces can be detected. In short, the impact of deployment position is difficult to estimate due to the uncontrollable deployment quality. The reason is we utilize our in-house business team with no deployment expertise (or incentive), and a deployed device can be moved as well, both of which typically leads to low reliability at some merchants.

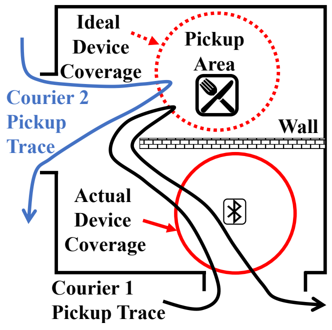

Fig 7: A Field Study of Deployment Position Impact

Impact of Phones Brands and OS on P^i_{Reli}. Our goal is to have most courier smartphones (if not all) to be compatible with aBeacon at both the hardware (i.e., phone brands and models) and software level (i.e., OS types). Given more than 109,000 couriers in Shanghai, it is challenging to either force the couriers to use specific smartphone brands or know if a courier uses an un-supported smartphone. To analyze the impact of smartphone OS, we divide all the orders in aBeacon merchants into two dimensions: whether its courier was detected by aBeacon or not; whether its courier was using an Android or iOS phone. As in Table 5, 63.4% of the orders

Table 5: Detected Ratio of Device OSs over All the Orders

Devices	Detected	Undetected
iOS	13.4%	2.4%
Android	63.4%	20.8%

were detected with the Android couriers (including 52 brands and 672 models), and their average P^i_{Reli} is $\frac{63.4\%}{63.4\%+20.8\%} = 75.2\%$; 13.4% of the orders were detected with the iOS couriers, and their average P^i_{Reli} is $\frac{13.4\%}{13.4\%+2.4\%} = 84.8\%$. We found iOS performs significantly better than Android. For different phone brands (different hardware), the average P^i_{Reli} varies. We show the average P^i_{Reli} of nine well-known brands in China in Fig.8, in which Nexus has the highest P^i_{Reli} of 92%, and iPhones has a P^i_{Reli} of 84%.

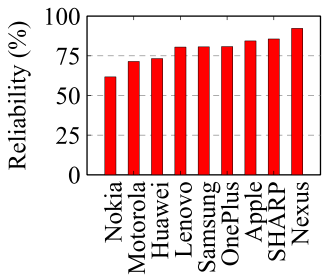

Fig 8: Impact of Smartphone Brand on Reliability

Lesson Learned 4: **Reliability in the Wild.** Many existing wireless sensing systems (e.g., proximity [36], gesture [58], breath [55], human-object interaction [22], and indoor pathway mapping [46]) are mainly tested in the environments with little uncertainty, so they have high reliability. However, we found that even the reliability of a simple presence detection (i.e., courier arrival) is far from guaranteed in a wild, and it is affected by many real-world factors including smartphone software& hardware combination (e.g., 52 phone brands and 672 phone models in Table 5 and Fig.8), and installation position (e.g., low-cost yet unprofessional installation and obstacles in Fig.7), and stay duration (e.g., no waiting time for couriers in Fig.6). In retrospect, we could add an OTA function to some of our devices (but not all devices) deployed in uncertain environments and update them with couriers' phones, e.g., increasing transmission power.

4.6 Performance Metric 3 Utility: P^i_{Util}

The overdue rate reduction is the metric we use to measure the utility P^i_{Util} of deploying an aBeacon device *i* at a particular merchant. For an overdue delivery order (e.g., longer than 30 mins for food), there is an overdue penalty C_{Over} with which the platform will compensate the customer. A typical C_{Over} is \$1, but an overdue penalty could be as high as 200% of the average profit per order if a customer brought delivery insurance. Specifically, the overdue rate is the percentage of the overdue orders among the total orders. So the overdue rate reduction is the difference between the overdue rates before and after an `aBeacon` device deployment. We note that other factors impact the overdue rates of a merchant, e.g., holidays and weathers, but they are out the scope of our paper. We use six months of data before `aBeacon` deployment and 24 months of data after `aBeacon` deployment in the evaluation. There are many features of a merchant that decide the utility of deploying an `aBeacon` device. We study two of them, i.e., Building Floor and City District, due to the space limitation.

Impact of Different Building Floors On P^i_{Util}. To evaluate the impact of deploying an `aBeacon` device on different floors on utility, we aggregate the overdue rate reduction on different floors and compare them with the average overdue rate of all merchants in Shanghai city before and after our `aBeacon` is deployed. The device scale distribution on different floors is given in Fig.9. As shown in Fig.10, the utility is higher

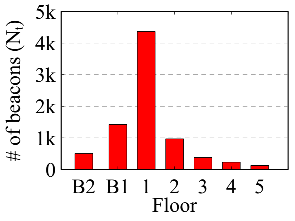

Fig 9: Device Distribution in Different Floors

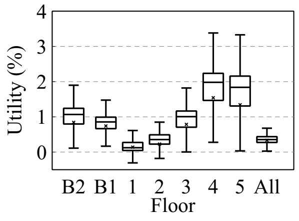

Fig 10: P_{Util} after Deployment in Different Floors

on higher floors or lower basements than the ground floor. This is because the stability of the courier indoor mobility is disproportional to the distance after they enter a building. The higher the floor, the longer the distance, the less stable of courier mobility behaviors (e.g., arrival), the higher benefit for `aBeacon` to detect these behaviors for later order scheduling.

Impact of Different City Districts on P^i_{Util}. To evaluate the impact of districts, we choose five typical districts in Shanghai and compare their average utility, i.e., the overdue rate reduction after `aBeacon` was deployed. As shown in Fig.11, Huangpu is a central business district with a population density of $32,004/km^2$, about three times of New York City ($10,194/km^2$). Songjiang is a suburban area with a population density of $2,892/km^2$, comparable to Los Angeles ($2,910/km^2$). As shown in Fig.12, P^i_{Util} for all merchants with `aBeacon` devices in Songjiang is lower than Shanghai city average; whereas P^i_{Util} in Huangpu is much higher than the average. This is because (1) there are more orders in a more populous area such as Huangpu where each device can serve more orders (we omit the results due to space limitation); (2) the overdue rate is more severe in the city center, and the `aBeacon` can detect couriers more effectively, which leads to better scheduling and thus higher overdue rate improvement.

$\boxed{\textbf{Lesson Learned 5:}}$ **Utility in the Wild.** Unlike other wireless infrastructures, e.g., Wi-Fi, we found the deployment locations with more courier interactions (i.e., demand) during

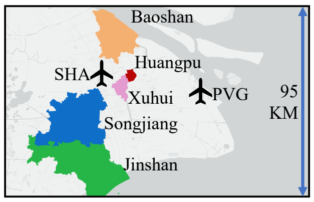

Fig 11: Five Districts

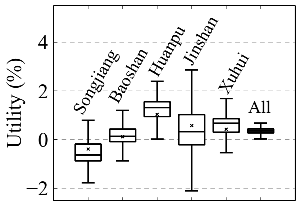

Fig 12: Districts' Utility P_{Util}

our system operation may not have higher utility (quantified by delivery overdue improvement). Instead, we found that the utility of an `aBeacon` device is proportional to the uncertainty of the courier behaviors it can detect (e.g., couriers in higher floors and basements or the downtown area as shown in Fig.9 and Fig.11) because detecting couriers in these uncertain environments can improve the later order scheduling, thus higher utility. This is different from Wi-Fi or cellular device deployment, which are mostly focused on the high user density area. In short, our above findings can provide **practical design guidance** for battery capacity, transmission frequency and power, OTA interface, better installation, and deployment strategies for future wireless systems in the wild.

4.7 Correlation between Different Metrics

Due to the space limitation, we briefly report the results of the correlation between different performance metrics. Our main finding is that for the same `aBeacon` device, when its reliability is low, usually its utility and lifetime are below average; whereas when its reliability is high, the utility is more impacted by the merchant's floors and districts. When reliability $P^i_{\text{Reli}} < 0.5$, this correlation might be caused by improper deployment, which (i) weakens the device utility due to limited data gathered for order scheduling, and (ii) reduces the device lifetime due to potential damage from improper deployment. It also implies that we need to consider other factors if we want to have a longer lifetime and push the utility to the limit when P^i_{Reli} is already high. In our analyses, lifetime and utility are not strongly correlated.

5 Discussions

5.1 Limitations of `aBeacon`

Manual Deployment: For a real-world deployment in the wild, hiring professional teams ensure reliable deployment results but introduces a higher deployment cost per device. In our project, we use our in-house business team to deploy and install `aBeacon` devices at more than 12,000 merchants. Our `aBeacon` system works well in general under this deployment strategy. We admit that our approach may not apply to other settings where such an in-house team is not available. However, we believe our approach can be implemented by Crowdsourcing [42] to deploy wireless devices with a lower labor cost, given little configuration is needed.

No Precise Locations: Another critical limitation of `aBeacon` is that it can only detect couriers' arrival at merchants but cannot perform localization. Given our design goal, a fine-grained localization would be a nice feature to have, but it may not provide higher system gain. Localization increases both hardware cost and deployment cost significantly (it may need onsite configuration or fingerprinting [19]), and may not reduce the overdue rates substantially since the order scheduling only needs coarse-grained locations of couriers.

5.2 System Security

In addition to the hardware cost reduction, another significant improvement in our customization stage is that we enable our devices' security functions. In traditional iBeacon protocol [25], a device ID tuple is fixed for each hardware and broadcast in clear words. It reduces the system complexity while making a device sniffer possible. For example, (1) malicious attackers or unauthorized users (free-riders) can easily restore the device map through war-driving around the devices; (2) if they replicate some device IDs somewhere else, wrong detection information will be collected by `aBeacon`. To address this problem, we designed and implemented a Time-based One-Time Password (TOTP) [53] algorithm to encrypt the device ID broadcast by changing the *major* and *minor* in the ID tuple periodically. A shorter period makes the mapping harder to be restored, whereas a longer period reduces the complexity and the server workload. We set a daily periodical change after exploring the trade-off. The mapping of the device IDs and the merchant locations was stored on the server so that only authorized users can access it. A detailed study of system security is out the scope of this work and will be reported in future work.

5.3 Courier Survey

Feedback is collected from couriers every month regarding multiple aspects, e.g., APP performance, order scheduling, employee care, and penalty appeal. Among the 433 negative feedback on "APP performance" in a recent month, we found the following feedback potentially related to `aBeacon` (# of reports): inaccurate localization (23), slow localization (14), cannot report arrival at the merchants (11), too much battery consumption (8), too much data consumption (2), mandatory Bluetooth on (2). The top three criticisms are all about localization. The underlying reason is that the couriers must report "arrival" at the merchants and customers, and the report must be conducted near (e.g. within 500m) the merchants or customers based on the courier's GPS and the latitude/longitude of the merchant or customer. GPS drifting due to the indoor environment is the main reason for failed reports. The feedback results indicate that alternatives are need besides GPS. `aBeacon` can help in some cases, but we still need to fix the cases when GPS and `aBeacon` fail at the same time. We should also take care of the battery and data consumption.

5.4 Ethics and Privacy

All the data sets are collected under the consent of the couriers. In all our analyses, we have been working on aggregate data. As a result, our results cannot be used to trace back to individuals. The courier ID is an anonymous key to join different data sets, and any other ID information cannot be tracked or identified in practice. We did not utilize personal information from the couriers, e.g., age, gender, income, to protect the couriers' privacy.

5.5 Additional Applications of `aBeacon`

In addition to the direct system gain we measure in this paper, Alibaba has been using `aBeacon` data for a few additional applications based on courier arrival detection.

Order Delivery Time Estimation: The Estimated Time of Arrival (ETA) problem is one of the critical issues in the delivery industry, especially hard for the indoor environment. Based on `aBeacon` data, we obtain travel time between different indoor merchants and build a data-driven model for delivery time prediction, which has been used by other Alibaba teams to predict the overdue rate for the order scheduling.

Merchant Location Correction: Accurate merchant locations are essential in the delivery service. Currently, these locations are provided by merchants themselves and consist of unintentional or intentional errors. Based on the `aBeacon` data, we can measure the travel time between different merchants, cross-validate the accuracy of these locations, and potentially correct them based on massive traveling data.

Anomaly Detection: Unlike GPS data that can be faked on the smartphone [37], `aBeacon` data provide a physical presence confirmation. `aBeacon` data have been used to detect cheating in the delivery process, e.g., frauds conducted by merchants and couriers for the platform subsidy. A detailed courier behavior study measured by manually reported data and automatically collected `aBeacon` data is out of this paper's scope and merits additional investigation.

5.6 `aBeacon+`: Next Generation of `aBeacon`

Since it is expected the maximum lifetime of `aBeacon` is two years, we have been working on a new system called `aBeacon+` built upon `aBeacon` to retain its strengths and address its limitations. In `aBeacon+`, under the merchants' consent, we use merchants' smartphones as `aBeacon` devices instead of deploying `aBeacon` devices, to avoid the hardware and deployment cost. `aBeacon+` does not suffer from vandalism, hardware malfunction, and merchant closures. We embed a broadcasting module in the official merchant APP based on the opportunity that almost every merchant owner needs to install a merchant APP to manage orders. The deployment and operation insights we obtained from `aBeacon` have guided our development of `aBeacon+`, e.g., batch-based deployment and merchant targeting (see our Lessons Learned for details).

We acknowledge the incentives and privacy issues need our attention to make `aBeacon+` practical and salable. However, we argue that the APP users may be willing to provide their locations voluntarily with appropriate incentives in some settings. In our case, a merchant provides this virtual `aBeacon` service on its smartphone. The virtual aBeacon can help the platform decide whether an overdue order is because of the merchant's long order preparation time or the courier's late pickup. Similar applications have been launched in Singapore and potentially in the US for public health purposes during the recent COVID-19 pandemic. TraceTogether [35], a BLE based APP developed in Singapore operates similarly to an aBeacon+ scheme that users nearby can detect each other for contact tracing purpose in response to COVID-19, which is another example of smartphone users' voluntary participation under some practical incentive.

5.7 Implications on Others Systems

Our study offers some interesting implications for current and future networked systems' design, verification, and operation.

Offline Ground Truth Collection for the Verification of Wi-Fi based Solutions: Along 48% of our merchants have stable Wi-Fi access, aBeacon can be used to collect offline ground truth for various applications based on Wi-Fi in the wild to verify existing assumptions or models on Wi-Fi systems and contribute to the community.

Deployment Strategies for 5G and Edge Computing: It has been widely accepted that the extreme densities of base stations and devices are needed to support 5G applications due to its high carrier frequencies with massive bandwidths [3, 8]. Edge computing networks also have a similar setting. Although these systems may need professional teams for the deployment since their devices typically require configuration, our five lessons learned on quantifying system gain, scale evolution, and performance metrics (e.g., lifetime, reliability, and utility) may reduce their indoor operation efforts.

6 Related Works

Table 6: Operational BLE Device Systems

Nation	Deployment Site	Application	Scale
Iceland	Eldheimar museum [34]	Localization	54 devices
U.S.	Beale Street [48]	Presence detection	100 devices
U.K.	Gatwick airport [21]	Localization	2,000 devices
India	Railway station [18]	Presence detection	2,000 devices
Brazil	Tom Jobim airport [4]	Localization	3,000 devices

Operational BLE Device System: To our knowledge, as we are proposing one of the largest BLE device systems in the world, it is worthwhile to give a summary of existing operational BLE device systems. As shown in Table 6, most BLE systems are operated in public sites such as airports or museums for presence detection or indoor localization. The largest BLE system we found is deployed in Tom Jobim airport in Brazil with 3,000 devices, which is fewer than the 12,109 devices in aBeacon we deployed in Shanghai, China. More importantly, these existing systems are operated in a controlled environment (e.g., airports, museums, train stations), but our operating environment is in the wild and out of control. It enables our system to provide some new insights from our lessons learned from large-scale system lifetime, reliability, utility, and cost.

BLE Device Studies: Existing BLE system studies can be categorized according to their applications: localization or presence detection. Indoor localization with BLE systems is similar to works done with Wi-Fi. Fingerprinting is studied in [19] to achieve the accuracy of < 4.8 m at the density of one device per 100 m^2, compared with < 8.5 m for Wi-Fi. Map matching is used in [56] to estimate a user's route based on devices with known locations. 1,600 BLE devices are deployed in all the classrooms and corridors of an institute for evaluation. Dynamic RSSI propagation modeling is proposed in [12] to achieve fine-grained (< 2 m) localization and tracking. There are also studies exploring the proximity information provided. Dining hall usage and student check-in are studied in [38] and [24] with BLE device proximity information. Hardware modifications such as energy harvester are also studied in [28] for better performance.

Real-world Sensing Systems: Another related topic is the large-scale real-world sensing system. These studies lay more emphasis on the system implementation and operation for practical problems. LiveTag is proposed in [22] to sense human-object interaction passively. [51] attempts to answer why RFID sensing systems remain research prototypes and have not been widely deployed in practice with theoretical analysis and real-world experiments.

7 Conclusion

This paper introduces aBeacon, a wireless indoor BLE device system in Alibaba, from its conception to its retirement by a unique operation study in Shanghai. We quantify aBeacon's performance by scale, lifetime, reliability, and utility, for all of which we provide some new insights obtained in our 3-year system operation in the wild. In particular, we built aBeacon from the ground up in a metric-based approach consisting of two phases, i.e., an 8-month pilot study and a 28-month deployment and operation in the wild, including devices in 12,109 merchants and interactions with 109,378 couriers. From the long-term city-wide study, we identify five key observations and lessons regarding system gain quantification, system scale evolution, lifetime, reliability, and utility in the wild. We believe these in-depth lessons learned have implications for other systems requiring long-term operations and broad geospatial coverage such as 5G and Edge Computing.

EarFisher: Detecting Wireless Eavesdroppers by Stimulating and Sensing Memory EMR

Cheng Shen[1], Jun Huang[2]*
[1]*Peking University,* [2]*Massachusetts Institute of Technology*

Abstract

Eavesdropping is a fundamental threat to the security and privacy of wireless networks. This paper presents EarFisher – the first system that can detect wireless eavesdroppers and differentiate them from legitimate receivers. EarFisher achieves this by stimulating wireless eavesdroppers using bait network traffic, and then capturing eavesdroppers' responses by sensing and analyzing their memory EMRs. Extensive experiments show that EarFisher accurately detects wireless eavesdroppers even under poor signal conditions, and is resilient to the interference of system memory workloads, high volumes of normal network traffic, and the memory EMRs emitted by coexisting devices. We then further propose a method to detect eavesdropper's countermeasure, which deliberately emits strong memory EMR to interfere with EarFisher's detection.

1 Introduction

Rendered by the broadcast characteristic of wireless medium, eavesdropping has been a fundamental threat to the security and privacy of wireless networks ever since the invention of wireless communication. While significant cryptographic research has been devoted to tackling this threat, in this paper, we take an orthogonal angle to explore the feasibility of wireless eavesdropper detection. A security primitive capable of this task is essential in a wide range of scenarios. First, in wireless networks serving public areas (e.g., airports, campus, malls, etc), Layer-2 encryption is commonly disabled to facilitate open access. Second, encryption algorithms are subject to extensive side channel analysis [7, 8, 11, 15, 16, 21, 22], which allow attackers to decipher encryption keys. Third, cryptographic protocols themselves often suffer fatal flaws that are difficult to identify before universal adoption. For example, in 2017, researchers uncovered that the four-way handshake of WPA2 is vulnerable to the key re-installation attack [35], which allows eavesdroppers to compromise encryption keychains. The flaw had been present since the release of 802.11i in 2004, leaving billions of Wi-Fi users potentially exposed to eavesdropping for more than 13 years.

*Corresponding author: junhuang@mit.edu.

Beyond complementing encryption schemes, an eavesdropper detector can be an essential building block of a secure network. For example, in quantum networks, legitimate receivers can detect eavesdroppers by leveraging the quantum physic law, where the state of a quantum bit 'collapses' whenever it is intercepted. Quantum key distribution protocols [9] use this law to verify the confidentiality of encryption keys, which leads to fundamentally assured communication security in quantum networks.

Unfortunately, to date, there has been no effective method to detect eavesdroppers in wireless networks. Unlike quantum eavesdroppers, wireless eavesdroppers can be completely passive without actively transmitting or altering signals in the air. Recent studies exploit the RF leakages of radio circuits to detect wireless receivers [13, 24, 26, 27, 32, 34, 36]. However, such leakages are extremely weak, limiting detection range to only a few feet. More importantly, because all wireless radios emit leakages during signal reception, this method cannot differentiate eavesdroppers from legitimate receivers.

In this paper, we present EarFisher – the first system that can detect wireless eavesdroppers and differentiate them from legitimate receivers. The key idea is based on the observation that, unlike legitimate receivers who drop others' packets in network interface cards (NICs), only eavesdroppers digest all packets in their CPU-memory systems. Inspired by this observation, EarFisher stimulates eavesdroppers by transmitting a flow of *bait* packets forged with a virtual receiver address, and then detects eavesdroppers by sensing the surge of their electromagnetic radiations (EMRs) when they write baits into their memories. Recent studies show that the multi-channel architecture of modern memories amplifies memory EMR [17], which helps EarFisher extend detection range.

To realize this idea, we tackle four key challenges. First, when multiple devices having the same memory frequency coexist in an environment, their memory EMRs mix in frequency spectrum, making it difficult to accurately sense them separately. Second, memory workloads of operating systems and applications also produce memory EMRs, which are difficult to distinguish from the eavesdropper's responses when the memory activities coincidentally occur at the same time of bait packet transmissions. Third, despite the amplification of multi-channel architecture, memory EMR is still very weak, requiring a long time of stimulus to trigger a sufficiently strong response at the eavesdropper. However, intensive bait packet transmissions in a large time window can block the wireless channel, and may present a distinguishable traffic pattern that can be noticed by crafty eavesdroppers. Fourth, eavesdroppers knowing the design and presence of EarFisher may deliberately write its memory, which will produce strong memory EMR that interferes with EarFisher's detection.

To address these challenges, EarFisher employs new signal processing algorithms to sense and separate the memory EMRs of different devices, obscures and disguises stimulus traffic as short bursts of normal packets, incorporates statistical tool to tolerate the interfering EMRs produced by system memory workloads, and exploits a fundamental dilemma of eavesdroppers to detect deliberate writing-based countermeasure. Extensive experiments show that EarFisher accurately detects eavesdroppers even under poor signal conditions, and is resilient to the interference of system memory workloads, high volumes of normal network traffic, and the memory EMRs of coexisting devices. We then further demonstrate EarFisher's effectiveness in a real testbed, where three EarFisher nodes are deployed to monitor an indoor area of 1600 ft^2. Experiment results show that EarFisher reliably detects eavesdroppers placed at different locations despite the complexity of indoor environments, such as the block of walls.

2 Related Work

Cryptographic attacks. Since the invention of wireless communication, encryption has been the primary security measure to combat eavesdropping. However, extensive research shows that eavesdroppers can compromise encryption based on a variety of side-channel attacks [7, 8, 15, 16, 21, 22]. In particular, Camurati et al. [11] show that the EM leakage of the processor on wireless chips can be inadvertently amplified by RF front-end, allowing an eavesdropper to decipher the encryption key from a distance.

Moreover, cryptographic protocols themselves often suffer fatal flaws that are difficult to identify before universal adoption. For example, Wired Equivalent Privacy (WEP), a security protocol ratified as a part of 802.11 in 1997, was found to have fatal flaws in 2001 [14]. WEP was then superseded by Wi-Fi Protected Access (WPA) in 2004, but history repeated itself. In 2017, researchers demonstrated that the four-way handshake of WPA has a fatal vulnerability, which allows eavesdroppers to compromise the encryption keychain using key reinstallation attacks [35]. From 2004 to 2017, the vulnerability of WPA left billions of Wi-Fi users potentially exposed to eavesdropping for more than 13 years.

Eavesdropper detection. Prior eavesdropper detectors commonly rely on sensing RF signals leaked from the front-end circuit of wireless receiver. This method was first proposed in [27, 36] to detect primary receivers in cognitive radio networks, and then extended to UWB, WiMAX, and MIMO channels to detect hidden radios [24, 26]. Ghostbuster [13] further augments this method using spatial cancellation of interference and frequency cancellation of signal artifacts, which allow it to extract leakages under poor signal conditions in the presence of ongoing wireless transmissions. However, Ghostbuster still suffers limited detection range (less than 1m for COTS Wi-Fi receivers) because of the weak power of leakage from RF circuit.

Recent studies [32, 34] show that superheterodyne and superregenerative receivers can be detected from a longer distance by exploiting the known characteristics of their RF leakages. However, these techniques are highly dependent on the receiver architecture. Unfortunately, superheterodyne and superregenerative receivers are commonly used in low-power wireless remote, but are far less common in mainstream wireless communication systems such as Wi-Fi.

More importantly, because all radios emit RF leakages during signal reception, existing eavesdropper detectors suffer a common limitation as they cannot differentiate eavesdroppers from legitimate receivers. To sidestep this limitation, Ghostbuster assumes a threat model where the number of legitimate receivers is known a priori [13]. This assumption restricts its usability to a very narrow range of specific scenarios.

EM side-channels. Recently, researchers leverage the EM side channels of CPU and memory for attestation [29], memory profiling [30], and malware detection [18, 25, 37]. Different from these passive analysis, EarFisher features a new paradigm that actively stimulates memory EMR. Moreover, EarFisher employs a signal processing algorithm that bases on fine-grained measurement and theoretical characterization of memory clock, which makes it possible to not only extract weak memory EMRs under poor signal conditions, but also separate and track individual memory EMRs when multiple devices having the same memory frequency coexist in a crowded environment.

3 Threat Model

A wireless eavesdropper is a malicious receiver who sniffs on other devices' packets. Typically, eavesdropping can be implemented by modifying the device driver to enable *monitor mode*, in which a wireless chip transfers all received packets to the host. A recent study shows that most drivers on major operating systems (e.g., Linus, Windows, macOS) support monitor mode by default [1].

By eavesdropping on network traffic, the attacker's goal is to gather sensitive data, such as personal and business related information, or secrets necessary to enable decipher and man-in-the-middle attacks. Typically, wireless chips are integrated with a microcontroller and a small RAM of at most a couple of MiBs. The on-chip system is tasked for simple computation such as checking receiver address and verifying packet checksum, but is far from capable of security- and privacy-intrusive processing. As a result, the eavesdropper must digest sniffed packets in the CPU-memory system of the host.

To this end, the wireless chip of the eavesdropper needs to write all sniffed packets to the memory of the host. This is typically under the control of DMA, and will produce EMR when sniffed packets are transferred over memory bus. Specifically, for SDRAMs, memory EMR can be observed as a radio signal around the frequency of memory clock. Because DDR uses double pumping, the clock frequency is a half of memory speed. In practice, the clock frequency of a modern DDR has 13 possible values ranging from 200 MHz of DDR2-400 to 1600 MHz of DDR4-3200. To sense memory EMR, one can scan DDR frequencies one by one, or use a group of sensors to monitor multiple frequencies in parallel. In the rest of this paper, we assume the memory clock frequency of the eavesdropper is known.

4 Characterizing Memory EMR

In this section, we present measurements and model to characterize memory EMR. Our measurements are conducted on two laptops of DDR3-1600 and DDR4-2133, respectively. A BladeRF with an omni-directional 5 dBi antenna is employed as the receiver.

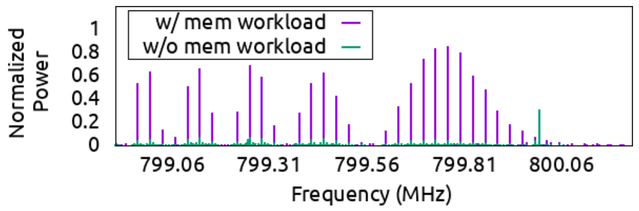
4.1 Spectrum Pattern

Measurement-based characterization. To measure the frequency spectrum of a device's memory EMR, we take FFT over an 1s window of signals captured around the clock frequency of the device's memory. To study how memory workload impacts on memory EMR, we created a process to write memory intensively[1], and then compare the spectrum patterns measured before and after the start of the process.

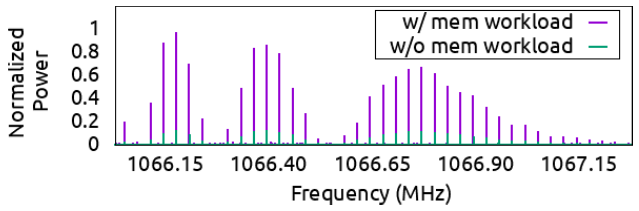
As shown in Fig. 1, we observe that the frequency spectrum of memory EMR features a series of energy peaks distributed over a side-band of about 1 MHz below the frequency of memory clock. In the presence of intensive memory workload, the amplitudes of all energy peaks increase simultaneously and significantly. To further characterize the spectrum pattern, we examine the auto-correlation of peak frequencies and find that the frequency interval between consecutive peaks is constant. Specifically, for the DDR3-1600 and the DDR4-2133, the frequency intervals are 31.8 KHz and 31.2 KHz, respectively.

Theoretical characterization. We then further characterize memory EMR based on the theoretical model of memory

[1]To write memory directly, we used SSE instructions to bypass cache.



(a) DDR3-1600.



(b) DDR4-2133.

Figure 1: The spectrum pattern of memory EMR with and without memory workload.

clock. Because memory clock injects fluctuating current into memory bus, it produces EMR at the clock frequency. As memory reads/writes are performed at clock edges, they amplify EMR amplitude of memory clock but will not affect the pattern of frequency spectrum.

The simplest form of a clock is a sine wave of which the energy is all concentrated at clock frequency. However, this leads to a high EMR intensity that may violate regulatory requirement for electromagnetic compatibility. To walk-around this issue, modern clock generators use spread spectrum techniques to reshape the energy distribution of clock. Denote an unspread clock as,

$$V_{clk}(t) = A\cos(2\pi f_0 t),$$

where f_0 is the frequency of memory clock. A spread spectrum clock is the frequency modulation of $V_{clk}(t)$, which can be expressed as,

$$V_{ssc}(t) = A\cos(2\pi f_0 t + \frac{\Delta f}{f_m}\sin(2\pi f_m t)), \tag{1}$$

where f_m and Δf are the modulation frequency and peak frequency deviation, respectively. By expanding Eqn. 1 using the Jacobi-Anger expansion, the frequency spectrum of $V_{ssc}(t)$ can be expressed as [10],

$$\|\mathcal{F}_{ssc}(f)\| \overset{\text{def}}{=} \|\sum_n J_{\text{n}}(\frac{\Delta f}{f_m})(\delta(f - f_0 + nf_m) \\ -\delta(f - f_0 - nf_m))\|.$$

where $J_{\text{n}}(\cdot)$ is the Bessel function of the first kind, and $\delta(\cdot)$ is the Dirac delta function.

To maintain a stable synchronization between memory and memory controller, $V_{ssc}(t)$ needs to be band-pass filtered before being used as a memory clock. Typically, the band-pass filter removes frequency components higher than memory clock frequency and then imposes a low cutoff to limit the

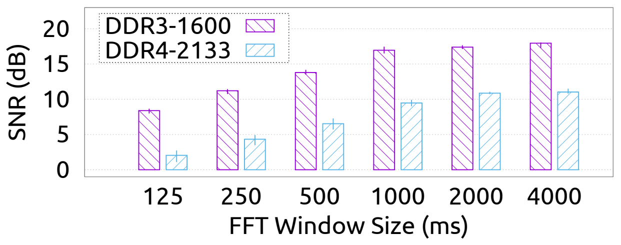


Figure 2: The SNR of received memory EMR as a function of FFT window size.

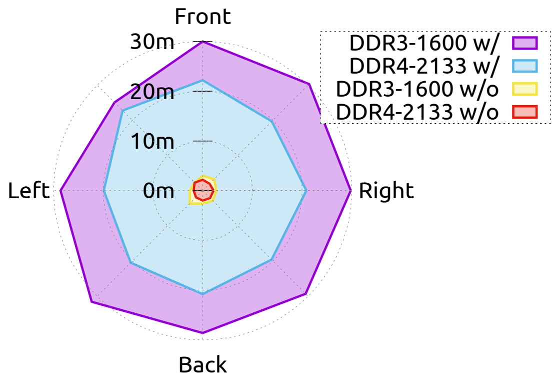

Figure 3: The 3 dB range of memory EMRs with and without memory activities.

maximum frequency deviation. After band-pass filtering, the frequency spectrum of $V_{ssc}(t)$ is transformed to,

$$\|\mathcal{F}_{ssc}(f)\| \overset{\text{def}}{=} \|\mathcal{A}(f)\sum_n J_n(\frac{\Delta f}{f_m})\delta(f - f_0 + nf_m)\|, \quad (2)$$

where $\mathcal{A}(f)$ is the impulse response of the band-pass filter.

Summary of characteristics. Eqn. 2 indicates that the energy of memory EMR is non-zero only at $f_0 - nf_m$, which interpreted the spectrum pattern shown in Fig. 1. In other words, memory EMR is composed of a series of *sub-clock components*, where the frequency interval between consecutive sub-clocks is f_m, and the first sub-clock is at f_0.

4.2 Directivity and Range

We then place receiver at different directions to measure the *3 dB range* of memory EMR, which is defined as the maximum distance from which the SNR of received memory EMR is higher than 3 dB. In this experiment, we calculate SNR of memory EMR using the sub-clock of the highest power.

It is worth noting that the SNR of received memory EMR is dependent on the size of FFT window. As shown in Fig. 2, the larger the FFT window, the higher the SNR. However, the gain yielded by enlarging FFT window gradually diminishes as the size of FFT window increases. To understand why, consider a FFT bin (whose size equals the inversion of FFT window size) that is large enough for containing one sub-clock. In this case, one can always reduce the FFT bin to suppress noise without affecting the sub-clock, thereby increasing SNR. On the other hand, if the size of FFT bin is already smaller than the bandwidth of sub-clock, then further reducing FFT bin will also reduce the energy of contained memory EMR, thus providing no SNR gain. Based on the results shown in Fig. 2, we set FFT window size to 1s in the following measurements.

Fig. 3 plots the 3 dB range of memory EMR measured from different directions. We observe that receiving direction has a slight impact on range, which should be attributed to the shape of shielding cases of particular devices. Moreover, because of the lower operating voltage, the range of DDR4-2133's EMR is about 25% shorter than that of DDR3-1600. Nevertheless, even when receiving from the worst direction, the 3dB ranges of DDR3-1600 and DDR4-2133 exceed 25m and 20m, respectively.

4.3 Response to Stimulus

To understand the impact of stimulus network traffic on eavesdropper's memory EMR, we setup an experiment where the laptop equipped with DDR4-2133 is employed to eavesdrop on an 802.11n transmitter. The experiment is conducted on a clean channel to avoid the interference of uncontrolled network traffic. The 802.11n transmitter is configured to send an 100 ms UDP flow every 200 ms. We then vary the rate of the UDP flow and repeat the experiment.

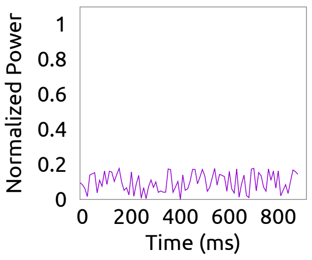
Fig. 4 shows the time varying amplitude of memory EMR measured in close proximity to the eavesdropper using a sliding FFT window of 100 ms. As shown in Fig. 4, the eavesdropper's memory EMR demonstrates a clear responsive pattern when the rate of UDP flow increases to only 2 Mbps. The amplitude of response can be significantly boosted by further increasing the rate of stimulus network traffic.

5 EarFisher Overview

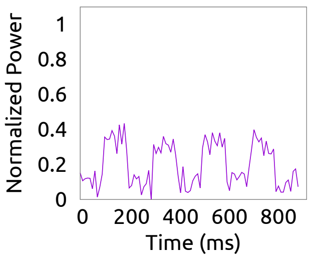
EarFisher is designed as a standalone system to detect eavesdroppers in a wireless network without the cooperation of other network nodes. It differentiates eavesdroppers from legitimate receivers based on an architectural criteria, where receivers are convicted of eavesdropping as long as they transfer other devices' packets to memory. In contrast, a legitimate receivers should drop other devices' packets immediately in wireless NICs.

As illustrated in Fig. 5, EarFisher consists of a stimulator and a detector. The stimulator is a wireless network of two cooperative nodes, which exchange packets to generate stimuli[2]. The detector senses memory EMR using a software defined radio, which is hosted by one of the stimulator nodes and is synchronized with the wireless NIC to monitor the variations of memory EMRs under traffic stimuli.

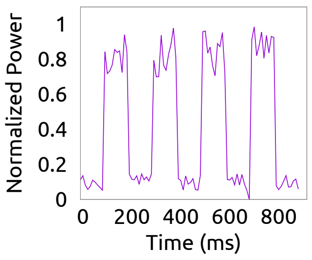
[2]A simpler method is to use a single wireless device to forge a packet flow. However, crafty eavesdroppers may detect the forged packet flow by noticing that the sender and the receiver manifest the same channel state information.



(a) Rate = 600 Kbps.



(b) Rate = 2 Mbps.



(c) Rate = 20 Mbps.

Figure 4: Time varying amplitude of memory EMR under the stimuli of periodic UDP flows.

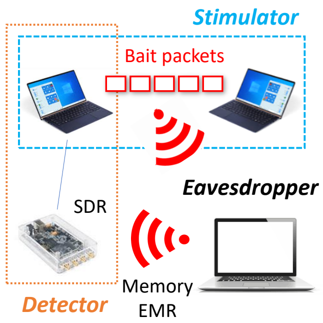


Figure 5: EarFisher architecture.

At a high-level, EarFisher features four key designs.

Sensing memory EMRs. Despite the amplification by multichannel architecture, memory EMR is still very weak and thus can be easily buried by noise when sensing from a distance. Moreover, when devices having the same memory frequency coexist in an environment, their memory EMRs will be mixed together in frequency spectrum, making it difficult to track them separately. EarFisher addresses these challenges by using folding [39] – a signal processing algorithm originally used by large radio telescopes to amplify astronomical signals – to sense weak memory EMRs. It then leverages the fingerprint of memory clock to separate and track the memory EMRs of different devices.

Obscuring stimulus traffic. Sensing weak memory EMRs requires a large FFT window to suppress noise. However, intensive transmission of stimulus traffic in a large time window may interfere with normal network traffic. In addition, it may introduce a distinguishable traffic pattern to alert crafty eavesdroppers. To address this challenge, EarFisher first splits a large block of bait packets into small pieces and then disguises them as normal network traffic. At the detector side, EarFisher stitches signal samples captured at the time instants of stimuli into a complete window before taking FFT.

Tolerating system memory workloads. Memory workloads of operating systems and applications also produce memory EMR, which is difficult to distinguish from the response of eavesdropper when memory activities coincidentally occur at the time instants of traffic stimuli. To avoid false alarm, EarFisher profiles the memory EMR incurred by system memory workloads for each device at runtime. It then tests the hypothesis if the surge of memory EMR under stimuli is sufficiently significant to claim a detection of response.

Detecting countermeasure. Eavesdroppers knowing the design and presence of EarFisher may actively write memory to emit strong EMR, which will interfere with EarFisher's detection. To detect this countermeasure, EarFisher exploits a fundamental dilemma faced by the eavesdropper, where intermittent writing of memory leaves significant chance of exposing the response to stimuli, while consistent writing presents an abnormal EMR pattern that can be distinguished from normal system memory workloads.

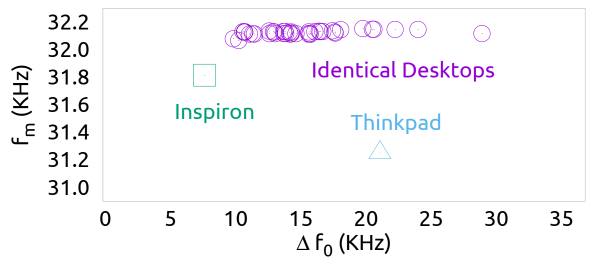

Figure 6: The distribution of memory clock fingerprints.

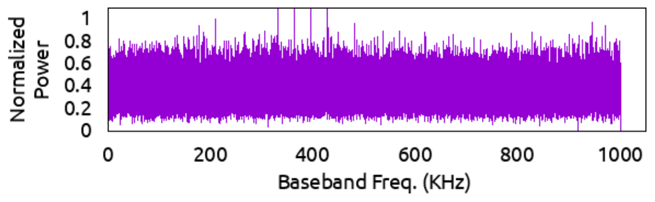
6 System Design

This section presents the design of EarFisher in detail. We first propose a sensing primitive to monitor memory EMRs, and then describe the design of stimulator and detector. Finally, we discuss how to detect eavesdroppers who deliberately write memory to interfere with EarFisher's detection.

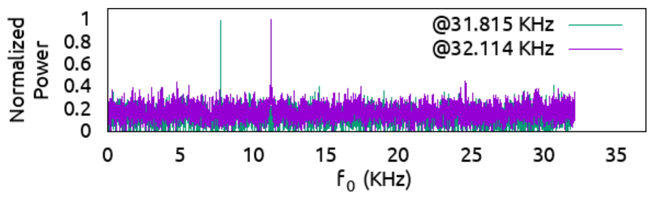
6.1 Sensing Memory EMRs

As discussed in section 4, memory EMR consists of a series of sub-clocks, where the i-th sub-clock is at $f_0 - if_m$. Due to minute manufacturing deviations, f_0 and f_m present a unique fingerprint, which distributes the sub-clocks of different devices to different frequencies. In the following, we first characterize memory clock fingerprint to study if it is sufficiently diverse to allow the separation of memory EMRs. We then discuss how to fuse sub-clocks to sense memory EMRs buried by noise, and develop a signal processing algorithm that exploits memory clock fingerprint to separate and track the memory EMRs of individual devices.

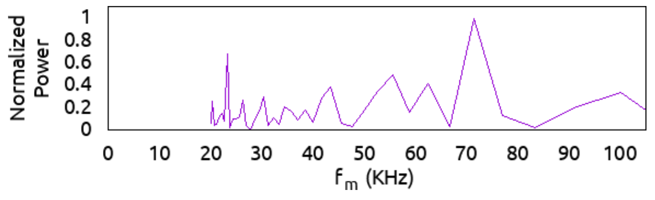
Characterizing memory clock fingerprints. To characterize the fingerprint of memory clock, we conduct measurements on 32 devices equipped with DDR3-1600, including a Dell Inspiron, a Thinkpad, and 30 identical desktops in the computer room of a university library. Fig. 6 plots the distribution of their memory clock fingerprints. We observe that f_0 differs even across the 30 identical desktops. In comparison, the offset of f_m is only significant across different devices, which should be attributed to the different modulation frequencies of their clock generators.



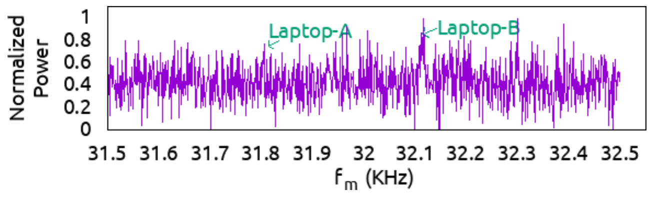
(a) Noisy spectrum after FFT.



(b) Results of folding.



(c) FFT.



(d) Auto-correlation.

Figure 7: Comparison between folding, auto-correlation and FFT over a noisy spectrum containing the memory EMRs of two computers whose f_m are 31.815 KHz and 32.114 KHz, respectively.

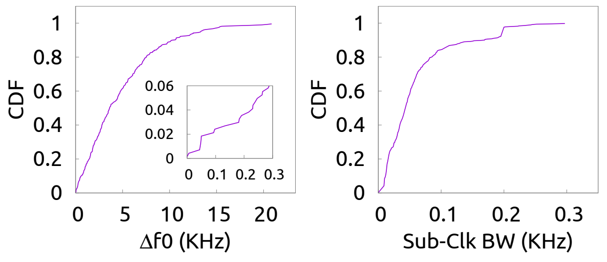


Figure 8: The CDFs of Δf_0 and sub-clock bandwidth.

To validate if the fingerprints are sufficiently diverse, consider an arbitrary pair of identical desktops. As they have similar f_m, the separation of their sub-clock components solely depends on the offset of f_0. Specifically, if the offset of f_0 is too small, sub-clock components will overlap in frequency in a pair-wise fashion. In this case, the overlapped bandwidth can be computed as,

$$\Delta BW = \frac{BW_a + BW_b}{2} - \Delta f_0,$$

where Δf_0 is the offset of f_0; BW_a and BW_b are the sub-clock bandwidth of the two devices, respectively. Clearly, their memory EMRs are separable if and only if $\frac{BW_a+BW_b}{2}$ is smaller than Δf_0. Fig. 8 further compares the distributions of Δf_0 and $\frac{BW_a+BW_b}{2}$ measured on the 30 identical desktops. We observe that Δf_0 is significantly larger than sub-clock bandwidth. Specifically, Δf_0 is larger than 300 Hz in 94% cases, whereas the bandwidth of all sub-clocks are smaller than 300 Hz.

Based on f_0 and sub-clock bandwidth measured on the 30 identical desktops, we further conduct a simulation to test the capacity of a memory ‘channel’, i.e., the maximum number of identical devices that can coexist on the same memory frequency without mixing memory EMRs. In each run of the simulation, we randomly add desktops to the memory channel until the produced memory EMRs become inseparable. After 10000 runs, we find that the average capacity is 7. We note that the capacity should be significantly higher if coexisting devices are different. In particular, for a pair of different devices, even if some of their sub-clock components are overlapping, others are likely separated because of different f_m.

Fusing sub-clocks. We then discuss how to fuse sub-clocks to boost the SNR of memory EMR. A key design requirement is to achieve computational efficiency, because the signal processing targets at high-resolution frequency spectra obtained by large FFT windows.

To this end, we propose a novel use of *folding* – a fast algorithm originally used by large radio telescopes to amplify periodic astronomical signals [23, 31, 39]. EarFisher utilizes folding to search for sub-clock components distributed over frequency. Suppose $\mathcal{P}$ represents the series of N points of the spectrum and $\mathcal{P}[i]$ ($i \in [1,N]$ is the amplitude of the ith point. The objective of folding is to search for a signal with a period of T. The spectrum is first divided into small windows of T points and then added in a window-wise fashion as,

$$\mathcal{F}_T[i] = \sum_{j=0}^{\lfloor \frac{N}{T} \rfloor - 1} \mathcal{P}[i + j * T].$$

When folding up the spectrum using a window size of f_m, the energies of sub-clock components will be fused while the sum of noise is likely smaller due to their non-periodicity. The position of *folding peak*, i.e., the i that maximizes $\|\mathcal{F}_T[i]\|$, is dependent on the offset between receiving frequency and the memory clock's f_0. Because the f_m of memory clock is unknown, EarFisher performs folding at each possible f_m to search for memory EMRs. Fig. 7a shows an example of a noisy spectrum containing the memory EMRs of two laptops, whose f_m is 31.815 KHz and 32.114 KHz, respectively. Fig. 7b plots the folded spectra where the peaks corresponding to the fused energies of sub-clocks can be clearly identified. In comparison, as shown in Fig. 7c and Fig. 7d, the performance of auto-correlation and FFT – two widely used signal processing algorithm of periodic signal detection – is worse than folding despite their higher computational overhead. Specifically, FFT fails to identify memory EMRs due to its poor resolution. Auto-correlation identified one of the laptops but is significantly more susceptible to noise than folding.

Separating memory EMRs. EarFisher exploits the diversity of memory clock fingerprints to separate and track memory EMRs. To this end, EarFisher performs two steps of processing iteratively. First, it folds up the spectrum at all possible f_m, and then identifies the highest folding peak caused by the device that has the strongest memory EMR. Name this device as Alice. Second, EarFisher outputs the highest folding peak, which reflects the fused amplitude of Alice's memory EMR, and then removes the sub-clock components of Alice from the spectrum. The goal is to eliminate possible peaks yielded by Alice in subsequent rounds of folding, which may prevent EarFisher from identifying the folding peaks of other devices. Note that each sub-clock component may include multiple spectral points depending on its bandwidth. EarFisher identifies sub-clock bandwidth using standard edge detection algorithm [19], and then removes all points included in the peak. The above procedure is repeated until the highest folding peak falls below a predefined threshold.

In practice, the spectrum may contain other signals produced by wireless communication. EarFisher classifies memory EMR and wireless communication based on two simple rules. First, the highest folding peak should trace-back to at least two peaks separated by the folding period in the spectrum. Second, the bandwidth of each trace-backed peak should not exceed 300 Hz – an empirical upper bound on sub-clock bandwidth obtained through extensive measurements. In comparison, the signal bandwidth of wireless communication is typically orders-of-magnitude higher in order to achieve a meaningful data rate.

Tracking memory EMRs. EarFisher tracks memory EMRs of different devices by using (f_0, f_m) as a device identity. In practice, (f_0, f_m) may experience small variance over time. To address this issue, EarFisher clusters folding peaks obtained at different time instants based on the euclidean distance of (f_0, f_m), where each cluster corresponds to one device. It then assigns a unique ID to each device and tracks the variation of f_0 and f_m using standard phase-locked loops.

6.2 Stimulator

The stimulator of EarFisher consists of two cooperative devices, which exchange packets to generate stimulus traffic. To detect eavesdroppers in a specific wireless network, the bait packets should be transmitted on the same frequency channel. In case the network to protect is operated on multiple channels, the stimulator can hop across channels to inject baits. In the following, we focus on the design of a Wi-Fi stimulator. The principle of the presented design is broadly applicable to other types of wireless networks.

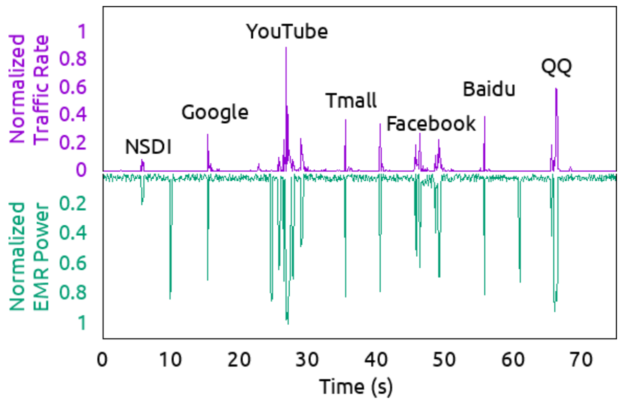

Figure 9: Eavesdropper's response to the stimuli of web page downloads.

Engineering stimulus traffic. EarFisher disguises the network of Wi-Fi stimulator as a WLAN where one device hosts a virtual access point and the other is attached as a client. To stimulate a Wi-Fi eavesdropper without incurring its alert, the client launches a sequence of webpage downloads at random time instants, where each download generates a short stimulus consisting of several MBs of data depending on the size of webpage[3]. Fig. 9 shows an eavesdropper's response to stimuli when it is sniffing on the downloads of the homepage of NSDI as well as 6 popular pages top-ranked in Alexa [2]. We observe that YouTube triggered the strongest response due to its large page size, suggesting that the stimulator should leverage media-rich pages for stimuli.

In practice, round-trip delays occurred at upper-layers prevent the stimulator from achieving a high throughput, thereby degrading the intensity of stimulus. For example, as can be seen in Fig. 9, the downloading traffic of Facebook page was divided into two parts due to large upper-layer delay, which significantly weakens the eavesdropper's response despite the large size of Facebook page. To address this issue, EarFisher first records the real traffic of webpage downloads, and then replays the traffic in the local network of stimulator.

Media access control. To further improve the effectiveness of stimulus, EarFisher leverages the following MAC-layer schemes. First, EarFisher utilizes the frame aggregation feature of 802.11 to bundle multiple bait packets in a single transmission, which effectively increases the throughput of stimulus traffic. Second, before transmitting bait packets, EarFisher uses RTS and CTS to mute normal network traffic. The goal is to reduce the chance of false alarm, which may happen if legitimate network nodes transmit or receive and thereby produce memory EMRs during stimulus period. One of our future work is to further control the timing of stimuli to minimize the interference with normal network traffic. This can be achieved by predicting the variation of normal network traffic using theoretical models [28] and then sending stimulus traffic only when the wireless channel is under-utilized.

[3]According to httparchive [4], the average webpage size has increased from 1.6 MB in 2014 to 4 MB in 2019.

6.3 Detector

At a high-level, the detector of EarFisher separates and tracks memory EMRs using the sensing primitive proposed in section 6.1, and then inspects each memory EMR to infer the response to traffic stimuli. Note that whenever transmitting bait packets, the stimulator will also emit memory EMR, which is difficult to distinguish from the response of an eavesdropper. To address this issue, a straightforward method is to count bait receivers and check if the number is larger than expected. In the design of EarFisher, we employ a simple alternative to walkaround receiver counting. Specifically, EarFisher employs two stimulators of different memory frequencies. In this case, because the eavesdropper's memory frequency must differ from that of at least one stimulator, the detector can quickly identify eavesdropper's memory EMRs based simply on emission frequency.

Profiling memory EMRs. To detect the presence of eavesdroppers, EarFisher compares the amplitudes of memory EMRs measured in the presence and absence of stimulus traffic, named as *stimulus set* and *baseline set*, respectively.

To profile the stimulus set, EarFisher first captures signals around the transmission time of bait packets, and then puts captured signals in a large FFT window. Once the window is completely filled, EarFisher runs the algorithm proposed in section 6.1 to identify memory EMRs. Suppose n memory EMRs are observed at $I^i = (f_0^i, f_m^i)$, $i \in (1,n)$. For each I^i, EarFisher establishes a stimulus set to record the amplitude of memory EMR, and then populates the set when new FFT windows are available.

Note that a surge of memory EMR under traffic stimuli could be a coincidence caused by system memory workload. To profile the probability of such coincidence, EarFisher keeps tracking the amplitude of memory EMR for each I^i to build the baseline set. To prevent memory EMRs caused by network activity from polluting the baseline set, EarFisher purges signals captured in the presence of ongoing network traffic, and then stitches remaining signals into FFT windows.

Statistical hypothesis testing. EarFisher then compares the stimulus and baseline set using a statistical hypothesis test called t-test, which is widely used to decide whether a drug has had a significant effect on the studied population. A t-test takes the means, variances, and the number of samples of the two compared sets, and then computes a t-value as follows,

$$t = \frac{\mu_{\text{stimulus}} - \mu_{\text{reference}}}{\sqrt{\frac{\sigma_{\text{stimulus}}}{n_{\text{stimulus}}} + \frac{\sigma_{\text{reference}}}{n_{\text{reference}}}}}, \tag{3}$$

where μ and σ are the mean and variance of a set, respectively; n is the number of samples, which determines the degrees of freedom of the test.

Once the t-value and degrees of freedom are determined, a p-value can be calculated. A large positive p-value is an evidence that μ_{stimulus} is significantly larger than μ_{ref}. EarFisher then compares the p-value with a a chosen level of statistical significance, denoted as α. Basically, a high α assures low false alarm rate but may raise miss detection. EarFisher exposes the configuration of α, which allows users to tune the balance between detection rate and false alarm.

6.4 Detecting Countermeasure

To counteract the detection of EarFisher, eavesdroppers knowing the design and presence of EarFisher may actively write memory to emit strong EMR, which will pollute the baseline set profiled by EarFisher, thus defeating the statistical test given in Eqn. 3. In the following, we propose a simple method to detect this countermeasure.

The dilemma of eavesdropper. Our insight is that, when actively writing memory, the eavesdropper faces a fundamental dilemma where intermittent writing leaves significant chance of exposing the response to stimuli, while consistent writing presents an abnormal pattern of memory EMR that can be distinguished from normal system memory workloads.

Specifically, to mask the response to traffic stimuli, the eavesdropper must erase the difference between the reference and stimulus set. However, because the stimulus set is built by stitching signals received under traffic stimuli, it captures the eavesdropper's memory EMR in a status of virtually consistent writing of memory. In order to defeat the statistical test, the eavesdropper must write memory at a comparable intensity to corrupt the baseline set.

On the other hand, due to the presence of hierarchical cache, a normal system rarely writes memory consistently. In particular, unlike wireless NICs that write received packets directly into memory, legitimate programs only read/write memory under cache miss, while modern Intel and AMD CPUs can maintain cache hit rate above 90%. Moreover, due to the high bus bandwidth of modern memory (ranging from a couple of GB/s of DDR to tens of GB/s of DDR4), the data transfer caused by normal memory workload typically completes in very short time, producing only intermittent bursts of memory EMRs. As an example, Fig. 10 shows the time-varying amplitude of memory EMR measured on a laptop running Ubuntu 18.04 and Windows 10 with no other programs. We observe that the operating systems alone yield noticeable variance of memory EMR. In contrast, consistent writing of memory can easily erase the variance, presenting a distinguishable pattern.

Exploiting the dilemma. To detect eavesdroppers who deliberately write memory to mask response to traffic stimuli, EarFisher complements the detector proposed in section 6.3 with an auxiliary detector to inspect abnormal EMR pattern caused by deliberate writing.

The auxiliary detector uses the variance of normalized memory EMR amplitude as a feature to investigate if the baseline set has been polluted by deliberate writing. However, because measuring memory EMR requires a large FFT window to suppress noise, obtaining a fine-grained estimation of EMR

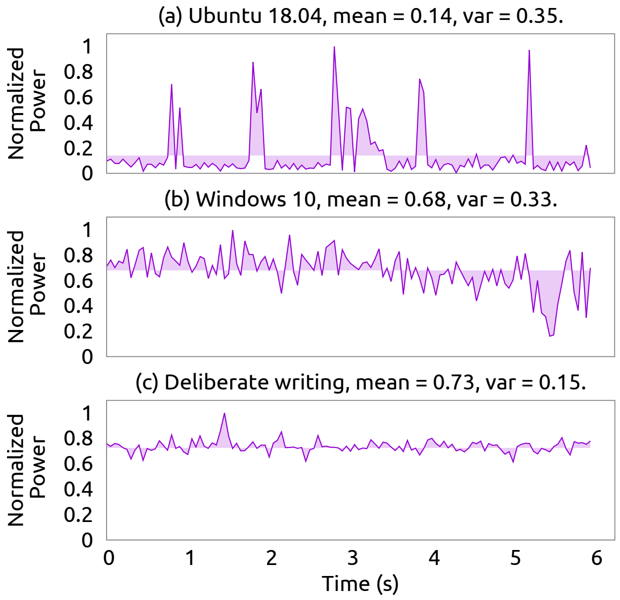

Figure 10: The time varying memory EMR induced by operating systems and deliberate writing.

variance may incur a long delay. EarFisher circumvents this issue by *oversampling* the baseline set. Specifically, EarFisher divides each FFT window in the baseline set into small blocks of signals, and then randomly picks blocks from different FFT windows to create new EMR samples. EarFisher then calculates the variance of created EMR samples, and repeats this for multiple rounds to profile a fine-grained distribution of EMR variance using a small number of FFT windows.

Once the distribution of EMR variance has been profiled, EarFisher performs t-test again to check if the mean of the distribution is smaller than an empirical threshold. To determine the threshold, we conduct extensive measurements on devices of different configurations. Our measurements lead to several findings. First, the variance is smaller on devices of larger cache and faster memory. Second, the variance is minimum when a devices is running no program except the operating system. Third, Windows typically demonstrates smaller variance than other operating systems. In our measurements condcuted on 39 devices, the minimum and maximum variance are 0.32 and 0.35, which are measured on a Dell Inspiron equipped with an 8 MB cache and DDR4-2133 running Windows 10, and a Thinkpad equipped with a 4 MB cache and DDR3-1600 running Ubuntu 18.04, respectively. Notice that the measured EMR variance may vary under different SNRs, we further profile the minimum EMR variance on Inspiron running Windows under different attenuation conditions. Before taking statistical test, EarFisher chooses a threshold based on the measured SNR of memory EMR. To avoid false alarm and account for devices of higher configurations, the current design of the auxiliary detector adopts a conservative threshold that is 10% lower than the empirically profiled minimum variance. Further refining the threshold for higher-end cache and memory configurations is left to our future work.

7 Evaluation

This section evaluates the performance of EarFisher in an 802.11n network. The current prototype of EarFisher employs BladeRF [3] to sense memory EMRs. To generate stimulus traffic, EarFisher replays the recorded traffic of YouTube page download at about 10 MB/s in its local stimulator network. Based on empirical measurements shown in Fig. 2, the FFT window size of memory EMR sensor is set to 1s, as larger windows increase detection latency but yield limited SNR gain. When performing statistical test to detect eavesdroppers, the stimulus and baseline set are profiled based on 1s and 3s of memory EMR signals, respectively. To improve the granularity of profiling, the baseline set is oversampled to create 10 FFT windows using the method described in section 6.4.

In the following, we first evaluate the accuracy of EarFisher in detecting eavesdropper and countermeasure, and then study its performance in a real deployment scenario where three EarFisher nodes are deployed to monitor an indoor environment of about 1600 ft^2.

7.1 Eavesdropper Detection

We conduct experiments on two commodity laptops, including a Thinkpad with DDR3-1600 and a Dell Inspiron with DDR4-2133. To evaluate the detection performance of EarFisher, we let the laptops act as eavesdropper (EV) and legitimate receiver (LR), and then compare the p-values computed by EarFisher. It is important to note that the p-values of EV and LR are NOT equivalent to the probability of detection and false alarm. Instead, the final detection result depends on the choose of p-value threshold, which EarFisher exposes to the user for configurable trade-off between detection rate and false alarm. In the following, we study the impacts of four key factors on EarFisher's detection performance, including the attenuation of memory EMR, system memory workloads, normal network traffic, and the interfering EMRs emitted by coexisting devices that have the same memory frequency.

Attenuation. We first study the impact of EMR attenuation on EarFisher's detection performance. We note that accurately controling EMR attenuation is difficult because we cannot connect an attenuator to the 'antenna' of the EMR emitter, i.e., the memory bus. To walk-around this issue, we first record the memory EMR of eavesdropper in close proximity, and then emulate a certain level of attenuation by mixing the recorded signal with an equivalent amount of white noise. In this experiment, the eavesdropper runs no software except OS, which allows us to exclude the interference of system memory workloads and study the optimal detection performance of EarFisher as a function of EMR attenuation.

As shown in Fig. 11, we observe that the p-values of DDR3 and DDR4 eavesdroppers are consistently higher than 0.9 before the amount of attenuation exceeds 29 dB and 21 dB, which typically translate to a line-of-sight path loss of about

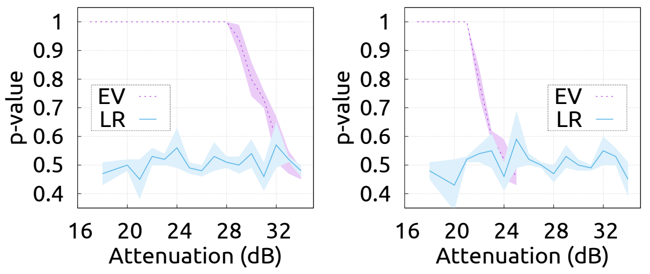

Figure 11: The p-values for the eavesdropper (EV) and the legitimate receiver (LR) as a function of EMR attenuation (left: DDR3, right: DDR4).

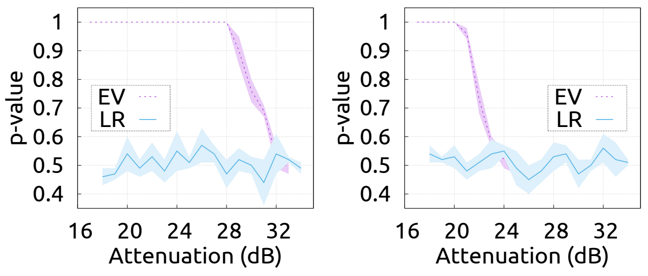
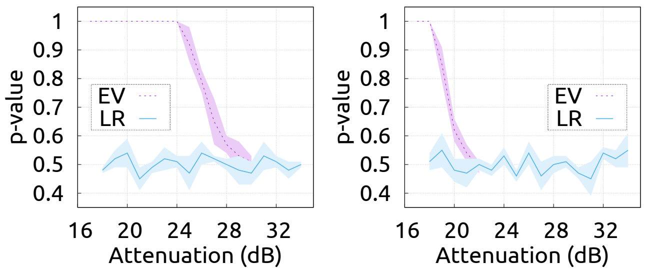


(a) Wireshark.



(b) VLC media player.

Figure 12: The impact of memory workloads (left: DDR3, right: DDR4).

30 m and 24 m, respectively. When the amount of attenuation further increases, the p-value for eavesdropper begins to decrease, as the surge of eavesdropper's memory EMR corresponding to the response to stimuli is gradually submerged by noise. We note that DDR3 is more resistant to attenuation than DDR4 because of the stronger EMR attributed to the higher operating voltage. In comparison, the p-value of legitimate receivers fluctuates in between 0.4 to 0.6 consistently despite the increase of attenuation. The results indicate that, if the user chooses a p-value threshold of 0.9, then EarFisher will detect all DDR3 and DDR4 eavesdroppers before attenuation reaches 29 dB and 21 dB while without miss-classifying any legitimate receivers as eavesdroppers.

System memory workload. Memory EMR produced by system memory workload will pollute the baseline profiled by EarFisher and thus will affect the result of statistical test. To study the impact of system memory workload, we let the laptops run two representative applications, including Wireshark – a widely used packet analyzer, and VLC media player, which reads memory intensively to load a high-definition video.

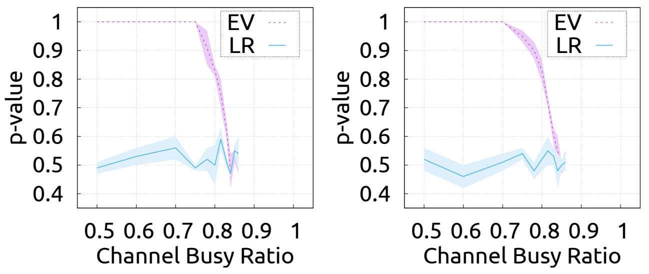


Figure 13: The impact of network traffic (left:DDR3, right:DDR4).

As shown in Fig. 12, compared with the results shown in Fig. 11, the attenuation resistance of EarFisher degrades by less than 1 dB and 5 dB when the eavesdroppers run Wireshark and VLC, respectively. VLC imposes a higher impact because it involves more frequent memory activities and thus produces a higher level of pollution to the baseline set. Nevertheless, even under the interference of VLC, the p-values of the DDR3 and DDR4 eavesdroppers are consistently higher than that of legitimate receivers as long as the levels of attenuation are below 25 dB and 19 dB, respectively.

We also observe that the p-values of legitimate receivers are not affected by Wireshark and VLC on both DDR3 and DDR4 laptops. This is because system memory workload will impact the baseline and stimulus set uniformly, hence the results of statistical test will remain unbiased.

Although we focus on only two representative applications in this experiment, we note that the interference caused by memory workload can be generally quantified using the busy ratio of memory bus. We will study EarFisher's performance as a function of memory busy ratio in section 7.2.

Network traffic. To study the impact of network traffic, we employ two additional 802.11n nodes to inject normal network traffic using iPerf [5]. In this experiment, we place eavesdroppers at 10m away from the EarFisher's detector. We then compare the p-values for eavesdroppers and legitimate receivers in the presence of different volumes of network traffic. We use channel busy ratio to quantify the interference produced by normal network traffic, because absolute volume can be misleading when characterizing interference intensity in wireless networks of different data rates.

As shown in Fig. 13, we observe that the detection performance of EarFisher is reliable as long as the channel busy ratio is below 73%. As channel busy ratio further increases, it becomes increasingly difficult to profile a clean baseline set not affected by network traffic. As a result, the p-value of the eavesdropper will begin to degrade.

Coexisting devices. We next evaluate EarFisher in a crowded environment where devices having the same memory frequency introduce interfering memory EMRs. We place the DDR3 eavesdropper in a library computer room that has 40 identical desktops, all having the same memory frequency as the eavesdropper. We then turn on desktops one by one and study the impact on EarFisher's performance.

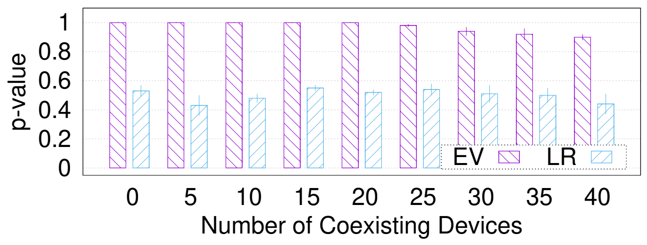

Figure 14: The impact of coexisting devices.

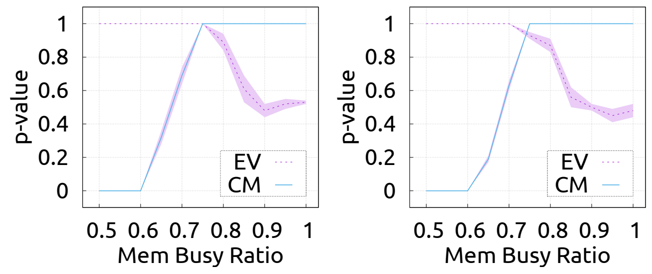

Figure 15: The p-values of the eavesdropper (EV) and the countermeasure (CM) detectors under different memory busy ratios (left: DDR3, right: DDR4).

Fig. 14 compares the p-values for eavesdropper and legitimate receiver as the number of coexisting desktops increases. We observe that EarFisher is fairly resistant to the interference of coexisting devices. Even when all 40 desktops are active simultaneously, the p-value for eavesdropper remains higher than 0.8, while the p-value of legitimate receiver fluctuates around 0.5. This should be attributed to the diversity of memory clock fingerprint, which allows EarFisher to separate the memory EMRs of different devices.

7.2 Countermeasure Detection

We next evaluate EarFisher's performance of detecting eavesdroppers that deliberately write memory to mask response to stimuli. We explore the parameter space of eavesdropper's countermeasure by tuning the ratio of deliberate writing, which results in different memory busy ratios. We then study the impacts on the p-values calculated by EarFisher's eavesdropper and countermeasure detector, denoted as EV and CM in Fig. 15, respectively. In this experiment, the eavesdropper is placed at 12 m away from EarFisher, which causes a path loss of about 15 dB.

As shown in Fig. 15, we observe that, as memory busy ratio increases, the p-value of eavesdropper detector decreases because the baseline set becomes increasingly polluted. In contrast, the p-value of countermeasure increases because the baseline set demonstrates increasing abnormality. For example, as the p-value for the DDR4 eavesdropper begins to drop when memory busy ratio increases to above 0.75, the p-value of countermeasure detector has reached 1.0. The results validate that the eavesdropper cannot defeat EarFisher's eavesdropper and countermeasure detectors at the same time.

7.3 A Deployment Case

In the following, we evaluate EarFisher on a testbed where three EarFisher nodes are deployed at different locations (i.e., S1-S3) in an indoor environment of 1600 ft^2, as shown in Fig. 16. We place the eavesdroppers at 9 locations in different rooms. We then randomly choose a node at another deployment location to stream a live video. The eavesdropper runs Wireshark and sniffs on the streamed video. All doors are closed during experiment. We study the precision and recall of EarFisher when the p-value threshold is set to 0.6 and 0.75, respectively.

As shown in Fig. 17, when the p-value threshold is set to 0.75, 8 of 9 DDR3 and 7 of 9 DDR4 eavesdroppers can be detected by at least one of the three EarFisher nodes with a recall higher than 90% while incurring no false alarms. In particular, eavesdroppers at location B and C can be accurately detected by EarFisher deployed at S3 and S2, despite the block of doors and walls. When the p-value threshold is relaxed to 0.6, the recall for the DDR4 eavesdropper at location F increases from 0% to 83%. However, this is at the cost of slightly reducing the precision from 100% to 94% and 97% at location A and B, respectively. We find that location G demonstrates as a blind spot due to severe EMR attenuation. We note that the performance of EarFisher can be further improved by leveraging advanced radio equipment such as high-gain LNA, better planing the deployment of EarFisher, or deploying more EarFisher nodes.

8 Discussion

In this section, we discuss important issues related to the design of EarFisher, including response mitigation-based countermeasures and EarFisher's limitations.

8.1 Response Mitigation

As discussed in section 6.3, EarFisher detects eavesdroppers by comparing the baseline and stimulus set to identify eavesdroppers' responses to stimuli. Accordingly, eavesdroppers can counter EarFisher by either polluting the baseline or mitigating the evidence of response in the stimulus set. In section 6.4 and section 7.2, we have shown how EarFisher effectively detects the first countermeasure. In the following, we discuss and analyze the second.

Eavesdropping on specified receivers. By modifying the firmware of wireless NIC, eavesdroppers can be configured to only sniff on packets transmitted to a specified receiver. EarFisher can detect such attacks by counting the receivers of packets sent to a specific address. This is feasible as long as the memory EMRs of the eavesdropper and the legitimate receiver can be separated in frequency spectrum, which is at a high probability as measured and discussed in section 6.1.

Figure 17: The recall (Re) and precision (Pr) for eavesdroppers deployed at different locations.

Weaponizing low-power wireless. Eavesdroppers may circumvent EarFisher's sensing by repurposing low-power wireless devices. As an example, ESP8266 [33] – a Wi-Fi enabled IoT – has a microcontroller that directly controls Wi-Fi chip via UART, thus avoiding strong memory EMR when receiving packets. However, such low-power architectural features typically limit the computation and storage capability of IoTs, making them ill-suited for security-intrusive tasks. For example, the on-board memory of ESP8266 is only 32 KiB for instruction and 80 KiB for data. In comparison, to crack a WEP key, the attacker needs to perform a computation over millions of encrypted packets [14]. As a result, to work as a full-fledged eavesdropper, low-power wireless devices have to rely on a host, which will leak strong memory EMR that can be captured by EarFisher.

Physical shielding. A physical method to mitigate response is to shield eavesdropper's memory bus to attenuate EMR. However, unlike shielding external emanation sources such as monitor cables, shielding memory bus can be prohibitively challenging and expensive.

8.2 Limitations

Excessive verdicts. By EarFisher's detection methodology, any device that digests others' packets in CPU-memory system will be convicted of eavesdropping. Unfortunately, it is difficult, if not impossible, to differentiate benign or malicious use of other's packets. As a result, all software radios will be identified as eavesdroppers as long as they transfer baseband signals to a host or process signals on board, both will emit strong memory EMRs. This is harsh but reasonable, because software radios process other devices' signal (albeit such processing may be only at the PHY layer) in an intrusted context with rich storage and computational resources capable of security- and privacy-intrusive tasks.

Besides software radios, recent wireless sensing and communication primitives such as backscatter [20] and localization [6, 38], may require Wi-Fi NICs to operate in monitor mode. To authenticate these applications, a possible method is to register legal eavesdropping devices a priori, and then let EarFisher count the number of eavesdroppers to determine the presence of illegitimate ones.

Low rate wireless networks. Experiment results shown in Fig. 4 suggest that a traffic stimulus of as slow as 2 MB/s suffice to trigger the eavesdropper's response. Unfortunately, this is still beyond the maximum data rate of many low-power wireless networks such as ZigBee. However, we expect that EarFisher will achieve better detection performance in the coming generation of high-rate wireless networks such as IEEE 802.11ax, which features GB/s level data rate, thus allowing for traffic stimuli of much higher intensities.

Blind spots. Eavesdroppers knowing the deployment of EarFisher may exploit locations subject to severe EM attenuation, such as room G shown in Fig. 16. Another example is to deploy eavesdroppers as *hidden terminals*, where the eavesdropper can hear the packets of a transmitter-of-interest, but is at a location relatively distant to EarFisher, such that the memory EMR cannot be accurately sensed. Such blind spots of detection can be mitigated by extending the coverage of EarFisher. Possible methods include but not limited to using high-gain LNA, leveraging advanced signal processing such as blind beamforming [12], or deploying more EarFisher nodes to monitor the area-of-interest.

9 Conclusion

This paper presents EarFisher – a system that detects wireless eavesdroppers by stimulating and sensing memory EMRs. Experiment results show that EarFisher accurately detects eavesdroppers despite poor signal conditions and the interference of normal network traffic, system memory workloads, and the interfering EMRs emitted by coexisting devices. We believe EarFisher provides an important block for building secure wireless networks. Incorporating EarFisher in wireless security protocols, such as to verify the confidentiality of key establishment, remains an important problem for future work.

Abstract

Recent years have witnessed the rapid deployments of wireless mesh networks (WMNs) for industrial automation, military operations, smart energy, etc. Although WMNs work satisfactorily most of the time thanks to years of research, they are often difficult to configure as configuring a WMN is a complex process, which involves theoretical computation, simulation, and field testing, among other tasks. Simulating a WMN provides distinct advantages over experimenting on a physical network when it comes to identifying a good network configuration. Unfortunately, our study shows that the models for network configuration prediction learned from simulations cannot always help physical networks meet performance requirements because of the simulation-to-reality gap. In this paper, we employ deep learning based domain adaptation to close the gap and leverage a teacher-student neural network to transfer the network configuration knowledge learned from a simulated network to its corresponding physical network. Experimental results show that our method effectively closes the gap and increases the accuracy of predicting a good network configuration that allows the network to meet performance requirements from 30.10% to 70.24% by learning robust machine learning models from a large amount of inexpensive simulation data and a few costly field testing measurements.

1 Introduction

Recent years have witnessed rapid deployments of wireless mesh networks (WMNs) for industrial automation [38, 95], military operations [57], smart energy [80], etc. For instance, IEEE 802.15.4-based industrial WMNs, also known as wireless sensor-actuator networks (WSANs), are gaining rapid adoption in process industries over the past decade due to their advantage in lowering operating costs [51]. Battery-powered wireless modules easily and inexpensively retrofit existing sensors and actuators in industrial facilities without the need to run cables for communication and power. Industrial standard organizations such as HART [31], ISA [38], IEC [37], and ZigBee [104] are actively pushing the real-world implementations of WSANs for industrial automation. For example, more than 54,835 WSANs that implement the WirelessHART standard [95] have been deployed globally by Emerson Process Management to monitor and control industrial processes [24].

Although WMNs work satisfactorily most of the time thanks to years of research, they are often difficult to configure as configuring a WMN is a complex process, involving theoretical computation, simulation, and field testing, among other tasks. Simulating a WMN provides distinct advantages than experimenting on a physical network when it comes to identifying a good network configuration: a simulation can be set up in less time, introduce less overhead, and allow for different configurations to be tested under exactly the same conditions. Significant efforts have been made to investigate the characteristics of wireless communication in the literature. For instance, there has been a vast array of research that empirically studied the low-power wireless links with different platforms, under varying experimental conditions, assumptions, and scenarios [6]. Decades of research have gathered precious knowledge and produced a set of mathematical models that capture the characteristics of wireless links, interference, etc, and enable the development of wireless simulators, such as TOSSIM [44, 84], Cooja [17, 65], OMNeT++ [63, 89], and NS-3 [61].

However, it is still very challenging to date to set up a simulation that captures extensive uncertainties, variations, and dynamics in real-world WMN deployments. Our study shows that the models for network configuration prediction learned from simulations cannot always help physical networks meet performance requirements because of the *simulation-to-reality gap*; therefore the advantages of using simulations to reduce experimental overhead, improve flexibility, and enhance repeatability come at the expense of questionable credibility of the results. On the other hand, data collection from many WMN deployments, which include the ones in industrial facilities, is costly; therefore it is difficult to obtain sufficient information to train a good model or identify an optimal policy for network configurations by relying solely on field testing.

In this paper, we formulate the network configuration prediction into a machine learning problem, use the configurations of a WirelessHART network [95] as an example to illustrate the simulation-to-reality gap, and then employ deep learning based domain adaptation to close the gap. Specifically, this paper makes the following contributions:

- We present the simulation-to-reality gap in network configurations and show that the models for network configuration prediction learned from simulations cannot always help physical networks meet performance requirements;
- We develop a teacher-student neural network[1] that learns robust machine learning models for network configuration prediction from a large amount of inexpensive simulation data and a few costly physical measurements; to our knowledge, our work represents the first systematic study of the effectiveness of domain adaptation in closing the simulation-to-reality gap in network configurations;
- We implement our method, evaluate it using four simulators and a physical testbed, and repeat our evaluation with different network topologies under various wireless conditions. Experimental results show that our method can significantly improve the prediction accuracy and help physical networks meet performance requirements.

The remainder of our paper is organized as the following sections. Section 2 reviews the related work. Section 3 introduces the background of WirelessHART networks. Section 4 presents our problem formulation, our feature selection study, the simulation-to-reality gap, and our method that closes the gap. Section 5 shows the design of our teacher-student neural network. Section 6 evaluates our method. Section 7 concludes the paper.

2 Related Works

The current practices in network configurations rely largely on experience and rules of thumb that involve a coarse-grained analysis of network loads or dynamics during a few field trials. For example, the WirelessHART standard specifies the use of all available channels after a human operator manually blacklists noisy ones [95], and Emerson Process Management [22] recommends using a constant value (60% in general or 70% for control and high speed monitoring) as the packet reception ratio (PRR) threshold to select links for routing [23]. Unfortunately, recent studies show that such specifications are problematic, because using more channels or a fixed PRR threshold is not always desirable in WirelessHART networks [30,75,76]. In the literature, significant research efforts have been made to model the characteristics of wireless networks and optimize network configurations through mathematical techniques such as convex optimization [52], game theory [2], and meta heuristics [73]. For instance, the characteristics of low-power wireless links have been studied empirically with different platforms, under varying experimental conditions, assumptions, and scenarios [6]. Runtime adaptation methods have been developed to improve the performance of wireless sensor networks (WSNs) by adapting a few parameters in the physical and media access control (MAC) layers [20,25,70,90,105]. Those methods are not directly applicable to configure a network with many interplaying parameters.

As wireless deployments become increasingly hierarchical, heterogeneous, and complex, a breadth of recent research has reported that resorting to advanced machine learning techniques for wireless networking presents significant performance improvements compared to traditional methods. Deep learning has been used to handle a large number of network parameters and automatically uncover correlations that would otherwise have been too complex to extract by human experts [5,14,42,54,97,101] and reinforcement learning has been employed to enable network self-configurations [18,32,36,45,47,53,56,59,60,67,72,74,91,93,96,98–100,103]. The key behind the remarkable success of those data-driven methods is the capability of optimizing a huge number of free parameters [33,35] to capture extensive uncertainties, variations, and dynamics in real-world wireless deployments, which not only yield complex features, such as communication signal characteristics, channel quality, queuing state of each device, and path congestion situation, but also have many control targets, such as resource allocation, queue management, and congestion control.

However, data collection from many wireless deployments that are not easily accessible (e.g., the ones in industrial facilities) is costly; therefore it is difficult to obtain sufficient information to train a good model or identify an optimal policy for network configurations. In such scenarios, the benefits of employing learning-based methods that require much data are outweighed by the costs. Industry has consequently shown a marked reluctance to adopt them. To address this limitation, there has been increasing interest in using simulations to identify good network configurations [7,40,46,49,75,76,79,82]. Unfortunately, our study shows that a straightforward deployment of a model learned from simulations results in poor performance in a physical network due to the simulation-to-reality gap.

Domain adaptation aims to learn from one or multiple source domains and produce a model that performs well on a related target domain; the assumption is that the source and

[1]To eliminate ambiguity, we use the word "network" to denote a wireless network and use the word "neural network" to represent a deep learning model in this paper.

target domains are associated with the same label space. It has been successfully used in computer vision [69, 92], natural language processing [66], and building occupancy estimation [3, 102]. Studies have shown that domain adaptation can mitigate the harmful effects of domain discrepancy by optimizing the representation to minimize some measures of domain shift, such as maximum mean discrepancy [13] or correlation distances [27]. Compared to fine-tuning the deep learning model, which is pre-trained using simulation data, employing domain adaptation is expected to close the gap between the simulated network (source) domain and the physical network (target) domain with fewer costly physical measurements. Recent work has focused on transferring deep neural network (DNN) representations from a labeled source dataset to a target domain where labeled data is sparse or non-existent. The main strategy is to guide feature learning via minimizing the difference between the source and target feature distributions. The maximum mean discrepancy (MMD) has been successfully used for domain adaptation, which computes the norm of the difference between two domain means [29, 86]. Several methods employed an adversarial loss to minimize domain shift and learned a representation that is simultaneously discriminative of source labels while not being able to distinguish between domains [19,26]. Despite the extensive literature on domain adaptation, little work has been done to investigate whether it can be applied to close simulation-to-reality gap in network configurations.

3 Background of WirelessHART Networks

To meet the stringent reliability and real-time requirements of industrial applications, WirelessHART networks [95] made a set of specific design choices that distinguish themselves from traditional WSNs designed for best effort services [51]. A WirelessHART network is managed by the centralized network manager, a software module, which is responsible for managing the entire network that includes generating routes, scheduling all transmissions, and selecting network parameters. Network devices include a set of field devices (sensors and actuators) and multiple access points. Each network device is equipped with a half-duplex omnidirectional radio transceiver compliant with the IEEE 802.15.4 standard [1].

WirelessHART networks adopt the time-slotted channel hopping (TSCH) technique [85], which combines time-slotted medium access, channel hopping, and multi-channel communication to provide time-deterministic packet deliveries[2]. Under TSCH, time is divided into 10*ms* time slots, each of which can be used to transmit a packet and receive an acknowledgment between a pair of devices. The network uses up to 16 channels in the 2.4 GHz ISM band and

[2]Packets must be delivered along the data flow (from a sensor to an access point and then to an actuator) by the specified time deadline.

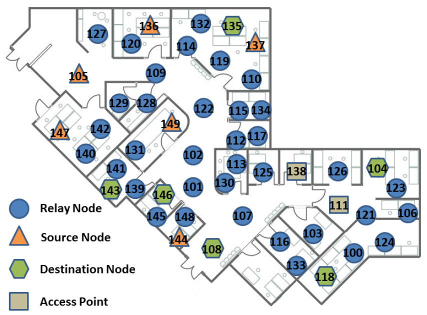

Figure 1: Device deployment on our testbed. The device ID ranges from 100 to 149.

performs channel hopping in every time slot to combat narrow band interference. WirelessHART networks support two types of routing: source routing and graph routing. Source routing provides a single directed path from each data source to its destination. Graph routing is designed to enhance network reliability by providing redundant routes between field devices and access points. A packet may be transmitted through the backup routes if the links on the primary path fail to deliver it.

4 Methodology

In this section, we first describe our experimental setup and data collection method. Then we formulate the network configuration prediction as a machine learning problem and present our feature selection study and the simulation-to-reality gap. Finally, we introduce our deep learning based domain adaptation method, which closes the gap.

4.1 Experimental Setup and Data Collection

We adopt the open-source implementation of WirelessHART networks provided by Li et al. [94] and configure six data flows on our testbed, which consists of 50 TelosB motes [81]. Figure 1 shows the device deployment on our testbed and Table 1 lists the source node (sensor), the destination node (actuator), the data generation interval (period), and the priority of each data flow. We employ the rate monotonic scheduling [48], an optimal fixed-priority policy, to generate the transmission schedule, set the data delivery deadline of each data flow to its period, and configure the devices with ID 111 and 138 to serve as two access points.

We consider three configurable network parameters, which include (i) the PRR threshold for link selection R, (ii) the number of channels used in the network C, and (iii) the number of transmission attempts scheduled for each packet A, and three network performance metrics, which include (1) the end-to-end latency L, (2) the battery lifetime B, and (3) the end-to-end reliability E. We consider $R \in \{0.7, 0.71, 0.72, ..., 0.90\}$[3], $C \in \{1,2,3,4,5,6,7,8\}$, and

[3]Emerson Process Management [22] recommends using a constant value

Table 1: Data flows.

Flow ID	Source	Destination	Period (ms)	Priority
1	147	146	500	1
2	144	143	500	2
3	105	104	500	3
4	149	118	1000	4
5	136	135	1000	5
6	137	108	1000	6

$A \in \{1,2,3\}$ as the possible parameter values, and combine them to create 744 $(31*8*3)$ network configurations. Please note that some network configurations make the network manager generate the same routes and transmission schedule. After removing all redundancy (the configurations leading to the same routes and transmission schedule), there are 88 distinct network configurations left under our experimental setup.

After deploying the data flows on the testbed, we implement the same network in the simulator[4], feed the PRR and noise traces, the routes, and the transmission schedule collected from the physical network into the simulator, and then run simulations to evaluate network performance under each network configuration. Specifically, the simulator generates simulated L, B, and E values under each network configuration (R,C,A). The network performance (L, B, and E values) is computed in every 50s. 75 network performance traces are collected under each network configuration. In total, we collect 6,600 $(88*75)$ data traces from simulations. Then, we run experiments on our testbed and measure the network performance under each network configuration. Similarly, we collect 6,600 data traces from our testbed. The data gathered from the simulated network and the physical network is denoted as $\mathcal{D}^s$ and $\mathcal{D}^p$, respectively.

4.2 Network Configuration Prediction

The primary task in network configurations is to select the configuration (the selections of parameters R, C, and A), which allows the network to meet the performance requirements (L, B, and E) specified by the application. The parameter selection should be as *accurate* as possible with *minimal data collection overhead*. We formulate the network configuration prediction task as a machine learning problem. Let $\mathbf{x} = concatenation(L,B,E)$ denote the given network performance requirements and $\mathbf{y} = concatenation(R,C,A)$ denote the configuration, which allows the network to meet performance requirements. The goal is to learn a nonlinear mapping $f_\theta(\cdot) : \mathbf{x} \rightarrow \mathbf{y}$. Based on the specific application, the user can set the performance requirements ($\mathbf{x}$). The input features in $\mathbf{x}$ are selected by the feature selection study in Section 4.3.

We use θ to denote the model parameters that are learned from data in a data-driven manner. Given the fact that the network configuration values ($\mathbf{y}$) can be discretized without losing the generality, we further restrict f_θ as a discriminative model to solve a classification problem: an application can set its performance requirements ($\mathbf{x}$), and the classifier (f_θ) will predict the network configuration ($\mathbf{y}$) to satisfy the application requirements. This data-driven learning-based model can take advantage of a large amount of data to consistently improve its performance. Experimental results (See Section 6.2) show that it significantly outperforms traditional optimization-based methods such as Response Surface Methodology (RSM) [9] and Kriging surrogate modeling approach [78]. The latter usually suffers the issues that include limited predictive power and being vulnerable to uneven data distribution [15].

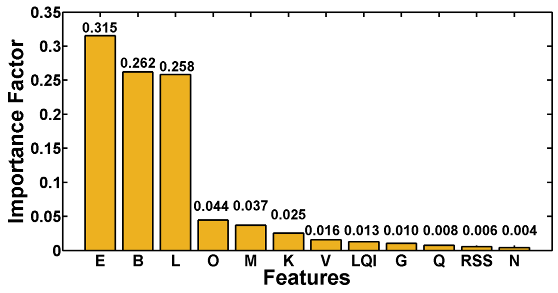

Figure 2: Importance factors of different features when using tree-based feature selection method. Under the tree-based method, the features that are selected at the top of the trees are in general more important than the features that are selected at the end nodes of the trees, as generally, the top splits lead to bigger information gains. We use the normalized importance factor generated by the tree-based method as a metric for feature selection.

4.3 Feature Selection

In addition to the features (L, B, and E) that represent performance requirements, we consider nine other features, which include the received signal strength RSS [8], the link quality indicator LQI [6], the background noise G [6], the packet delay variation O, the power consumption variation K, the network reliability variation M, the received signal strength variation V, the link quality indicator variation Q, and the background noise variation N. Using all features that are relevant to the network configuration prediction problem may not necessarily achieve the best performance but rather increases computational cost and data collection overhead. We perform a study that employs three classic feature selection methods (the tree-based method [50], the univariate feature selection method [39], and the recursive feature elimination

(0.6 in general or 0.7 for control and high speed monitoring) for R [23]. We did not consider R lower than 0.7 because of the consistent low reliability we observed.

[4]We repeat our experiments using four simulators: TOSSIM, Cooja, OMNeT++, and NS-3.

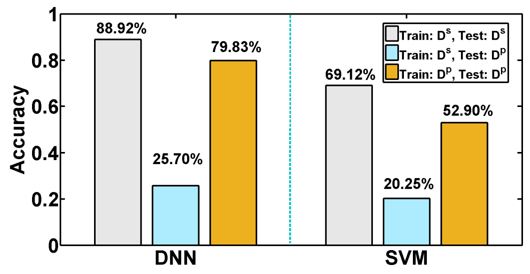

Figure 3: Modeling accuracy when model is trained and tested on different data sets ($\mathcal{D}^s$: the simulation data produced by OMNeT++ and $\mathcal{D}^p$: the physical data). The difference between the grey bar and the blue bar indicates the simulation-to-reality gap.

method [16]) to pick the most useful features. Figure 2 plots the importance factors of different features when we use the tree-based method. As Figure 2 shows, L, B, and E have much higher importance factors (0.315, 0.262, and 0.258) than the rest. Similar results are observed when we use other methods. Therefore, we use L, B, and E as the input features for WirelessHART networks. Please note that our method can accept more features for other networks.

4.4 Simulation-to-reality Gap

Our goal is to learn a classifier to predict network configurations on the physical data. However, it is a nontrivial task to learn the model from either the physical data ($\mathcal{D}^p$) or the simulation data ($\mathcal{D}^s$). Instead, we propose to use both $\mathcal{D}^p$ and $\mathcal{D}^s$ to learn the model as explained in the next section.

Using only physical data ($\mathcal{D}^p$): This would result in significant time and energy consumption due to the costly data collection process. We first leverage the physical data ($\mathcal{D}^p$) collected from the physical network to train machine learning models and explore its feasibility for our network configuration prediction problem. We employ two machine learning models, DNN and support vector machine (SVM), for classification. The input to the models is network performance requirements and the output is network configurations. We normalize the collected data ($\mathcal{D}^p$) into the $[0,1]$ range and split it randomly for training and testing. The yellow bars in Figure 3 show the modeling accuracy[5], when DNN and SVM models are used for the network configuration prediction, respectively. Both DNN and SVM models trained based on the physical data can provide high modeling accuracy when we test the models on the physical data (DNN: 79.83% and SVM: 52.90%), as the yellow bars show. This justifies the feasibility of our proposed machine learning method in Section 4.2 for the network configuration prediction and we may use the measurements collected from the physical network to train a good model. Unfortunately, relying on running experiments on a physical network to explore the configuration parameter space is impractical in many cases because running experiments on a physical network is very costly and time-consuming. The left side of Table 2 shows the modeling accuracy, data collection time, and device energy consumption when we train the DNN model with different sizes of the physical data (collected from a physical network). The modeling accuracy increases significantly from 19.39% to 79.83% with the size of the training set ($\mathcal{D}^p$) that increases from 88 traces to 3,960 traces. However, the time spent on collecting the training data ($\mathcal{D}^p$) increases from 1.22*hours* to 55.00*hours*. Moreover, the energy consumed by each field device for data collections on average increases from 310.61J to 13,974.26J, which represents 0.73% and 32.73% of its total energy capacity.

Using only simulation data ($\mathcal{D}^s$): This would result in low modeling accuracy due to the simulation-to-reality gap. The simulation data can be quickly and cheaply obtained from a simulator. As the right column of Table 2 show, the time spent on generating the simulation data varies from 27.41s to 1,231.40s and no energy is consumed by any field devices. However, a classifier that is trained based on the simulation data ($\mathcal{D}^s$) may suffer the following issue when applied on the physical data. As the grey bars in Figure 3 show, both models provide high modeling accuracy when we train based on the simulation data ($\mathcal{D}^s$) and test the models on the simulation data (DNN: 88.92% and SVM: 69.12%). However, the modeling accuracy drops rapidly when we test the models on the physical data ($\mathcal{D}^p$) as shown in blue bars (DNN: 25.70% and SVM: 20.25%). The differences on the modeling accuracy (DNN: 63.22% and SVM: 48.87%) clearly show the effect of the simulation-to-reality gap, a subtle but important discrepancy between reality and simulation that prevents the simulated experience from directly enabling effective real-world performance [12, 77]. The simulation-to-reality gap exists in network configurations because the theoretical models adopted by the simulator cannot capture all real-world performance-related factors. For example, the prerecorded noise traces and the probability-based prediction on packet reception cannot precisely capture the effects of packet failures caused by extensive uncertainties, variations, and dynamics in real-world wireless deployments (see Section 6.5). We observed similar discrepancy gaps when using Cooja, TOSSIM, OMNeT++, and NS-3. Because of the simulation-to-reality gap, the machine learning models trained based on simulation data ($\mathcal{D}^s$) for network configurations, no matter how large the data volume is, may not generalize well to a physical network.

4.5 Close the Gap by Domain Adaptation

The observations presented in Section 4.4 motivate us to explore the feasibility of using a substantial amount of inexpen-

[5]The modeling accuracy is defined as, given a set of input network performance requirements (L,B,E), the percentage of the testing set that a model can select the network configuration (R,C,A), which allows the network to meet performance requirements.

Table 2: Modeling accuracy (%), data collection time (s), and device energy consumption (J) when using the physical data ($\mathcal{D}^p$) or the simulation data ($\mathcal{D}^s$) produced by OMNeT++ for training. For comparison, our solution achieves 70.24% accuracy with only 440 data samples which are collected in 22,000s with 1,502.88J of energy (see Section 6.2).

# of Data Samples Used for Training	From a Physical Network (Train: $\mathcal{D}^p$, Test: $\mathcal{D}^p$)			From Simulations (Train: $\mathcal{D}^s$, Test: $\mathcal{D}^p$)		
	Accuracy (%)	Collection Time (s)	Energy (J)	Accuracy(%)	Collection Time (s)	Energy (J)
88	19.39	$4.40*10^3$	310.61	6.52	27.41	0
528	42.16	$2.64*10^4$	1,863.53	13.70	163.09	0
968	57.92	$4.84*10^4$	3,416.34	17.69	301.95	0
2,024	67.68	$1.01*10^5$	7,143.11	20.17	633.11	0
3,080	78.82	$1.54*10^5$	10,869.61	22.44	933.99	0
3,960	79.83	$1.98*10^5$	13,974.26	25.70	1,231.40	0

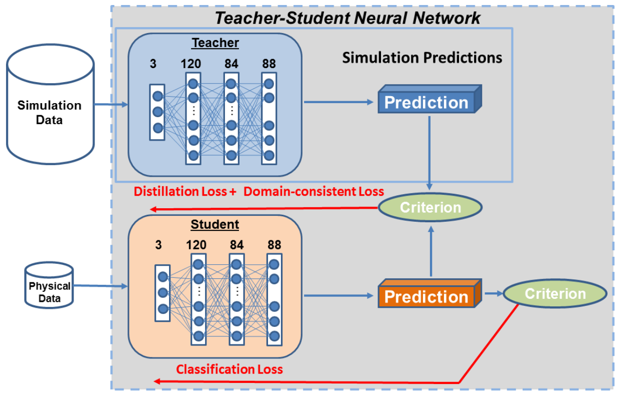

Figure 4: Our teacher-student neural network.

sive simulation data together with a small amount of costly physical data to train the model for network configuration prediction. To this end, our objective narrows down from solving a classification problem to using domain adaptation to address the domain discrepancy issue. Specifically, we first gather N^s data tuples by running simulations (source domain) and then acquire N^p data tuples by conducting experiments on the physical network (target domain). We assume $N^s \gg N^p$ due to the significant data collection overhead on the physical network (See Section 4.4). We assume that the source and target domains are characterized by different probability distribution q_1 and q_2, respectively. Our goal is to construct a deep learning model that can learn transferable features that bridge the cross-domain discrepancy and build a classifier $\mathbf{y} = f_\theta(\mathbf{x})$, which can maximize the target domain accuracy ($f_s \rightarrow f_p$) by using a small amount of physical data (N^p). The detailed design of our teacher-student neural network will be discussed in Section 5.

5 Teacher-Student Neural Network

In this section, we present our teacher-student neural network for domain adaptation. Our goal is to build a classifier that can maximize the target domain (physical network) accuracy by using a small amount of physical data (N^p) and adequate simulation data (N^s) where $N^s \gg N^p$ due to the significant data collection overhead (See Section 4.4) on the physical network. The teacher and student use independent parameters and the teacher generates the soft labels [4, 34] to transfer its knowledge to the student. Figure 4 shows our teacher-student neural network. The first stream (teacher) operates on the simulation data and the second stream (student) operates on the physical data. Classification loss, distillation loss, and domain-consistent loss are used in the training process for the student.

5.1 Teacher Neural Network

The teacher takes advantage of the large amount of simulation data for training and the training data ($\mathcal{D}^s$) consists of a total number of N^s data tuples. We follow Multilayer Perceptron (MLP) [71] to design the architecture of three layers: 120 and 84 neurons in the first two hidden layers, and 88 neurons in the output layer to represent the totally 88 distinct configuration categories. Rectified linear unit (ReLU) and softmax are employed to activate the hidden and output layers, respectively. The teacher's parameters (θ_1) are learned by minimizing the cross-entropy loss:

$$\mathcal{L}(\theta_1) = -\mathop{\mathbb{E}}_{\mathbf{x}\sim\mathcal{D}^s} \mathbf{y} log(f_{\theta_1}(\mathbf{x})), \tag{1}$$

where $\mathcal{D}^s$ denotes the training data generated from simulations, θ_1 denotes the teacher's parameters, y denotes the one-hot label, and $f_{\theta_1}(\mathbf{x})$ is the prediction made by the teacher. We use the Adam optimizer [41] with a learning rate of 0.01 to optimize the parameters of the teacher. A total number of 100 training epochs with a batch size of 128 have been used to train the neural network.

5.2 Student Neural Network

We train the student based on the N^p physical data with the help of the teacher. The student can be quickly learned using only a few shots of physical data ($N^p \ll N^s$). To achieve this, we leverage the teacher to facilitate the training of the student where knowledge is transferred from the simulation domain to the physical domain. The student shares the same architecture with the teacher but uses independent parameters. ReLU and softmax are employed to activate the hidden and output layers, respectively. The student's parameters (θ_2) are learned by minimizing the following loss:

$$\mathcal{L}(\theta_2) = \mathcal{L}_{cls} + \alpha \mathcal{L}_{dis} + \beta \mathcal{L}_{mmd} \tag{2}$$

where α, and β are weights. We empirically set $\alpha = 1$, and $\beta = 0.2$ which can provide good performance.

Classification loss $\mathcal{L}_{cls}$: This loss function allows the student to learn from the limited (N^p) physical data through employing the cross-entropy loss:

$$\mathcal{L}_{cls} = - \mathop{\mathbb{E}}_{\mathbf{x} \sim \mathcal{D}^p} \mathbf{y} log(f_{\theta_2}(\mathbf{x})), \tag{3}$$

where $\mathbf{y}$ is the one-hot label and $f_{\theta_2}(\mathbf{x})$ is the prediction made by the student.

Distillation loss $\mathcal{L}_{dis}$: This loss function allows the teacher to transfer its knowledge to the student. The generalization ability of the student can be enhanced by the loss generated by the soft labels, which carry the information of probability distribution for each class [4, 34]. To compute $\mathcal{L}_{dis}$ with soft labels, we use the following formula:

$$\mathcal{L}_{dis} = - \mathop{\mathbb{E}}_{\mathbf{x} \sim \mathcal{D}^s} \mathbf{q} log(f_{\theta_2}(\mathbf{x})), \tag{4}$$

where $f_{\theta_2}(\mathbf{x})$ is the prediction made by the student and $\mathbf{q}$ is the tempered softmax probability generated by the teacher. $\mathbf{q}$ is computed by:

$$\mathbf{q} = \frac{exp(z_i/T)}{\sum_j^k exp(z_j/T)} \tag{5}$$

where T is the temperature [34] and z_i is the pre-softmax output of the teacher. When T increases, the soft label q approaches a uniform distribution and the probability distribution generated by the softmax function becomes softer, which provides more information as to which class the teacher finds more similar to the predicted class, instead of giving a hard prediction that indicates which class is correct. We set $T = 10$ to generate soft labels for the student.

Domain-consistent loss $\mathcal{L}_{mmd}$: This loss function is employed to achieve domain-consistent representations between the source and target domains. Matching the distributions in the original input feature space is not suitable because some features may have been distorted by the domain shift. The key idea of domain-consistent regularization is to align two domains, the target (physical data) and the source (simulation data), in a latent embedding space. Our method uses the MMD [21] to achieve this goal. MMD is a hypothesis test that tests whether two samples are from the same distribution by comparing the means of the features after mapping them to a Reproducing Kernel Hilbert Space (RKHS) [68]. We calculate the loss as:

$$\mathcal{L}_{mmd} = || \mathop{\mathbb{E}}_{\mathbf{x} \sim \mathcal{D}^s} f_{\theta_1}(\mathbf{x}) - \mathop{\mathbb{E}}_{\mathbf{x} \sim \mathcal{D}^p} f_{\theta_2}(\mathbf{x}) || \tag{6}$$

where $f_{\theta_1}(\cdot)$ and $f_{\theta_2}(\cdot)$ denote the pre-softmax output of the teacher and the student, respectively. We use a learning rate of 0.01 with the stochastic gradient descent (SGD) optimizer to train the student. The momentum is set to 0.05 and the weight decay parameter is set to 0.003, which governs the regularization term of the student. A total number of 500 epochs have been trained on the student.

6 Evaluation

We perform a series of experiments to validate the efficiency of our method to identify good network configurations. We first evaluate the capability of our method to effectively improve the modeling accuracy and compare our method against seven baselines, which include five machine learning based methods: (i) Using the physical data for both training and testing (TPTP); (ii) Using the simulation data for training and the physical data for testing (TSTP) [75, 76]; (iii) Fine-tuning (FT) method [83]; (iv) CCSA: Unified deep supervised domain adaptation and generalization [58]; and (v) Domain adaptive neural network (DaNN) [28], and two non-machine learning methods: (vi) RSM method [9, 87] and (vii) Kriging method [11, 78]. Table 3 summarizes the training and testing data used by each method. All methods use L, B, and E as their input features. We then apply the network configurations selected by our method on our testbed and measure the network performance. We repeat our experiments with different network setups under various wireless conditions. Finally, we evaluate the effects of our method on closing the gap when employing different simulators and radio models.

6.1 Experimental Setup

As presented in Section 4.1, we configure six data flows on our testbed. On each data flow, sensor data is generated by

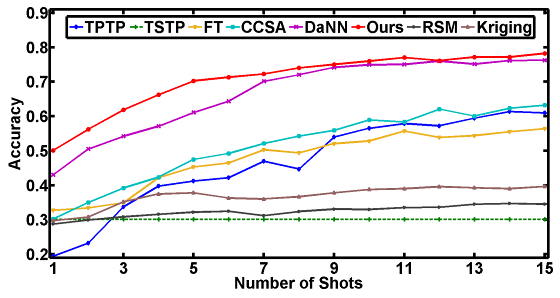

Figure 5: Modeling accuracy of our method and baselines when different number of shots of physical data are added into simulation data (3,960 data samples in total) for training. One shot includes 88 data samples (one data sample under each network configuration).

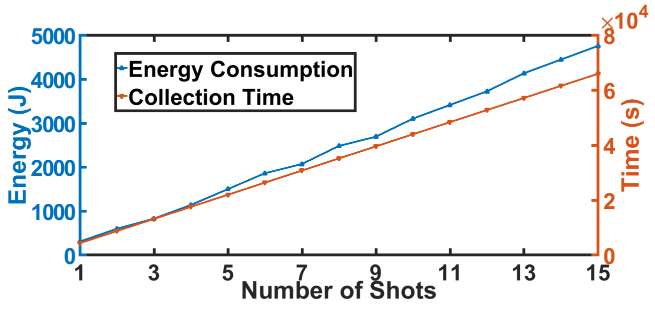

Figure 6: Time and energy consumption to collect different number of shots of data from a physical network. Using only physical data to train the model is infeasible due to unacceptable time and energy overhead.

the source node and forwarded to the access points (uplink) and then a corresponding control command is sent to the destination node (downlink). We calculate the latency, energy consumption, and reliability every 50*s*. We employ the same DNN architecture for the teacher and the student in our method with independent weights (see Section 5). Each neural network has 120 and 84 neurons in the first two hidden layers, and 88 neurons in the output layer. The weight β of MMD is 0.2 and the temperature T is 10. The learning rate is 0.01 with the SGD optimizer for the student. CCSA uses the cross-entropy loss and the semantic alignment loss between the source and target domains with the Siamese architecture. DaNN uses the standard classification loss and the MMD regularization for classification and domain adaptation. FT first uses the simulation data to train the initial model and then fine-tunes the neural network parameters to fit the target domain using a small amount of physical data. FT uses the learning rate of 0.001 to tune the parameters of the last layer in the DNN with the physical data. RSM and Kriging methods use simulation data and different amount of physical data to build RSM and Kriging models and use them to predict network configurations. Specifically, RSM is a black-box modeling technique and uses polynomial functions to approximate the model functions between the inputs and the outputs [9], while Kriging leverages spatial interpolation that uses complex mathematical formulas to estimate values at unknown points based on the values, which are already sampled [78].

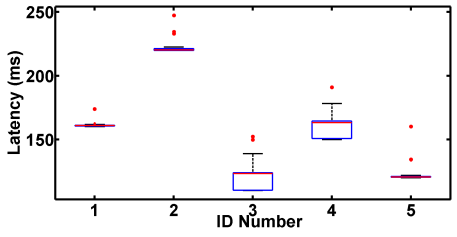
6.2 Performance of Our Method

We first evaluate the modeling accuracy of our method and compare its performance against seven baselines using the data traces presented in Section 4.1. 3,960 data samples from the simulation data are used for training under all methods except TPTP, which uses only the physical data for training. Figure 5 plots the modeling accuracy of all methods when different number of shots of physical data are added into the simulation data for training. As Figure 6 plots, collecting one shot of physical data (one data sample under each of 88 network configurations) takes 1.22 hours and consumes 310.61J of energy. Please note that TSTP uses only the simulation data for training (see Table 3) and provides the lowest accuracy (30.10%) due to the simulation-to-reality gap. The results clearly show that the model trained with the simulation data does not work well on the physical data. RSM and Kriging also provide poor performance with the maximum accuracy of 35.06% and 46.87%, respectively. Our method achieves the best performance. With only one shot of physical data (88 data samples), our method provides an accuracy of 50.12%. With four more shots of physical data, our method hits 70.24% accuracy. Using a small amount of physical data to provide a good model represents an important feature of our method because the data collection from a physical network is very time and energy consuming. As a comparison, without using the simulation data, TPTP provides only an accuracy of 19.39% and 41.21% at one shot and five shots, respectively. This highlights the importance of learning knowledge from simulations and transferring it to a physical network for network configurations.

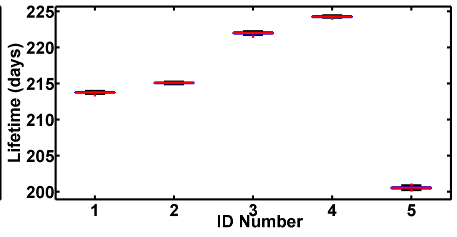
We also observe that the accuracy improves slowly from 70.24% to 78.25% when the number of shots increases from 5 to 15. However, collecting 10 more shots of physical data from a physical network takes a long time and consumes much energy. As Figure 6 plots, the collection of five shots of physical data takes 6.11*hours* and consumes 1,502.88J of energy, while collecting 15 shots take 18.33*hours* and consumes 4,758.70J of energy. The improvement on the modeling accuracy is largely shadowed by the significantly increased data collection overhead. Therefore, we use five shots in the rest of our evaluation. Figure 5 and 6 also show that only using physical data to train the model is inefficient. It takes 18.33*hours* to collect enough data from a physical network, which allows TPTP to provide an accuracy of 60.95%. By comparing the accuracy provided by our method and TPTP, we can clearly see the effectiveness of our method on reducing the data collection time for training good mod-

Table 4: Six example network configurations selected by our method and TSTP. Figure 7 and 8 show the network performance after applying the configurations selected by our method and TSTP on our testbed, respectively. Our method can meet all performance requirements. The performance requirements that TSTP fails to meet are highlighted.

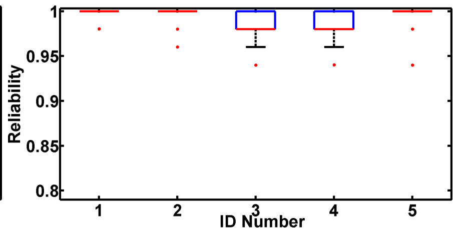
ID #	Input			Output (our method / TSTP)		
	Latency (*ms*)	Battery lifetime (*days*)	Reliability (%)	PRR threshold (%)	# of Channel	# of Tx Attempts
1	**170**	**210**	98	84 / 82	4 / 7	3 / 3
2	225	**214**	97	90 / 88	5 / 1	3 / 3
3	**130**	**220**	95	84 / 78	4 / 8	2 / 3
4	**165**	**224**	95	90 / 89	4 / 6	2 / 2
5	**130**	200	**98**	87 / 72	2 / 1	3 / 2



(a) Boxplot of latency.



(b) Boxplot of battery lifetime.



(c) Boxplot of reliability.

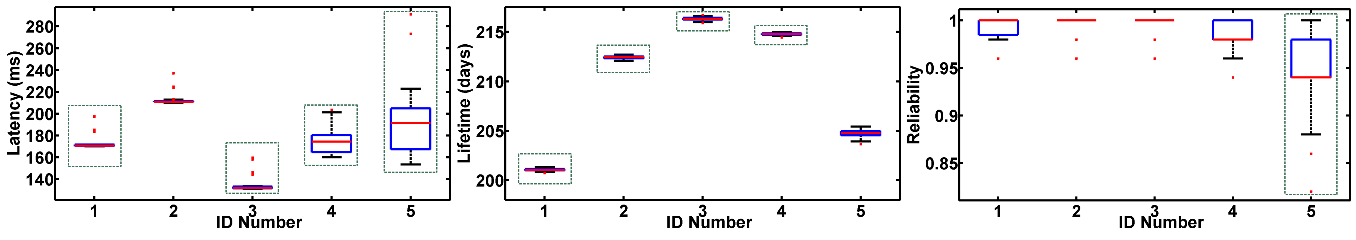
Figure 7: Network performance when employing the network configurations selected by our method (listed in Table 4). Central mark in box indicates median; bottom and top of box represent the 25th percentile (q_1) and 75th percentile (q_2); red dots indicate outliers ($x > q_2 + 1.5 * (q_2 - q_1)$ or $x < q1 - 1.5 * (q_2 - q_1)$); whiskers indicate the range that excludes outliers.

els for network configuration prediction. Our method consistently outperforms those two existing domain adaptation methods (DaNN and CCSA), which use the Siamese DNN model with different distance loss functions. For example, our method provides an accuracy of 70.24% when it uses five shots of physical data for training, while CCSA and DaNN provide 47.46% and 61.07% accuracy, respectively. The accuracy provided by FT increases from 32.73%, to 33.42%, and then to 56.40% when the number of shots increases from 1, to 2, and to 15 shots.

Our method can consistently outperform the baselines because it not only uses two different neural networks to learn two specific models for different but highly related domains with the soft labels but also employs the MMD regularization, while both DaNN and CCSA use same weights between the source and target domains for domain adaptation. Moreover, the distillation loss $\mathcal{L}_{dis}$ of our method provides a set of candidate network configurations for the student to choose and the student can quickly adapt to the target domain. The results also show that the domain-consistent loss, as a distribution distance measure, is effective for eliminating domain divergence between the source domain (simulated network) and the target domain (physical network). Our method also significantly outperforms FT. The low accuracy provided by FT shows that changing only the weight of the last layer in the DNN cannot produce a good adapted model.

We further validate the network configurations selected by our method on our testbed by examining the actual network performance. Specifically, we feed different network performance requirements to our method, employ the selected network configurations, and then measure the network performance. We repeat the experiments under each network configuration 108 times. Table 4 lists six example network configurations selected by our method and TSTP when facing different network performance requirements. Figure 7 plots the boxplots of latency, battery lifetime[6], and reliability when employing six network configurations selected by our method. As Figure 7 shows, our method always helps the network meet the network performance requirements posed by the application (listed in Table 4). For instance, the latency, battery lifetime, and reliability requirements are 170*ms*, 210*days*, and 98% in the first example ($ID = 1$). When employing the network configuration selected by our method (84% as PRR threshold, four channels, three transmission attempts for each packet), the network achieves a median latency of 161.00*ms*, a median battery lifetime of 213.76*days*, and a median reliability of 100%, which meet all given requirements. Similarly, the latency, battery lifetime, and reliability requirements are 165*ms*, 224*days*, and 95% in the fourth example ($ID = 4$). When employing the

[6]To compute the battery lifetime, we assume that each field device is powered by two Lithium Iron AA batteries with a total capacity of 42,700J. We compute the radio energy consumption based on the timestamps of radio activities and the radio's power consumption in each state according to the radio chip data sheet.



(a) Boxplot of latency. (b) Boxplot of battery lifetime. (c) Boxplot of reliability.

Figure 8: Network performance when employing the network configurations selected by TSTP (listed in Table 4). The dotted boxes highlight the network performance that fails to meet the requirements. Compared to Figure 7, our method always provides better network configurations than TSTR and help the network meet the application performance requirements.

network configuration selected by our method (90% as PRR threshold, four channels, two transmission attempts for each packet), the network achieves a median latency of 163.33*ms*, a median battery lifetime of 224.28*days*, and a median reliability of 98%, which meet all given requirements. Larger variations on latency are observed when the number of transmission attempts for each packet is small, which confirms the observations reported in our previous study [75, 76]

As a comparison, we also employ the network configurations selected by TSTP when facing the same network performance requirements. Table 4 lists the network configurations selected by TSTP and Figure 8 plots the resulting network performance. Due to the simulation-to-reality gap, the network configurations selected by TSTP cannot always meet all network performance requirements. The dotted boxes in Figure 8 highlight the network performance that fails to meet the application requirements listed in Table 4. For instance, the latency, battery lifetime, and reliability requirements are 130*ms*, 200*days*, and 98% in the fifth example ($ID = 5$). When employing the network configuration selected by TSTP (72% as PRR threshold, one channel, two transmission attempts for each packet), the network achieves a median latency of 191.40*ms*, a median battery lifetime of 204.74*days*, and a median reliability of 94.00%, which fail to meet the latency and reliability requirements.

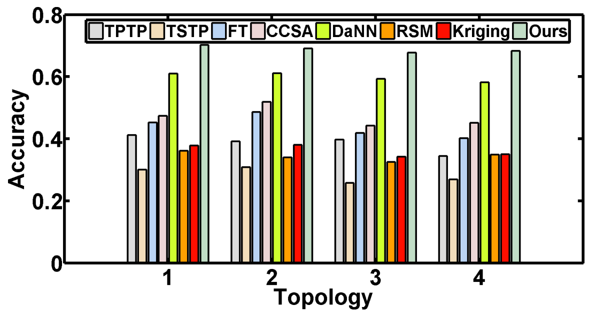


Figure 9: Accuracy comparison among different methods with different network topologies. All methods use five shots of physical data. Topology 1 is used for Figure 5.

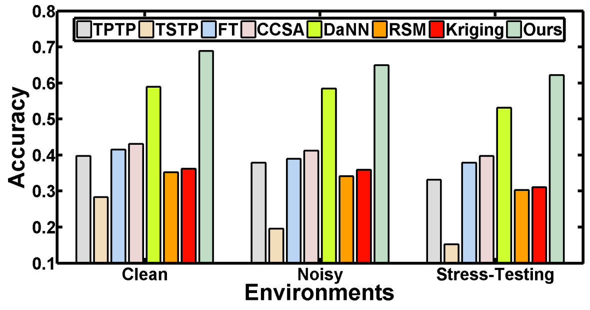

Figure 10: Accuracy comparison among different methods under different wireless conditions.

6.3 Performance with Different Network Topologies under Various Wireless Conditions

To examine the applicability of our method, we repeat our experiments with different network topologies under various wireless conditions. We first vary the number of data flows, the number of devices in the network, and the locations of source nodes, destination nodes, and access points and measure the performance of our method. Figure 9 plots the accuracy comparisons between our method and seven baselines under four example network topologies. Our method consistently provides the highest accuracy. For instance, our method achieves an accuracy of 67.09% under the third network topology, while CCSA and DaNN provide 44.23% and 59.37% accuracy, respectively. TPTP, TSTP, FT, RSM, and Kriging achieve 39.72%, 25.78%, 41.90%, 32.56%, and 34.26% accuracy, respectively. The results confirm the improvements presented in Section 6.2 and show our method can consistently outperform the state of the art.

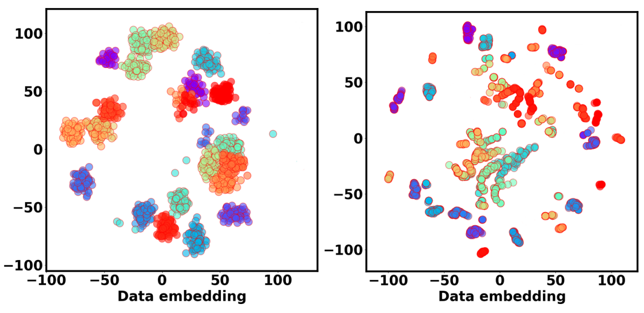
We also examine the performance of our method under different wireless conditions. We set up three jammers on our testbed (ID 116, 131, and 134 in Figure 1) and run Jamlab [10] on them to generate controlled WiFi interference with various strengths. We create three wireless conditions: a clean environment without controlled interference, a noisy environment with moderate controlled interference, and a stress-testing environment with strong controlled interference. We train the model again with different physical data under different wireless conditions. Figure 10 plots the modeling accuracy under three wireless conditions when employing our method and seven baselines. As Figure 10 shows, the accuracy provided by our method decreases from 68.89%, to 64.99%, and then to 62.20% when stronger interference is introduced. We observe similar trends when employing other methods.

This exposes a limitation of current wireless simulators, which cannot precisely simulate the effects of external interference and environmental dynamics. To better understand the physical data distribution, we visualize the data distribution of (L,B,E) collected from the physical data $(\mathcal{D}^p)$ using the t-Distributed Stochastic Neighbor Embedding (t-SNE) algorithm [88], a dimension reduction tool for data visualization. Figure 11 shows the network performance visualization provided by t-SNE where different colors stand for different network configurations. Figure 11(a) and Figure 11(b) plot the data distributions when the network operates with and without the presence of strong controlled interference, respectively. Please note that those two figures include the same amount of data points. Many data points in Figure 11(b) overlap each other. These larger variations, result from the interference, significantly increases the difficulty on transferring knowledge learned from simulations to a physical network. With the presence of interference, our method still consistently outperforms all baselines. For instance, in the stress-testing environment, our method provides an accuracy of 62.20%, while other methods provide up to 53.21% accuracy.

To illustrate the differences between physical data and simulation data, Figure 12 plots the reliability measured from the physical network and simulated by TOSSIM under four network configurations. Because of the simulation-to-reality gap, the measured reliability is different from the simulated one. More importantly, the variations of the measured reliability values are much larger than the simulated ones. Such differences highlight the important of our method, which effectively closes the gap and increases the accuracy of predicting a good network configuration that allows the network to meet performance requirements.

6.4 Effects of Different Losses

To study the effects of different losses on the performance of our method, we repeat the experiments by disabling one or two losses among the classification loss $\mathcal{L}_{cls}$, the distillation loss $\mathcal{L}_{dis}$, and the domain-consistent loss $\mathcal{L}_{mmd}$. We conduct our experiments using Topology 1 in Figure 9 in a clean environment. Figure 13 plots the accuracy when our method uses different combination of loss functions. As Figure 13 shows, our method with a single loss provides very low classification accuracy ($\mathcal{L}_{dis}$: 28.22%, $\mathcal{L}_{mmd}$: 26.81%, and $\mathcal{L}_{cls}$:41.21%). The accuracy is also very low (36.84%) when our method uses $\mathcal{L}_{dis}$ and $\mathcal{L}_{mmd}$ due to the critical need of the classification loss on the target domain. The accuracy increases to 64.60% when our method combines $\mathcal{L}_{cls}$ with $\mathcal{L}_{dis}$, because the distillation loss $\mathcal{L}_{dis}$ provides a set of candidate network configurations for the student to choose and the student can quickly adapt to the target domain by combining the knowledge distillation loss and classification loss. The accuracy further increases to 70.24% when our method uses all three losses. The results show that the domain-consistent loss, as a distribution distance measure, is effective for eliminating domain divergence between the source domain (simulated network) and the target domain (physical network).



(a) In the stress-testing environment. (b) In the clean environment.

Figure 11: Data visualization provided by t-SNE [88]. Larger variations are observed in stress-testing environment, which significantly increase the difficulty on transferring knowledge learned from simulations to a physical network.

6.5 Effects of Simulators and Radio Models

Finally, we study the effects of different simulators and radio models on the performance of our method. Unit Disk Graph Medium (UDGM) [55] and Directed Graph Radio Medium (DGRM) [55] are the two most popular radio models supported by Cooja [17, 65]. UDGM in Cooja uses the disk communication model and assumes that the receiver inside the communication range of the sender can successfully receive its packets with a constant PRR (i.e., 90%). DGRM in Cooja allows its user to specify the PRR of each link and use it together with a random number to determine whether each packet can be delivered successfully. Closest-fit pattern matching (CPM) in TOSSIM allows its user to input ambient noise traces and specify the gain value (propagation strength) between each pair of devices on every channel and then generates statistical models based on the CPM algorithm to compute the packet delivery ratio for each pair of devices [43]. We create DGRM-E by extending DGRM by allowing an user to specify different PRRs on different channels for each link, and then integrate it with TOSSIM. DISTANCE in NS-3 allow its user to specify the locations of all wireless devices and use the shadowing model to determine packet receptions [62]. OMNET++ allows its user

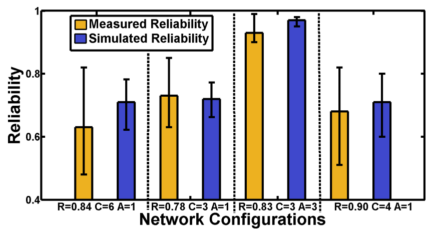


Figure 12: Reliability measured from the physical network and simulated by TOSSIM under four network configurations.

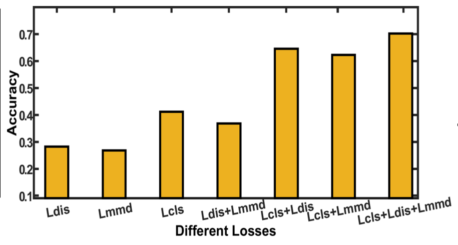

Figure 13: Accuracy when our method uses different loss functions.

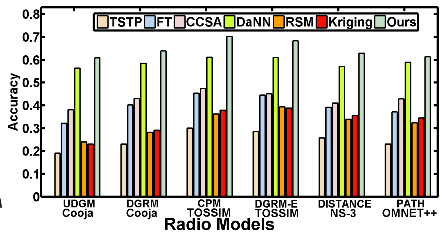

Figure 14: Accuracy comparison when using different simulators and radio models.

to specify device locations and background noise levels and uses the signal propagation model (path loss model) to compute the RSS values for packet reception prediction [64].

Figure 14 plots the accuracy of our method and our baselines when they use the simulation data generated from different simulators with various radio models. As Figure 14 shows, all methods achieve better performance when they use a more realistic model, which benefits from a smaller domain discrepancy. For instance, our method achieves 70.24% and 68.32% accuracy when it employs CPM and DEGRM-E in TOSSIM, respectively. The high accuracy results from the use of real-world noise or PRR traces in simulations. Our method provides a slightly lower accuracy (63.95%) when it uses DGRM in Cooja, which makes an unrealistic assumption that the PRRs of a link are the same on all channels. The worse performance (60.83%) appears when our method uses the simple disk model (UDGM) in Cooja. Similarly, the accuracy provided by TSTP decreases from 30.10% to 19.13% when it uses a less realistic radio model. More importantly, our method consistently provides the best performance and makes better use of more realistic simulations compared to other methods. The accuracy increases from 60.83% to 70.24% (a 9.41% increase) when our method uses CPM in TOSSIM instead of UDGM in Cooja, while the accuracy improvement offered by DaNN is 4.77% when making the same change.

The consistent low accuracy provided by TSTP shows that the simulation-to-reality gap is not tie up with a particular simulator or radio model. Although the theoretical models adopted by those simulators work satisfactorily in general, they cannot capture all real-world performance-related factors. For instance, the CPM approach in TOSSIM allows its user to input noise traces collected from a physical network and specify the gain value (propagation strength) between each pair of devices on every channel and then generates statistical models to predict packet receptions during simulations based on the CPM algorithm. Such an approach may introduce simulation inaccuracies because it has to use prerecorded noise traces and predefined gain values to simulate packet failures, and the probability-based prediction cannot precisely capture the effects of packet failures caused by extensive uncertainties, variations, and dynamics in real-world wireless deployments.

7 Conclusions

Over the past decade, WMNs have been widely used for industrial automation, military operations, smart energy, etc. Due to years of research, WMNs work satisfactorily most of the time. However, they are often difficult to configure as configuring a WMN is a complex process, involving theoretical computation, simulation, and field testing, among other tasks. Relying on field testing to identify good network configurations is impractical in many cases because running experiments on a physical network is often costly and time-consuming. Simulating the network performance under different network parameters provides distinct advantages when it comes to identifying a good network configuration, because a simulation can be set up in less time, introduce less overhead, and allow for different configurations to be tested under exactly the same condition. Unfortunately, out study shows that many network configurations identified in simulations cannot help physical networks achieve desirable performance because of the simulation-to-reality gap. To close the gap, We leverage a teacher-student deep neural network for efficient domain adaptation, which transfers network configuration knowledge learned from simulation to a physical network. Our method first uses the simulation data to learn a teacher neural network, which is then used to teach a student neural network to learn from a few shots of the physical data. Our experimental results show that our method consistently outperforms seven baselines and achieves a modeling accuracy of 70.24% with only 440 data samples collected from the physical network.

Practical Null Steering in Millimeter Wave Networks

Sohrab Madani*, Suraj Jog*, Jesus O. Lacruz†, Joerg Widmer†, Haitham Hassanieh*
*University of Illinois at Urbana Champaign, †IMDEA Networks

Abstract – Millimeter wave (mmWave) is playing a central role in pushing the performance and scalability of wireless networks by offering huge bandwidth and extremely high data rates. Millimeter wave radios use phased array technology to modify the antenna beam pattern and focus their power towards the transmitter or receiver. In this paper, we explore the practicality of modifying the beam pattern to suppress interference by creating nulls, i.e. directions in the beam pattern where almost no power is received. Creating nulls in practice, however, is challenging due to the fact that practical mmWave phased arrays offer very limited control in setting the parameters of the beam pattern and suffer from hardware imperfections which prevent us from nulling interference.

We introduce Nulli-Fi, the first practical mmWave null steering system. Nulli-Fi combines a novel theoretically optimal algorithm that accounts for limitations in practical phased arrays with a discrete optimization framework that overcomes hardware imperfections. Nulli-Fi also introduces a fast null steering protocol to quickly null new unforeseen interferers. We implement and extensively evaluate Nulli-Fi using commercial off-the-shelf 60 GHz mmWave radios with 16-element phased arrays transmitting IEEE 802.11ad packets [33] . Our results show that Nulli-Fi can create nulls that reduce interference by up to 18 dB even when the phased array offers only 4 bits of control. In a network with 10 links (20 nodes), Nulli-Fi's ability to null interference enables 2.68× higher total network throughput compared to recent past work.

1 Introduction

Millimeter wave (mmWave) networks introduced a major leap in data rates and scalability for 5G cellular networks, next generation wireless LANs, and IoT devices [10, 41, 46]. At the heart of millimeter wave technology are phased arrays which can focus the power of the antenna beam pattern in real-time towards the client to compensate for the large attenuation of mmWave signals. At mmWave frequencies ($\geq$ 24 GHz), phased arrays can fit many antennas into a small area due to the mm-scale wavelength of the signal [63], enabling very narrow directional beams as shown in Fig. 1. Ideally, using narrow beams would shield a mmWave device from interference outside the main direction (main lobe) of its beam. However, phased arrays suffer from side-lobe leakage as shown in Fig. 1(a). Hence, they still receive interfering signals even if these signals come from directions outside the main lobe. Past work has shown that side-lobes can lead to a significant amount of interference which can degrade the data rate and in dense networks reduce the total network throughput to half (by up to 18 Gbps) [14, 27, 44, 55, 61].

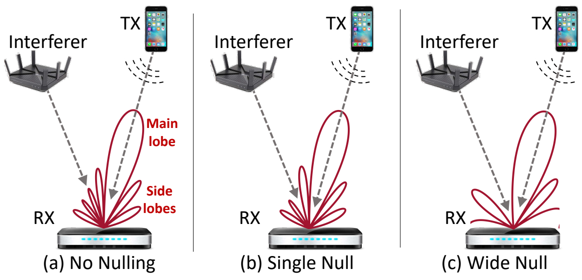

Figure 1: Directional beams in mmWave networks

To address the above problem, we leverage the fact that phased array beam patterns exhibit nulls, directions in the beam pattern where the transmitted or received power is suppressed as shown in Fig. 2(b). Thus, we can substantially reduce interference by having a null in the direction of the interferer. However, simply shifting the beam pattern to align the null with the interferer can misalign the main lobe and lead to worse performance as we show in section 6. Hence, we must create a new beam pattern to introduce a null in the direction of the interferer while preserving the alignment of the main lobe as shown in Fig. 1(b). This problem is commonly referred to as null steering.

Past mmWave systems research has mainly focused on beam alignment and steering [13, 17, 20, 40, 51, 56, 65], i.e. creating and steering the main lobe of the beam. Creating and steering nulls, however, while ensuring the main lobe is preserved is significantly harder. To better understand why, consider the phased array diagram shown in Fig. 2(a). The beam pattern of the array is created by modifying complex weights applied to each antenna element of the phased array. These complex weights alter the magnitude and phase of the signal received on each antenna. We can adjust these weights to align signals on the antennas coming from a certain direction to sum constructively creating a main lobe as shown in Fig. 2(d). In contrast, to create a null, we must ensure that the signals sum up destructively to cancel each other.

Setting the complex weights to ensure the signals from the direction of the interferer cancel each other while signals from the main lobe direction continue to sum up constructively is challenging in practice for several reasons. First, commercial mmWave phased arrays only allow us to change the phase of the complex weight but do not offer any control over the amplitude [11, 64]. While it is sufficient to rotate the phase of the signals to ensure they sum up constructively, it is hard to ensure signals cancel each other without modifying their

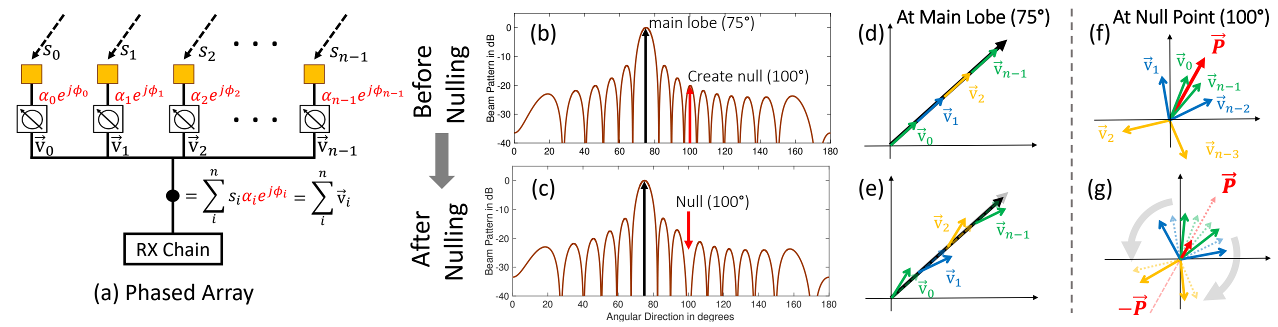

Figure 2: (a) phased arrays weight combination, (b-g) Nulli-Fi's Nulling Algorithm

amplitude. This is further complicated by the fact that phase control in practical arrays is highly quantized using at most 2 to 5 bits to control the phase shifts.[1] Moreover, practical phased arrays suffer from hardware imperfections [38] which have little impact on the main lobe but can limit the ability to null [38, 43]. For example, in an array with 8 antennas, if the phase on one antenna is off by 5°, the received signal along the main lobe degrades by only 0.004 dB whereas the interference signal along a null increases by 10 dB as we describe in more details in section 4.1.

Furthermore, unlike the main lobe which is naturally wide and, hence, can tolerate small errors in the direction of communication, nulls are narrow as shown in Fig. 2. As a result, any small error in the direction of the interferer will misalign the null and prevent us from effectively eliminating interference. To address this, we must create wider nulls rather than point nulls as shown in Fig. 1(c). In addition, in dense networks, we would need to null multiple different directions to account for multiple interferers or multipath reflections. Creating multiple nulls and wider nulls impose even more requirements that are hard to meet given the constraints and hardware imperfections of practical phased arrays.

Due to the above challenges, past work on null steering remains simulation based [5, 32, 53] and has not been implemented on practical mmWave phased arrays. Furthermore, most past work focuses on creating a single point null and none of the past work accounts for hardware imperfections.

This paper presents Nulli-Fi, the first practical mmWave null steering system that is able to null interference on commercial off-the-shelf phased arrays while preserving the main lobe. Nulli-Fi addresses the above practical challenges by combining a new theoretically optimal algorithm that accounts for limitations in practical phased arrays with a novel discrete optimization framework that overcomes hardware imperfections and enables multiple and wider nulls.

Nulli-Fi's optimal algorithm is able to create a single null within the constraints of practical phased arrays. To understand how this algorithm works, consider the example shown in Fig. 2. The goal is to have the main lobe at 75° and create a null at 100°. Each vector in Fig. 2(d)-(g) represents the signal received on a given antenna element. For signals received along 75°, Nulli-Fi sets the phase shifters to rotate the phase of each of these signals to sum up constructively as shown in Fig. 2(d). For signals received along 100°, the signals will have different phases and the vectors will sum up to some vector $\vec{P}$ as shown in Fig. 2(f). Our goal is to rotate these vectors by changing the phase on the phase shifters in order to null $\vec{P}$ while preserving the main lobe. To do so, Nulli-Fi restricts further phase-shifts on each antenna to a limited range. For example, if we restrict it to $\pm 15°$ on all antennas, the main lobe does not change by more than 0.3 dB, as shown in Fig. 2(e). Nulli-Fi then leverages the insight that the vectors are symmetric around $\vec{P}$ as shown in Fig 2(f).[2] By rotating pairs of symmetric vectors towards $-\vec{P}$, as shown in Fig 2(g), we reduce the amplitude of $\vec{P}$. We iteratively rotate the vectors until we null $\vec{P}$ or achieve the best possible reduction which we prove is optimal given the restrictions on the phase shifts.

The above algorithm provides a simple, optimal way to create nulls under limited phase control but it does not account for hardware imperfections, nor can it create nulls in more than one direction. To address this, we introduce a discrete optimization framework customized to null steering. The framework is inspired by genetic algorithms which have proven effective in discrete optimizations [19, 60]. However, genetic algorithms are very slow and can take thousands of iterations to converge [60] which prevents practical realtime null steering as we discuss in detail in section 7. Like many other optimization techniques, the initialization and stopping criterion are among the most contributing factors to the algorithm's convergence speed [48, 62]. To address this, Nulli-Fi uses the solution to its optimal algorithm. First, it initializes the optimization framework using the solution from the above algorithm which gives Nulli-Fi a significant head-start and helps it converge faster as we show in section 6. Second, since Nulli-Fi's algorithm is optimal, it can serve as a stopping criterion to the optimization framework (i.e., the algorithm knows if it has reached a reasonable solution). Combining the two methods gives Nulli-Fi a powerful framework that is both fast and is able to handle hardware imperfections.

Finally, to enable a practical system, Nulli-Fi develops a

[1]For example, 802.11ad compliant consumer-grade devices use only 2 bit phase shifters, i.e. we can set the phase only to 0°, 90°, 180°, or 270°.

[2]We prove this in lemma 4.2 to be true for any directions of the main lobe and the null for even number of antennas.

fast null steering protocol that is able to quickly find the direction in which to create a null whenever a new unforeseen interferer appears. The protocol leverages the intuition that the interferer direction is more likely to be at the large side-lobes shown in Fig. 2(b). Hence, instead of searching all possible directions, Nulli-Fi starts with a large side-lobe where it creates a wide null and iterates through the side-lobes until the interferer is nulled.

We have implemented and extensively evaluated Nulli-Fi using commercial 60 GHz, 16 element phased arrays transmitting IEEE 802.11ad packets [33]. Our results show that for 4 bit phase shifters, Nulli-Fi is able to create 3° narrow nulls that suppress interference by 18 dB and 10° wide nulls that supress interference by 10.5 dB while maintaining the main lobe within 1 dB. For 2 bit phase shifters, Nulli-Fi is still able to null interference by 12.6 dB. Nulli-Fi is also able null up to 5 different directions. We further compare Nulli-Fi with past null forming algorithms and demonstrate up to 10 dB better nulling and 37× faster convergence. We also evaluate NullFi's fast null steering protocol on top of the mm-Flex platform [33] to show that Nulli-Fi can find the direction of an unknown interference and null it within 290 ns. Finally, to demonstrate the effectiveness of Nulli-Fi in dense mmWave networks, we compare Nulli-Fi to past work that leverages the directionality of mmWave radios to enable many concurrent transmissions [27]. By nulling interference from side lobes, Nulli-Fi is able to achieve 2.6× higher data rate when 10 mmWave links (20 nodes) are transmitting concurrently.

Contributions: The paper has the following contributions:

- The paper presents the first practical system that can create nulls on mmWave phased arrays.
- The paper introduces a theoretically optimal algorithm for creating nulls and a novel discrete optimization framework that account for practical challenges in mmWave systems.
- The paper develops a fast null steering protocol to deliver a practical system.
- The system is built and evaluated on real phased arrays to demonstrate significant gains in suppressing interference.
- We have open sourced implementations of our algorithms and baselines on our git repository [36].

2 Related Work

There is a significant literature on millimeter wave beam shaping and steering. Past mmWave systems research, however, has mainly focused on beam alignment, i.e. developing protocols to quickly find the best direction to align the beams of a transmitter and receiver or to switch the beam to a different path to avoid blockage [17, 20, 27, 40, 56, 65, 66]. Some works also explore the problem of beam pattern synthesis [13, 42, 51]. However, these works focus on shaping the main lobe of the beam to achieve good antenna gain along the direction of communication. In contrast, we focus on forming and steering nulls to suppress interference.

Past work on mmWave networks proposes leveraging the directionality of mmWave links to enable dense spatial reuse and maximize the number links that can transmit simultaneously [27, 28]. However, the work shows that side lobe leakage from practical mmWave phased arrays limits the ability to enable spatial reuse. In section 6, we compare with this work to show that Nulli-Fi can enable 2.43× higher throughput than [27] when 10 links are transmitting concurrently. Another work [59] mitigates interference by aligning the natural nulls in the beam pattern toward the interferer. This, however, comes at the cost misaligning the mainlobe [59]. In section 6, we show that this can reduce the SNR by up to 10 dB. In contrast, Nulli-Fi creates new nulls that suppress interference while preserving the main lobe alignment.

Previous work on null forming in phased arrays is simulation based and to the best of our knowledge has not been implemented on practical mmWave phased arrays. Most of the past work ignores many of the practical limitations. Table 1 summarizes past work. Specifically, most methods assume that it is possible to arbitrarily set the phase and amplitude of the complex weights. Others do not require amplitude control but assume phase control is continuous and can be set arbitrary. However, mmWave phased control is highly quantized offering only 2 to 5 bits to control the phase [2, 11, 47]. Two works [49, 52] assume a digital phased array, i.e. each antenna is connected to a district transmitter or receiver and the complex weights can be set arbitrary in digital. Commercial mmWave phased arrays are mostly analog and have a single digital transmitter or receiver as shown in Fig. 2(a) [2–4, 33].

The closest to our work are [22, 23, 35] which use genetic algorithms to create nulls in case of discrete phase only control with 6 bits of quantization. However, these systems are not implemented in practice, ignore hardware imperfections, take many iterations to converge and can only create a point null for which Nulli-Fi has a closed-form solution. In section 6, we implement and compare with these methods to show that even if they account for hardware imperfections, Nulli-Fi still achieves 10 *dB* better nulling with the same running time, and is 37× faster with the same performance.

Authors in [8, 15] implement nulling on custom built phased arrays. However, they operate in the sub-6 GHz frequency range where it is significantly easier to build phased arrays with flexible control. In particular, [8] works at 4.5 GHz and uses phase shifters with a 9-bit control, i.e. it is possible to set the phase at a resolution of 0.7°. They first solve the nulling problem in the continuous phase domain using gradient descent and then round off the continuous values to the 9-bit discrete space. Millimeter wave phase shifters, however, typically support 2 to 5 bits phase shifters for which the quantization error become too large. In section 6, we implement and compare with this work and show that its performance significantly degrades as the number of bits decreases. Another work [15] operates at 2.4 GHz and use deep neural networks to create the nulls. However, the DNN architecture can only output continuous values and can suffer from over-fitting.[3] In contrast, this paper presents and extensively evaluates a solution that works for highly quantized phase on practical mmWave phased array.

Some works propose changing the positions of the antennas to create nulls in the beam pattern or reduce the side lobes [7, 24, 26, 31]. However, these techniques require new custom built hardware and are only suitable only for static applications with a fixed beam pattern and null locations. Finally, there is a large body of work that proposes interference nulling using MIMO techniques at sub 6 GHz frequencies [16, 18, 34, 37, 45]. These works are complementary to Nulli-Fi as they require multiple digital transmitters or receivers to perform digital beamforming and set arbitrary complex weights in digital to null the signals.

3 Primer

In this section, we provide a primer on phased arrays as well as genetic algorithms on which we base our optimization.

1. Phased Arrays: In analog phased arrays, an array of antennas is connected to a single transmitter or receiver through a single chain. The signal on each antenna n is multiplied with a complex weight $a_n = |a_n|e^{j\alpha_n}$ as shown in Fig. 2(a). By changing these weights, we can change the beam pattern and steer the main lobe of the beam in any direction. The beam pattern along a direction ϕ can be written as:

[3]Specifically, the paper mostly provides simulation results and only shows three examples of nulls created on real hardware.

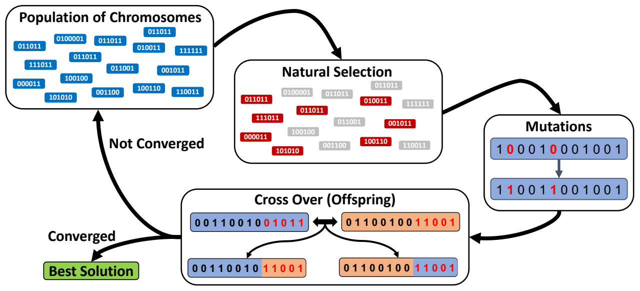

Figure 3: Overview of genetic algorithm

$$P(\phi) = \sum_{n=0}^{N-1} a_n e^{2\pi j \frac{d}{\lambda} n cos(\phi)} \quad (1)$$

where N is the number of antennas, λ is the wavelength of the signal, and d is the separation between adjacent antennas. We can steer the main lobe towards the direction ϕ by setting the complex weights to $a_n = e^{-2\pi j \frac{d}{\lambda} n cos(\phi)}$ which will cause the signals coming from direction ϕ to sum up constructively. For example, by setting $\phi = 75°$, we get the beam pattern shown in Fig. 2(b). The beam pattern exhibits natural nulls where $P(\phi) = 0$ and no signal is received along that direction. In practice, however, such perfect nulls are not possible. Hence, we define a null as a point in the beam pattern where $P(\phi)$ is extremely small (e.g. -25 dB relative to the main lobe). The deeper the null, the more effective it is at suppressing interference. Our goal is to find a setting of the complex weights to create a null along a certain angle ϕ_{null} while maintaining the amplitude level of the pattern at $\phi_{\text{main lobe}}$.

If we are able to control both amplitude and phase of the complex weights in a continuous manner, then we can easily create any beam pattern. In particular, we can transform Eq. 1 into a Fourier Transform by setting $f = -d/\lambda \cos(\phi)$. We can then construct any desired pattern and take its inverse Fourier transform to find the set of complex weights that we should use. Most practical phased arrays, however, do not support controlling the amplitude of the complex weights especially since modifying the phase is sufficient to steer the main lobe of the beam. These phased arrays use a component called a phase shifter to shift the phase of the signal on each antenna element. Hence, the problem is restricted to having $|a_n| = 1$, i.e. $a_n = e^{j\alpha_n}$. Unfortunately, the problem becomes even harder when we are limited to a quantized set of phase shifts, especially when the number of control bits used to set the phase shifter is small as the problem becomes non-convex and the search space is exponentially large. For example, for a 16 element array, and 4 bits (= 16 values) of resolution in phase-shifters, we get $16^{16} \approx 1.8\text{e}19$ possible patterns.

2. Genetic Algorithms: Genetic Algorithms (GAs) are a family of evolution-inspired algorithms designed to solve optimization problems. They are particularly useful when the search space is discrete and has many local maxima [60]. A high-level overview of the algorithm structure is depicted in Fig. 3. The algorithm starts by considering a set of *initial chromosomes* referred to as the *population*. Each chromosome represents one possible solution of the problem e.g. a setting of complex weights $(a_0, a_1, \cdots, a_{n-1})$. The first stage of the algorithm is *natural selection* where the chromosomes are ranked using a fitness function that evaluates how well each chromosome solves the problem e.g. how good of a null it creates. Fraction of chromosomes that are most fit to solve the problem are then selected and the rest are discarded. The remaining chromosomes give rise to new potentially fitter, chromosomes, which repopulate the population via *mutation* and *crossover*. In *mutation*, random bits used to represent the chromosomes are flipped to create new chromosomes whereas in *crossover*, two random parents give birth to two new chromosomes as shown in Fig. 3. Once the population reaches its original size, the fitness of the chromosomes is re-evaluated and the best chromosome is selected. The entire process keeps repeating until the algorithm converges, i.e. reaches some stopping criteria. While genetic algorithms work surprisingly well, they are completely arbitrary and do not exploit the underlying structure of the problem. As a result they take a long time to converge and can give sub-optimal results. Nulli-Fi builds on the high-level structure of such algorithms to design a new optimization framework customized to the problem of null steering.

4 Nulli-Fi

4.1 Nulling Algorithm

Assumptions: To begin, we state the set of assumptions under which we optimally solve the nulling problem. We will assume that the number of antenna elements, N, is even, and that the physical distance of adjacent antenna elements is $d \leq \lambda/2$, where λ is the wavelength. We further assume that we only have phase control over antenna elements, and before nulling, all the antenna elements are beamforming towards some direction ϕ_0, i.e. the phase shifts $\alpha_n = -2\pi nd/\lambda \cos\phi_0$ as described in Eq. 1 [4].

Preserving the Main Lobe: In order to preserve the main lobe of the beam directed towards ϕ_0, we limit any additional phase-shifts on each antenna element to $\pm\alpha^*$, i.e. $|\Delta\alpha_n| \leq \alpha^*$ for all n. We show that this limits the loss in the main lobe to at most $sin^2(\alpha^*)$. In particular, we prove the following lemma in Appendix A.5:

Lemma 4.1 *If $\alpha^* \leq 90°$, a maximum phase shift restricted to $\pm\alpha^*$ for each antenna element will result in a loss of at most $\sin^2(\alpha^*)$ in the main lobe.*

This would mean that for $\alpha^* = 15°$ (or 30° of freedom), the main lobe changes by at most 0.3 dB.

[4] In a discrete phase scenario, aligning towards any angle ϕ_0 is not possible and we must set all elements to the closest discrete value to ϕ_0.

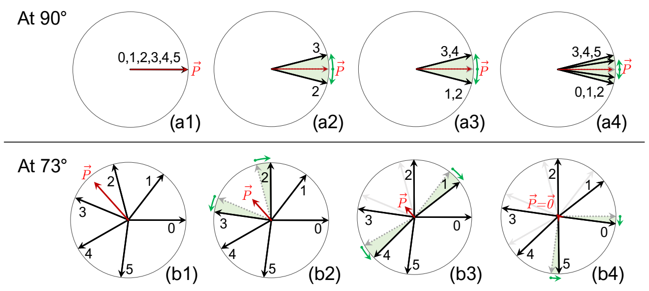

Figure 4: Example Nulli-Fi's nulling algorithm for $N = 6$ antenna elements with the main lobe at 90° an nulling at 73°.

Problem Formulation: Given the restrictions on the phase shifts to preserve the main lobe and the above assumptions, our problem becomes: *Given an angle ϕ, find a set of additional phase-shifts $\Delta\alpha_n$, such that $|P(\phi)|$ is zero (or as close to zero as possible), subject to $|\Delta\alpha_n| < \alpha^*$.*

Algorithm: Our algorithm works by representing the signal on each antenna as a vector in the complex plane. This representation is particularly useful since applying a phase shift is equivalent to rotating these vectors. Thus, our goal is to rotate these vectors to null the signal in the direction of ϕ. To better understand how this works, consider the example shown in Fig. 4. In this example, we have $N = 6$ antenna elements beamforming towards $\phi_0 = 90°$. The vectors $\vec{v_n}$ representing the signal on each element are indexed by: $0, 1, \cdots, 5$, and our goal is to create a null at $\phi = 73°$.

Initially, the vectors are aligned to sum up constructively to $\vec{P_{\phi_0}}$ along 90° as shown in Fig. 4(a1). [5] However, they are aligned differently along 73° and sum up to $\vec{P_\phi}$ as the signals come with a different phase at that direction as shown in Fig. 4(b1). To create a null along 73°, we will rotate each vector by an additional $\Delta\alpha_n$ to minimize the $\vec{P_\phi}$. The restriction $|\Delta\alpha_n| \leq \alpha^*$ will ensure that $\vec{P_{\phi_0}}$ along the main lobe is preserved as shown in Fig. 4(a2–a4). However, it will prevent us from arbitrarily rotating the vectors along 73°. To address this, we leverage the following key observation: *At any direction ϕ, all the vectors summing up to the pattern $\vec{P_\phi}$ come in pairs symmetrically located around the pattern.* For example, in Fig. 4(b1), the following pairs: $\{0, 5\}$, $\{1, 4\}$ and $\{2, 3\}$ are symmetrically located around $\vec{P_\phi}$.

The following lemma formalizes this observation. The proof of the lemma can be found in Appendix A.5.

Lemma 4.2 *At any direction ϕ, if $\Delta\alpha_n = 0$ for all n, then $\vec{v}_n$ and $\vec{v}_{N-1-n}$ are symmetrical around $\vec{P_\phi}$ for all n. That is, $\frac{1}{2}(\angle\vec{v}_n + \angle\vec{v}_{N-1-n})$ is the same as $\angle\vec{P_\phi}$ or $\angle\vec{P_\phi} + \pi$.*

Given this observation, the algorithm proceeds as follows. Choose a pair of symmetrical vectors around the pattern $\vec{P_\phi}$ and symmetrically rotate them towards $-\vec{P_\phi}$ as much as possible (i.e. until α^* degrees, or until a null is achieved). This

[5] In fact, $\vec{P} = 6e^{j0}$ but we have downscaled it by 6 for better visualization.

will reduce the beam pattern amplitude along ϕ as shown in Fig. 4 (b2) but it will *not* change its angle. This means that all the vectors remain symmetrical around the $\vec{P}_\phi$. If a null is achieved, we stop. If not, we repeat with another symmetrical pair as shown in Fig. 4 (b3,b4). Note that the same rotations are also applied at the main lobe in Fig. 4 (a2-a4). While these rotations result in a null at 73°, they cause only a 0.2 dB loss at 90°.

A pseudocode of the algorithm can be found in Alg. 1 in Appendix A.1. We also prove the following theorem regarding the optimality of our algorithm in Appendix A.5.

Theorem 4.3 *Given the constraint $|\Delta\alpha_n| < \alpha^*$, Alg. 1 gives the best nulling performance at any angle ϕ.*

It is worth noting that given the constraints, it is not always possible to achieve a perfect null i.e. $\vec{P}_\phi = \vec{0}$. In such cases, the above algorithm yields the deepest possible null. This also allows the algorithm to identify directions that can be perfectly nulled from those that cannot. In Appendix A.4, we provide further analysis and closed form solutions for the bounds of achievable nulling performance as a function of the direction of the null.

4.2 Optimization Framework

In this section, we show how to account for hardware imperfections and achieve multiple and wider nulls. We extend our definition of a null to be an interval 2β degrees wide around ϕ i.e., $[\phi-\beta,\phi+\beta]$ where the magnitude of the beam pattern is lower than a certain threshold. The input to our optimization are multiple such intervals $([\phi_i-\beta_i,\phi_i+\beta_i])$ where we wish to null interference. A pseudocode of our optimization framework can be found in Alg. 3.

Encoding: We will encode the solution i.e. the setting of the phase shifts α_n into chromosomes that form the basis of the genetic algorithm. Suppose the phase shifts are quantized using q bits, then each α_n can be represented as a bit string $(b_{n,1},\cdots,b_{n,q})$ where $b_{n,i}$ is the i^{th} most significant bit of α_n. A chromosome A can then be encoded as a concatenation of the N binary representations of the phase shifts: $A=(b_{0,1},\cdots,b_{0,q},b_{1,1},\cdots,b_{1,q},b_{N-1,1},\cdots,b_{N-1,q})$. We define P_A as the beam pattern associated with chromosome A.

***Initialization*:** While genetic algorithms generally start from a set of randomly generated chromosomes, we use the output of Alg. 1 to initialize our genetic algorithm. Specifically, for each null region $([\phi_i-\beta_i,\phi_i+\beta_i])$, we run Alg. 1 and find the optimal setting of α_n to create a null along ϕ_i. Each solution will give us a single initial chromosome. We then slightly perturb the values of the phase shifts to create a larger population of initial chromosomes. This dramatically improves the optimization's performance as we show in section 6.2.

Fitness function $F(A)$**:** This function evaluates the performance of any given chromosome A. In our problem setup, we

A_3 $\alpha''_0,\alpha''_1,\alpha''_2,\alpha''_3,\cdots,\alpha''_{N-1}$
$\alpha''_i=\frac{1}{2}(\alpha_i+\alpha'_i)$
(b)

Figure 5: Nulli-Fi's crossover operation using buckets

define the fitness function as

$$F(A)=\min_{\substack{i=\{1,\ldots,L\}\\ \phi\in[\phi_i-\beta_i,\phi_i+\beta_i]}} -10\log_{10}\left(|P_A(\phi)|^2\right),$$

where $P_A(\phi)$ can be calculated from Eq. 1 by setting the complex weights to $e^{j\alpha_n}$. This fitness function $F(A)$ optimizes for the *worst* nulling performance in dB across all the regions we wish to null. In particular, the min point of $-10\log_{10}\left(|P_A(\phi)|^2\right)$ is the max point in $|P_A(\phi)|^2$ which is the least nulled point. Hence, the fittest chromosome, $A^*=\arg\max_A F(A)$, will give the best nulling performance across all directions since we optimized for the worst case.

***Natural Selection*:** At each iteration, we evaluate the fitness function for every chromosome and keep the ones with the best performance.In our implementation, we typically keep the top 50% of the chromosomes.

Cross-over. Recall from section 3, this operation is meant to combine two parent chromosomes A_1 and A_2, to give birth to a new, potentially fitter chromosome, A_3. Typically, the two parents A_1 and A_2 are chosen randomly. However, Nulli-Fi employs a more intelligent selection criteria. For simplicity, let us consider a single null point and use the same vector representation we used in section 4.1 to explain Nulli-Fi's cross-over operation.

To begin, we first group chromosomes into different buckets $1,\cdots,2B$. Bucket i contains all chromosomes A with $(i-1)\frac{\pi}{B}\le\angle\vec{P}_A<i\frac{\pi}{B}$. Fig. 5 (a) shows an example of these buckets for $B=4$, where buckets on the opposite sides of each other have the same color. In our cross-over operation, two parents A_1 and A_2 are then chosen at random, under the constraint that $\vec{P}_{A_1}$ and $\vec{P}_{A_2}$ are in opposing buckets (for example, B_3 and B_7). Then, a new chromosome A_3 is created by averaging the phase shifts of A_1 and A_2, as shown in Fig. 5 (b). The intuition behind this is that by taking the average phase shift of the two parents, the new chromosome will approximately have a pattern vector equal to the sum of its parents. Since the parents come from opposing buckets, the summation of their patterns will likely result in a smaller vector. This is depicted in Fig. 5 (a) where the red vector corresponding to the child chromosome A_3, is smaller than the pattern of either parent (depicted black and blue vectors). By exploiting the structure of the problem, Nulli-Fi is able to quickly generate fitter

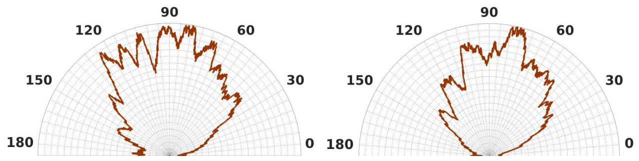

Figure 6: Non uniform radiation patterns of antenna elements

chromosomes with smaller $|P_A(\phi)|$ i.e. deeper nulls which improves the results as we show in section 6.2.

Mutation. In this step, we randomly flip bits in the parent chromosome with some probability to give rise to a new chromosome. Note that we preserve the current best chromosome A^* which remains unchanged during mutation.

Convergence. The algorithm converges once the best performing chromosome reaches a fitness threshold, or a maximum number of iterations has been reached. In the case of a single null, this threshold is directly governed by the output of Alg. 1. For multiple nulls, as one would expect, the performance usually does not reach the theoretical performance of a single null. In our implementation, we reduce the threshold by around 1 dB for every extra null region.

Preserving the main lobe. Similar to the optimal algorithm, we maintain $|\Delta\alpha_n| \leq \alpha^*$ to preserve the main lobe. This can be done by simply fixing the $q - \log_2(\pi/\alpha^*)$ most significant bits of α_n and not changing them throughout the optimization. However, in cases where q is very small, e.g. 2 bit phase shifters, such an approach does not hold. To address this, Nulli-Fi sets aside a subset of the antenna elements and does not change their phase shift throughout the entire optimization. This subset will contribute to the main lobe whereas the remaining antennas will contribute to create the null. Nulli-Fi dynamically chooses the antenna elements that are contributing the most to the main lobe to be in this subset and allows phase shifts for the ones that are contributing the least to the main lobe. A pseudocode for this process can be found in Alg. 2 in section A.1 of the appendix.

Accounting for Hardware Imperfections: There are two types of hardware imperfections: (1) phase offsets due to different wire lengths or paths that the signals traverse, and (2) non-uniform antenna element radiation patterns. In particular, the signal on each antenna incurs an additional δ_n and signals coming from a direction ϕ incur an additional attenuation of $R_n(\phi)$. Fig. 6 shows the radiation patterns of two antenna elements on our hardware setup described in section 5. As can be seen, antennas do not receive the signal uniformly across all directions. While these factors do not severely affect the quality of the main lobe, they have a more significant impact on the nulling performance of the phased array, as we show in section 6. This is because the beam pattern computed using Eq. 1 and used for evaluating the fitness function is no longer valid in practice. We can measure these imperfections using a simple calibration procedure outlined in detail in appendix A.2. Once measured we can modify Eq. 1

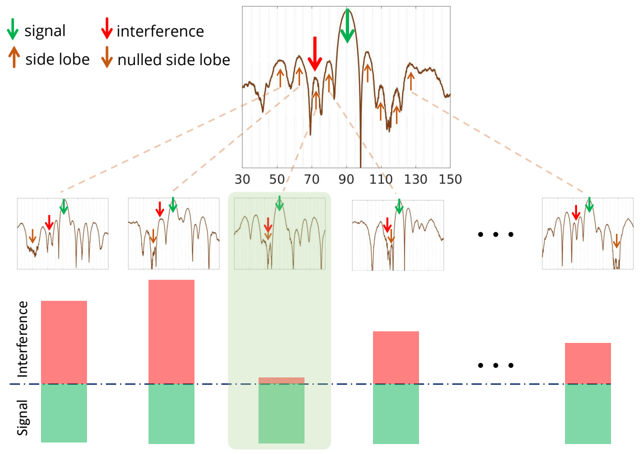

Figure 7: Illustration of Nulli-Fi's nulling alignment and interference suppression.

as follows:

$$P(\phi) = \sum_{n=0}^{N-1} a_n R_n(\phi) e^{j\delta_n} e^{-2\pi j \frac{d}{\lambda} n cos(\phi)}, \qquad (2)$$

We observe these imperfections to be stable and, hence, can be measured once. By modifying the fitness function to account for these hardware imperfections, we can generate beam patterns that achieve good nulling performance in practice.

4.3 Fast Null Steering Protocol

Now that we have a framework to form nulls at any desired direction, we need to find a practical way to align and suppress nulls in a real network. In this section, we present a simple yet fast and practical protocol to do so. The protocol finds and suppresses interferers in succession, by enforcing wide nulls at the high-level side-lobes of the pattern.

We begin with a simple example, where there is only one interferer. Consider the pattern in Fig. 7. As can be seen, the pattern has a number of significant side lobes, denoted by upwards brown arrows, which are the most likely to receive interference from other links in the network. Nulli-Fi finds these side-lobes, and computes corresponding patterns that have nulls at each side lobe as shown on the second row in Fig. 7, while keeping the main lobe. The hardware then quickly sweeps through these patterns, computing the Received Signal Strength (RSS) corresponding to each pattern. If the RSS drops for one of these patterns, it means that the interference was suppressed. This way, we can eliminate the interferer. To make the algorithm even faster, Nulli-Fi checks the SINR value at after each beam switch, and stops if the SINR is within a threshold of its original value.

Following this example in case of multiple interferers, we first suppress the one with the highest power. Once this interferer is nulled, we keep a null at its direction at all times,

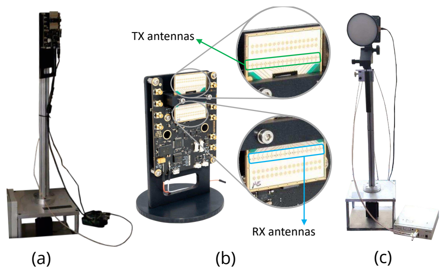

Figure 8: Hardware used in Nulli-fi.

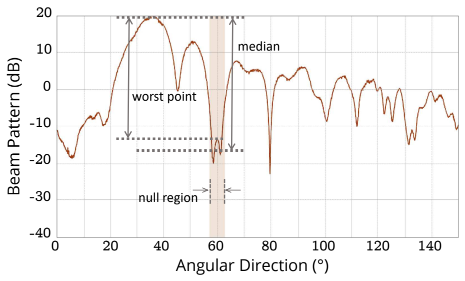

Figure 9: Defining the evaluation metrics.

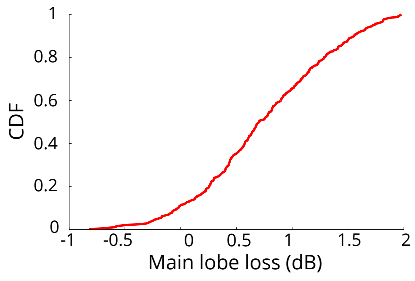

Figure 10: Main lobe loss in Nulli-Fi.

and search for the next interferer with the highest power. We repeat this process until all interferers are suppressed. We note that since our protocol only looks for interferences at high-level side lobes of the pattern, it will be much faster than a full scan, while remaining effective in improving the SINR, as we show in section 6.4.

5 Implementation

Nulli-Fi's Setup. Nulli-Fi is implemented using the off-the-shelf Sivers IMA EVK06002 platform [3], equipped with a 60 GHz 16-element linear phased array shown in Fig. 8(b). In order to measure the beam patterns, we mount the phased array radios on a steerable platform controlled through an Arduino as shown in Fig. 8(a). Our testbed also includes a 60 GHz Pasternack PEM009-KIT [1] equipped with a directional 3-degree horn antenna (Fig. 8(c)) which we use to transmit signals in order to measure the generated beam patterns. All hardware devices were connected to a machine running Ubuntu 18.04 through USRP N210 software defined radios. The center frequency in all experiments was 60.48 GHz. We run our experiments in 4 different rooms in 8 different locations, and in each location, we test 125 distinct combinations of directions of communication and interference. The EVK06002 platform offers flexible phase control for each of the antenna element weights which allows us to experiment using different number of bits. We evaluate Nulli-Fi using at most 4 bits of phase resolution, i.e. 16 distinct phase shift values per antenna element. We also show Nulli-Fi's performance for more coarse-grained control on phase, specifically 2 bit and 3 bit phase resolution. We also calibrate the array as described in Appendix A.2.

Nulli-Fi + mm-Flex Setup. We also implemented Nulli-Fi on top of the mm-Flex platform [33], to evaluate our null steering protocol. We transmitted IEEE 802.11ad control frames, where we use 10 Golay sequences to switch beam patterns. Our setup can switch between beam patterns once every 54.5 nanoseconds, during which we are able to measure RSS values corresponding to that pattern. This way, sweeping through 10 beam patterns takes less than 0.55μs. Further details of this setup can be found in Appendix A.3.

6 Results

6.1 Evaluation Metrics

We start by describing the evaluation metrics used to quantify Nulli-Fi's performance. Fig. 9 illustrates some of the metrics on an example beam pattern created by Nulli-Fi.

• *Null Width:* Since we create wide nulls, we define the null width as the region of directions nulled in the beam pattern.
• *Worst-point nulling performance:* Minimum amount of nulling in the target null region, measured as the difference between the peak of the main lobe and maximum point in the null region as shown in Fig. 9.
• *Median nulling performance:* Median amount of nulling in the target nulling region measured as the difference between the peak of the main lobe and median point in the null region.
• *SINR Gain:* Gain in Signal-to-Interfernce plus Noise Ratio before and after nulling the interferer.
• *Main Lobe Loss:* Loss in the main lobe power compared to a beam pattern without the imposed nulls.
• *Number of Nulls:* Number of different directions in which nulls are created.
• *Quantization Level:* Number of control bits used to set the phase on the phase shifters.
• *Number Iterations:* Number of iterations it takes for the optimization to converge.
• *Null Steering Latency:* Time it takes to steer the null towards an interferer once the interferer appears.

6.2 Baselines

We compare Nulli-Fi to the following baselines:

(1) Quantize-Continuous [8] – This baseline solves the problem in the continuous domain and then quantizes the phase solution to the nearest available discrete phase values.

(2) Genetic-Algorithms [22] – We compare Nulli-Fi to past work that uses genetic algorithms to create nulls.

(3) Shift-Pattern [59] – This baseline steers the main lobe a bit away from the direction of communication in order to align the natural nulls in the signal with the interferer.

(4) BounceNet [27] – This work aims to enable dense spatial reuse in mmWave networks by leveraging the directionality of mmWave beam patterns.

(a) worst-point performance (b) median performance

Figure 12: Nulli-Fi's performance using fewer bits.

6.3 Nulling Performance

We start by evaluating Nulli-Fi's ability to create nulls and compare it with past work.

1. Nulli-Fi's Nulling Performance: Fig. 11 shows a few examples of beam patterns with nulls created by Nulli-Fi on our phased array for different null directions, main lobe directions, null widths, and number of nulls using 4-bit phase shifters. As can be seen in Fig. 11(e, h), Nulli-Fi can create nulls as deep as -20 dB and -35 dB (40 dB and 55 dB below the main lobe respectively). Nulli-Fi can also create nulls that are as wide as 20° while maintaining a median nulling performance that is 20 to 25 dB below the main lobe as shown in Fig. 11(b, g). It can create up to 5 different nulls as shown in Fig. 11(d).

Fig. 12 shows a CDF of the median and worst-point nulling performance in more than 1000 experiments. Nulli-Fi's 50^{th} percentile is about 29 dB for the median nulling and 25 dB for the worst-point nulling. Since commercial 802.11ad hardware today, like laptops and tablets, comes equipped with only 2 bit phase control in the phased arrays [2, 11], we evaluate Nulli-Fi's performance using fewer bits of phase resolution. Fig. 12 also plots the CDF of the nulling performance with Nulli-Fi using 2 and 3 bits of phase control. While the nulling performance degrades with fewer bits, Nulli-Fi is still able to achieve a 24.1 dB median and 21.1 dB worst-point performance using only 2 bits, and 26.2 dB median and 24.3 dB worst-point performance using 3 bits of phase resolution.

Finally, we measure the main lobe loss suffered due to creating nulls, and plot the empirical CDF in Fig. 10. As can be seen, the median and the 90^{th} percentile values of the main lobe power loss are only 0.58 dB and 1.46 dB respectively, demonstrating Nulli-Fi's ability to preserve the main lobe while creating nulls.

2. Nulling Performance vs. Null Width: There is a natural trade-off between the width of the null created and its median (or worst-point) performance. To examine this, we evaluate Nulli-Fi's ability to create very narrow nulls like the ones shown in Fig. 11 (a, h) as well as very wide null regions like the ones shown in Fig. 11 (b, c). We run experiments where we create nulls of different widths ranging from 1° to 50°, and plot the median and worst-point performance in Fig. 13(a).

While the median nulling performance remains more than 25 dB even for nulls as wide as 50°, the worst-point performance deteriorates much more quickly. This point becomes clear when we consider the fact that the total radiated power in the beam pattern has to be conserved, implying that nulling one region will cause other regions to have an amplification in power. Therefore, while it may be possible to keep the median point in the target null region low for wide nulls, it becomes increasingly difficult to ensure that the worst-point in the target null region remains low as well.

It is worth noting that such overly wide nulls might not be needed in practice and nulls with width of 5° to 10° might be more than enough to account for inaccuracy in the estimating the direction of interferer. One could, however, use very wide null to preemptively supress less powerful interferers.

3. Nulling Performance vs. Number of Nulls: As mentioned previously, in practical networks there could be multiple sources of interference (separate signals or multipath), each occurring at a different angle. Thus, we test Nulli-Fi's ability to create l simultaneous null regions for $1 \leq l \leq 5$. We run 200 experiments for each l by randomly assigning the null regions. We constrain all null regions to be at most 10° wide, and in the case of multiple nulls, any two null regions should be at least 10° apart (otherwise, we observe that the two nulls

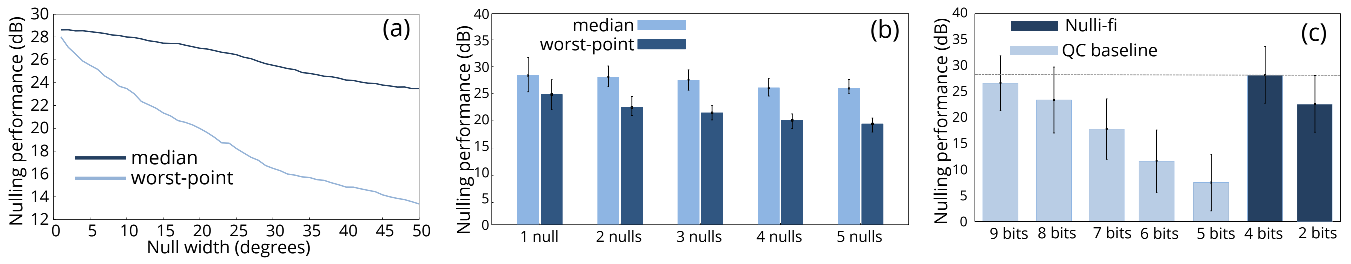

Figure 13: (a) Null performance versus width of the null. (b) Null performance versus number of nulls. (c) Nulli-Fi verus baseline as a function of number of quantization bits.

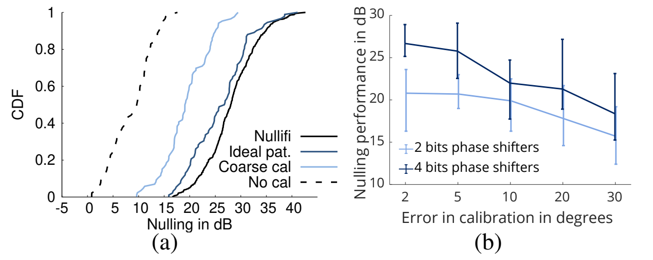

Figure 15: Importance of accounting for hardware imperfections and sensitivity to calibration errors.

merge into one wider null). Fig. 13(b) shows the median and worst-point nulling performance for different numbers of null regions. Note that for multiple null regions, we present the median and worst-point performance numbers for the poorest performing null in the beam pattern. As can be seen in Fig. 13(b), even with 5 null regions, Nulli-Fi is able to achieve 25.8 dB median and 19.1 dB worst-point performance. Fig. 11(d) shows an example of 5 null regions generated by Nulli-Fi.

4. Nulling Performance vs. Baselines: We run more than 1000 experiments for creating nulls at different angles, with different main lobe directions and null widths. Our nulling angles and main lobe directions range from the 30° to 150° region, and null widths range from 5° to 20° width. In all of the experiments, the target null region does overlap with the ±10° region around the main lobe direction. In these experiments, we focus on the performance for creating a single null. In Fig. 13(c), we compare Nulli-Fi's performance against the *Quantize-Continuous* baseline. The continuous solutions are quantized to $b = 5, 6, \cdots, 9$ bits of phase resolution, whereas Nulli-Fi is implemented on real hardware with 4 bits of phase resolution. Nulli-Fi's performance exceeds *Quantize-Continuous* even with 9 bits of phase resolution compared to Nulli-Fi's 4 bits. This shows that simply quantizing the continuous phase solution (especially quantizing to less than 7 bits) does not work for practical phased arrays.

We also compare Nulli-Fi with genetic algorithm [22] (*Genetic*) as well as with Nulli-Fi's optimization framework without initializing it with the solution of our optimal algorithm (*Nulli-Fi No optimal*). We run experiments where each algorithm is required to create single nulls at 200 different directions. We fix a target nulling performance of −20 dB and record the number of iterations required to achieve the desired nulling. Fig. 14(a) plots a CDF of the No. of iterations, showing that Nulli-Fi converges almost two orders of magnitude faster than *Genetic*. The figure also shows that Nulli-Fi's optimal algorithm enables much faster convergence and in many cases already gives a nulling performance of −20 dB. Hence, Nulli-Fi converges in a single iteration.[6] Moreover, By comparing the 99th percentile of *Genetic* and *Nulli-Fi(No optimal)*, which comprises cases where it is more difficult to create nulls, we can see that Nulli-Fi's novel crossover scheme helps in pushing the algorithm faster towards the desired nulling performance. Next, we fix the number of iterations to 10 for all three algorithms and plot the CDF of the nulling gain achieved by Nulli-Fi over each algorithm in Fig. 14(a). Nulli-Fi achieves a median gain in nulling of 10 dB over *Genetic* and 4 dB over *Nulli-Fi (No optimal)*.

5. Sensitivity to Calibration & Hardware Imperfections To show the significance of accounting for hardware imperfections, we run experiments to evaluate nulling performance using coarse and absent calibration on the phased array front-end. We also run experiments without accounting for non-uniform antenna radiation patterns discussed in Section 4. As mentioned previously, such imperfections have little effect on the location and power of the main lobe, but will lead to significant errors in null forming [43]. Fig. 15a, shows a CDF of the nulling performance. Without accounting for hardware imperfections, the median nulling is only 10 dB which is 17 dB worse than Nulli-Fi. With simple coarse calibration, the performance already improves by 7 dB. The figure also shows that while ignoring the non-uniform radiation patterns is not as severe, it still reduces the median nulling performance by 3 dB compared to Nulli-Fi. Finally, Fig. 15b shows the sensitiv-

[6]The baselines might also converge in a single iteration if the desired null happens to align with a natural null in the beam pattern.

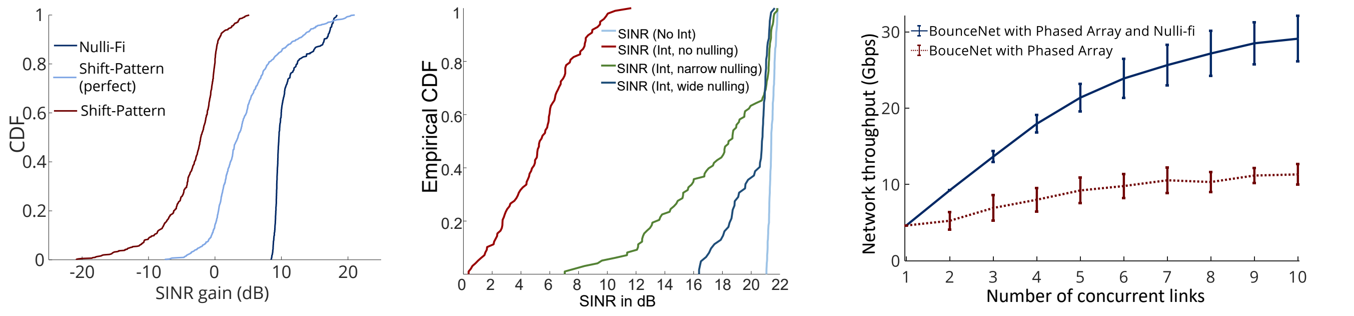

Figure 16: (a) Nulli-Fi's SINR gain over shifting the pattern baseline. (b) Nulli-Fi's ability to steer to and suppress interference. *Int* in the legend indicates the presence of interference. (c) Nulli-Fi's network throughput gains in dense networks

ity of Nulli-Fi's performance to errors in calibration. While the performance degrades as the calibration error increases, the figure shows that Nulli-Fi is robust to calibration errors less than 5° and can still null even if the calibration errors are 30°. It is worth noting that the degradation is less sharp in the case of 2 bit phase shifters. This is likely due to the fact that the phase is highly quantized and hence any calibration error is within the quantization errors.

6.4 Suppressing Interference & Improving Throughput

In this section, we present results for Nulli-Fi's ability to steer the null to suppress interference.

1. Null Steering Algorithm: Here we show the performance of Nulli-Fi's ability to suppress new, unforeseen interferences. To this end, we implemented Nulli-Fi on mm-Flex [33], and we ran close to 700 experiments with different relative locations, power levels for the interference. The experimental setup of this part was explained in section 5.

Fig. 16(b) shows the CDF of Signal to Interference plus Noise (SINR) ratio under four different conditions. As revealed by the figure, throughout all experiments, we set the SINR for when there is no interference to around 21 dB. By introducing the interference (shown by the maroon curve) whose location and power is unknown to the system, the SINR drops to as low as < 1 dB. Then, by running Nulli-Fi's null steering algorithm as described in section 4.3, Nulli-Fi chose and suppressed the side lobes one by one in order to restore the original SINR. The algorithm would stop once it reached within 1 dB of the original SINR, or it suppressed each side-lobe once (up to 10 side lobes).

We did this experiment in two regimes of narrow (2°) and wide (10°) nulls, shown by green and dark blue curves respectively. As seen in both curves, Nulli-Fi can improve the SINR by a median of 13 dB and 15 dB for narrow and wide nulls respectively [7]. We therefore see that Nulli-Fi is able to bring the SINR very close to its original value in the absence of the interferer in all cases. This shows that it is sufficient to look for interference only at the side lobes, as opposed to performing a full scan.

[7]These experiments were run in the IMDEA networks lab. We found that the SINR gains of Nulli-Fi + mm-Flex is around 3-5 dB larger than Nulli-Fi alone due to a slightly different hardware setup and a lower noise floor

We mention a trade-off between using narrow (2°) and wide (10°) nulls. We expect wide nulls to have a higher chance of capturing the interference, albeit with lower suppressing power as we showed in section 6.3. We see here that this is indeed the case: Compared to narrow nulls, wide nulls have a higher chance of capturing the interference, while narrow nulls suppress the interference better. This is also reflected by the tails of the green and the dark blue curves in Fig. 16 (b). We also compare the runtime of Nulli-Fi's algorithm against the baseline of fully scanning all angles. The numbers are reported using the fast beam switching and RSS measurement technique implemented in [33]. We see that Nulli-Fi's algorithm run on average in 290 nano-seconds, with a standard deviation of 115ns, which is more than 10× faster than a full search scheme, whose average and standard deviation for running time are 3.280 and 1.616 μs, respectively.

Finally, we compare Nulli-Fi's performance in gaining SINR with the Shift-Pattern baseline. We fix the signal and the interference power, and we move the interferer to different angles, and run 100 experiments to measure the gain in SINR. We compare Nulli-Fi with this baseline in two cases. In the first case, *Shift-Pattern (perfect)*, we assume perfect knowledge of the beam pattern, in which case Shift-Pattern chooses the best (deepest) null direction out of all direction within an interval of 10 degrees around the current pattern. We note that although this always reduces the power at the desired null location, it may lead to significant losses in the mainlobe, as we can see in Fig. 16(a). Things get even worse once we use the theoretical beam pattern to predict the optimum shifting amount (*Shift-Pattern*), which almost always results in a loss of SINR, due to inaccuracy of the theoretical beam pattern in predicting the real one. Nulli-Fi, on the other hand, always gives at least $8dB$ improvement in SINR, outperforming both versions of the baselines in almost all cases. This shows that simply shifting the pattern does not work in a practical system, since by shifting towards a null, we also shift the main lobe away from the direction of communication.

2. Throughput in Dense Networks: Fig. 16(c) demonstrates

No. of Links	Max Gain	90^{th} Perc. Gain	Median Gain	No. of Links	Max Gain	90^{th} Perc. Gain	Median Gain
1	1×	1×	1×	6	3.60×	2.83×	2.33×
2	2×	2×	1.58×	7	3.50×	2.72×	2.38×
3	3×	3×	1.8×	8	3.38×	2.94×	2.41×
4	4×	2.86×	2.12×	9	2.97×	2.77×	2.44×
5	4.16×	2.81×	2.27×	10	3.09×	2.68×	2.43×

Table 2: Gains in Total Network Data Rate from Nulli-Fi

Nulli-Fi's performance gains in dense networks. To do so, we implement and compare with BounceNet [27] which exploits the directionality of mmWave phased arrays to enable dense spatial resuse. We incorporate Nulli-Fi's nulling into BounceNet. Fig. 16(c) plots the total network data rate as the number of links in the network increases from 1 to 10. We compare Nulli-Fi against a regular phased array testbed using standard codebook-based beam patterns without interference nulling. As seen in the figure, due to significant interference in dense networks caused by side lobe leakages and multipath, a regular phased array equipped testbed can achieve only up to 11.31 Gbps network data rate for 10 links. Nulli-Fi, on the other hand, can effectively null out interference at each link and can increase the total data rate for the same phased array testbed to 29.1 Gbps, providing a gain of 2.6×.

In Table 2, we present further statistics on the gains in total data rate achieved by Nulli-Fi over a regular phased array testbed for different number of links n in the network. For each n we perform 100 different experiments by randomizing the client and AP positions. The result shows that for up to $n = 4$ communication links, Nulli-Fi can achieve the maximum possible gain of $n\times$ over the vanilla phased array testbed. Thus, in certain experiments Nulli-Fi was able to get all 4 links to communicate simultaneously by nulling out interferences, whereas the regular phased arrays were not able to exploit any spatial reuse whatsoever due to side lobe leakages and interference. Note that this gain saturates and begins to fall as the number of links increases due to increased interference. Nonetheless, Nulli-Fi is still able to achieve gains as high as 3.09× in network data rate for 10 links in the network. Table 2 also shows results for 90^{th} percentile and median gains.

7 Discussion and Limitations

In this paper, we introduced novel algorithms that significantly boost the convergence speed and improved the nulling performance compared to past work. Furthermore, the system enabled the first practical implementation of null steering by accounting for hardware restrictions, incorporating hardware imperfections and achieving wide and multiple nulls.

Importance of Convergence Speed: One might wonder, however, why having a faster algorithm is important in practical network deployments. The reason has to do with today's commercial phased array hardware. In particular, the hardware typically stores a codebook of different beam patterns in the on-board memory, and the mmWave radio beams towards different directions by reading the precomputed phase shift values from the codebook. As such, it is not possible to store precomputed beam patterns for all combinations of main-lobes and nulling directions. For instance, if we consider beam patterns with just one null, we would need to store a beam pattern corresponding to each main-lobe direction and each null direction, so a total of 180×180 beam patterns to achieve a null accuracy of 1 degree. This requirement grows exponentially with the number of nulls and would require gigabytes of memory for more than 2 nulls. Compare this to today's millimeter wave phase array that can store 16 to 256 codebooks. Hence, pre-computing and storing the beam patterns is not feasible. This is precisely why it is important to have an efficient algorithm that can converge quickly and compute the required beam patterns in real-time operation. This can allow even further optimization of the beam pattern at run-time which was not possible earlier in the codebook approach. Therefore, the speed of convergence is an important metric in evaluating the different nulling algorithms.

Limitations. We point out a few matters worth considering.

• In this paper, Nulli-Fi enables nulling the interference at the receiver. This is because it is easy for receivers to sense the direction of interference and change their beam pattern to suppress it. That said, there is an opportunity to perform nulling from the transmitter side where the transmitter creates a null in its beam pattern to suppress its own signal in direction of other receivers. This, however, would require an efficient protocol that allows the transmitter to discover the direction of those other receivers at which it is creating interference. Performing nulling from both transmitter and receive side would further improve the performance of the network. However, we leave that for future work.

• Once Nulli-Fi successfully nulls an interferer, it may not sense when it disappears. As a result, if new interferers appear, Nulli-Fi may not know whether to create more nulls or to switch the direction of the null. This can potentially be solved by periodically checking each nulled region for the presence of interference when it is not receiving packets.

• Nulli-Fi's framework is designed for phase shifters that use analog beamforming, which is common for commercial, practical phased arrays. While digital beamforming introduces a substantial overhead in terms of cost and power consumption, the in-between class of hybrid beamforming allows for more flexibility in terms of nulling. Exploring nulling in hybrid beamforming is left for future work.

A Appendix

A.1 Pseudocode

Here we present pseudo codes to Nulli-Fi's algorithms discussed in section 4.

Algorithm 1: OPTIMALNULLING($N, \phi, \phi_0, d, \lambda, \alpha^*$)

```
$\theta \leftarrow 2\pi \frac{d}{\lambda}(cos(\phi) - cos(\phi_0))$;
$v_P \leftarrow \exp(j\frac{N-1}{2}\theta)$;
for n in range($N$):
    $v_n \leftarrow \exp(jn\theta)$;
    $\Delta\alpha_n \leftarrow 0$;
for $n$ in range($\frac{N}{2}$):
    if $|\angle(v_P, v_n) - \pi| < \alpha^*$:
        $\Delta\alpha_n = \pi - \angle(v_P, v_n)$;
    $\Delta\alpha_{N-n-1} = \angle(v_P, v_n) - \pi$;
    elseif $\angle(v_P, v_n) < \pi - \alpha^*$:
        $\Delta\alpha_n = \alpha^*$;        $\Delta\alpha_{N-n-1} = -\alpha^*$;
    elseif $\angle(v_P, v_n) > \pi + \alpha^*$:
        $\Delta\alpha_n = -\alpha^*$;        $\Delta\alpha_{N-n-1} = \alpha^*$;
    if $\angle(v_P, \sum_{n=0}^{N-1} v_n \exp(j\Delta\alpha_n)) \neq 0$:
        return 0;
return $|\sum_{n=0}^{N-1} v_n \exp(j\Delta\alpha_n)|$;
```

Algorithm 2: CHOOSESUBSET(N, q)

```
S $\leftarrow \emptyset$;
$(\alpha_0, \cdots, \alpha_{N-1}) \leftarrow$ ideal phase shifts for main lobe;
for $n$ from 0 to $N-1$:
    if $\alpha_n$ is within $t$ degs of an available phase shift:
        add $n$ to $S$;
return $S$;
```

A.2 Phase Calibration

Here we explain Nulli-Fi's phase calibration in detail. In order to calibrate for the difference in the lengths of the wires coming out of each antenna element, we pick one reference antenna element i^*, and calibrate the remaining antennas with respect to this reference. Note that, the process of calibration is finding the additional phase shift one has to apply to antenna j in order to bring it in phase with the reference antenna i^*. To do so, we run a series of simple experiments as follows. We note that throughout the all of these experiments, transmitter and receiver are directly facing each other.

- First, for a fixed i, $0 \leq i \leq 15$, we turn off all antenna elements except i. We then apply phase shifts to the weight of antenna element i over time to cover all the possible phase values, and capture the received power over time. For antenna element i and its nth phase shift $\alpha_i[n]$, we denote the received signal amplitude by $a_i[n]$.
  We repeat this for all i from 0 to 15.
- We repeat the previous phase for all antennas i save for a chosen reference, i^*. Throughout these experiments, we keep element i^* turned on with a constant amplitude a_0, and for the experiment with element i and nth phase shift, we call the corresponding received amplitude $b_i[n]$. Now $b_i[n]$ is the sum of the signals received from i^* and i. If there is a α_{i,i^*} phase shift between the two elements, then we must have

$$b_i(t) = |a_i(t) + e^{\alpha_{i,i^*}} a_0|,$$

Therefore we can find α_{i,i^*} by performing a simple binary search over all possible values in $[0, 360]$ degrees. An example of the two normalized curves, before and after calibration, is shown in Figure 17.

Algorithm 3: NULLI-FI-GENETIC

```
Initialize $\mathscr{A} = \{A_1, \cdots, A_M\}$ using
OPTIMALNULLING($N, \phi, \phi_0, d, \lambda, \alpha^*$);
if $q \leq 3$:
    $S \leftarrow$ CHOOSESUBSET($N, q$);
else:
    $S \leftarrow \{1, 2, \cdots, N\}$;
Limit the adaptive elements to $S$;
while not converged:
    for i from 1 to $M$:
        $f_i \leftarrow F(A_i)$;
    sort $A_i$ according to $f_i$;
    keep $\mathscr{A} = \{A_1, \cdots, A_{\eta M}\}$ and discard others;
  while $|\mathscr{A}| < M$:
        Randomly choose two chromosomes $A_i$, $A_j$;
        perform CROSSOVER($A_i$,$A_j$);
        Randomly mutate some $A$'s with prob. $p_m$;
output $A_1$.
```

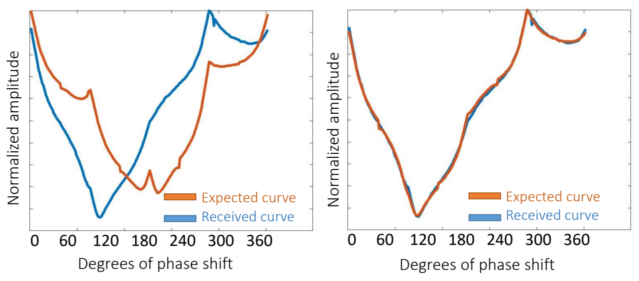

Figure 17: Expected versus measured power of two antenna elements before and after calibration.

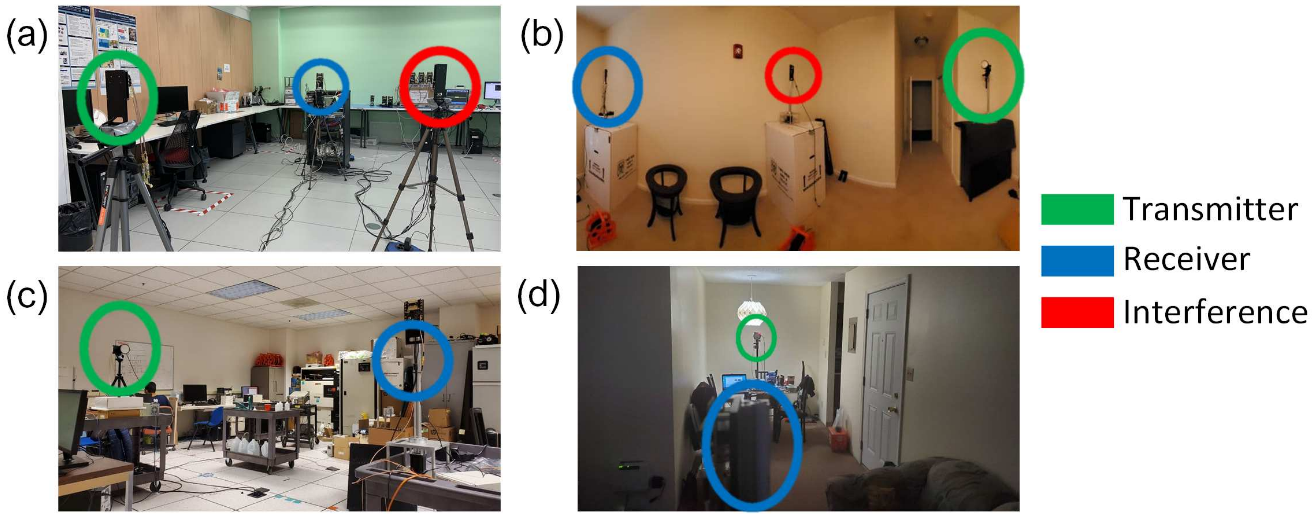

Figure 18: Different locations where we ran our experiments.

A.3 Experimental Setup

Experiment Locations. We ran our experiments in 4 different rooms shown in Fig. 18. Two locations (a, c) were inside a lab environment with many metal cabinets that contributed to multi path reflections. The other 2 locations (b, d) were different rooms inside apartments with many indoor objects. In all rooms, there were human subjects in the background during the experiment, thus constituting dynamic environments.

Nulli-Fi + mm-Flex. One transmitter/receiver pair are implemented using a single FPGA device in a full-duplex manner, i.e. transmitter and receiver functionalities are used at the same time. This pair corresponds to the transmitter and the receiver implementing Nulli-Fi.

We use a second FPGA (mounted on the same hosting chassis) which serves as the interferer. Since both FPGAs are mounted on the same chassis, long cables (5m) are used to carry the baseband signals to the corresponding transmitting antennas (the one transmitting the packets of interest and the one from the interferer). Therefore, with this setup, we are able to easily cover indoor scenarios.

Both FPGAs are managed from a control and management processor integrated in the same hosting chassis. This is used to send/receive frames to/from each baseband processor, configure ADCs/DACs, IP blocks, as well as the setup for the 60GHz Siversima RF-frontends.

A.4 Further Analysis of Nulling Performance

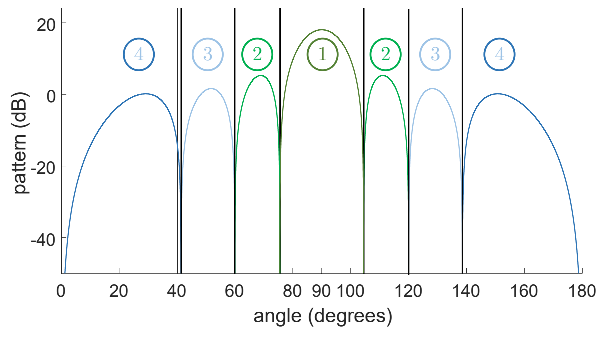
Closed Form Solutions. Alg. 1 offers a step by step solution to find nulls. It is also possible to find closed form solutions for bounds of achievable nulling performance as a function using the algorithm. This can be done by going thorough the algorithm with by keeping the symbol ϕ as opposed to setting it to a specific value. Doing so will result in explicit formulas for the angles for which perfect nulling is possible. For the angles that perfect nulling is not possible, we can find explicit formulas that determine the deepest possible nulls as a Piecewise-defined function of the angle ϕ. Different cases of this piecewise-defined function are separated by the naturally occurring nulls in the original beam pattern. An example of this for $N = 8$ antennas is shown in Fig. 19(a) where there are four cases separated by natural nulls, with each case having its own piecewise formula. For example, Theorems A.1 and A.2 show examples of closed form solutions for nulling around the main lobe as a function of number of elements N, angle of nulling ϕ, the main lobe angle ϕ_0, and the maximum phase shift allowed on each antenna α^*:

Theorem A.1 *The two closest perfect nulls to the main lobe given a maximum phase shift of α^* for each element are given by* $\phi^* = \arccos\left(\cos(\phi_0) \pm \frac{\lambda}{Nd}(1-\frac{2\alpha^*}{\pi})\right)$.

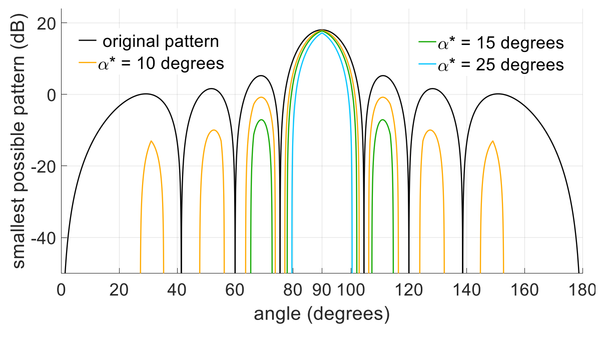
Theorem A.2 *For the area around the main lobe that perfect nulling is not possible, the deepest possible null at direction ϕ is given by* $N\cos(\frac{N}{4}\theta+\alpha^*)$, *where* $\theta = \frac{2d}{\lambda}(\cos(\phi)-\cos(\phi_0))$.

Specifically, Theorem A.1 determines the areas where perfect nulling is possible, and Theorem A.2 determines the deepest possible nulls for angles where perfect nulling cannot be achieved. For $N = 8$, these formulas correspond to the case 1 in Fig. 19(a). Following similar methods demonstrated in the proofs of these theorems in section A.5 we can find explicit formulas for other cases too.

Using the closed form formulas, we have plotted the best achievable nulling performance (i.e., the lowest possible value of the pattern P for each angle) for $N = 8$ antennas, and $\alpha^* = 10, 15$ and 25 degrees in Fig. 19(b). As revealed by



(a)



(b)

Figure 19: (a) The closed form solutions for the single null problem are piecewise-defined functions, with the cases separated by the nulls naturally occurring in the original pattern. Here there are four color-coded cases each corresponding to their own explicit formulas. For instance, Theorems A.1 and A.2 determine the best possible nulling for case 1. (b) Best achievable nulling performance for $N = 8$ elements are depicted for different angles and values of α^*. when a curve is not present at an angle, perfect null (i.e. $P = 0$) is achievable there.

the figure, there is a trade-off between how much we lose in the main lobe, and how strongly we can null different angles. For instance, while $\alpha^* = 15^\circ$ ensures a maximum main lobe loss of 0.3 dB, there are certain regions depicted by the green curve that cannot be nulled. As can be seen, for lower α^* (orange curve) there are more regions that cannot be nulled, while a higher α^* (blue) shows only an area around the main lobe that cannot be nulled. Since Alg. 1 is optimal, we believe it can help decide the degree of trade-off in different applications. This is especially useful as these curves also define as a stopping criterion for our algorithms especially when we lump in the hardware imperfections into the optimization problem. For example if we know that it is not possible to get a nulls stronger than 20 dB in the ideal case (i.e., without hardware imperfections), we can expect that with hardware imperfections the nulling performance cannot get far beyond 20 dB, as we explain in section 4.2.

Alternative Algorithms. In the walk-through example with 6 antennas in section 4.1, the final configuration of the antennas is shown in Fig. 4 (b4). As can be seen from the figure, pairs $\{0,3\}$, $\{1,4\}$ and $\{2,5\}$ are perfectly canceling each other, yielding a null. Looking at this configuration, one might wonder if we can always try and create *pairs* of opposing vectors, such that the sum of every pair is zero. However, it is possible to construct examples where this solution does not work, but Alg. 1 achieves a perfect null. In fact, for larger values of N, it is possible to construct examples in which no set of $K < N$ vectors sum to zero while the sum of all N vectors is still zero. For further information, we refer the interested reader to our git repository where we have implement and compare these algorithms.

A.5 Proofs

Proof of lemma 4.1. We align the main lobe toward some angle ϕ_0, and therefore the signal coming from that angle will sum up coherently. Specifically,

$$|P|^2 = \left|\sum_{n=0}^{N-1} e^{-2\pi j \frac{d}{\lambda} n\cos(\phi_0)} e^{j\alpha_n}\right|^2 = \left|\sum_{n=0}^{N-1} 1\right|^2 = N^2.$$

Imposing additional phase shifts $\Delta\alpha_n$ in order to enable nulling would give us:

$$\begin{aligned}|P'|^2 &= \left|\sum_{n=0}^{N-1} e^{j\Delta\alpha_n}\right|^2 \\ &= \left(\sum_{n=0}^{N-1}\cos(\Delta\alpha_n)\right)^2 + \left(\sum_{n=0}^{N-1}\sin(\Delta\alpha_n)\right)^2 \\ &\geq \left(\sum_{n=0}^{N-1}\cos(\alpha^*)\right)^2 + 0 = N^2\cos^2(\alpha^*)\end{aligned}$$

since $|\Delta\alpha_n| \leq \alpha^* \leq 90^\circ$. Hence, $|P'|^2 \geq |P|^2\cos^2(\alpha^*)$ and the loss in the main lobe power is at most $1 - cos^2(\alpha^*) = sin^2(\alpha^*)$.

Proof of lemma 4.2. Replacing θ, we get $v_n = e^{jn\theta}$. Since they are unit vectors, v_k and v_{N-1-k} are symmetric around their sum. Further, we have

$$\begin{aligned}\angle(v_k + v_{N-i-k}) &= \angle(e^{jn\theta} + e^{j(N-1-n)\theta}) \\ &= \angle\Big(e^{j\frac{N-1}{2}\theta} \times 2\cos(\frac{N-1-2n}{4})\Big) \\ &= \angle e^{j\frac{N-1}{2}}\theta + \angle\cos(\frac{N-1-2n}{4}\theta) \\ &= \frac{N-1}{2}\theta \pm \pi,\end{aligned} \tag{3}$$

where the last line follows from the fact that the phase of a real number is either 0 or π. Since the phase of these vector pair sums are the same (up to $\pm\pi$), so is the sum of all of them, P. This concludes the proof of the lemma.

Proof of Theorem 4.3. For a given nulling angle ϕ, we identify two possible cases. First, if it is not possible to create a perfect null at ϕ, and second, if it is possible to create a perfect null at ϕ.

- In the first case, Alg. 1 does not stop until all vectors $v_0, \cdots, v_{N-1}$ have rotated by $\pm\alpha^*$. In this case, following the exact same argument in the proof of Theorem 4.4, Eq. 6 hold with equality, which means that the best nulling performance is achieved.
- In the second case Alg. 1 where nulling is possible, at some point in the algorithm, $\nu = \angle(v_P, \sum_{n=0}^{N-1} v_n \exp(j\Delta\alpha_n)) \neq 0$ should at some point return π. Otherwise, it remains 0 until the end, in which case nulling should not be possible, contradicting our assumption. Therefore, a some point in the algorithm, $\nu \neq 0$, so the output of the algorithm will be 0, meaning it predicts a perfect null.

In both cases, the output of the algorithm gives the best nulling performance, proving that the Alg. 1 is optimal.

Proof of theorem A.1. For a given ϕ, assume an x-y coordinate for the complex plane, such that $\angle P(\phi) = 0$. In this coordinate, let each vector v_k have the representation (x_k, y_k). We are looking for the first possible ϕ for which there exists a set of additional phase shifts, $\Delta\alpha_k$, such that $P(\phi) = (0,0)$. In its general form, P is expressed as

$$\begin{aligned}
P(\phi) &= \sum_n v_n e^{j\Delta\alpha_n} \\
&= \Big(\sum_n \cos((n - \frac{N-1}{2})\theta + \Delta\alpha_n), \sum_n \sin((n - \frac{N-1}{2})\theta + \Delta\alpha_n)\Big) \\
&= \Big(\sum_n x_n, \sum_n y_n\Big),
\end{aligned} \tag{4}$$

where θ is defined according to section 4.1. Note that

$$\begin{aligned}
x_n^* &:= \min\{\cos((n - \frac{N-1}{2})\theta + \Delta\alpha_n) \mid -\alpha^* \leq \Delta\alpha_n \leq \alpha^*\} \\
&\in \{-1, \cos((n - \frac{N-1}{2})\theta \pm \alpha^*)\}.
\end{aligned} \tag{5}$$

Further, we can bound the absolute value of the pattern P as follows.

$$\begin{aligned}
|P(\phi)|^2 &= \big(\sum_n x_n\big)^2 + \big(\sum_n y_n\big)^2 \\
&\geq \big(\sum_n x_n^*\big)^2,
\end{aligned} \tag{6}$$

where we have bounded the second term with zero. This inequality holds as long as $\sum_n x_n^*$ is positive, which is true around the main lobe, before the first possible null.

Let us rotate each vector v_n to get x_n^* as its x component. Using lemma 1, v_n rotates by $\pm\alpha$ if and only if v_{N-1-n} is rotated by $\mp\alpha$. This means that the two vectors remain symmetrical around the x axis. Therefore, we will necessarily have $\sum_n y_n = 0$, bringing equation 6 to an equality. Hence, as long as $\sum_n x_n^* > 0$, nulling is not possible.

The first point at which nulling becomes possible can therefore be derived by finding the solution to $\sum_n x_n^* = 0$. Using equation 5 combined with lemma 1, we get

$$\sum_{n=0}^{N-1} x_n^* = 2 \sum_{n=0}^{\frac{N}{2}-1} \cos((n - \frac{N-1}{2})\theta + \alpha^*) = 0, \tag{7}$$

The solution to which is $\theta = \pm\frac{2}{N}(\pi - \alpha^*)$, or its corresponding ϕ value given in the theorem.

Proof of Theorem A.2. Using Theorem 4.3, we have to run the output of the algorithm for the assumptions in this theorem. Since nulling is not possible, the algorithm will run from 0 to $N-1$, yielding vectors $\cos(n\theta + \alpha^*)$ for $0 \leq n \leq \frac{N}{2} + 1$, and $\cos(n\theta - \alpha^*)$ for $\frac{N}{2} + 1 \leq n \leq N-1$. Summing them up, we get the result in stated in the theorem.

SyncScatter: Enabling WiFi like synchronization and range for WiFi backscatter Communication

Manideep Dunna, Miao Meng, Po-Han Wang, Chi Zhang, Patrick Mercier, Dinesh Bharadia

University of California, San Diego

Abstract

WiFi backscattering can enable direct connectivity of IoT devices with commodity WiFi hardware at low power. However, most existing work in this area has overlooked the importance of synchronization and, as a result, accepted either limited range between the transmitter and the IoT device, reduced throughput via bit repetition, or both. In this paper, we present SyncScatter, which achieves accurate synchronization with incident signals at the IoT device level while realizing maximum possible sensitivity afforded by a backscatter link budget. SyncScatter creates a novel modeling framework and derives the maximal optimal range and synchronization error that the receiver can tolerate without significant performance compromises. Next, SyncScatter builds a novel hierarchical wake-up protocol, which, together with a custom ASIC, achieves a range of 30+ meters and the peak throughput of 500Kbps, with an average power consumption of 30μW.

1 Introduction

Ubiquitous wireless network coverage is required to enable the next-generation of Internet of Things(IoT) devices. In smart homes, offices, industrial environments, and more, WiFi is by far the most ubiquitous form of connectivity. However, enabling WiFi connectivity at the IoT device level requires high power consumption - to the point where most such IoT devices must be either plugged into wall power, must use large and frequently re-charged batteries, or simply cannot afford to transmit data at high average throughput [13, 22].

Recent work has proposed using backscatter communication techniques to reduce power, which forgoes direct WiFi signal generation by instead modulating data on top of ambient WiFi transmissions generated by existing access points (APs) [10, 40]. There are three components to backscattering systems: 1) the transmitting radio which generates the excitation signal; 2) the IoT device which reflects the incoming signal by encoding its information, and 3) a receiving radio (WiFi-compatible) which receives the packets and decodes the data from the IoT device. By avoiding any signal generation or amplification directly at RF, the power consumption of backscatter communication can be low - on the order of microwatts - such that small energy harvesters or batteries can directly power the IoT devices.

Existing work on WiFi-backscattering can be broadly classified into two major categories: the first set of WiFi-backscattering is inspired by the RFID style of backscatter communication systems [8, 21], wherein a tone-generator is deployed as the excitation radio. This gives the IoT device the freedom to begin backscattering at any time it likes, along with the freedom to create any backscattered waveform like WiFi to encode its information. This tone-based backscattering approach requires additional custom hardware - the tone generator - beyond commodity WiFi hardware, and thus deployment timelines and costs can be appreciable [21].

In contrast, the second set of works [40, 42] leverage existing WiFi infrastructure for both the excitation and receiving radios, therefore requiring no additional infrastructure deployment. In this approach, an existing WiFi radio's transmission is used as excitation signal, and the IoT device modulates the underlying data in the excitation signal in a specific manner according to the IoT device's data which is then reflected back to the environment. Properly backscatter modulated signals will retain a WiFi-compatible form, and therefore can be decoded by another WiFi radio. Ideally, the IoT device should synchronize itself to the incident signal, such that it knows precisely when to perform backscatter modulation. To ensure the superimposed data (i.e., the data from the incident source and the IoT device data) is readable by a commodity WiFi receiver, this synchronization should be down to the symbol level. Unfortunately, no prior work in WiFi backscatter synchronizes down to the symbol level [20, 21, 40].

Synchronizing to the symbol level with high-accuracy is challenging, as all ISM, including WiFi transmissions, are made up of complex digital waveforms at fairly high data rates. A large literature has worked on optimizing the power consumption of the synchronization routines in WiFi transceivers, which still takes considerable power [5]. Furthermore, the power consumption of synchronization increases exponentially to make it work at lower incoming signal power. Therefore, prior WiFi backscattering work such as Hitchhike [40] employs a very simply energy-detecting synchronization scheme that consumes low power but can only synchronize to an accuracy of 2μsec at an input power of $-20dBm$. Since the symbol rate in 802.11b WiFi is 1μsec, this means Hitchhike will effectively begin backscatter modulation at a random location within a symbol, which ultimately limits its achievable distance to be no more than 6m from the transmitter. Unfortunately, this comes directly at the cost of decreased achievable throughput, increased inter-symbol interference(ISI), and ultimately reduced communication range.

In this paper, we present SyncScatter, which is the first

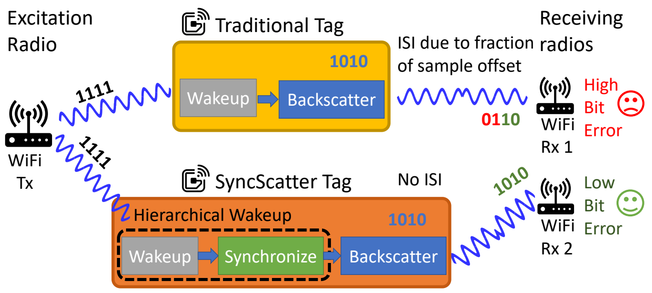


Figure 1: Shows a traditional tag form [40] which backscatter signal without accurate synchronization, leading to higher BER. In contrast the SyncScatter tag accurately synchronizes to the incoming signal.

integrated circuit-based backscattering platform that can enable symbol-level synchronization through a hierarchical wakeup and synchronization protocol, shown in Fig. 1, which works up to theoretical sensitivity levels. Such symbol synchronization enables longer range, higher-throughput, and more reliable backscatter communication than prior art for all forms of communication (not just WiFi). Here, we specifically built and prototyped SyncScatter to demonstrate the first fully-WiFi-compatible symbol-level synchronized, long-distance, extremely low-powered backscatter system. Furthermore, SyncScatter can support multiple IoT devices to co-exist without interfering with each other. SyncScatter is designed on a custom ASIC, enabling ultra-low-power consumption.

In order to bound the design space, we begin the paper by asking some fundamental questions: how accurate does the synchronization need to be? How far away from the transmitter can we work? What sensitivity level should we target at that range? How do we do all of this while keeping power low? To answer the first question, we present analysis wherein we add increasing amount of synchronization error and observe the performance (SNR vs BER), and choose point where the gains are incremental beyond it. Then, we leverage FCC specifications on maximum available transmit power along with the minimum SNR required to decode a certain ISM backscatter, accounting for loss in backscattering and the noise figure of the corresponding receiver, to derive the maximum path loss, and therefore distance, a backscatter system could potentially work at. This analysis also gives us the sensitivity level needed at the backscattering tag, which as we will show turns out to be $-35dBm$. Importantly, we discuss how improving sensitivity beyond this level is wasteful. This is the first analysis of its kind that combines path loss, synchronization accuracy, and sensitivity.

The next natural question for SyncScatter is how to achieve the required tight synchronization accuracy and desired high sensitivity while consuming microwatts of power? To keep power low, a direct envelope-detector (ED) approach is typically used; however, such a system's sensitivity typically reduces with increasing bandwidth. Since achieving a high synchronization accuracy requires high bandwidth, this poses a direct trade-off between accuracy and sensitivity. The only way to break this trade-off is to add RF amplification before the ED. However, this can cost significant power - upwards of 100s of microwatts.

To break this trade-off, our key insight is to create a two-stage, hierarchical wake-up and synchronization protocol, wherein a first stage (the wake-up receiver) is designed with single-digit microwatt power and leverages low-bandwidth energy detection to simply wake-up the tag at approximately the right time, at which point a second stage (the synchronization receiver) uses higher-power active RF amplification to enable the desired sensitivity at the desired bandwidth, but is turned on only for a short time to synchronize, and is powered down immediately post synchronization. SyncScatter creates a new protocol where two packets with controlled length are sent apriori to backscattering. The time duration of the two packets encodes the tag's identity, which results in an enable signal from the first stage wake-up receiver. The second stage turns on just before the start of the backscatter payload packet, samples the incoming signal at high bandwidth, looking for the beginning of the packet and the symbol boundary, and then promptly goes to sleep. Once symbol-level synchronization is achieved, the backscatter modulation logic reflects the incoming signal by overlaying its data in a synchronized fashion.

SyncScatter specifically builds an RF integrated circuit and hardware design for the entire hierarchical wake-up protocol, along with single-sideband backscattering circuits, which can backscatter any ISM 2.4 GHz signals. SyncScatter's WiFi transmitter and receiver are implemented using open-wrt [25] on TP-Link devices. SyncScatter is evaluated in indoor office environments to achieve the following results:

- SyncScatter achieves a sensitivity of up to -35 dBm via the custom integrated circuit, with a synchronization accuracy of 150 ns, which enables a 30+ meter link operation as measured in a regular office environment. As a result, the longer wake-up distance offered by SyncScatter allows the use of WiFi APs deployed in a typical home or office environment without requiring additional smartphones, unlike in HitchHike [40].
- SyncScatter tag enables symbol-level synchronization at very low power consumption by utilizing a hierarchical wake-up receiver with a false negative rate of 10^{-3}.
- SyncScatter tag supports backscatter communication over a wide range of the transmitter(Tx) to tag and receiver(Rx) to tag distances whose product is $\leq 169\ m^2$, i.e., 13m from Tx and 13m from Rx or 33m from Tx and 5m from Rx.
- SyncScatter supports multiple tags running concurrently and supports 802.11b waveforms, modulating at symbol level providing peak bit-rates of 500 Kbps.

2 Synchronization & Sensitivity Requirements

This section introduces a model that helps scope out requirements for the custom IC designed for WiFi backscattering. The methodology presented herein could also be used to design any ISM backscatter systems.

2.1 Synchronization Requirements for WiFi

Synchronization is at the heart of all communication systems, and must be thought through carefully, even for backscatter systems (at least, ones that do not use tone generators, like fully WiFi-compatible systems). In this sub-section, we specifically discuss the need for synchronization and establish the minimum required synchronization accuracy, which is needed for minimal performance reduction in a fully WiFi-compatible backscatter system.

To describe the synchronization problem we are solving, we will start with a brief discussion of the problem with a figure, specifically on a representative 802.11b signal in Fig. 2. To backscatter a valid 802.11b signal, the tag performs code-word translation on the ambient 802.11b packets, similar to [40]. The tag embeds its data on the ambient 802.11b WiFi packet by changing the phase of each of the 802.11b symbols in the packet. The resulting backscattered signal is a product of the incident signal and the tag's phase modulation. Therefore, changing each symbol's phase ensures that the chip sequence on each symbol retains the 11-bit barker code and backscatters a valid 802.11b signal, which is then decodable by the WiFi receiver without inter-symbol interference shown on the right.

As observed in [40], the HitchHike tag, and in fact all past work that backscatters ambient signals, do not accurately synchronize with the incoming transmitter signal and therefore applies code-word translation with incorrect boundaries shown in the Fig. 2 left. Misalignment between the backscatter symbol timing and the original symbols in the 11b packet will start to change the barker code, which hurts the signal to interference ratio and, therefore, hurts the receiver's ability to decode the backscatter packet and can result in errors.

To quantitatively understand the impact of synchronization, we emulate the backscatter system wherein we transmit the reflected packet using an SDR while intentionally adding an increasing amount of synchronization error from 0 ns to 625 ns as shown in Fig. 3a. The synchronization errors are added after the header of the transmission, as the backscattered payload is applied only after the header. The transmission is received using an off-the-shelf WiFi AP. We measure 10000 packets with backscatter payload in a total of 1 million bits to generate the SNR to BER plot. As we can observe, synchronization errors up to 150ns do not lead to significant BER degradation. However, errors beyond this can lead to 7dB or more degradation.

A natural question is how did past work resolve this issue. Due to power-related issues that we will discuss shortly, prior work such as [40] achieved synchronization accuracies of anywhere from 1 to 10 μsec, which is well beyond the symbol period. This means that the backscattered signal modulated on top of the existing WiFi packet will have a random phase offset for each packet. To combat this problem, [40] uses a

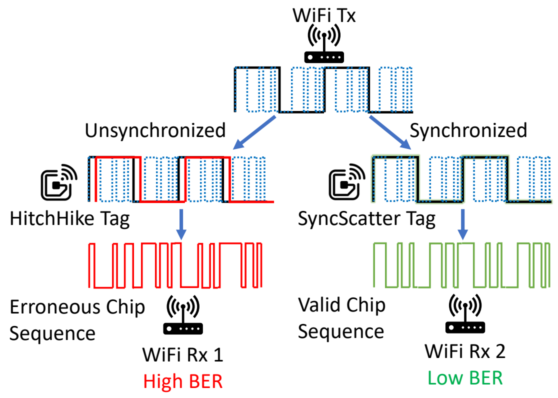

Figure 2: Impact of in-accurate synchronization, and resulting loss in signal quality at the receiver.

preamble to help the receiver find the start of backscatter data in the packet and decode the tag data. Further, to ensure proper decoding of tag data, each tag data bit is repeated multiple times(repetition coding), reducing the available throughput. Said differently, it would lose significant SNR gain due to lack of synchronization. A more severe consequence is that the CRC(cyclic redundancy check) of the packet often fails with past work. Instead, we can ensure CRC checks can be met with proper synchronization, enabling more WiFi cards as receivers while simultaneously enabling higher average channel throughput.

Generalization of Synchronization requirements to other wireless standards: An obvious next step is to know the synchronization requirements for backscatter systems based on different wireless standards like BLE(Bluetooth low energy) and 802.11g WiFi. In BLE transmissions, a data bit 0/1 is encoded as different frequency modulated sine tone signals. Backscatter tag modifies the frequency of sine tones present in the BLE symbols to encode backscatter data on top of BLE packets. The backscatter encoder must know the symbol boundaries to ensure that backscattering is successful. Otherwise, the backscatter data is spread on two consecutive symbols, and the receiver fails to decode the packet. Similarly, 802.11g WiFi backscatter systems encode data on top of an OFDM symbol by changing the signal phase. Hence the backscatter encoder must be aware of the OFDM symbol boundaries. To understand the synchronization delay's impact, we perform Matlab simulations of backscattering BLE and 20MHz standard OFDM signals as given in [42] and introduce synchronization(sync) delay while finding symbol boundaries. Our simulations reveal that BLE backscatter loses 4 dB SNR at 10^{-3} BER for 100 ns sync delay and can tolerate up to 50 ns sync delay(More details in Appendix 9). On the other hand, OFDM backscatter can handle up to 1000 ns sync delay and lose more than 10 dB SNR at 10^{-3} BER for 1200 ns sync delay. These observations suggest that symbol-level synchronization is essential for backscatter systems based on other protocols as well.

Figure 3: (a) BER-SNR curve for different amount of synchronization errors, **(b)**Maximum distance analysis and operating point for IoT device sensitivity assuming a co-located Tx and Rx, **(c)** Received Signal Strength (RSS) measured at the SyncScatter tag vs. distance.

2.2 Sensitivity of the backscatter tags

For an IoT device to backscatter its data, it needs to detect the incoming signal from the excitation radio. Prior work has shown very short distance backscatter from excitation radio to the tag, for example, less than 6 meters for WiFi backscattering [20, 40]. Given the flexibility in the design parameters with integrated circuit design, we would like to understand better the sensitivity for which the backscatter tag should be designed to optimize for range while minimizing power consumption.

At the outset, the above question looks ill-posed. To simplify the above question and perhaps get a more coherent answer, let us take an example of the same 11b signals transmitted at 1 Mbps. To simplify the above analysis, we would assume the worst-case mono-static backscatter communication scenario, i.e., the transmitting radio and the receiving radio are co-located. The challenge with the backscatter system is that it suffers from two-way path loss. Specifically, the transmitter to the tag suffers a path loss of $\frac{1}{d^2}$. Then the signal is re-radiated back from tag to the receiver, which suffers a multiplicative path loss of $\frac{1}{d^2}$, which implies $\frac{1}{d^4}$ path loss (or additive in dB). Said differently, it would suffer the same loss as traveling quadratic distance.

With that analysis in place, we can leverage the maximum possible dynamic range by operating at the highest possible transmit power and minimum receiver sensitivity at which we can decode the packet. For WiFi at 2.4GHz, the maximum average transmit power is 24 dBm (11b has a peak power of 30 dBm and 6 dB of PAPR), while a receiver sensitivity to decode 1 Mbps is at -97 dBm as shown in Fig. 3b. Given a tag can have ideal insertion loss of 3dB, this provides a dynamic range of 24 dBm $-(-97$ dBm$) - 3$ dB $= 118$ dB for decode-ability. Assuming a worst-case range condition where the tag communicates with a co-located transmitter and receiver AP, this suggests operation with 59 dB of one-way path loss, for a worst-case incident signal power 24 dBm -59 dB $= -35$ dBm.

To find the path loss in indoor environments, we measure the received signal strength with increasing distance between the transmitter and IoT device, up to a point where the received signal strength at the IoT device goes below the threshold of -35 dBm, providing us the range up to which we expect the backscatter to work. Fig. 3c plots the received power with increasing distance, and received power or sensitivity of -35 dBm would provide the maximum range benefit, i.e., from 15 – 21 meters, one-sided range. Note that prior systems have achieved -15 dBm sensitivity, with 6 meters working range [40].

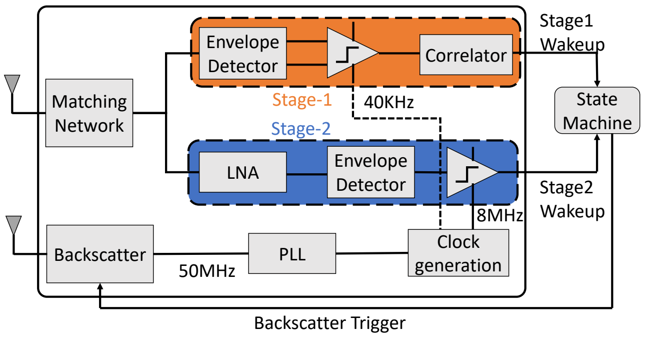

Figure 4: Design Overview of SyncScatter.

In summary, we need to achieve a sensitivity of -35 dBm beyond which the gains are incremental and concurrently achieve synchronization accuracy of 150 ns, all while keeping low power. Achieving this specification at the micro-watt level is extremely challenging.

3 SyncScatter Tag Design Overview

In this section, we describe the architecture of SyncScatter's tag and show how it can wake-up to properly-designed incident WiFi signals, perform symbol-level synchronization to said incident WiFi signals, and then perform backscatter modulation. This is accomplished by three separate subsystems: a wake-up receiver, a sync stage edge-detector, and a backscatter modulator as shown in Fig. 4.

In most prior works [40,42], the wake-up receiver and sync stage are combined into a single circuit. i.e., a single circuit is responsible for determining if an appropriate WiFi signal is incident on the tag and then indicating to the tag when to begin backscatter modulation. This is, however, a problematic approach if the tag desires low-power and sufficient sensitivity and synchronization accuracy, as these items all trade-off directly with one another. Thus, breaking wake-up functionality apart from synchronization functionality via the proposed hierarchical approach can serve to break this trade-off, enabling a low-power yet sufficiently sensitive and accurate design.

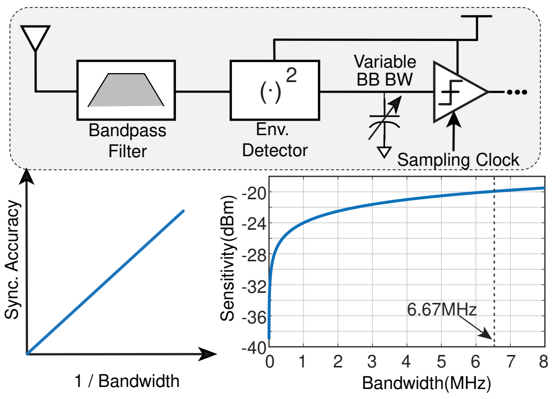

Figure 5: Analysis on Direct-Envelope Detector (ED) Structure

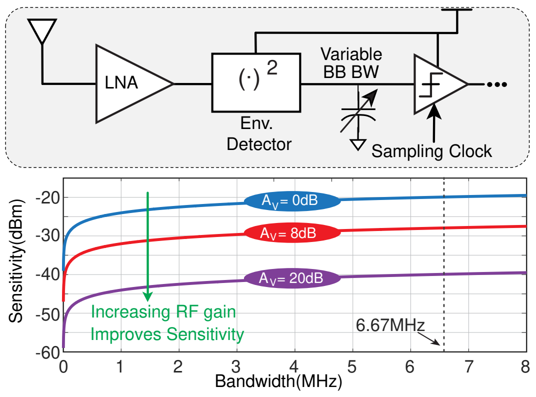

Figure 6: LNA Based ED Improvements

3.1 Sync Stage Receiver

As aforementioned, the best we can do given FCC WiFi transmitter power limitations and the best achievable WiFi receiver noise figure is to achieve a sensitivity at the tag of approximately −35 dBm. Achieving a sensitivity better than this does not improve the system's performance or range in any meaningful manner and is thus just wasteful. At the same time, we need to detect the symbol boundary of an incident WiFi packet with an accuracy of at least 150 ns. Again, doing better than this does not meaningfully improve performance. Thus, the design space here is: achieve these sensitivity and synchronization accuracy specifications while consuming as little power as possible.

To find the accurate symbol boundaries, we can use the fact that multiple symbols together constitute a packet. If we can somehow find the exact time instant at which the packet starts, we can determine the symbol boundaries by keeping track of the time elapsed from the beginning of the packet. The packet boundary is indicated by a change in the signal power received, and it can be used to find the start of the packet. Assuming we have already woken-up to a pre-specified WiFi signature (as described in the following section), we can then measure the instantaneous signal amplitude by passing the signal through an envelope detector (ED) and monitoring its envelope for a strong rising edge representing the beginning of the packet that will be backscatter modulated.

Before we present how we can perform necessary synchronization, it is first instructive to provide a brief overview of very low-power energy-detecting radio receivers. The simplest and lowest power receiver directly connects an antenna to an ED, whose output is low-pass filtered and then sampled. Fig. 5. shows a simplified block diagram of this approach. This approach's main benefit is that the ED can be passive and thus consumes zero power; this circuit's only power consumption is due to the sampler/comparator, which can be in the low single-digit microwatt regime. Note that this approach energy-detects everything at its input, and thus there is usually a filter at the input to ensure out-of-band interferers do not get demodulated.

The main design parameter in such a receiver is the baseband bandwidth, BW_{BB}, set by the combination of the effective resistance of the ED itself and its load capacitance as a simple first-order *RC* filter. The larger the baseband bandwidth, the more precise an ED will be able to detect a rising packet edge, and therefore the better the synchronization accuracy will be. To first order, this is a one-to-one trade-off, as shown in Fig. 5, assuming that the comparator is sampling at the Nyquist rate (i.e., 2× the baseband bandwidth). To achieve a synchronization accuracy of 150 ns, we would need a baseband bandwidth of at least 6.7 MHz.

However, the complication here is that the larger the baseband bandwidth, the larger the noise bandwidth becomes. As described in [18, 34], with no gain in front of the ED, the receiver's sensitivity is typically dominated by the noise of the ED itself. Interestingly, RF noise is immaterial in such a scenario because a passive ED's noise is so much larger than all downconverted RF noise. As a result, increasing the baseband bandwidth directly increases the noise, which degrades the sensitivity with a $5\log(BW_{BB})$ trade-off (where $5\log()$ instead of $10\log()$ is used to account for the squaring function of the ED). Specifically, the sensitivity of a direct-ED receiver is given by equation 1.

$$P_{sensitivity} = \frac{20}{k_{ED} * A_V^2}\sqrt{BW_{BB} * PSD_0 * SNR_{MIN}} \qquad (1)$$

where k_{ED} is the scaling factor of envelope detector, A_V is the front-end voltage gain (equals to 1 for a direct-ED receiver), PSD_0 is the output-referred baseband noise, and SNR_{MIN} is the required minimum signal-to-noise ratio. The result of this equation is plotted in Fig. 6 for representative values of k_{ED}, PSD_0, and SNR_{MIN} to be 250/V, 300 nV^2/Hz and 6 dB, respectively. Achieving a synchronization accuracy of 150ns requires a baseband bandwidth of 6.7MHz, which, as shown per these numbers, permits a sensitivity of at best −20 dBm. This is obviously unacceptable.

Since we cannot further reduce the noise floor of a passive ED, the only recourse is to either provide more voltage gain before the ED or build an active ED to reduce its noise floor. It turns out that building an active ED with sufficiently low noise is not only not easy but also only helps with a $5\log()$ benefit. On the other hand, providing voltage gain before the ED helps with a $20\log()$ benefit and is thus far more attractive.

In fact, it is possible, even at 2.4 GHz, to provide some amount of voltage gain completely passively through an impedance transformation network. For example, the π network (shown in Fig. 8a later) can take the 50 Ω antenna impedance and transform it to a 300 Ω impedance, theoretically giving $20\log(\sqrt{Z_o/Z_i}) = 8$ dB of "free" voltage gain without consuming power. As shown in Fig. 6, adding 8 dB of voltage gain improves the sensitivity by 8 dB for a net sensitivity of -28 dBm. This is still not good enough. Considering that the detector's impedance is of the order of $100k\Omega$, can we get more voltage gain if we build a better matching network? Unfortunately, the ability to do this is limited by the low-quality factor of components at high frequencies, along with parasitics - where for example, even 0.1 pF of parasitic capacitance presents as 600 Ω of impedance. Likewise, a 0.8 nH high-Q inductor from Coilcraft (0402DC-N80XR, Coilcraft, Illinois, USA) has $Q = 110$, which at 2.4 GHz is a series resistance of 25 mΩ, which limits Z_o to 300 Ω. Thus, it is very difficult to get much more than $\sim$8 dB of passive voltage gain at these frequencies.

As a result, the only remaining way to improve sensitivity is to add active RF gain. This is typically undesired by designers of backscatter tags, as the main purpose of doing backscatter modulation is to avoid having to build active circuits operating at RF since they tend to consume significant power. For example, in this work, we have built a custom RF amplifier into the integrated circuit, which provides a gain of 12dB for a power consumption of 240 μW. With the matching network, the provided gain improves the sensitivity by 20dB, which now meets the desired -40 dBm sensitivity specification (with some margin). However, while still significantly lower than the 10's to 100's of mW a typical WiFi transceiver would consume, the power consumption is still higher than desired.

We can now get to the key insight provided by SyncScatter: the high bandwidth needed for synchronization only needs to occur when we know we are about to backscatter - that is after we have already woken up. As a result, we only need to turn this RF amplifier on for a short amount of time to detect the rising edge of the packet to be backscatter modulated. We can shut-off the RF amplifier before and after this event. By duty-cycling the amplifier in this manner, we can cut down its average power consumption significantly. For example, the sync receiver needs to be turned on only for 50us throughout the 500 μs wakeup + 2000 μs data packet duration. The duty-cycled power, in this case, turns out to be $\frac{50}{2500} \times 240\mu\text{W} = 4.8\mu\text{W}$.

Again, the key insight in SyncScatter is that we can decouple the precise symbol level synchronization from the wake-up functionality, so that we can spend high power momentarily during symbol synchronization to achieve the desired bandwidth and sensitivity, while duty-cycling this down to low average power at times when we are not expecting the packet edge. Unlike other works which combine wake-up and synchronization in a single circuit, this work proposes a hierarchical method - where a low-power wake-up receiver is used to detect a WiFi compliant signature that indicates the next incident packet should be backscatter modulated, which then hierarchically turns on a sync stage receiver to provide the necessary high-bandwidth synchronization accuracy. This hierarchical approach, of course, only helps if we can design a wake-up path with low power and sufficient sensitivity, as will be described next.

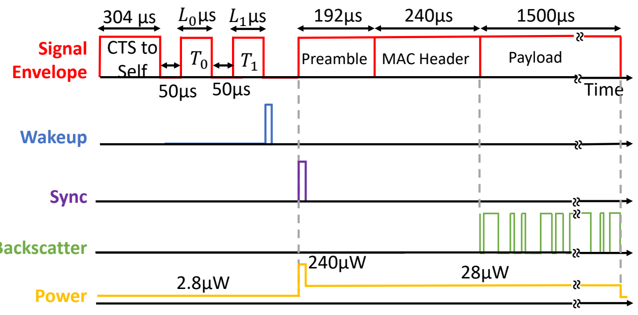

Figure 7: Timing Digram of SyncScatter.

3.2 Wake-up Receiver – First Stage

The wake-up stage's goal is to monitor the RF spectrum for a pre-specified set of packets that indicate the next packet is the one to be backscatter modulated. This should occur with the same sensitivity as the sync stage receiver, but ideally at much lower power since it must be on for potentially long durations of time while waiting to be triggered by a WiFi AP. If the wake-up stage is sufficiently low power, and the sync stage only needs to operate over a small duty-cycle, then the overall hierarchical approach can consume low average power.

The logical question is then: how can the wake-up path consume lower power and yet achieve the same sensitivity as the sync stage receiver? The answer is that the wake-up stage does not require the same amount of bandwidth since it is not being used to perform symbol-level synchronization. Reduced baseband bandwidth enables a reduction in the required amount of pre-ED RF gain to the point where no active RF amplification is needed, all while still meeting the desired -35dBm sensitivity level (with margin).

The wake-up pattern is constructed as follows. A WiFi-compatible identifier is transmitted by a WiFi AP first consisting of a CTS-to-self to temporarily reserve the channel, followed by the transmission of two packets, T0 and T1, with pre-determined lengths corresponding to the IoT tag that is supposed to be woken up. This sequence is illustrated in Fig. 7. Multiple tags can then be uniquely woken up by choosing different T0 and T1 packet lengths. At the tag level, the wake-up stage uses an 8 dB passive voltage gain network that is directly connected to an ED. The ED energy detects the entire packets and samples the energy with a comparator. Since the packet lengths are restricted to a minimum 50 μs, the required ED baseband bandwidth is 20 kHz. As shown previously in Fig. 6, with 8 dB of passive voltage gain, this results in a sensitivity of -40 dBm - which is the desired level (with margin). The comparator's output passes into a counter that counts the number of logic '1's, given by the presence of a packet (vs. a logic '0', which would occur in the inter-packet interval), at a sampling rate of 40 kHz. If the expected number of 1's and 0's occur in the right order, the wake-up stage's output triggers the sync stage receiver. Importantly, this wake-stage is achieved with a purely passive ED that consumes zero power. As a result, the only power here is that of the comparator, correlator, and clock generator (Fig. 4), which consumes only 2.8 μW during active mode.

3.3 Backscatter Communication

Once the tag has woken up and the sync stage identifies the exact packet start instant, the system starts backscattering with zero data. This ensures that the incident WiFi packet's header is backscattered to a different WiFi channel for reception by another WiFi AP without any modification using a Single side-band (SSB) modulation technique similar to [40]. While this is occurring, the tag counts the number of clock cycles until the header is complete, after which it can begin to introduce its data into the backscatter modulator. The backscatter data is XORed with the incident 11b symbol data, also known as code-word translation similar to [40]. The backscatter data is recovered at the receiving AP by XORing the received data again with the original 11b symbol data.

3.4 Putting it all Together

In the subsection, we discuss the end-to-end life-cycle of data packet exchange from an IoT device to the WiFi AP. A WiFi AP with the firmware support to transmit an excitation signal transmits a CTS-to-self packet to reserve a slot of 5 milli-second. Next, the transmitting AP transmits the two packets T0 and T1, whose lengths are a multiple of 25μsec. The tag notices a special pattern of three packets using the wake-up stage receiver by measuring the duration of CTS-to-self, T0, and T1 packets.

Downlink to a Specific Tag: Each IoT device is pre-coded with the lengths for T0 and T1 (akin to a destination address), which is the tag's identity. The finite state machine (Figure 4) at the tag continuously runs the wake-up receiver to look and match the three packet durations consuming 3 μW, with the trigger level of the reference voltage for ED set to -40 dBm. Whenever the three measured lengths match with the precoded sequences, it enables the specific IoT device to receive the downlink data.

A fixed number of bits are allocated for downlink in the finite state machine. The AP transmits the packets with varying lengths to encode the downlink data with 25 μsec granularity. The wake-up receiver at the IoT device uses the packet length to decode the downlink message. Therefore, the downlink data-rate supported is 40 Kbps. We reserve 3 bits for downlink in our implementation, which are used to set the reflection side-band upper or lower.

Uplink from the Tag: Upon completing the downlink, the tag fires up the sync receiver at the IoT device to acquire synchronization to uplink the data. The AP transmits a longer packet which we use to uplink the data. The tag synchronizes to the receiving packet with 150 ns accuracy, assuming incoming power is higher than -40 dBm. The tag starts backscattering at 50 MHz without any data, as soon as it receives a trigger from the sync receiver. Back-scattering with no-data ensures the incoming packet is reflected on channel 11, assuming transmission was on channel 1. The receiving AP on channel 11 starts receiving the packet. It successfully receives the PHY and MAC header of a total of 432 μsec. Upon completion of 432 μsec, the IoT device starts backscattering data, which is compliant to WiFi standards, as discussed in the next section. The receiving AP decodes the packets successfully, with CRC matching ensuring the packet is reported to the higher layers. The receiving AP XORs its data with the transmitted data in the cloud to recover data from the IoT device, thus connecting the IoT device to the AP.

3.5 Working with COTS WiFi

In the previous sub-section, we assumed certain capabilities for COTS WiFi. We will present how our system is compatible with using commercial WiFi transceivers. Specifically, we explain our test setup to receive the backscatter packets and decode them. We also discuss how the physical layer modulation schemes in the 802.11b protocol affect the bit-data processing at the backscatter IC and the receiver end.

Generating the wakeup pattern: The wakeup pattern is an On/Off pattern made up of WiFi compliant packets. It contains two WiFi packets separated by a DCF interframe spacing(DIFS) gap between two successive packets. The WiFi packets are broadcast packets that are of 107us duration, each separated by 50us corresponding to the DIFS gap. We note that typical 802.11b data packet sizes are of the order of few milliseconds, and 500us (CTS-to-self + wakeup pattern) duration do not add significant overhead for the backscatter communication.

Scrambling and Differential encoding: 802.11b WiFi APs randomize the data by scrambling it before transmission. At the receiver end, a de-scrambler is used to de-randomize the data and obtain the original bits. So, the backscatter data bits have to be scrambled before they are transmitted. The backscatter bits are scrambled using a 7^{th} order polynomial implemented as a feedback shift register initialized with a fixed seed [3]. Since the seed is fixed in 11b transmissions, all the tags can be programmed with this seed to facilitate data scrambling. Following the scrambling operation, the bits have to be encoded in a differential manner following the 802.11b PHY differential modulation scheme so that the receiver can decode the backscatter bits correctly.

4 Hardware and IC Design

Each SyncScatter tag is built upon a custom integrated circuit that was fabricated in TSMC's 65nm GP process. Our chip design is inspired by previous works [35, 36], which like other works HitchHike [40] lacks synchronization at the necessary sensitivity levels. Our IC design includes the proposed wake-up, sync receiver, and SSB backscatter modulator. The remainder of this section describes the chip design and operation, along with board-level integration efforts.

IoT Device: Daughterboard: The 65 nm die is directly mounted onto a custom printed circuit board, hereafter referred to as the daughterboard. The daughterboard(Figure 9b) routes all power and digital control traces to headers, which interface with a larger motherboard. Although not strictly necessary, the daughterboard is fabricated to utilize two RF antennas for ease of initial design: one for the wake-up path and one for the backscatter-path. However, we can use a simple switch to include both these paths to interact with a single antenna. The chip is clocked primarily from a 16 MHz crystal oscillator, with the oscillator circuit integrated on the chip, and the crystal soldered onto the daughterboard.

4.1 Wake-up receiver:

The wake up receiver consists of passive voltage gain directly feeding an ED and then to comparator which is sampled at 40kHz sampling rate as shown in Fig. 4.

Passive Voltage gain: At power levels of -40 to -30 dBm, the voltage seen at the antenna port are on the order of 5-20 mV. A passive voltage gain network is included to boost this according to the benefits outlined in the previous section. In this design, an *CLC*-based π matching network is employed, as shown in Fig. 8a, which provides 8 dB of voltage gain. The maximum achievable gain is limited by the quality factor, Q, of the constituent components at 2.4 GHz, along with the input impedance of the ED. In the current implementation, the employed inductor's Q is 110.

Envelope detector and comparator: Since the antenna is single-ended, it's easier to achieve high passive voltage gain with a single-ended matching network. Thus, the ED should also be single-ended. However, in general, it is better to perform baseband signal processing in a differential manner. Considering that the input impedance, output referred noise, and conversion gain are all important parameters to optimize in ED design, a multi-stage fully passive ED design is employed. In particular, a single-ended-to-differential Dickson-based topology is selected, thus acting as a pseudo-balun.

The ED's output bandwidth is controlled in part by the body bias voltage, which controls the ED's effective resistance, along with a variable capacitor. For the stage one design, a bandwidth of 200 kHz is targeted, which is sufficient to enable detection of the presence of T0 and T1 packets and their lengths, though without precise synchronization accuracy.

The pseudo-differential outputs of the stage one ED then feed into a differential comparator based on a Strong-ARM regenerative latch topology. This comparator effectively acts as a 1-bit analog-to-digital converter (ADC), and thus to extract useful timing information, it must be oversampled. As a result, it is clocked at 40 kHz. This clock is derived directly from the on-board crystal, after an on-chip division by a factor of 400. The comparison threshold voltage is tuned by externally controlling the bulk voltages of the input pair of the preamplifier implemented by a *gmC* integrator.

4.2 Sync Receiver

Once the first stage has determined that packets T0 and T1 have been transmitted, we turn on the sync receiver, and its purpose is to look for the rising edge of the subsequently transmitted packet header. It must do so with a bandwidth and sampling frequency greater than 6.67 MHz to meet the 150 *n*sec timing accuracy requirements. Since increasing the envelope detector's bandwidth will, without any other action, decrease sensitivity, this is countered by adding some active gain in front of the envelope detector.

The schematic of the sync receiver is shown in Fig. 4. Here, the stage two design shares the same antenna and passive voltage gain network as the first stage. But, instead of going directly into an envelope detector, it first goes into a low-noise amplifier (LNA). The LNA is designed to support a gain of 11 dB and an active-mode power consumption of 240 μW. If this second stage were on all of the time, this would be a significant power burden to the entire system. This is the beauty of the hierarchical wake-up feature: the LNA only needs to be turned on after the first stage wake-up receiver triggers reception of the appropriate signature. Otherwise, the LNA is nominally in a low-power sleep state. As a result, its average power consumption is extremely low - limited by the frequency of activation by stage one.

A schematic of the LNA is shown in Fig. 8c. A current reuse common source amplifier is implemented to achieve the desired gain with sufficiently low noise. Its output then feeds into a second envelope detector, optimized in a similar manner to wake-up receiver, though in this case for a bandwidth of 32 MHz to ensure a highly accurate rising edge timing. To compensate for the higher bandwidth, an active ED with decreased noise and increased conversion gain is employed in place of the passive ED in the wake-up receiver. A similar comparator as in the wake-up receiver with externally tunable reference voltage is used after the envelope detector, though in this case sampled at 8 MHz, which is sufficient to achieve a 150 ns synchronization time.

4.3 Clock generation:

The 16 MHz crystal oscillator clock is divided on chip into 8 MHz, 2 MHz and 40 kHz to be used by sampling clocks for sync receiver, PLL reference clock and sampling clock for wake up receiver, respectively. To drive the backscatter modulator, an integer-N PLL is adopted with a 2 MHz reference frequency and a dividing ratio of 25. The voltage controlled oscillator is implemented via a current starved ring oscillator with tunable current to ensure stable clock generation against PVT variations and it consumes 1.5 μW power.

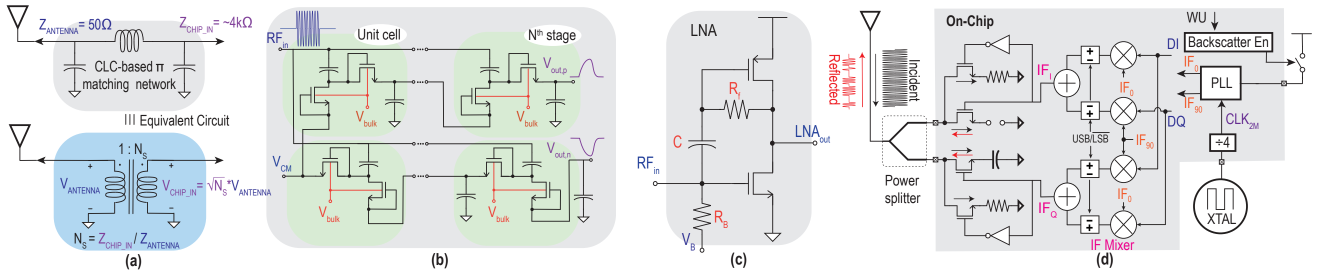

Figure 8: **(a)** CLC-based π matching network, **(b)** Schematic of passive pseudo-balun ED,**(c)** Schematic of LNA, **(d)** Transmission-line-less SSB QPSK Backscatter.

4.4 Backscatter circuit:

Single-side-band QPSK modulation is achieved by the backscatter circuit via the approach shown in Fig. 8d. Here, a power splitter/combiner breaks incident wireless power into two separate paths. The first path meets one of two possible termination conditions: 50 Ω or $Z_{L,0}$, depending on the state of $\mathrm{IF}_{\mathrm{OUT,I}}$. If it meets 50 Ω, then all of the incident RF energy is absorbed by this resistor, and no reflection is generated. However, if it meets $Z_{L,0}$, which is designed to be an open circuit in this implementation, then all of the incident RF power will be reflected back through the power combiner and to the antenna for re-radiation purposes. A similar situation occurs on the other path of the power splitter/combiner, which is terminated by either 50Ω or $Z_{L,90}$, depending on the status of $\mathrm{IF}_{\mathrm{OUT,Q}}$. If $Z_{L,90} = -j \times 50$, then all the signal is reflected, though in this case with a 90° phase shift. If I/Q mixers drive the two paths with 90° separated IF clocks, most of the energy will result in a single sideband, in the same way that a single-side-band mixer operates. Importantly, this approach only requires $Z_{L,90}$ to be a 1.2 pF capacitor - which is very easy to design on chip. This is in contrast to prior work, which required a transmission line to generate the requisite 90° phase shift [40].

4.5 Mother board

The prototype motherboard contains various voltage regulators for the chip and an ultra-low-power microcontroller for generating the data sequence with the correct timing. The voltage regulators generate all the different supply voltages required for the chip. To tune the LNA sensitivity and comparator thresholds, DACs are used to generate the variable voltages, which are controlled by the microcontroller through I2C/SPI buses. The chip's backscatter data input, wake-up signal, and synchronization signals are connected to the microcontroller(MCU) as well. The MCU turns on the sync receiver circuits once the wake-up pattern is detected, and it starts sending the data to the chip after an appropriate delay when the synchronization signal is asserted. The delay ensures the PHY header of the frame is preserved and stays valid. In a practical design, all the regulators and the microcontroller can be integrated onto the same chip, which would greatly reduce size and power consumption.

5 Evaluation

In this section, we first present micro-benchmarks to demonstrate the working of the individual modules in the SyncScatter tag. Then we evaluate the end-to-end performance of the SyncScatter in terms of Bit Error Rate (BER) and goodput by placing the tag in a large indoor environment (30m x 15m) as shown in Fig. 9a. We conduct the experiments by placing the Transmitter AP, Tag, and the receiver AP in both line of sight and non-line of sight conditions to demonstrate that SyncScatter tag is suitable for deployment in an office environment. We also conduct experiments to find SyncScatter's maximum range by co-locating the transmitter and receiver AP. To understand the impact of the co-existence of multiple tags, we perform goodput measurements by keeping two multiple tags in the same environment.

5.1 Micro-benchmarks

Here we verify the tag's functionality with micro-benchmarks to explain wake-up, synchronization, backscattering modules, and overall system design.

Tag Wake-up Accuracy: To test the robustness of the wake-up receiver, we measure the accuracy of wake-up with varying input power levels. To evaluate this, we conduct a wireless experiment to send a wake-up packet at different power levels. If the tag has woken up to the T0 and T1 packet, then it generates a trigger signal at the end of the wake-up packet. We send 1000 wake-up packets at varying power levels at the tag from -38 dBm to -30 dBm and monitor the number of triggers generated by the tag. The wake-up error rate is calculated as the number of successful triggers divided by the number of wake-up packets sent. Fig. 10a shows the wake-up accuracy for different power levels. SyncScatter's sensitivity is approximately -34 dBm, and for power levels above -34 dBm, the wake-up rate is very close to 1. Hence the tag responds well up to power levels of -34dBm, and SyncScatter will thus be able to wake up at a distance of up to 30 m.

Synchronization Jitter: The synchronization stage is prone to have some timing jitter in detecting the variation of power level. Here we quantify the jitter at different input power levels by doing a wireless experiment similar to the previous setup. To measure the jitter, we send an 802.11b packet from an RF signal generator and monitor the output of the synchronization stage. Then, we measure the time elapsed from

the moment the RF signal is applied and the instant at which the rising edge appears at the synchronization stage's output. We repeat this experiment by sending a thousand packets at different power levels and report the standard deviation of all the measurements at each power level. Figure 10b shows the synchronization jitter is below 150ns at -35 dBm power level and beyond, achieving desired optimal spec.

SSB Backscatter: Here we evaluate the performance of the single sideband backscatter in terms of the image rejection of SyncScatter tag. To measure the image rejection, we configure the tag to shift by 25MHz to the upper sideband and send a Wi-Fi signal on channel 6. Figure 10c shows the backscattered signal on channel 1 and channel 11. We observe that the left sideband signal i.e on channel 1, is ∼16 dB lower than the channel 11 signal.

5.2 Chip power consumption

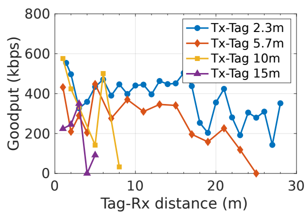
Here we evaluate the power consumption of the wake-up receiver, sync receiver, and backscatter stages of the chip. We report each stage's power consumption as the product of the supply voltage and the current drawn from the supply. The chip is powered from a 0.5v supply, and we use a source measurement unit [2] that can measure the current drawn by the circuit with a precision of 1μA. We observe that the on-board 16MHz oscillator and the wake-up receiver draw a current of 5.6 μA consuming 2.8μW. Since the chip spends most of its time in the wake-up state looking for the right time to backscatter, its average power consumption is dominated by the stage one wake-up receiver. Once the wake-up receiver detects T0 and T1 packets, then sync receiver is turned on, which draws 480 μA current and thus consumes 240μW, but only for an average of 50μs, to account for 40kHz sampling rate error. For a nominal wake-up duration of 500μs and data packet duration of 2ms, the duty-cycled power of the sync receiver is $\frac{50}{2500} \times 240\mu W = 4.8\ \mu W$. Thus, the sync receiver is controlled by a power switch and duty-cycled to conserve power. When the circuit is actually backscattering, the chip draws 56μA current consuming 28μW of power. The power consumption of the backscatter stage is dominated by the PLL to generate the 50MHz clock. Since the backscatter stage is powered on only during the data packet duration, the duty-cycled power turns out to be $\frac{2000}{2500} \times 28\mu W = 22.4\mu W$. So, the total average power from the three stages throughout the communication duration is 2.8 + 4.8 + 22.4 = 30μW, which is in the same range of Hitchhike [40] tag's power consumption.

5.3 End-to-End Results

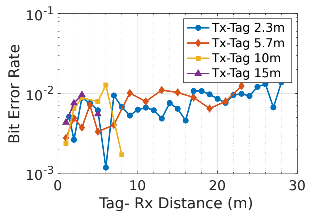
Here we use WiFi radios as both the transmitter and the receiver. The transmitter transmits 802.11b signals at a peak power of +30dBm on WiFi channel 1, and the tag is configured to backscatter to channel 11. The receiver AP is set to monitor channel 11 using Wireshark [4], a packet capture software that allows us to collect the backscatter packets and compute bit error rate (BER) and the goodput.

5.3.1 Impact of synchronization stage on BER

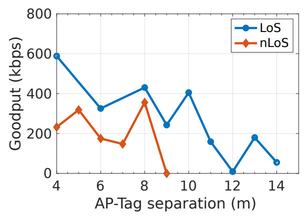
To understand the impact of synchronization on BER, we keep the transmitter, SyncScatter tag, and the receiver AP at 20m away from each other and capture the backscattered packets on channel 11. We perform this experiment in two ways, both with and without using the synchronization stage.



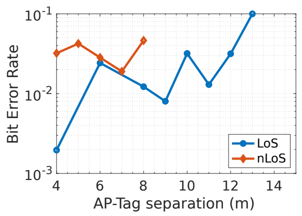
(a) Tx-Rx separated Goodput



(b) Tx-Rx separated BER

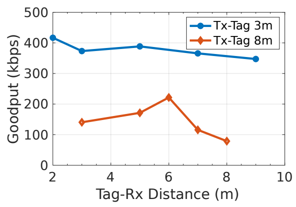


(c) Tx-Rx co-located Goodput

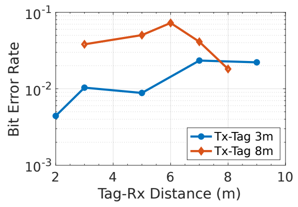


(d) Tx-Rx co-located BER

Figure 11: Goodput and BER performance with various Tx-tag and tag-Rx distances for separated case and co-located case.

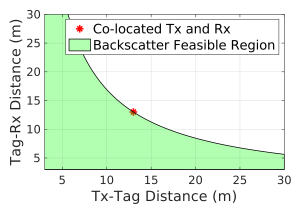


(a) NLOS Goodput

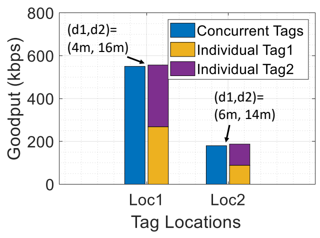


(b) NLOS BER

Figure 12: Goodput and BER performance with various Tag-Rx distances for the NLOS case.



(a) Range Plot



(b) Multi-tag Plot

Figure 13: Backscatter range plots.

We transmit 1000 data packets and plot the CDF of the bit error rates of the captured packets. As shown in Figure 10d, when the synchronization receiver is not used, more than 80 percent of the packets have BER higher than 0.1. But when the synchronization receiver is used to find the packet start, 70 percent of the packets have BER less than 10^{-3}, which is a substantial improvement over the other case.

5.3.2 Goodput/BER for a Single Tag

Here we compute the Goodput and the bit error rates by placing the transmitter, tag, and the AP in different Line of Sight(LoS) as well as non-line of sight(nLoS) configurations. We calculate goodput by taking into consideration the MAC and PHY layer overheads which account for approximately 40 percent of the packet data.

Line of Sight: We perform LoS experiments by placing the Tx, tag, and the Rx in a long corridor. We vary both the Tx to Tag distance and Tag to Rx distance while measuring the performance of SyncScatter tag. Figure 11a shows that when Tx to Tag distance is 2.3m, SyncScatter tag gives an average goodput of 450kbps at up to 30m from the tag. As expected, when we increase the transmitter to tag separation, we observe that the range of backscatter tag decreases due to higher path loss. For example, when tag and transmitter are separated by 10m, SyncScatter tag provides 400kbps goodput only until 9m tag to receiver separation. As shown in Figure 11b, the BER remains to be 10^{-2} over the whole range. We note that although the BER remains low over a wide range of Tx to tag and tag to Rx separations, there is a drop in the goodput values at certain locations. This could be attributed to the multipath nature of wireless channel causing deep fades at certain locations, impacting the number of successful packets decoded which in turn influences the goodput.

Non Line of Sight: In a real-world deployment, true line of sight conditions do not necessarily occur. So, we test our tag setup in a non-line of sight(nLoS) condition where the transmitter and tag are blocked by a wall between them. We vary the transmitter to tag separation and compute the bit error rate and goodput for various tag to receiver separations as plotted in Figure12a and Figure12b. Measurements show that the SyncScatter tag is able to be wake-up successfully even when blocked by a wall and has a backscatter range of 9m. Blockage due to the wall attenuates the signal, resulting in the throughput and BER being worse when compared to the line of sight case. When the Tx to tag separation is 3m, the tag offers an average goodput of 400kbps, and it falls to 100kbps when the Tx to tag separation is increased to 8m.

5.3.3 Co-located Tx and Rx set up

We also evaluate SyncScatter by placing the Transmitter and Receiver at the same location in both LoS and nLoS conditions. In LoS case, the backscatter range is limited to 13m which is smaller than the 30m range observed in the previous experiments where the Tx and Rx are at different separations from the tag. When the Tx and Rx are co-located, the backscatter signal suffers from the path loss twice due to the back and forth travel from the AP to the tag and back to the same location, impacting the maximum range. This argument also supports our observation that the rate of decrease in the goodput with separation is high as shown in Fig.11d and Fig. 11c. In the nLoS scenario, the tag offers an average throughput of 200kbps, with the maximum backscatter range reducing to 8m because of the wall blockage between the Tx and the tag.

5.3.4 Range of the SyncScatter Tag

Now we describe the maximum range until which SyncScatter tag works. In the co-located experimental setup, we observed that the backscatter packet decoding is successful up to 13m AP to tag Line of sight separation. Since the backscatter communication range is determined by the product of

Tx-tag (d_1), Tag-Rx separations(d_2). Any tag location satisfying the relation $d_1 \times d_2 \leq 13 \times 13 = 169m^2$ and $d_1 \leq$ maximum wake-up distance should be within the backscatter range. Fig. 13a shows the feasible backscatter range, which goes up to 30m in either direction.

5.3.5 Co-existence of Multiple Tags

Finally, we find out if multiple SyncScatter tags can exist together, specifically we want to know if the two tags wake-up simultaneously and cause interference to each other. In this experiment, we place the Tx and Receiver separated by 20m. The two tags are placed in line of sight(LoS) with the Tx and Rx and approximately at the same location. Fig. 13b shows the network goodput when both the tags are present and compare it against goodput when only one tag is present. We note that the concurrent goodput is slightly less than the averaged goodput of individual tags.

6 Related Work

SyncScatter is related to prior backscatter based networking with ambient signals [13, 22] that provides low-cost and energy-efficient communication [24, 31]. However, none of the past literature has shown the ability to synchronize at extremely low power with incoming WiFi signals. Furthermore, SyncScatter for the first time analyses the fundamental range limitation for WiFi backscattering, and provides a necessary synchronization specification to maximize the range. Using the analysis and a custom IC hardware design, SyncScatter improves the range, data-rate, and scales to multiple tags over existing literature, even prior IC implementations [35]. SyncScatter is related to the following topics:

Tone based WiFi backscatter communication: SyncScatter synchronizes with ambient commodity WiFi signals, therefore do not require deployment of new tone generators. In contrast, traditional backscatter system like RFID [12, 15, 16, 27, 29, 33, 39, 41] require reader device which act as both tone-generator and receiver. Recent work has shown the ability to backscatter WiFi from an incoming tone signal [19–21, 28, 32], which requires an excitation radio that can generate sine tone. For example, [19] uses a Bluetooth radio to generate a tone, but with the standards-limiting the maximum transmit power, the backscatter range is limited to smaller distances. In contrast, since SyncScatter leverages existing WiFi infrastructure for both excitation and receiving radio, it simplifies the deployment while improving range.

Backscatter communication with Ambient signals: Recently, there have been multiple works on backscattering ambient signals, wherein the excitation radio and receiving radio use existing infrastructure like WiFi [21, 40]. In general, the infrastructure-based backscatter that leverages WiFi [11, 20, 23, 38], LTE [13], Bluetooth [14, 19], ZigBee [22, 43], LoRa [17, 26, 28] or even visible light signal [37] can all benefit from SyncScatter's hierarchical protocol to improve the transmitter-to-tag range and throughput. For example, recent work which backscatters LTE signals [13] tag uses a preamble while backscattering due to the lack of synchronization with incident signals. In such scenarios, the hierarchical wake-up receiver can enable synchronization and improve the tag's performance.

Prior WiFi-based backscatter works focus on the core-principle of codeword translation: changing one OFDM symbol to another valid OFDM symbol [42] and [6] extends backscatter communication to leverage features of the MAC layer. Multi-hop backscatter [45] builds a mesh network of tags, and a few other works [9, 23, 44, 46] propose to leverage spatial multiplexing on the backscatter tag. However, none of the existing works provide extended coverage due to their fundamental inability to synchronize with the ambient signals.

7 Discussion and Future Work

SyncScatter presents a first integrated circuit to achieve synchronized backscatter communication with ambient signals.

802.11b and Beyond: Although 802.11b is an old technology, most modern APs come with dual-band radios supporting both 2.4GHz and 5 GHz radios. The recent 802.11ax standard is designed to be backward compatible with 11b/g devices and hence backscattering on 802.11b signals is still very applicable. Moreover, all the symbol-based backscatter systems such as FreeRider [42] which use 802.11g signals, requires synchronization making our design suitable for modern WiFi standards as well.

Adapting WakeUp Receivers to different protocols: Our hierarchical wake-up receiver design can be extended to backscatter systems based on BLE, OFDM, and LoRA protocols with some minor modifications. We observe that BLE and LoRA signals have a constant signal envelope similar to 11b signals, and they would work with our design. However, since LoRA networks demand long-range, the wake-up receiver has to be designed with more sensitivity at the expense of more power consumption on the tag. In the case of OFDM signals, the wake-up packets have to be engineered to have a small peak to average power ratio (PAPR) so that they appear like a constant envelope signal to the envelope detectors.

Integrated Power Management and Energy Harvesting: In the current implementation, we design the integrated circuit without integrated power management solutions, leading to higher power consumption. In future work, we would integrate the power management circuits such as voltage regulators, power switches within the integrated circuit itself. We note that our chip can be powered using a rechargeable coin cell such as CR2032 [1] and can have a continuous operation for more than 3 years. We can further enhance its life by exploring RF energy harvesting [7, 30] techniques to replenish the battery and integrate them onto the fabricated chip.

9 Appendix

9.1 BLE synchronization requirement

To find the synchronization requirement for BLE(Bluetooth low energy) backscatter communication, we perform Matlab simulations for different synchronization delays. BLE signals encode the data bits using two different sine tones located 250kHz on either side of the center frequency, where each symbol in the BLE packet occupies a duration of $1\mu s$. To encode tag data on a BLE packet, the frequency of the sine tone present in a BLE symbol is modified by the backscatter tag. In our simulation, we consider incident data packets that are modulated using FSK(frequency shift keying) technique. The tag's modulation signal is also generated from the tag bits using the FSK technique. To incorporate the synchronization delay while backscattering, we delay the tag modulation by a fixed duration (given by the synchronization delay) beginning from the packet start instant. The resulting backscattered signal is also an FSK signal and is decoded by an FSK receiver. Fig 14 plots the BER vs SNR curve for different values of synchronization delay. As can be seen, the BLE backscatter loses 4 dB of SNR at 10^{-3} BER due to a synchronization delay of 100 ns. For 150ns synchronization delay, it loses more than 8 dB SNR. To not degrade the SNR, BLE backscatter requires a synchronization accuracy better than 100 ns which is equal to $\frac{1}{10}$ th of the symbol duration.

9.2 OFDM Synchronization requirement

To simulate OFDM backscatter synchronization requirements, here we consider the standard 20MHz OFDM signals. A WiFi packet contains many OFDM symbols, with each symbol containing 64 sub-carriers. Each OFDM symbol occupies 3.2 us duration and is preceded by a cyclic prefix of 0.8us duration. To encode data onto a WiFi packet, the backscatter tag changes the phase of an OFDM symbol. For instance, to convey tag data 1, the tag induces an additional phase of π radians on all the sub-carriers. Similarly, to encode bit 0, the phase of the sub-carriers is left unchanged. In this way, a sequence of tag bits is encoded on a WiFi packet by modifying the phase of each OFDM symbol in the packet. At the receiver, these phases are extracted to decode the tag data. If the backscatter tag is not aware of the OFDM symbol boundary, the tag bits will not be appropriately encoded on the WiFi packet, and the WiFi packet suffers from loss of SNR. The BER vs SNR curves for different synchronization delays are plotted in Fig 15. We note that the OFDM backscatter is able to tolerate a large synchronization delay of up to 1000ns. The primary reason the tolerance is very large is that every OFDM symbol has a cyclic prefix of length 800ns discarded while decoding the packet at the receiver. So, if the signal that is part of a cyclic prefix is corrupted, it will not impact the bit error rate. Another reason is that the same tag bit is encoded on every sub-carrier of the OFDM symbol, implying if the majority of the sub-carriers are decoded correctly, the BER would not be impacted much. From Fig 15, we notice that the BER floors, although the SNR increases and it loses more than 10 dB SNR to achieve 10^{-3} BER. This suggests synchronization delay plays a major role in reducing the bit error rate.

Abstract

Orthogonal frequency-division multiplexing (OFDM) has been widely used in WiFi, LTE, and adopted in 5G. Recently, researchers have proposed multiple OFDM-based WiFi backscatter systems [33, 35, 36] that use the same underlying design principle (i.e., codeword translation) at the OFDM symbol-level to transmit the tag data. However, since the phase error correction in WiFi receivers can eliminate the phase offset created by a tag, the codeword translation requires specific WiFi receivers that can disable the phase error correction. As a result, phase error is introduced into the decoding procedure of the codeword translation, which significantly increases the tag data decoding error. To address this issue, we designed a novel OFDM backscatter called TScatter, which uses high-granularity sample-level modulation to avoid the phase offset created by a tag being eliminated by phase error correction. Moreover, by taking advantage of the phase error correction, our system is able to work in more dynamic environments. Our design also has two advantages: much lower BER and higher throughput. We conducted extensive evaluations under different scenarios. The experimental results show that TScatter has i) three to four orders of magnitude lower BER when its throughput is similar to the latest OFDM backscatter system MOXcatter [36]; or ii) more than 212 times higher throughput when its BER is similar to MOXcatter. Our design is generic and has the potential to be applied to backscatter other OFDM signals (e.g., LTE and 5G).

1 Introduction

By reflecting ambient signals, backscatter systems conduct passive communication which can provide low power consumption, low cost, and ubiquitous connectivity for Internet of Things (IoT) devices to support various applications (e.g., smart buildings and smart health) [4]. To achieve ubiquitous connectivity and leverage the advantages of the ambient signals, researchers have developed various backscatter systems that reflect ambient signals from TV or frequency modulation

*Both authors contributed equally to the paper.
†Ting Zhu is the corresponding author.

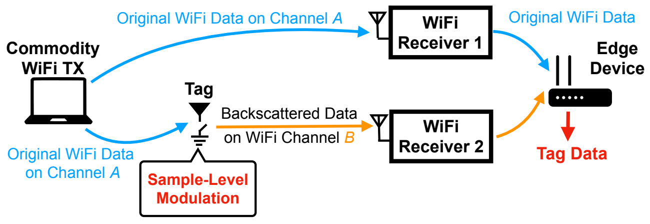

Figure 1: A general architecture of OFDM-based WiFi backscatter systems [33, 35, 36]. Different from existing systems that modulate the tag data at the symbol-level, our backscatter system uses the sample-level modulation (highlighted in a red color).

(FM) radio towers, LoRa, or WiFi [7, 12, 16, 27]. Therefore, these backscatter systems are complimentary to each other and have their own unique advantages in terms of energy efficiency, throughput, deployment cost, etc.

In this paper, we mainly focus on the design of the WiFi backscatter due to i) pervasively available WiFi signals inside buildings; ii) numerous WiFi devices; and iii) abundant applications supported by WiFi. All of these can significantly increase the adoption of our developed techniques. The pioneer work on WiFi backscatter [11] achieved up to 1 kbps throughput and 2.1 meters range. Follow up works improved the performance of WiFi backscatter by using customized full-duplex WiFi access points [6] or standard 802.11 b/g/n WiFi devices [33, 35, 36]. Since the majority of the WiFi signals in buildings are using an advanced modulation scheme – orthogonal frequency-division multiplexing (OFDM), researchers recently proposed a general architecture of OFDM-based WiFi backscatter systems (shown in Fig. 1) to leverage productive WiFi data communication from the surrounding WiFi devices. This architecture has demonstrated to be effective in supporting the smart offices application, in which WiFi receivers can be connected by Ethernet backhaul to decode the tag data [33, 35, 36].

However, these systems [33, 35, 36] require specific WiFi receivers that can disable the phase error correction. This is because the phase error correction can eliminate the phase offset created by the tag, and cause incorrect tag data decoding.

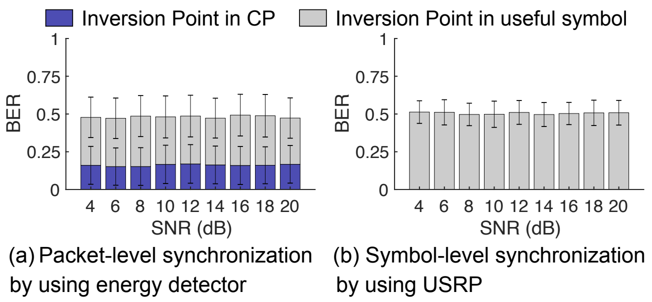

Figure 2: High BER identified in experiments with a total number of 128,000 data points transmitted

On the other hand, the phase error correction is very important for the WiFi demodulation because phase errors in the WiFi systems may be dynamically changing due to the changes of environment (e.g., temperature of the oscillators and object movement). Therefore, WiFi protocols always arrange a certain number of pilot subcarriers in each OFDM symbol to track and correct phase errors. Without the phase error correction, the WiFi demodulation error will increase. Similarly, disabling the phase error correction will also introduce the phase error into the demodulation procedure of the codeword translation, which will increase the tag decoding error.

To demonstrate the limitation of these OFDM-based WiFi backscatter systems, we rebuilt these systems using USRPs that ran the standard 802.11g stack which contains the phase error correction. We identified the high bit error rate (BER) which happens even when the signal to noise ratio (SNR) is high (shown in Fig. 2). By using an energy detector (which is a low-power component to measure the signal strength in the air) as introduced in previous systems, the tag is synchronized with the WiFi sender at the packet-level. From the result (Fig. 2(a)), we can observe that the total BER is around 50% even with a high SNR. Since a tag embeds the tag data by inverting the phase of the incoming signal, the inversion point can settle anywhere in a symbol with packet-level synchronization. After conducting a thorough analysis, we found that one portion of the inversion points (in blue) settle in cyclic prefixes (used to prevent inter symbol interference), which causes decoding failures because the cyclic prefix is removed at the receiver. The other portion of the inversion points (in gray) settle in useful symbols (used to carry real WiFi data), however, this portion will also cause the bit error. We also conducted symbol-level synchronization and found that the blue part can be eliminated with a precise synchronization (results shown in Fig. 2(b)). However, the BER is still very high across different SNRs.

To address this issue, we conducted comprehensive studies and designed a new OFDM backscatter system called TScatter to achieve higher reliability (lower BER) and higher throughput. We propose a sample-level modulation scheme, in which the phase offsets on pilot subcarriers are very different from that on the data subcarriers. Thus, the phase offsets on the data subcarriers cannot be eliminated by the phase error correction. Therefore, we can extract the tag data while the phase error correction is present. Moreover, since the phase error correction is present, our system is able to work in more dynamic environments and achieve much lower BER.

Our sample-level backscatter system has a lot of benefits. On one hand, the system provides high reliability (low BER) allowing tags to work in various scenarios, such as non-line-of-sight or underground. On the other hand, our TScatter can be configured in high throughput mode with Mbps level throughput to support IoT edge computing applications such as ubiquitous surveillance in smart buildings. Further more, high throughput provides high energy efficiency (bit/joule). Given the same amount of harvested energy, our backscatter system can transmit more data than existing ambient WiFi backscatter systems. Moreover, higher energy efficiency also provides another benefit – given the same amount of data to be transmitted, our backscatter system needs much less energy. Therefore, our backscatter system can be deployed in places that are further away from the wireless energy transferring sources than the latest WiFi backscatter systems [33, 35, 36].

The main contributions of this paper are as follows:

• We verified existing OFDM-based WiFi backscatter systems and redesigned the system with a novel sample-level modulation technique, which can retrieve tag data from the process of phase error correction in modern OFDM-based wireless communication system. Potentially, this technique can be applied to LTE and 5G which also use OFDM modulation schemes.

• To demodulate the high granularity modulated data, we built demodulation models that capture the WiFi demodulation procedure and derive a minimization function to estimate the tag data. We further enhanced our modulation and demodulation design to support different WiFi modulation schemes (e.g., BPSK, QPSK, 16QAM, and 64QAM). Our evaluation results demonstrate the effectiveness of our design.

• We built a hardware prototype of our proposed backscatter system that contains a low power FPGA and a simple RF switch. We also designed a tag IC for estimating the power consumption. Our empirical results show that TScatter has i) three to four orders of magnitude lower BER when its throughput is similar to the latest OFDM backscatter system MOXcatter [36]; or ii) more than 212 times higher throughput when its BER is similar to MOXcatter.

2 Background of Existing OFDM Backscatter

To fully reveal the impact of phase error correction on the codeword translation technique, it is necessary to first understand how the technique works. Generally, current OFDM backscatter techniques mainly consist of three parts: (i) the excitation OFDM signal generation on the sender side; (ii) the phase modulation on the tag side; and (iii) the codeword decoding on the receiver side.

The Sender: To produce the OFDM symbol, the sender conducts an Inverse Discrete Fourier Transform (IDFT) on its subcarriers in the frequency domain. The output samples of

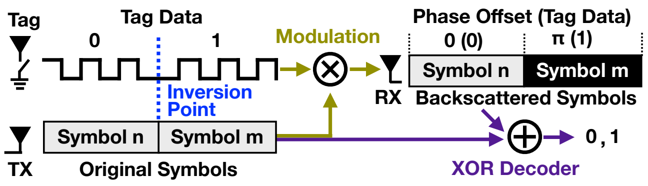

Figure 3: Overview of the existing OFDM backscatter technique

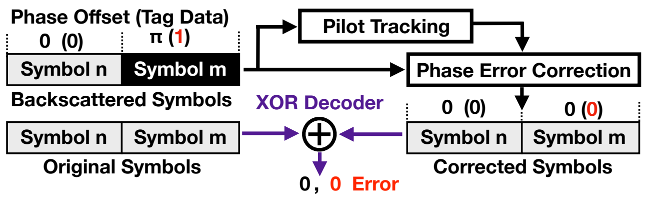

Figure 4: The phase offset π is eliminated by phase error correction, which causes tag data 1 to be mistakenly decoded as tag data 0.

the corresponding IDFT will form a single OFDM symbol $\mathcal{S}(t)$ in the time domain, which can be represented as:

$$\mathcal{S}(t) \; = \; \text{IDFT} \; [\; \mathcal{X}_k \;] \tag{1}$$

where $\{\mathcal{X}_k\}$ are the subcarriers. Multiple symbols are concatenated to create the final excitation OFDM signal.

The Tag: Existing OFDM-based WiFi backscatter systems allow a tag to convey information by inverting the phase of OFDM symbols in the time domain [33, 35, 36]. An example is shown in Fig. 3, the backscatter tag uses zero phase offset to transmit data zero and a phase inversion to transmit data one. Then, the backscattered symbol $\mathcal{B}(t)$ is given by:

$$\mathcal{B}(t) \; = \; \begin{cases} \mathcal{S}(t)e^{j0} & \text{Tag data 0} \\ \mathcal{S}(t)e^{j\pi} & \text{Tag data 1} \end{cases} \tag{2}$$

To improve the data rate, the tag can create additional phase offsets to covey more information, which is shown below:

$$\mathcal{B}(t) \; = \; \begin{cases} \mathcal{S}(t)e^{j0} & \text{Tag data 00} \\ \mathcal{S}(t)e^{j\frac{\pi}{2}} & \text{Tag data 01} \\ \mathcal{S}(t)e^{j\pi} & \text{Tag data 10} \\ \mathcal{S}(t)e^{j\frac{3\pi}{2}} & \text{Tag data 11} \end{cases} \tag{3}$$

We note that to achieve above codeword translations (Eqn. 2 and 3), the tag needs to synchronize the tag data with the symbol. Formally, we define the point that concatenates two different tag data as the tag data **inversion point**. As shown in Fig. 3, the tag data inversion point (from 0 to 1) is aligned with the beginning of the OFDM symbol m.

The Receiver: A Discrete Fourier Transform (DFT) is performed to convert the backscattered symbols to the frequency-domain backscattered subcarriers. Because of the linearity of the DFT, the operation of the phase change in the time domain corresponds to the frequency multiplication. Therefore, the backscattered subcarriers can be represented as:

$$\mathcal{X}_k e^{j\delta} \; = \; \text{DFT} \; [\; \mathcal{B}(t) \;] \tag{4}$$

where δ is the phase offset. Then, we can decode the tag data by computing the XOR operation of backscattered subcarriers and original subcarriers:

$$\mathcal{X}_k e^{j\delta} \oplus \mathcal{X}_k \; = \; \begin{cases} \text{Tag data 0} & \delta = 0 \\ \text{Tag data 1} & \delta = \pi \end{cases} \tag{5}$$

3 Why Existing OFDM Backscatter Systems Disable Phase Error Correction?

The underlying assumption in the codeword translation is that backscatter systems can be free of the effect of the phase error. However, we point out that failure to consider the effect of phase error will significantly increase the BER of OFDM backscatter systems. Therefore, in this section, we first investigate influences of the phase error correction on codeword translation. Then, we extensively analyze all the scenarios that will affect the BER of the codeword translation. At last, we outline the desired properties to reduce the BER of OFDM backscatter systems.

3.1 Tag Data is Eliminated

In real-world scenarios, due to the changes of environment (e.g., temperature of the oscillators and object movement), the OFDM receiver is required to perform the phase error correction to eliminate the phase error on the signal. This process also eliminates the phase offset created by the tag.

Specifically, the phase error correction is to use available pilot subcarriers $\{\mathcal{X}_p\}$ to track the phase error. Since the phase error can be simply modeled as a constant multiplicative component across a symbol (e.g., $e^{j\phi}$ [25]), the backscattered subcarrier in Eqn. 4 should be $\mathcal{X}_k e^{j(\delta+\phi)}$ while the backscattered pilot subcarrier should be $\mathcal{X}_p e^{j(\delta+\phi)}$. Then, the phase error $\mathcal{H}$ can be computed by comparing backscattered pilot subcarriers and original pilot subcarriers:

$$\mathcal{H} \; = \; \frac{\sum \mathcal{X}_p e^{j(\delta+\phi)}}{\sum \mathcal{X}_p} \; = \; e^{j(\delta+\phi)} \tag{6}$$

Finally, the backscattered subcarriers can be corrected as:

$$\mathcal{X}_k e^{j(\delta+\phi)} \cdot \mathcal{H}^{-1} \; = \; \mathcal{X}_k \tag{7}$$

The key observation from the above expression is that the phase error $e^{j\phi}$, as well as the phase offsets $e^{j\delta}$ from the codeword translation, are eliminated from subcarriers. In other words, as shown in Fig. 4, if the tag transmits arbitrary data, the XOR decoder may never output data 1. This is because the codeword translation makes the pilot subcarriers have the same phase offset as other subcarriers, which makes it feasible to eliminate phase offsets by the phase error correction. As a result, since phase offsets are eliminated, tag data 1 will be mistakenly decoded as tag data 0 (i.e., zero phase offset in Eqn. 2). The effect of phase error correction will become more severe when the tag increases its data rate. As shown in Eqn. 3, the tag uses four phase offsets to double the data rate. However, due to the phase error correction, the receiver may not extract these phases offsets correctly. In this case, the tag data 01, 10, 11 will be mistakenly decoded as tag data 00.

The above analysis mainly focuses on the scenario that the inversion point is perfectly aligned with the beginning of the

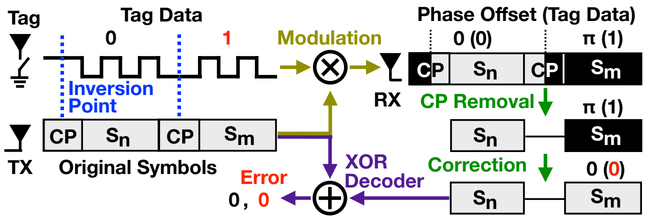

Figure 5: When the inversion point is located in the CP, the phase offset π representing tag data 1 can still be eliminated.

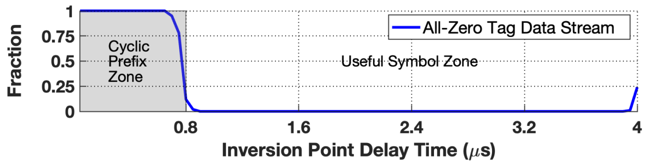

Figure 6: Experiments demonstrate that if the inversion point is within the cyclic prefix zone, the decoded tag data are all zeros regardless whatever data is sent by the backscatter tag.

symbol. In following sections, we will show that even when the inversion point is not perfectly aligned with the beginning of the symbol (i.e., the inversion point is in the cyclic prefix or the inversion point is in the useful symbol), the receiver may still face high bit error rate.

3.2 Inversion Point in Cyclic Prefix

The XOR decoder cannot extract the tag data correctly when the tag data inversion point is located in the cyclic prefix (CP). Because the OFDM receiver will first remove CP to prevent intersymbol interference introduced by the multipath effect, the inversion point in the CP is removed as well. As shown in Fig. 5, after the CP removal, although the useful symbol S_m still has the phase offset π, the phase error correction will eliminate the phase offset, which causes the decoding error.

We conduct an experiment to show the effect of the inversion point in the cyclic prefix. In this experiment, an 802.11g OFDM-based WiFi physical layer is implemented on the USRP B210 [1]. In order to precisely control the synchronization between the OFDM symbol and the tag data, the tag is connected to the USRP using two wires: one for common ground and another for signal. When the USRP transmits the WiFi signal to the air, it will also transmit the starting signal through the wire to tell the tag to embed tag data in the WiFi signal. By modifying the delay after the starting signal, we can synchronize the tag data inversion point with the different timings in the OFDM symbol duration ($4\mu s$). The original tag data is an arbitrary data stream. However, as shown in Fig. 6, when the inversion points are within the cyclic prefix zone (i.e., the inversion point delay is less than $0.7\ \mu s$), the decoded tag data are all zeros, because the phase offsets of the tag data 1 are eliminated. When the inversion points are within the useful symbol zone, the decoded tag data is not all zeros. However, as we will discuss in Section 3.3, it may still have a high BER. When the inversion point delay is between $0.7\ \mu s$

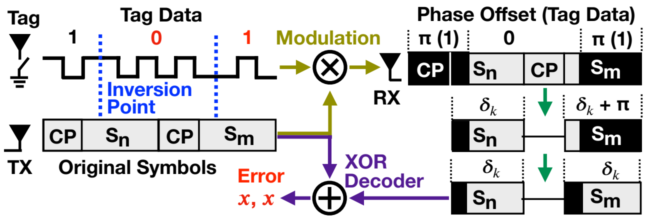

Figure 7: When the inversion point is located in the useful symbol, the decoding result is the same and thus causes the decoding error.

and $0.8\ \mu s$, although it is theoretically within the cyclic prefix zone, the decoded tag data is not all zeros. This is because of the multipath effect in the real-world, so the inversion point may be moved to the useful symbol zone.

3.3 Inversion Point in Useful Symbol

In this section, we analyze the scenario that the inversion point is located in the useful symbol. As shown in Fig. 7, since the phase offsets introduced in the symbols of S_n and S_m are opposite, the subcarriers of S_n and S_m have the opposite phase offsets δ_k and $\delta_k + \pi$ after the CP removal, where k is the subcarrier index. Obviously, the subcarriers of S_m have a common phase offset π, which can be eliminated by the phase error correction. Therefore, the final phase offsets on S_n and S_m are almost the same, which causes the same decoding result and corresponding errors. We note that δ_k on each subcarrier is different and determined by the inversion point position. Hence, the decoding result x might be 1 or 0.

3.4 Desired Properties and Our Solution

From the analysis in Sec. 3.2 and 3.3, the OFDM backscatter should satisfy the following two properties to avoid the decoding error caused by the phase error correction:

1. *The tag data inversion point should fall into the useful symbol.*
2. *The tag data should be represented by phase offsets that cannot be eliminated.*

Since the backscatter tag is a low power device, we cannot use a high power circuit to conduct precise synchronization between the inversion point and the useful symbol. To overcome this challenge, we explore a high granularity modulation scheme, sample-level modulation. By doing this, the phase offsets on the pilot subcarriers are different from that on the data subcarriers. Thus, the phase offsets on the data subcarriers cannot be eliminated by the phase error correction.

To satisfy the second property, we utilize orthogonal coding technique for reliable data transfer. Specifically, to reduce the bit error rate and achieve high reliability, we propose orthogonal pseudo-random noise (PN) sequences to represent the tag data. With the help of the sample-level modulation, each data bit in the PN sequence can represent a phase offset. As a result, the sequences of phase offsets are also orthogonal and the tag data can avoid being eliminated.

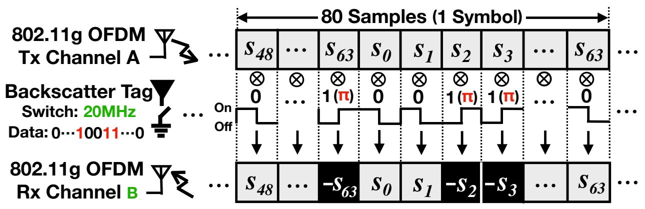

Figure 8: When a switching cycle is equal to a sample duration, the switching action can appropriately change the phase of the sample.

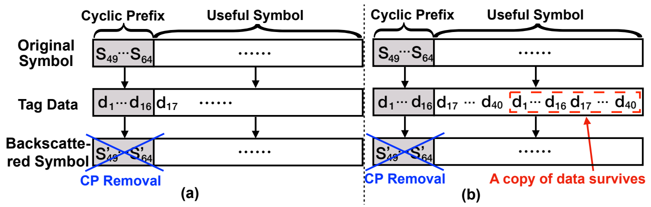

Figure 9: In (a), the tag data embedded in the CP are lost due to the CP removal. In (b), the tag embeds 40 bits of data twice in the symbol. A copy of data can survive after the CP removal.

By satisfying the two properties, compared to prior works [33, 35, 36], our backscatter system can take advantage of the phase error correction on the demodulation side and is able to achieve much lower BER. On the modulation side, since multiple tag data bits can be transmitted within one symbol by using our sample-level modulation, more robust coding methods (such as orthogonal code or convolutional code) than codeword translation can be utilized to further improve the BER.

4 Sample-Level Modulation

Our sample-level modulation has two design goals: i) embedding the tag data in the OFDM signal at the sample-level, and ii) minimizing the interference from the original band channel. In order to achieve the first design goal, we propose to use the tag to change the phase of any sample in the OFDM symbol. To achieve the second design goal, the tag needs to shift the center frequency of the backscattered samples to the adjacent band channel. Fig. 8 shows how TScatter leverages the switching action to change the phase of the sample. For the sake of simplicity, we first assume that the on and off edges of switching actions are aligned with the samples. We discuss the situation that the switching actions and the samples are not edge-aligned in Sec. 6.1.

A fundamental basis for our sample-level modulation is that the OFDM symbol can be divided into the sample-level, whose duration is much shorter than the symbol-level. When 802.11g OFDM generates a symbol in the transmitter, the IDFT converts the 64 subcarriers into a 64-sample sequence. The samples can be represented by rewriting Eqn. 1 with the definition of IDFT:

$$\mathcal{S}_n \;=\; \text{IDFT}\;[\,\mathcal{X}_k\,] \;=\; \frac{1}{64}\sum_{k=0}^{63}\mathcal{X}_k e^{j2\pi kn/64} \tag{8}$$

Where, $n \in \{0,...,63\}$, $\mathcal{S}_n$ denotes the n'th sample and X_k denotes the k'th subcarrier. To prevent inter-symbol interference, the last 16 samples $[\mathcal{S}_{48},\ldots,\mathcal{S}_{63}]$ are replicated in front of the 64 samples. Thus, a symbol consists of a total of 80 samples.

When the tag toggles its RF switch to backscatter the OFDM signals, it essentially uses square waves to modulate the phases of the samples. We use θ_n to represent the initial phase of the n'th square wave $\mathcal{W}_n$. Then, $\mathcal{W}_n$ can be represented using a Fourier series as follows [9]:

$$\mathcal{W}_n(f_s,\theta_n) = 0.5 + \frac{2}{\pi}\sum_{m=1,3,5,...}^{\infty}\frac{1}{m}cos(2\pi m f_s t + \theta_n) \tag{9}$$

Where, f_s is the toggling frequency of the switch.

Since each symbol is 4 μs long and contains 80 samples, when the tag toggles its switch at $f_s = 20MHz$, the switching cycle ($0.05\ \mu s = \frac{1}{20MHz}$) will be equal to the sample duration ($0.05\ \mu s = \frac{4\ \mu s}{80}$). Therefore, the switching action can appropriately modulate the phase of the sample. The n'th backscattered sample can be calculated by multiplying the n'th sample and the 1st harmonic of the n'th square wave:

$$\begin{aligned}\mathcal{S}_n\mathcal{W}_n^{m=1} &= \frac{2}{\pi}\mathcal{S}_n cos(2\pi f_s t + \theta_n)\\ &= \frac{1}{\pi}\{\mathcal{S}_n e^{j\theta_n}e^{j2\pi f_s t} + \mathcal{S}_n e^{-j\theta_n}e^{-j2\pi f_s t}\}\end{aligned} \tag{10}$$

Summary: From Eqn. 10, one can observe that our two design goals are achieved. First, there are two backscattered samples $\mathcal{S}_n e^{j\theta_n}$ and $\mathcal{S}_n e^{-j\theta_n}$. They are formed by changing the phase of the original sample $\mathcal{S}_n$ by θ_n and $-\theta_n$, respectively. If we change θ_n according to the tag data, the tag data is embedded into the sample. For example, if the tag wants to use the 4-phase scheme (0, $\pi/2$, π and $3\pi/2$) to transmit the tag data, we can define the tag data '00' as $\theta_n = 0$, '01' as $\theta_n = \pi/2$, '10' as $\theta_n = \pi$ and '11' as $\theta_n = 3\pi/2$. Second, the two backscattered samples are multiplied by $e^{j2\pi f_s t}$ and $e^{-j2\pi f_s t}$, respectively, which means the backscattered samples are shifted by $f_s = \pm 20MHz$ into the adjacent band channels and thus isolated from the original band channel. Therefore, a OFDM receiver can obtain the backscattered samples without the interference from the original band channel [34]. For these two sidebands, one is desired and the other is unwanted and wasted. The unwanted sideband can be easily eliminated by making the signal have a negative copy on the unwanted sideband as introduced in HitchHike [32].

5 Tag Coding Scheme

In this section, we discuss the coding methods on the tag, which aim to avoid the tag data inversion point being removed by the cyclic prefix removal and the phase offset being eliminated by the phase error correction, and make TScatter achieve highly reliable backscatter communication.

5.1 Surviving from Cyclic Prefix

Since the receiver removes the cyclic prefix (i.e., the first 16 samples of each symbol) directly prior to the procedures in the OFDM module, a portion of the tag data may be removed as well because the tag may embed this data in the cyclic

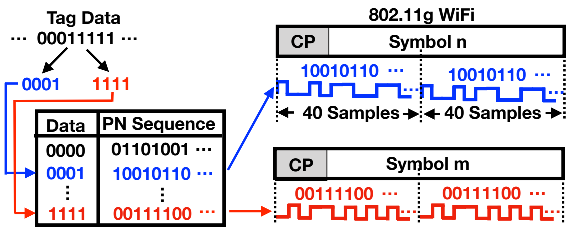

Figure 10: TScatter uses PN sequences to represent the tag data.

prefix. Fig. 9(a) shows an example that the tag data d_1 to d_{16} are lost due to the CP removal.

A naive solution is to utilize an envelope detector to detect the start of the cyclic prefix and embed the tag data in the useful symbol. However, it is unlikely to obtain an accurate CP detection using a packet-level detection on the envelope detector. Instead, TScatter simply embeds 40 bits of tag data twice on 80 samples in a symbol (shown in Fig. 9(b)). By doing this, there still exits a 40-sample sequence which stores a copy of 40 bits of tag data after the CP removal. Hence, the tag does not have to rely on the synchronization accuracy of the envelope detector to avoid the cyclic prefix. This approach can be easily implemented on the tag without extra energy cost or computing resources.

At the receiver side, to decode the 40 bits of tag data in each symbol, we need to know which sample in the symbol is the starting sample of the 40-sample sequence. To find the starting sample, we designed a backscatter header (shown in Appendix B) with a duration of two symbols. The backscatter header is predefined as a flag sequence. Even though a portion of the flag sequence is removed due to the CP removal, there still exits a backscattered symbol whose samples are modulated only by the flag sequence. We add a sliding-window-based algorithm to the decoding algorithm (detailed in Sec. 6.3) to search which part of the flag sequence is the best matching decoding result of this symbol . Then we can obtain the position of the starting sample. When the decoding result matches the two-symbol long predefined backscatter trailer, it signifies the end of the tag data.

5.2 Coding Scheme for Low BER

To avoid the phase offsets being eliminated, TScatter uses predefined nearly orthogonal pseudo-random noise (PN) sequences to represent the tag data (Appendix A lists the PN sequence table). As shown in Fig. 10, the tag data is divided into multiple groups. Each group will be spread to a special 40-bit long PN sequence. Then each bit in the PN sequence is transmitted by using the sample-level modulation. With the help of the sample-level modulation, each bit in the PN sequence can represent a phase offset. As a result, the sequences of phase offsets are orthogonal to each other and the tag data can avoid being eliminated. As described in Sec. 5.1, to avoid being removed by the CP removal, each sequence is transmitted twice. To reduce the coding complexity on the tag, we implant a lookup table of the sequences to map the tag data to the corresponding PN sequence.

Using orthogonal PN sequences to represent the tag data has three benefits. First, since the sequences are orthogonal to each other, the effective signal-to-noise ratio (SNR) of backscattered signals is improved at the receiver side. Second, since the sequences are predefined, the receiver can solve the decoding algorithm by directly finding which sequence is the best-match rather than estimating the sequence, which lowers the computational complexity (detailed in Sec. 6.3). Third, TScatter can be used in lower order modulation schemes of OFDM, such as BPSK or QPSK.

5.3 Coding Scheme for High Throughput

The coding scheme for high throughput is a combination of convolutional code and predefined data when the OFDM sender utilizes higher order modulation schemes, such as 64QAM or 16QAM. The convolutional code is a rate 2/3 feedforward encoder. The predefined data is to increase the estimation accuracy by constricting the estimation result to a smaller range of values during the decoding process (detailed in Sec. 6.3). For 64QAM, in the 40-sample sequence, we use 32 samples to embed the convolutional coded tag data. The remaining 8 samples are modulated by the predefined data. For 16QAM, we use 18 samples to embed the convolutional coded tag data and 22 samples to embed the predefined data.

6 Decoding of Tag Data

One benefit of our sample-level modulation is that it does not require an accurate synchronization with the OFDM sender because the phase offset caused by a lack of accurate synchronization can be corrected by the phase error correction. In this section, we first analyze the phase offset, then describe the OFDM demodulation model and mathematically demonstrate how the phase offset is corrected by the OFDM receiver. In the end, we describe how to decode the tag data.

6.1 Phase Offset Analysis

The phase offset can be characterized by three factors:

• *Envelope Detection Delay.* The tag leverages an envelope detector to identify the WiFi transmission. However, due to an uncertain delayed response, the detector cannot accurately identify when the sample starts. Then it always occurs that the switching actions and the samples are not edge-aligned. We can consider a time delay τ that exists between them and causes a phase offset $\beta = 2\pi f_s \tau$.

• *Wireless Channel.* The wireless channel introduces a phase offset of ϕ to the samples.

• *Frequency Offset.* The frequency offset causes two phenomenas: carrier frequency offset (CFO) and sampling frequency offset (SFO). In Appendix B and C , we demonstrate the CFO and SFO can be estimated and corrected.

Thus, a backscattered sample can be expressed as follows:

$$\mathcal{R}_n = e^{j(\beta+\phi)} e^{j\theta_n} \mathcal{S}_n \qquad (11)$$

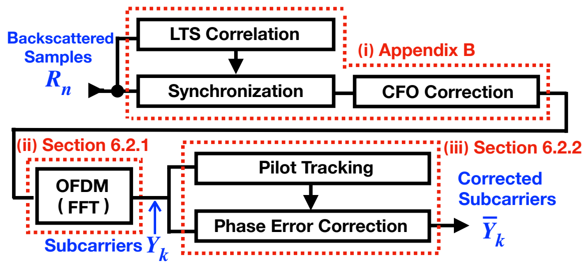

Figure 11: The demodulation process in 802.11g WiFi receiver from the backscattered samples to the corrected subcarriers.

In Sec. 6.2.2, we demonstrate that the phase offset caused by the envelope detection delay and wireless channel can be eliminated and do not affect the values of data subcarriers.

6.2 Demodulation Model

The objective of TScatter's demodulation is to decode the tag data on OFDM subcarriers. To achieve this objective, we need to understand how the OFDM receiver converts the backscattered samples to the subcarriers. To do so, we divide the workflow of an 802.11g receiver into 3 parts (shown in Fig. 11), and build models for these parts.

6.2.1 Modeling OFDM

The 80 backscattered samples of each symbol first go through the CP removal module, where the first 16 samples are removed. Then the remaining 64 samples are applied to the DFT to generate the complex values of OFDM subcarriers. The subcarrier's value can be derived as:

$$Y_k \;=\; \text{DFT}\;[\;\mathcal{R}_n\;] \;=\; e^{j(\beta+\phi)}\sum_{n=0}^{63} e^{j\theta_n}\mathcal{S}_n e^{-j2\pi nk/64} \tag{12}$$

Where, $k \in \{0,\dots,63\}$ and Y_k is the complex value of the k'th OFDM subcarrier. Eqn. 12 shows that the tag data is transfered from the backscattered samples in time domain to the subcarriers in frequency domain by OFDM.

6.2.2 Modeling Phase Error Correction

While the tag data is transfered into the subcarriers, the phase offset $\beta+\phi$ is also transfered into the subcarriers (shown in Eqn. 12), which may increase the tag data decoding error. We had an important observation that the OFDM receiver can leverage pilot subcarriers to eliminate the phase offset. In this section, we mathematically demonstrate the procedure of phase error correction.

The phase error estimation is performed by calculating the rotating phase of the four pilot subcarriers. In the sender, the four pilot subcarriers are $\{\mathcal{X}_{11},\mathcal{X}_{25},\mathcal{X}_{39},\mathcal{X}_{53}\}$ and their initial values are $\{1,1,1,-1\}$ [2]. In the receiver, we use $\{Y_{11},Y_{25},Y_{39},Y_{53}\}$ (shown in in Eqn. 12) to represent the four pilot subcarriers. The rotating phase of the pilot subcarriers can be estimated as:

$$\begin{aligned}\Psi &= \angle(Y_{11}+Y_{25}+Y_{39}-Y_{53})-\angle(\mathcal{X}_{11}+\mathcal{X}_{25}+\mathcal{X}_{39}-\mathcal{X}_{53})\\ &= \beta+\phi+\angle\Gamma \end{aligned}\tag{13}$$

Where,
$$\Gamma = \sum_{n=0}^{63} e^{j\theta_n}\mathcal{S}_n\Big(\sum_{k=11,25,39} e^{-j2\pi nk/64} - e^{-j2\pi n\frac{53}{64}}\Big) \tag{14}$$

From Eqn. 13 and 14, we observe that a new phase offset $\angle\Gamma$ is introduced which is caused by the backscatter modulation on the pilot subcarriers. Eqn. 13 also illustrates that although the backscatter modulation change the pilot subcarriers, the phase offset $\beta+\phi$ is isolated from the tag data.

Since 48 out of the 64 subcarriers are used to carry the payload data ($k \in \{6,\dots,58\}$ and $\notin \{11,25,32,39,53\}$), the OFDM receiver multiplies 48 data subcarriers by $e^{-j\Psi}$ to correct the phase offset:

$$\begin{aligned}\overline{Y}_k &= e^{-j\Psi}\,Y_k \\ &= e^{-j\angle\Gamma}\,\cancel{e^{-j(\beta+\phi)}}\,\cancel{e^{j(\beta+\phi)}}\sum_{n=0}^{63} e^{j\theta_n}\mathcal{S}_n e^{-j2\pi nk/64}\end{aligned}\tag{15}$$

Where,
$$e^{-j\angle\Gamma} = \frac{Re\{\Gamma\} - j*Im\{\Gamma\}}{\sqrt{Re\{\Gamma\}^2+Im\{\Gamma\}^2}} \tag{16}$$

Eqn. 15 demonstrates that the phase offset $\beta+\phi$ is eliminated and does not affect the tag data decoding. On the other hand, Eqn. 15 also demonstrates that the values of data subcarriers were affected twice: The first one happens during the backscatter modulation stage, when the values of the data subcarriers were changed according to the tag data; the second one happens during the phase error correction stage, when the values of data subcarriers were corrected by the phase offset calculated from pilot subcarriers. Although Γ exists in Eqn. 15, Eqn. 14 shows that the only unknown value in Γ is the tag data. Therefore, we can leverage Eqn. 15 to decode the tag data without being affected by the phase offset $\beta+\phi$.

6.3 Decoding Tag Data

Eqn. 15 shows that the phase change on each subcarrier is different and determined by all 64 backscattered samples. If the tag data on any backscattered sample change, the phase change on each subcarrier changes. Therefore, we must use all subcarriers' information to decode each tag data.

We observe that the inputs of Eqn. 15 are the tag data θ_n and the original OFDM sample $\mathcal{S}_n$, while the outputs of Eqn. 15 are the corrected data subcarrier $\overline{Y}_k$. Hence, if we obtain the values of $\mathcal{S}_n$ and $\overline{Y}_k$, we can decode θ_n.

The values of original OFDM sample $\mathcal{S}_n$ can be calculated by using Eqn. 8. However, the challenge is that we cannot obtain the real value of $\overline{Y}_k$. Normally, OFDM backscatter uses the coded data linear transform technique in [33, 35, 36] to track the phase change on the subcarriers. If we follow the same technique to get the subcarrier values, we find that the subcarrier values deviate from $\overline{Y}_k$. This is because the OFDM receiver maps $\overline{Y}_k$ to the nearest QAM points (we assume $\overrightarrow{Y}_k$).

Since $\overrightarrow{Y}_k$ are the nearest QAM points of $\overline{Y}_k$, we can estimate the tag data θ_n by calculating the minimum Euclidean distance between the corrected data subcarrier values $\overline{Y}_k$ and their mapped points $\overrightarrow{Y}_k$:

$$\begin{bmatrix} \tilde{\theta}_0 \\ \vdots \\ \tilde{\theta}_{63} \end{bmatrix} = \underset{[\theta_0,\dots,\theta_{63}]}{\arg\min} \sum_{\substack{k=6 \\ k\neq 11,25,32,39,53}}^{58} ||\overrightarrow{Y}_k - \overline{Y}_k||_2 \tag{17}$$

$$= \underset{[\theta_0,\dots,\theta_{63}]}{\arg\min} \sum_{\substack{k=6 \\ k\neq 11,25,32,39,53}}^{58} ||\overrightarrow{Y}_k - e^{-j\angle\Gamma} \sum_{n=0}^{63} e^{j\theta_n} S_n e^{-j2\pi nk/64}||_2$$

Where, k are the indexes of the data subcarriers, $\overrightarrow{Y}_k$ are provided by the receiver and Γ can be represented using Eqn. 14. The only unknown value in Eqn. 17 is the tag data θ_n. Therefore, we can leverage Eqn. 17 to decode the tag data.

Since each tag data θ_n has limited values (i.e., either 0 or π), Eqn. 17 is a constrained linear least-squares problem. We note that the left side of Eqn. 17 is 64 unknown values $(\tilde{\theta}_0,\dots,\tilde{\theta}_{63})$, while we only have 48 data subcarrier values $\overrightarrow{Y}_k$ ($k \in \{6,...,58\}$ and $\notin \{11,25,32,39,53\}$) on the right side. That means Eqn. 17 is not full row-rank. Mathematically, to determine a unique solution using Eqn. 17, we need to minimize the number of unknown values on left side to 48. A simple way to do this is that the number of unknown tag data in each symbol is no more than 48 and the remaining tag data are predefined. For example, we predefine $e^{j\theta_{48,...,63}} = e^{j0} = 1$ and calculate the unknown data $e^{j\theta_{0,...,47}}$. Therefore, the left side (the unknown tag data) and the right side (the data subcarrier values) have the same size, and Eqn. 17 is now full row-rank. In fact, Eqn. 17 illustrates that the maximum number of samples used to store the unknown tag data in each symbol is 48. This is because we rely on the data subcarriers' values to calculate the unknown tag data and each symbol provides only 48 data subcarriers. The coding scheme in Sec. 5.1 requires that the number of the tag data embedded in each symbol is no more than 40, which is also less than 48.

Eqn. 17 is solved by using the matrix decomposition, whose computational complexity is $O(n^3)$ [3], where n is the number of the unknown tag data. When n gets to the maximum value (i.e., 48), there are $n^3 = 110592$ floating-point operations. A low power edge computing platform Jetson Nano [21] (only cost \$99) implemented on an ARM A57 processor with 472G floating-point operations per second, can solve the problem in $\frac{110592}{472*10^9} = 0.25\mu s$, which is less than a symbol duration $4\mu s$.

7 Lite Version of TScatter

In prior works [33, 35, 36], the codeword translation works only when the phase error correction is disabled. In this section, we demonstrate that TScatter can also use the codeword translation at the symbol level without disabling the phase error correction and introduce the lite version of TScatter.

Prior works use the symbol-level modulation (i.e., phase change once per symbol) to realize the codeword translation. Based on our observation from Sec. 3.3, when the inversion point settles in the useful symbol, the corrected subcarriers are different from the original ones. Since the symbol-level modulation is essentially a special case of the sample-level modulation (i.e., multiple phase changes per symbol) by setting the number of phase changes as 1 within one symbol, it is possible to use the codeword translation to achieve the basic idea of TScatter without disabling the phase error correction. We call this approach Lite TScatter because its design principle is derived from our sample-level modulation by setting all the tag data values inside a symbol to be all-one or all-zero.

Specifically, the whole procedure of Lite TScatter is as follows: before the tag transmits the data, it first transmits a long all-one (or all- zero) sequence to reflect the preamble and several symbols. Since there is no phase change in the long sequence, the corrected subcarriers are the same as the original ones. Then, the tag transmits the first data. The first data is predefined, and its value should be different from that of the long sequence. For example, if the long sequence is all-one, the first data should be defined as zero. Since there is a phase change between the long sequence and the first data, we can find the first symbol which is different from the original one. Next, the tag can transmit arbitrary data. If the corrected subcarriers are the same as the original ones, it implies there is no phase change and the tag data should be equal to the last one. If the corrected subcarriers are different from the original ones, it implies there is a phase change and the data should be different from the last one. Therefore, we can decode the tag data one by one. By modifying the codeword translation decoder in Eqn. 5, the decoding function of Lite TScatter is as follows:

$$\text{Tag data } d_n = \begin{cases} d_{n-1} & \mathcal{X}_k e^{j\delta_k} \oplus \mathcal{X}_k = 0 \\ 1-d_{n-1} & \mathcal{X}_k e^{j\delta_k} \oplus \mathcal{X}_k \neq 0 \\ \text{Predefined} & n=1 \end{cases} \tag{18}$$

Eqn. 18 provides a lite version of TScatter, which enables codeword translation work with WiFi protocols that enable the phase error corrections. However, Lite TScatter's throughput is relatively low because the tag data is modulated at the symbol level instead of the sample level.

8 Evaluation

In this section, we present the implementation of TScatter and show the experimental results of our extensive evaluation.

8.1 Implementation

TScatter (shown in Fig. 12) is implemented on an open-source backscatter platform [29], which mainly consists of two components: a Microsemi AGLN250 low power FPGA and an ADG902 RF reflective switch. To compare different levels of

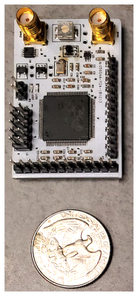

Figure 12: TScatter Tag

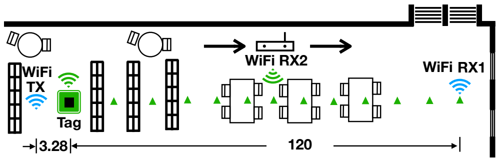

Figure 13: Library (in feet)

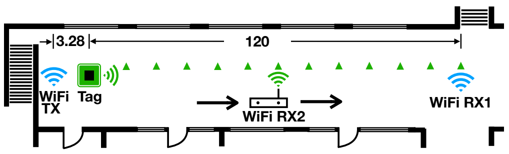

Figure 14: Hallway (in feet)

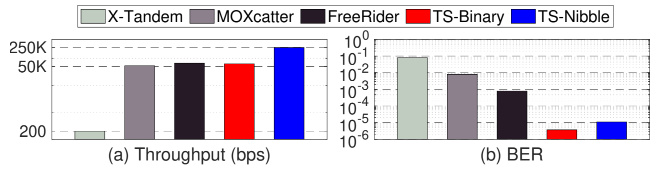

Figure 15: Comparing with state-of-the-art with similar throughput

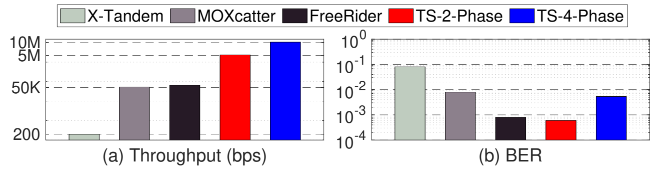

Figure 16: Comparing with state-of-the-art with similar BER

coding and modulation schemes, we implemented both the coding schemes of **binary** and **nibble** (i.e., 4-bit) (shown in Appendix A) and the modulation schemes of **2-phase** and **4-phase** (introduced in Sec. 4) in the FPGA.

To conduct fair comparisons, the distance between the WiFi transmitter and the backscatter tag is 1 meter (i.e., 3.28 feet), which is the same as the one in FreeRider [33]. The WiFi transmitter is implemented on a ThinkPad T420s laptop which transmits the IEEE 802.11g compatible signals. The WiFi transmitter utilizes 64QAM as its modulation scheme by default. In Sec. 8.6, we evaluate TScatter's performance with different WiFi modulation schemes.

To extensively evaluate TScatter's performance, the experiments were conducted in three different scenarios: **Library** (Fig. 13), **Hallway** (Fig. 14), and **Stadium**. The WiFi receivers are implemented using DELL XPS 9550 laptop and USRP-B210 with 802.11g PHY layer. WiFi receiver 1 is used to obtain the original WiFi information. WiFi receiver 2 listens for the backscattered WiFi signal. To assess the system performance, we use the following two metrics:

Throughput: The throughput is defined as correctly demodulated data bits at PHY layer.

Bit error rate (BER): The BER is defined as the number of bit errors divided by the total number of transmitted bits.

8.2 Comparing with State-of-the-art

We first compare the performance of TScatter with the reported best results produced by recent OFDM-based WiFi backscatter systems (i.e., X-Tandem [35], MOXcatter [36] and FreeRider [33]). Fig. 15 shows BER results when TScatter and state-of-the-art solutions have similar level of throughput. As we can observe from this figure, the BERs of TScatter are much lower than that of the state-of-the-art solutions. Fig. 16(a) shows the comparison of throughput. We can observe that, with 4-phase modulation scheme, TScatter achieves 10.61 Mbps. The main reason TScatter achieves orders of magnitude better performance is that it takes advantage of the phase error correction. State-of-the-art solutions require specific commodity NICs that can disable the phase error correction. However, the phase error correction is very important for the OFDM demodulation because the phase error may be dynamically changing due to the changes of environment (e.g., temperature of the oscillators and object movement). Without the phase error correction, the OFDM demodulation error will increase. Similarly, disabling phase error correction will also introduce phase error into the decoding procedure of the codeword translation, which will increase the tag data decoding error. In contrast, TScatter takes the phase error correction into consideration. On the demodulation side, TScatter builds the demodulation model from the backscattered samples to the corrected subcarriers that can not only correct the phase error due to the dynamic environments but also decode the tag data by estimating the minimal Euclidean distance rather than by using XOR. On the modulation side, TScatter leverages the sample-level modulation to apply more robust coding methods to further improve the BER or throughput. As a result, the BERs of TScatter are around $\mathbf{10^2}$, $\mathbf{10^3}$ and $\mathbf{10^4}$ **times** as low as that of FreeRider, MOXcatter and X-Tandem, respectively. The throughputs of TScatter are 53,050, 212, and 176 times higher than X-Tandem, MOXcatter, and FreeRider, respectively.

8.3 Library

To understand how TScatter works in a multipath rich environment, we conducted the experiments in a library (shown in Fig. 13). Since there are a lot of shelves, tables, and chairs in the library, these obstacles not only block the direct line-of-sight transmission path but create more multipath effects as well. In this setting, the backscatter tag and WiFi transmitter are deployed on the shelves. We move the WiFi receiver from shelves to tables to vary the multipath environment.

Fig. 17 and Fig. 18 show the throughput and BER over different communication distances, respectively. As we can observe from these figures, the throughput of TScatter is similar over the change of distances while the BER increases slowly. When the communication distance reaches 120 feet, the average BERs of TScatter are still around 10^{-3} and 10^{-4} for Nibble and Binary, respectively. Since the multipath effect will become more severe as the distance increases in the library scenario, we can conclude that TScatter is resistant to the wireless channel interference. Because the demodulation process (described in Sec. 6.1) takes the phase error intro-

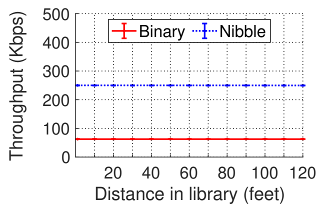

Figure 17: Throughput

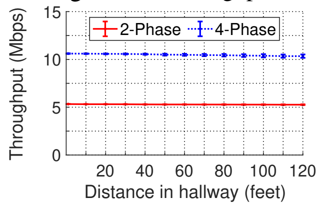

Figure 19: Throughput

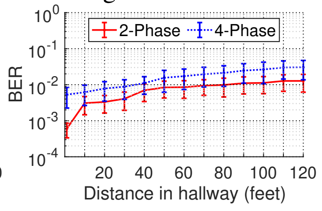

Figure 20: BER

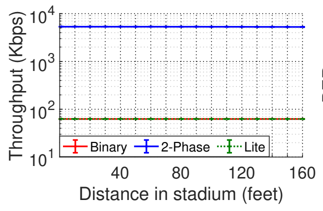

Figure 21: Throughput

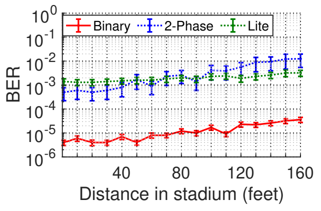

Figure 22: BER

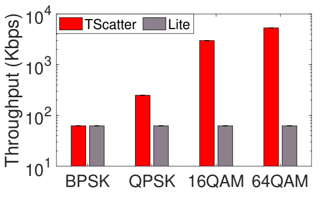

Figure 23: Throughput v.s. WiFi OFDM modulation scheme

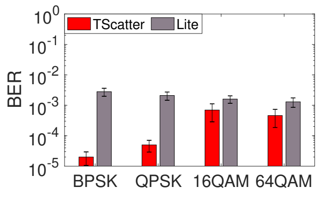

Figure 24: BER v.s. WiFi OFDM modulation scheme

duced by the wireless channel into consideration, TScatter shows great advantages in this scenario.

8.4 Hallway

In this section, we evaluate TScatter in the hallway scenario. As shown in Fig. 14, the hallway is on the second floor of an academic building. This scenario is selected to reflect TScatter's real-world performance with less environmental impact because the hallway is relatively spacious. In this scenario, the backscatter tag and the WiFi receiver were kept in line-of-sight. The distance between the tag and the receiver is changing from one foot to 120 feet.

Fig. 19 shows the throughput of our TScatter system using different modulation schemes (i.e., 2-phase and 4-phase). Overall, TScatter can achieve a maximum of 10.61 Mbps and the throughput is stable over different communication distances because it has a high granularity modulation scheme. Fig. 20 shows the BER under different communication distances. We can observe that the BER for the 2-phase modulation scheme is very low. The average BER is lower than 1% when the distance increases to 70 feet. Even when the distance increases to 120 feet, the average BER is still around 1%. This is because our demodulation model captures the impact of the phase error correction on the received subcarriers.

8.5 Outdoor Stadium

To understand the performance of TScatter with different modes (i.e., low BER, high throughput, and lite version) in the same scenario, we conduct experiments in an outdoor stadium. The distance between the tag and the receiver is changing from one foot to 160 feet.

Fig. 21 shows the throughput over different communication distances. The high throughput mode (2-phase) outperforms the low BER mode (binary) and Lite TScatter because it has a high granularity modulation scheme. When the receiver is 160 feet away from the tag, the throughput of binary, 2-phase, and Lite TScatter are around 62.5 Kbps, 5.26 Mbps and 62.3 Kbps, respectively. Fig. 22 shows the BERs at different distances. The BER of low BER mode and Lite TScatter is more stable than that of high throughput mode despite the fact that the signal strength degrades across distance. Specifically, the BER of low BER mode is much less than that of the other two modes. Therefore, the low BER mode has the significant advantage on providing reliable backscatter communications. When the distance reaches 160 feet, the average BERs of binary, 2-phase, and Lite TScatter are still around 10^{-5}, 10^{-2} and 10^{-3}, respectively.

8.6 Impact of OFDM Modulation Scheme

In Sec. 5.2 and 5.3, we introduced how TScatter deals with lower and higher level WiFi OFDM modulation schemes respectively. In this section, we compare sample-level modulation TScatter's performance (in terms of throughput and BER with low BER or high throughput coding scheme) with Lite TScatter (which uses symbol level modulation) under different WiFi OFDM modulation schemes (i.e., BPSK, QPSK, 16QAM, and 64QAM). Fig. 23 shows the throughput result. We observe that the throughput of Lite TScatter is almost the same under different OFDM modulation schemes because one bit of data is embedded in per symbol no matter what the OFDM modulation scheme is. For TScatter, the throughput increases while the OFDM modulation scheme changes from the lowest level (i.e., BPSK) to the highest level (i.e., 64QAM). At 64QAM, the throughput reaches 5.33 Mbps. The reason of this growing trend is that higher level OFDM modulation schemes can provide higher resolution to decode the tag data, which can accommodate more tag data per symbol.

Fig. 24 shows the result of BER versus OFDM modulation scheme. We can observe that TScatter's BER is lower than Lite TScatter's across all kinds of modulation schemes even when the OFDM transmitter utilizes BPSK. This is because the demodulation model captures the impact of the phase error correction on the received subcarriers. Moreover, TScatter leverages the sample-level modulation to apply more robust coding methods to further improve the BER.

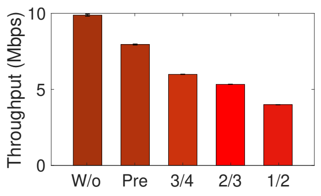

Figure 25: Throughput v.s. Tag Coding Scheme

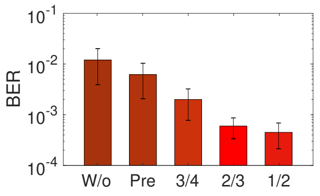

Figure 26: BER v.s. Tag Coding Scheme

8.7 Impact of Tag Coding Scheme

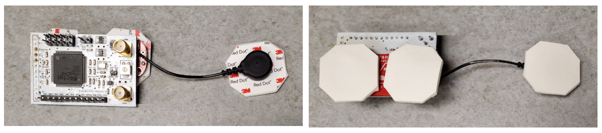
In Sec. 5.3, we have described TScatter's coding schemes for high throughput. Fig. 25 and 26 show TScatter's performance with different code rates. "W/o" denotes the results without using coding scheme. "Pre" denotes the results that TScatter only uses predefined data without coding. "3/4", "2/3", and "1/2" denote the results that TScatter uses both predefined data and coding with a code rate at $3/4$, $2/3$, and $1/2$, respectively. Since the experiments show similar trends, we show the results with the 2-phase modulation scheme in the hallway scenario. The WiFi transmitter utilizes 64QAM.

When no coding scheme is utilized, the whole 40-sample sequence is used to store the unknown tag data (described in Sec. 5.1). Consequently, TScatter has the highest throughput (shown in Fig. 25) as well as the highest BER (shown in Fig. 26) among all coding schemes. The reason of the high BER is that the corrected data subcarrier values deviate from their mapping points, which cause estimation errors in Eqn. 17. To reduce the estimation errors, we replace 8 unknown tag data with the predefined data to constrict the estimation result to a smaller range of values. Fig. 26 shows that the BER decreases to below 1%. To achieve a more reliable communication, we combine the predefined data and the convolutional code to generate the tag data. When the code rate is up to 2/3, the BER is lower than 0.1% and the throughput is as high as 5.33 Mbps, which provides a reliable high throughput communication.

8.8 Energy Consumption Analysis

We designed an integrated circuit for TScatter's digital processing module and conducted a simulation using Cadence Spectre for TSMC 65nm process. In the power consumption simulation, multiple factors are considered including Vdd (1.6V $\sim$ 2V), temperature (25°C), system clock frequency, and power mode.

The IC design consists of four modules: clock, energy detector, control module and RF transistor. TScatter first detects the WiFi packet by using the energy detector. When the WiFi packet is detected, the clock synthesizes a 20MHz frequency for the control module. Then the control module reads the data from the sensor, latches and codes the sensor data, and toggles the RF transistor according to the coded data. Since the power consumption of the energy detector and the RF transistor is very low (around $0.3\mu W$), we mainly introduce the implementation details of the clock and the control module:



(a) Front (b) Back

Figure 27: EMG connected TScatter tag

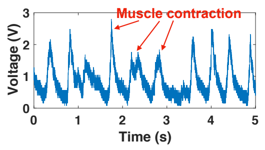
Clock. The bottleneck of the power consumption of the TScatter system is the clock. We use a ring oscillator to synthesize a 20MHz frequency. The frequency accuracy is sensitive to temperature change. We add a thermistor to design a temperature compensation circuit to compensate for the frequency drift. Moreover, we add a trimming pad to correct the frequency. The simulation result shows that the power consumption of the ring oscillator is $23.7\mu W$.

Control module. The control module contains a cache circuit to store the sensor data, a code circuit to code the sensor data, and an inverter to toggle the RF transistor as a fan-out. The cache is constructed by the basic cache cell. The cache cell is composed of one D latch and one transmission gate. Through connecting the output of D latch to the input of the transmission gate, a cache cell with simultaneous read and write capability is created. The reason we use the latches rather than flash to store the sensor data is that the power consumption of latches is very low even when they are working at 20MHz. The code circuit contains a lookup table for low BER mode, which is composed of 32 PN sequences (shown in Appendix B), and a convolutional encoder for high throughput mode, which is composed of 7 latches and 3 XOR gates. The lookup table is also constructed by basic logic gates. The inverter is minimum sized. The simulation result shows that the power consumption of the control module is around $6.2\mu W$.

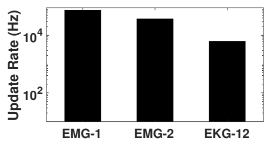
From the above analysis, the overall power consumption of TScatter is **30.2μW**, which is similar to that of other OFDM backscatter systems. This is mainly because the most power-hungry part of the backscatter tag is the clock. No matter the sample-level modulation or the symbol-level modulation, they all need to shift the incoming WiFi signal to the adjacent band channel to minimize the interference from the original band channel, which can be done by toggling the RF switch at a specific frequency. The minimum value of the frequency equals a WiFi channel bandwidth, i.e., 20MHz. Consequently, to toggle the RF switch at 20MHz, the logic control modules of the symbol-level modulation and the sample-level modulation are all operating at 20MHz. Although TScatter performs the convolutional coding in high throughput mode, the encoder which is constructed by 7 D latches and 3 XOR gates has a very low power consumption even when it works at 20MHz. Therefore, the energy consumptions of TScatter and other OFDM backscatter systems are similar.

9 Application

In this section, we show that biometric measurements (such as EMG and EKG) can be wirelessly transmitted in real-time by using TScatter. Fig. 27(a) (front side) and Fig. 27(b)



(a) EMG data



(b) Update Rate (log scale)

Figure 28: (a) shows the EMG data while the system is attached to arm muscle and the participate is doing dumbbell lifting. Each peak corresponds to a muscle contraction. (b) shows the average update rate when the system is connected with 1-channel EMG (sleeping monitoring), 2-channel EMG (fitness monitoring), and 12-channel EKG.

(back side) show a prototype that an EMG sensor that is connected to the TScatter tag. By using foam electrodes, the tag and sensor can be attached to a muscle to record the electrical activity produced by the muscle. Fig. 28(a) shows one set of data while the system is monitoring arm activities. In this figure, each peak corresponds to a muscle contraction. Fig. 28(b) shows the average update rate under different configurations: i) EMG-1, 1-channel EMG is attached to a leg muscle for monitoring sleep abnormalities [5]; ii) EMG-2, 2-channel EMG is attached to upper and lower arm for fitness monitoring; and iii) EKG-12 , 12-channel EKG is generated to test how TScatter works with multi-channel EKG. With a typical sampling rate at 1 KHz and 24-bit resolution, the required bit rate for 12-channel EKG is 288 Kbps. With different modulation schemes, our TScatter can provide around 5 ~10 Mbps throughput at the physical layer. Even after deducting the performance loss due to the wireless signal attenuation caused by the human body and upper layer overheads (e.g., ACKs), TScatter's throughput should be sufficient for 12-channel EKG measurements.

10 Related Work

Recently, backscatter has played an attractive role in the passive communication field because of its significant performance on power consumption. Researchers have proposed various kinds of novel techniques [8, 10, 17–20, 26, 30, 31] to support various applications. For example, ReMix [26] enables backscattering of deep tissue devices by overcoming interference from the surface of a human body and localizing the in-body backscatter device. Living IoT [8] enables smart farming applications by placing backscatter devices on live insects. NICscatter [31] introduces a backscatter communication method on commercial Wi-Fi NICs that enables malware to covertly convey information. PAB [10] enables long-term ocean applications by backscattering acoustic signals in underwater environments.

To leverage existing infrastructures, such as TV band [16, 22], FM radio [27], LoRa [7, 23, 24], Bluetooth [9], ZigBee [13], and WiFi [6, 11, 12, 32–37], researchers have also explored various solutions. Specifically, in the WiFi backscatter field, Passive WiFi [12] demonstrates for the first time that the backscatter can generate 802.11b transmissions. Interscatter [9] shows that Bluetooth transmissions can be used to create 802.11b transmissions using backscatter communication. HitchHike [32] allows a tag to backscatter existing 802.11b transmissions from a commodity WiFi transmitter. To further support more complex WiFi structures, such as OFDM, WiFi Backscatter [11] conveys information by modulating the CSI and RSSI measurements at the OFDM receivers. BackFi [6] uses customized full-duplex devices to clean out the effect during backscattering OFDM signals. FS-Backscatter [34] minimizes the interference from the original band by shifting the backscattered OFDM signals to an adjacent band. FreeRider [33] proposes the OFDM-based codeword translation technique, which piggybacks the tag data by changing the phase of backscattered OFDM symbols. Built on top of FreeRider, MOXcatter [36] and X-Tandem [35] realize a MIMO OFDM backscatter system and a multi-hop OFDM backscatter system, respectively. However, FreeRider, MOXcatter, and X-Tandem require specific WiFi receivers that can disable the phase error correction.

Different from the above backscatter systems, TScatter is the first work that conducts sample-level coding and subcarrier-level decoding based on OFDM waveforms. More importantly, it is able to achieve orders of magnitude lower bit error rate or much higher throughput than existing approaches.

11 Discussion & Conclusion

Although our system was tested using USRPs, we believe that our Lite TScatter can potentially be deployed on commodity WiFi devices with little modification because it is a natural extension of FreeRider and MOXcatter. Based on the description of prior works and WiFi specification [2, 14, 33, 35, 36], to implement the full version of TScatter on commodity devices, we expect to address the following engineering problems: 1) Since the backscattered WiFi packets have been modified, commodity WiFi receivers may drop these packets due to their failure to pass the cyclic redundancy check (CRC). To address this problem, we need to use a WiFi card that can be configured into monitor mode which can obtain packets with bad checksums [33]; 2) we need to know the scrambling seed (i.e., the initial state of shift register) to decode the tag data. For different WiFi cards, we need to take different approaches. For example, in ath5k supported WiFi cards (e.g., Atheros AR5112 and AR2425), the scrambling seed can be derived by setting the register of the driver [14].

We note that the main contribution of this paper is a novel backscatter design principle (i.e., sample-level modulation) for OFDM backscatter. We extensively evaluated the performance of TScatter in various real-world scenarios. Evaluation results demonstrate that TScatter is able to achieve orders of magnitude lower bit error rate or much higher throughput than existing approaches [33, 35, 36].

Appendix B Synchronization Between Sender and Receiver & CFO Correction

In this section, we build a mathematical model for the synchronization and carrier frequency offset (CFO) correction (i.e., part (*i*) in Fig. 11). Once the WiFi transmission is identified, the WiFi receiver first leverages the preamble to synchronize the symbol timing and then correct the CFO. Therefore, we start with an analysis of how the tag performs the synchronization between the WiFi sender and the WiFi receiver.

Fig. 29 shows our synchronization solution. The preamble includes two long training (LT) sample sequences. Each sequence is composed of 64 samples. By identifying where the two peak values of the correlation between the received samples and training pattern occur, the WiFi receiver can find where the symbol starts [15]. Therefore, to avoid changing the training sample's value, when TScatter detects the WiFi transmission by using the RF energy detector, it first uses continuous square waves to only reflect the preamble and does not embed any data into the preamble. After the square waves, TScatter starts to modulate the WiFi samples.

One may ask whether the phase offset (described in Sec. 6.1) will change the preamble value, therefore affects the synchronization. We note that TScatter does not change the preamble sample's value. Without loss of generality, let us assume the phases of continuous square waves are $\theta_n = 0$ and the training pattern value is $\overline{LT}_i$. Then, the positions of two peak values of the correlation between the received samples $\mathcal{R}_l$ (described in Eqn. 8) and the training pattern $\overline{LT}_i$ are:

$$\begin{aligned}(l_1, l_2) =& \underset{l}{\text{argmax}_2} \Big|\Big| \sum_{i=0}^{63} (\mathcal{R}_{l+i} * \overline{LT}_i) \Big|\Big|_2 \\ =& \underset{l}{\text{argmax}_2} \Big|\Big| e^{j[\beta+\phi]} e^{j*0} \sum_{i=0}^{63} (\mathcal{S}_{l+i} * \overline{LT}_i) \Big|\Big|_2 \\ =& \underset{l}{\text{argmax}_2} \Big|\Big| \sum_{i=0}^{63} (\mathcal{S}_{l+i} * \overline{LT}_i) \Big|\Big|_2 \end{aligned} \tag{19}$$

Where, argmax$_2$ provides the two sample numbers (l_1, l_2) for two peak correlation values.

Eqn. 19 proves that the positions of two peak correlation values are only related to the original sample values $\mathcal{S}_l$ and are not affected by the phase offset. Therefore, the phase offset will not affect the synchronization. Our experimental result (shown in Fig. 30) also illustrates that when the tag uses continuous square waves to reflect the WiFi signals, it does not interfere with the positions of two peak correlation values, and the receiver can achieve a precise synchronization.

In the WiFi receiver, the received sample at frequency f_c is down-converted to baseband with a local carrier frequency $(1+\varepsilon)f_c$. At the receiver side, the frequency offset εf_c causes two phenomenas: carrier frequency offset (CFO) and sampling frequency offset (SFO). The CFO introduces an extra phase offset of $\alpha = 2\pi\varepsilon\frac{f_c}{f_s}$ on the samples during each down-conversion procedure. When the l'th sample of the frame is down-converted, the phase offset applied to the sample is accumulated to $l\alpha$.

$$\mathcal{R}_{l,n} = e^{j(\beta+\phi)} e^{j(l\alpha)} e^{j\theta_n} \mathcal{S}_n \tag{20}$$

Where l and n point to the same sample. Since a WiFi frame contains multiple symbols, l is the sample number in the frame, while n is the sample number in the symbol.

Since the tag does not affect the synchronization, the CFO can be estimated accurately. An estimation of the CFO can be obtained simultaneously when the synchronization is achieved. According to the WiFi specification [2], the WiFi receiver uses LT samples to estimate the CFO. The starting LT sample number is computed as l_1. Let us denote the t'th LT sample as $\mathcal{R}_{l_1+t}$. The CFO estimator is given by:

$$\alpha = \frac{1}{64}\angle\left(\sum_{t=0}^{63} \mathcal{R}^*_{l_1+t}\, \mathcal{R}_{l_1+t+64}\right) \tag{21}$$

To correct the CFO, the received sample $\mathcal{R}_{l,n}$ is multiplied by $e^{-jl\alpha}$. Through the synchronization, the WiFi receiver learns the sample number l. Thus, the received sample can be updated to the corrected sample S_n:

$$\mathcal{R}_n = \mathcal{R}_{l,n} * e^{-jl\alpha} = e^{j(\beta+\phi)} e^{j\theta_n} x_n \cancel{e^{jl\alpha}} \cancel{e^{-jl\alpha}} \tag{22}$$

Eqn. 22 shows that the impact of CFO is canceled by the CFO correction module in the WiFi receiver.

Appendix C SFO Correction

Like the CFO, an SFO also exists, which causes a phase offset to OFDM subcarriers after the DFT [28]:

$$\alpha_{sfo} = -2\pi\varepsilon rk\frac{N+N_g}{N} \tag{23}$$

Where, $N = 64$ is the DFT size, $N_g = 16$ is the cyclic prefix length, r is the symbol number which is learned through the synchronization, k is the subcarrier number and ε can be calculated from the estimated CFO ($\varepsilon = \frac{\alpha f_s}{2\pi f_c}$, described in Sec. 6.1). The OFDM subcarriers are corrupted as $Y_k e^{j\alpha_{sfo}}$.

From Eqn. 23, we know the key to correct the SFO is to estimate CFO accurately. In Appendix B, we have demonstrated the tag does not change the preamble value so that the receiver can achieve a precise CFO estimation. The output subcarriers are multiplied by $e^{-j\alpha_{sfo}}$ (i.e., $Y_k = Y_k \cancel{e^{j\alpha_{sfo}}} \cancel{e^{-j\alpha_{sfo}}}$) to correct the offset.

Simplifying Backscatter Deployment: Full-Duplex LoRa Backscatter

Mohamad Katanbaf[1,2*], Anthony Weinand[1], and Vamsi Talla[1]

[1]Jeeva Wireless
[2]University of Washington

Abstract

Due to the practical challenges in the deployment of existing half-duplex systems, the promise of ubiquitous backscatter connectivity has eluded us. To address this, we design the first long-range full-duplex LoRa backscatter reader. We leverage existing LoRa chipsets as transceivers and use a microcontroller in combination with inexpensive passive elements including a hybrid coupler, inductors, tunable capacitors, and resistors to achieve 78 dB of self-interference cancellation and build a low-cost, long-range, and small-form-factor Full-Duplex LoRa Backscatter reader.

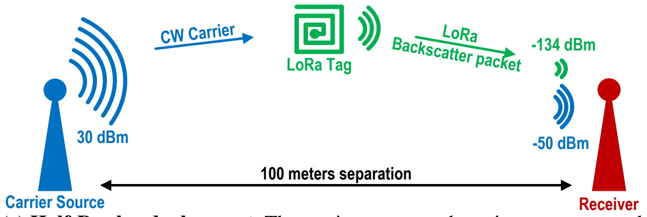
We evaluate our system in various deployments and show that we can successfully communicate with a backscatter tag at distances of up to 300 ft in line of sight, and through obstacles, such as walls and cubicles, in a 4,000 ft^2 office area. We reconfigure our reader to conform to the size and power requirements of a smartphone, and demonstrate communication with a contact-lens-form-factor prototype device. Finally, we attach our reader to a drone and demonstrate backscatter sensing for precision agriculture with an instantaneous coverage of 7,850 ft^2.

1 Introduction

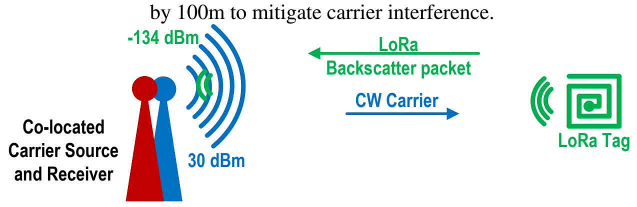
Recent advances [47, 56, 66, 73, 84, 88] have demonstrated the potential of backscatter to replace power-hungry, large, expensive radios [1] with an orders of magnitude lower power, smaller-size, cheaper, potentially battery-free connectivity solution. This promise, however, has run into practical limitations in regard to existing backscatter infrastructure. Full-duplex (FD) RFID readers [18, 22] and other proprietary full-duplex systems [30, 35], in which a single reader communicates with tags are easy to deploy, but these existing readers are large, complex, expensive, and have limited range.

To address this, recent half-duplex (HD) backscatter systems have leveraged the economies of scales and ubiquity of industry-standard protocols such as WiFi [56, 88], Bluetooth [43, 53, 89], ZigBee [64, 89], and LoRa [73, 84] to reduce the cost, size, and complexity of reader infrastructure and achieve longer range. However, these systems suffer from deployment issues, as the half-duplex topology requires two physically-separated radio devices: one for transmitting the carrier, and another for receiving the backscattered data packet. The need to deploy multiple devices in different locations significantly limits the use cases for backscatter.

We present the first Full-Duplex LoRa Backscatter reader which combines the low-cost, long-range, and small-form-factor benefits of a standard-protocols-compliant backscatter system with the simple deployment of a full-duplex system. This addresses one of the remaining pain points of backscatter and opens backscatter to a plethora of applications. A low-cost, long-range, small-form-factor full-duplex reader could be easily integrated into existing devices. This would enable peripheral, wearable, and medical devices such as pill bottles [33, 70], insulin pens [45, 60], smart glasses [59, 75], and contact lenses [36, 48] to use backscatter to directly communicate with a cellphone, tablet, or laptop. Similarly, in agriculture, aerial surveillance drones could be equipped with



(a) **Half-Duplex deployment.** The carrier source and receiver are separated by 100m to mitigate carrier interference.



(b) **Full-Duplex deployment.** The carrier source and receiver are co-located and need 78 dB interference cancellation.

Figure 1: Overview of HD and FD Backscatter Deployments.

*Work was done while the author was at Jeeva Wireless.
[1]active RFIDs are also radios

a backscatter reader to collect data from sensors distributed throughout a field.

To understand the challenge in building an FD LoRa Backscatter reader, consider the traditional HD LoRa backscatter system, shown in Fig. 1(a). The first radio transmits a single-tone carrier at power levels up to 30 dBm. A tag uses subcarrier modulation to backscatter a packet at an offset frequency, which is then received by the second radio, 100 m from the transmitter. The physical separation is necessary to attenuate the out-of-band carrier at the receiver to a level where it does not impact the sensitivity [84]. This illustrates the fundamental challenge in a FD LoRa Backscatter system, as shown in Fig. 1(b): The single-tone carrier needs at least 78 dB of suppression, a 63-million $\times$ reduction in signal strength, between the transmitter and a commodity LoRa receiver chipset, both integrated on the same PCB. This suppression must be implemented in the analog RF domain without substantially increasing the cost, complexity, or power consumption of the system. Furthermore, unlike path-loss attenuation, which is wide-band, typical cancellation techniques have a trade-off between cancellation depth and bandwidth [31, 61, 65]. If the cancellation bandwidth is insufficient, the carrier phase noise will show up as in-band noise at the receiver. Therefore, a second requirement is to bring the phase noise of the carrier at the offset frequency to below the receiver's input noise level.

Existing FD cancellation techniques, including analog, digital, and hybrid designs used in full-duplex radios have different or more relaxed requirements and, as a consequence, are insufficient to meet the needs of our system. Analog and hybrid cancellation techniques require bulky and expensive RF components such as circulators [9], vector modulators [21], and phase shifters [23] to achieve sufficient cancellation, each of which increases cost and size. Digital cancellation techniques require access to IQ samples, which are unavailable on commodity radios, and instead use SDRs [28, 31, 35, 83], FPGAs [85], or DSPs [29], which are all prohibitively expensive. For a detailed analysis of why existing techniques are insufficient, see §8.

Our key idea is to leverage the ubiquity and economies of scale of existing LoRa transceivers and microcontrollers and add inexpensive passive components to fulfill the two requirements of full-duplex operation. This enables us to build a *low-cost, long-range, small-form-factor*, Full-Duplex LoRa Backscatter reader. We use a single-antenna topology with a hybrid coupler to interface the transmitter and the receiver with the antenna. The leakage from the transmitter to the receiver, i.e. self-interference, is a function of the impedance at the coupled port. A microcontroller adaptively tunes an impedance network, tracking variations in the antenna impedance and environmental reflections with the objective of minimizing interference at the receiver.

We introduce a *novel, two-stage, tunable impedance network* to achieve 78 dB suppression of carrier signal. The extent to which a carrier is suppressed is a function of how closely the tunable impedance can track the variations in antenna impedance, which in turn depends on the resolution of the impedance network. A single-stage network is limited by the step size of its digital capacitors and does not have a high enough resolution to reliably achieve 78 dB cancellation [38, 50, 54, 65]. Our two-stage network is built by cascading two stages, each consisting of four, 5-bit tunable capacitors and two fixed inductors with an attenuating resistor network between the stages. The two-stage design provides the fine-grain control and coverage necessary to meet the 78 dB carrier cancellation target across the expected range of variation in antenna impedance. To achieve the second objective of bringing the phase noise of the carrier at the offset frequency below the noise floor of the receiver, while simultaneously obtaining 78 dB cancellation at the carrier frequency, is very challenging. There is a fundamental trade-off between the cancellation depth and bandwidth [31, 61, 65], and we prioritize the 78 dB cancellation requirement at the carrier frequency. We use a COTS synthesizer with low phase noise to relax the cancellation requirement at the offset frequency.

We implement the Full-Duplex LoRa Backscatter system using only COTS components, for a total cost of \$27.54 at low volumes, only 10% more than the cost of two HD units. Our evaluation shows that the two-stage impedance network achieves >78 dB carrier cancellation and >46 dB of offset cancellation in practical scenarios with a tuning time overhead of less than 2.7%. Results are summarized below:

- The FD reader can communicate with tags at distances of up to 300 ft in line of sight. When placed in the corner of a 4,000 ft^2 office space with concrete, glass, and wood structures and walls, tags can operate within the entire space.
- We integrate a low-power configuration of the FD reader into portable devices. We attach the prototype to the back of a smartphone and show that the tags can communicate at distances beyond 50 ft at 20 dBm, 25 ft at 10 dBm, and up to 20 ft at 4 dBm.
- We build two proof-of-concept applications. We prototype a contact-lens-form-factor antenna tag and show that it can communicate with FD reader attached to a smartphone at distances of up to 22 ft and when the reader is inside a user's pocket. We also attach the FD reader to a quadcopter and fly it to 60 ft above a field. The reader is able to communicate with tags placed on the ground at a lateral distance of up to 50 ft, corresponding to an instantaneous coverage of 7,850 ft^2.

2 Background

Our work brings full-duplex operation to a LoRa Backscatter system. We start with a background on LoRa backscatter, followed by a primer on the full-duplex operation.

2.1 LoRa Backscatter Primer

Backscatter communication eliminates RF carrier generation at the tag and, instead, uses switches to reflect existing, ambient RF signals for data transmission. This drastically reduces the cost, size, and power consumption of wireless communication [30,56,84]. In HD backscatter deployment, as shown in Fig. 1(a), a radio source generates the single-tone carrier, a backscatter tag reflects the carrier to synthesize LoRa packets, then a receiver decodes the backscattered packets. However, the carrier signal also ends up as a strong source of interference at the receiver, which degrades the receiver's ability to decode packets. Backscatter systems use two key techniques to mitigate carrier interference [26,43,46,47,49,56,64,73,78,81,84,89,92,93]. First, the tag uses subcarrier modulation to synthesize packets at a frequency offset from the carrier frequency. The receiver operates at the offset frequency, pushing the interference, i.e. the carrier signal, out of band at the receiver. Since receivers are designed to operate in the presence of out-of-band interference, the receiver can decode the backscattered packets with minimal loss in sensitivity. Second, the transmitter and receiver are physically separated to attenuate that carrier to a level where it does not affect the receiver's sensitivity. However, in full-duplex systems, by definition, the transmitter and receiver cannot be physically separated.

LoRa receivers have low sensitivity and high blocker tolerance, making them ideal candidates for long-range backscatter connectivity, as demonstrated by prior HD backscatter designs [73,84]. LoRa has two key protocol parameters that can be used to trade off data rate with receive sensitivity: spreading factor and bandwidth. Since our system transmits up to 30 dBm, the FCC mandates frequency hoppingand a maximum channel dwell time of 400 ms [17]. So, we limit our system to protocols with packet lengths shorter than this limit, which corresponds to a sensitivity of -134dBm. Longer packet lengths are incompatible with frequency hopping unless we implement intra-packet frequency hopping. Doing so would require tuning in the middle of packet reception, which is not feasible on commodity radio receivers.

2.2 Full-Duplex Primer

FD radios transmit and receive at the same time on a single device, allowing simultaneous communication between devices without delay. The main obstacle in achieving FD functionality is self-interference; the strong transmit signal leaks to the sensitive receiver and appears as interference, degrading its performance. Hence, the key is to suppress the interference before it reaches the receiver. Broadly speaking, there are two approaches to FD operation: out-of-band and in-band.

Cellular standards such as WCDMA and LTE implement out-of-band full-duplexing by using Frequency Division Duplexing (FDD), where two distinct fixed frequency bands are used for uplink and downlink. In FDD systems, the operating frequency and frequency offset are fixed, and a frequency selective duplexer is used to suppress the transmitter leakage in the receive band. At first glance, it may look like FD backscatter is similar, as the tag backscatters the data packet at a frequency offset, however, FDD systems use much higher offset frequencies, at least 40 MHz for WCDMA and LTE bands above 800 MHz [20], in line with the requirements of practical frequency duplexers and passive filters. Backscatter systems, in contrast, transmit the carrier and receive the packet within the same frequency band, keeping the frequency offset low to minimize the power consumption of the tag. For example, the LoRa backscatter system operating in the 902-928MHz ISM band uses an offset frequency of 2-4 MHz. With such a small offset, we cannot leverage passive filters or frequency duplexers used in FDD systems.

In recent years, researchers have demonstrated success with In-Band Full-Duplex (IBFD) radios [31,35,41,61], where radios transmit and receive simultaneously on the same frequency. IBFD radios suppress self-interference by using a combination of analog and digital cancellation techniques to bring the signal strength of the typically-wideband carrier below the noise floor of the receiver over the entire receive bandwidth. IBFD radios use isolation and analog cancellation techniques in the RF domain to first bring the carrier signal below the saturation level of the receiver front end. Next, digital cancellation techniques are used in the baseband to suppress the signal below the noise floor across the receiver bandwidth. Since the frequency offset in a backscatter system is small, an FD backscatter system can leverage SI suppression techniques similar to IBFD devices, such as isolation and analog cancellation. However, there are two key differences. First, the FD LoRa Backscatter system uses a single-tone signal as the carrier, so we need to suppress a very narrow-band signal. Second, unlike IBFD radios, the FD LoRa Backscatter system uses existing COTS radios, which do not provide access to signals in the digital baseband of the receiver. Hence, unlike IBFD systems, which use digital cancellation in addition to analog cancellation, we need to achieve 78 dB of SI cancellation entirely within the analog domain.

3 FD LoRa Backscatter Requirements

In this work, we focus on the cancellation requirements for a LoRa backscatter system, but the design techniques and architecture are not LoRa specific. They can be extended to build FD backscatter systems for other wireless standards such as WiFi, Zigbee, Bluetooth, SigFox, or NB-IoT that use a single-tone carrier and subcarrier modulation to synthesize backscatter packets [43,47,56]. However, these techniques are not directly applicable to systems which do not use sub-carrier modulation [30] or use wide-band Wi-Fi or LoRa packets as carrier [64,73,89].

We divide the cancellation requirements into two categories: carrier cancellation and offset cancellation.

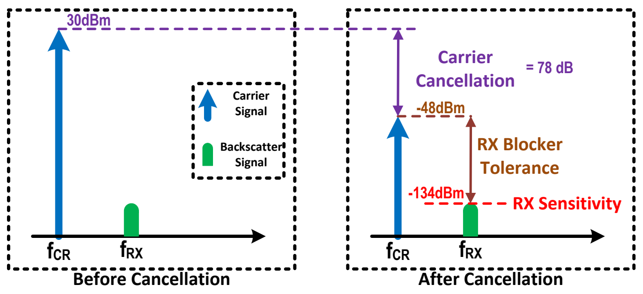


Figure 2: **Carrier Cancellation.** The 30 dBm single-tone carrier needs 78 dB of attenuation to meet the Rx blocker tolerance and ensure packet reception down to Rx sensitivity.

3.1 Carrier Cancellation

We define carrier cancellation (CAN_{CR}) as the required cancellation of the carrier signal (the source of self-interference) at the center frequency. The carrier acts as a *blocker* i.e. a strong signal in the vicinity of the desired signal that can affect a receiver's performance and reduce its sensitivity. A strong blocker can saturate the LNA, forcing it to reduce gain and increase the noise floor. Secondly, post LNA, a blocker can mix with the receiver local-oscillator phase-noise and contribute to in-band noise. Finally, baseband filters have limited stopband attenuation, and even a small portion of the blocker passing through the filter reduces the signal-to-noise and -interference ratio.

We compute the minimum required carrier cancellation as

$$CAN_{CR} > P_{CR} - Rx_{Sen} - Rx_{BT} \tag{1}$$

where P_{CR} is the carrier power, Rx_{Sen} is the receiver sensitivity, and Rx_{BT} is the receiver blocker tolerance.

For example, as per the SX1276 datasheet, the blocker tolerance at a 2 MHz offset for $BW = 125\ kHz$, $SF = 12$, -137 dBm sensitivity protocol is 94 dB [19]. Based on equation 1, for $P_{CR} = 30$ dBm, at least 73 dB of SI cancellation is required. However, the datasheet blocker specification assumes a 3 dB degradation in sensitivity, which is substantial for backscatter systems. Additionally, the datasheet provides blocker specifications for only a subset of frequency offsets and protocol parameters. To get a more comprehensive set of requirements, we perform our own blocker experiments for a range of frequency offsets (2, 3, and 4 MHz) and protocol parameters (366 bps - 13.6 kbps data rates). We connect a LoRa transmitter and a single-tone generator to two variable attenuators and combine their outputs at a LoRa receiver. First, we get a baseline sensitivity by turning off the single tone and increase the LoRa transmitter attenuation till we reach receiver sensitivity, defined by PER < 10%. Next, we turn on the single-tone generator with maximum attenuation and reduce the attenuation, thereby increasing blocker power, until the PER exceeds 10%. We record the maximum tolerable interference power for different frequency offsets, receiver bandwidths, and spreading factors to achieve different data rates and conclude that 78 dB is the most stringent carrier-cancellation specification. As mentioned prior, the blocker performance of a receiver depends on both the RF front end and digital baseband. Our analysis shows that the SX1276 baseband has sufficient digital baseband filtering to suppress the blocker at the offset frequency, and additional filtering would not help in this specific case.

Fig. 2 illustrates the carrier cancellation requirement. Before cancellation, the carrier signal is much stronger, but after cancellation, the SI is dropped to a level that the receiver can tolerate. The difference between these levels is CAN_{CR}. Note that a lower cancellation may suffice for some data rates and frequency offsets, but our design supports all configurations.

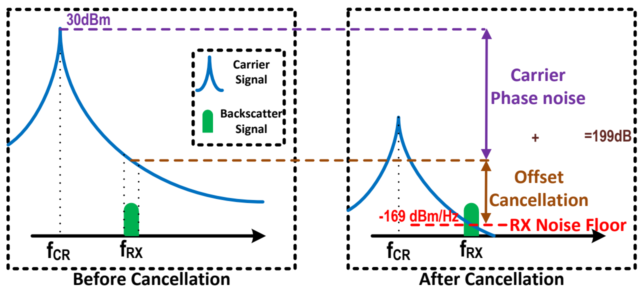

Figure 3: **Offset Cancellation**. The phase noise of the single-tone carrier at the frequency offset after cancellation should be less than the noise floor of the receiver.

3.2 Offset Cancellation

We define offset cancellation (CAN_{OFS}) as cancellation of the carrier signal at the offset frequency. We use a single-tone signal as the carrier. An ideal oscillator generates a pure sine wave, with the entire signal power concentrated at a single frequency. However, practical oscillators have phase-modulated noise components, which spreads the power to adjacent frequencies. This results in noise side bands [76] and is characterized by the source's phase noise, i.e. power spectral density (dBc/Hz) of the noise at a frequency offset from the center frequency. Since the receiver operates at a frequency offset from the carrier, the carrier phase noise shows up as in-band noise to the receiver. For optimal receiver performance, the SI signal after cancellation at the offset frequency should be less than the receiver noise floor. We compute the minimum required offset cancellation as

$$P_{CR} + \mathcal{L}_{CR(\Delta f)} + 10Log(B) - CAN_{OFS} < 10Log(KTB) + Rx_{NF}$$

$$CAN_{OFS} - \mathcal{L}_{CR(\Delta f)} > P_{CR} - 10Log(KT) - Rx_{NF} \tag{2}$$

where $\mathcal{L}_{CR(\Delta f)}$ is the carrier phase noise at the offset frequency (Δf), B is the receiver bandwidth, K is the Boltzmann constant, T is temperature, and Rx_{NF} is receiver noise figure. We show this requirement in Fig. 3. Before cancellation, the backscattered signal is buried under the carrier phase noise, but, after cancellation, the carrier phase noise is pushed below the receiver noise floor.

As per the SX1276 datasheet $Rx_{NF} = 4.5$ dB, so for $P_{CR} = 30$ dBm, $CAN_{OFS} - \mathcal{L}_{CR(\Delta f)} > 199.5$ dB. The offset cancellation depends on transmit power, carrier phase noise, and

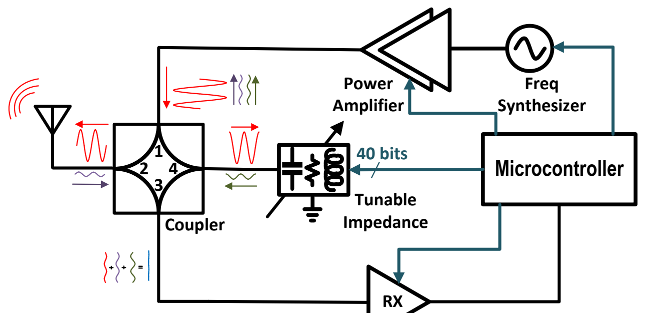

Figure 4: **System Architecture.** We use a single-antenna hybrid-coupler architecture with a two-stage tunable impedance network for cancellation. A microcontroller controls all components and implements the tuning algorithm.

receiver noise figure. Interestingly, since the channel bandwidth appears on both sides of equation 2, offset cancellation is independent of the receiver channel bandwidth. In other words, we can use the carrier phase noise per unit bandwidth and receiver noise floor per unit bandwidth instead of the aggregate noise over the entire bandwidth.

In an HD system, the transmitter and receiver are physically separated, and the carrier attenuation via RF propagation does not significantly change with frequency. So, if the 78 dB carrier cancellation requirement is met, the phase noise at the offset frequency would also be attenuated by the same amount. However, cancellation networks do not have the same wide-band frequency characteristics [38, 40, 54, 65, 77]. The inequality shows that satisfying the offset cancellation requirement for an FD system requires a joint design of the carrier source and the cancellation network. If we use a high-phase-noise carrier, we would need high offset cancellation, whereas if we lower the phase noise of the carrier source, we can relax the offset cancellation requirements. Carrier and offset SI cancellation are functions of offset frequency, and both typically relax with an increase in offset frequency. However, an increase in offset frequency increases the tag power consumption. Thus, the frequency offset presents a trade-off between tag power consumption and SI cancellation requirements. 2-4 MHz is a reasonable compromise; we use a 3 MHz offset frequency in this work.

4 FD LoRa Backscatter Reader Design

The FD LoRa Backscatter system uses a single antenna and a hybrid coupler with a two-stage tunable impedance network to achieve carrier and offset cancellation. The cancellation network uses only passive components, minimizing cost, complexity, power consumption, and noise. Fig. 4 shows the block diagram of our design. The antenna is connected to the transmit and receive paths via a hybrid coupler. The fourth port of the coupler is connected to a tunable impedance network that tracks the antenna impedance to reflect and phase shift a portion of the single-tone carrier, suppressing the SI that flows to the receiver. The carrier signal is generated by a frequency synthesizer and fed to a power amplifier (PA) to transmit up to 30 dBm. An on-board microcontroller controls the synthesizer, PA, receiver radio, and digital tunable impedance network using a SPI interface. We use RSSI readings from the receiver to measure the SI there.

Below, we describe the principle of operation for the hybrid coupler. This is followed by the two-stage tunable impedance network design and the choice of carrier source to meet the carrier and offset cancellation requirements. Finally, we describe the tuning algorithm.

4.1 Coupler: Principle of Operation

Couplers are four-port devices that divide an incident signal between the output and coupled port while keeping the fourth port isolated [72, 74]; we use this property to isolate the transmitter and receiver. We connect the transmitter to the input port (1), the receiver to the isolated port (3), the antenna to the output port (2), and the tunable impedance network to the coupled port (4). The carrier signal is split between the antenna and coupled ports, leaving the receiver isolated. The received signal at the antenna port is split between the receiver and the transmitter, leaving the tunable impedance isolated. Couplers are reciprocal elements, meaning that the signal split described above is symmetrical. Ideally, we would want the entire PA output to go to the antenna (low TX insertion loss) and the entire received signal from the antenna to go to the receiver (low RX insertion loss). A higher coupling factor would direct more of the PA output to the antenna at the cost of reducing signal transmission from the antenna to the receiver. Since our goal is to maximize the communication range, we must minimize the sum of the transmit and receive insertion losses. A hybrid, or 3 dB coupler, equally divides the input power between the output and coupled ports and minimizes total loss to 6 dB.

Two factors limit the practical SI cancellation of a hybrid coupler. First, every coupler has leakage: a typical COTS coupler provides $\sim$ 25 dB of isolation between the transmit and receive ports [16], far lower than our requirement. Second, and more important, is the effect of the antenna. Typical antennas, including low-cost PIFAs, are characterized by -10 dB return loss, and any reflection from the antenna port would couple to the receiver and further contribute to the SI.

Antenna Impedance Variation. Environmental variations affect antenna impedance, i.e. nearby objects can detune the antenna or create additional reflections that contribute to variation in its reflection coefficient. Since SI cancellation is dependent on antenna impedance, it is essential to characterize the expected variation. We design a 1.9 in $\times$ 0.8 in PIFA for our implementation and use this antenna to quantify impedance variation. We connect the PIFA to an Agilent 8753ES VNA [3] and subject it to environmental variations

by placing the antenna upright on a table, and measure S_{11} as a hand and other objects approach it from different directions. Our results show that the magnitude of the reflection coefficient, $|\Gamma|$, reaches a maximum of 0.38, and we set expected $|\Gamma| < 0.4$ for the antenna.

4.2 Two-Stage Tunable Impedance Network

We use a tunable impedance at the coupled port [50, 54, 65] to negate SI leakage due to variation in antenna impedance. However, the cancellation depth is a function of how precisely we can tune this impedance. To achieve 78 dB carrier cancellation, we need a very fine resolution for the tunable impedance, which is not available in COTS digital capacitors. To solve this, we introduce a novel two-stage tunable impedance network that allows us to achieve deep cancellation, using only passive components.

To understand how the tunable impedance network improves the SI suppression from the coupler, follow the flow of signals in Fig. 4. The carrier (red) splits between the antenna port and the coupled port. The impedance at the coupled port is tuned such that the reflection from this port (green) cancels out both the leakage of the coupler and the reflection from the antenna port (purple) to achieve deep cancellation at the receive port (blue). In the worst case of a significantly detuned antenna, reflection from the antenna is much stronger than the leakage, and this should be canceled by the reflection from the tunable impedance.

We use a topology of two fixed inductors and four digitally tunable capacitors terminated with a resistor to cover the range of expected impedance values required to cancel strong reflections from the antenna [65]. We observe that in a tuning network terminated with a resistor, only a small portion of the signal is reflected, and most of it is dissipated. We replace the termination resistor with a resistive signal divider, followed by a second tunable impedance, as shown in Fig. 5(a). The signal reflected by the second stage flows through the resistive divider twice, effectively lowering the impact of impedance changes in the second stage on the overall reflected signal. This allows us to use the second stage to make much more fine changes in impedance, increasing the tuning resolution and enabling deep cancellation. However, the first stage still determines the tuning range and offset cancellation. The second stage provides the fine resolution to accurately match the reflection from the balanced port with the leakage and reflection from the antenna port. To eliminate dead zones, we choose the resistive divider such that the fine tuning network covers the step size of the coarse tuning network. This coarse and fine tuning approach is similar to using a hybrid coupler combined with an analog feed-forward path. The second stage effectively provides the functionality of a feed-forward path, but without additional noise and at a lower cost, lower complexity, and lower power.

We simulate the behavior of our tunable impedance network to demonstrate the efficacy of our approach. We plot the tuning network reflection coefficient at 915 MHz in Fig. 5 (c) for a step size of six LSBs for each capacitor in the first stage. For visibility, the plot only shows 1,296 impedance states out of more than 1 million first-stage impedance states and more than 1 trillion total states. The plot demonstrates that our design can cover the impedances corresponding to the antenna reflection coefficient circle of $|\Gamma| < 0.4$. Next, we show the fine tuning of the second stage in Fig. 5 (d). We select an initial state (the large, red square in the center) and change each capacitor in the first stage by one LSB to get the other eight red dots. Without the second stage, we would not be able to achieve any impedance between these dots. For each of these nine states, we use a step size of 10 LSBs for each capacitor in the second stage and show the resulting impedances in blue. The blue cloud shows the fine resolution control covering the dead zone between the first-stage steps. Finally, we simulate SI cancellation for 400 random points of antenna impedance inside the $|\Gamma| < 0.4$ circle and plot the cancellation CDF in Fig. 5 (b). Cancellation of > 80 dB is achieved for the 1st percentile, which satisfies our requirement.

4.3 Carrier Source Selection

The phase noise of the carrier source determines the required cancellation at the offset frequency, as shown in equation 2. In order to understand the requirements of the carrier source, we first simulate SI cancellation at different frequency offsets.

We tune the capacitors to achieve a minimum of 78 dB carrier cancellation and then sweep the operating frequency. Our results show that at 3 MHz frequency offset, 47 dB cancellation or more is achieved in 90% of the simulated cases. If we use SX1276 with a phase noise of -130 dBc at 3 MHz offset as our transmitter, then 47 dB of offset cancellation is insufficient.

The tuning network has multiple poles that can be optimized to increase cancellation bandwidth [57, 65]. However, doing so reduces the cancellation at the center frequency. This approach would also require a wide-band receiver to provide feedback on the SI power over the entire bandwidth to tune the capacitors, which is unavailable on the SX1276 (max. BW = 500 kHz). We need > 78 dB of SI cancellation at the carrier frequency and prioritize this requirement. Instead of SX1276, we use ADF4351 [10] frequency synthesizer to generate the single tone carrier, which has a lower phase noise of -153 dBc at 3 MHz offset. Although the ADF4351 is slightly more expensive, it relaxes the offset cancellation requirement to 46.5 dB and eliminates the need for an additional wide-band receiver or a power detector, justifying the design choice.

4.4 Tuning Algorithm

Our design uses a two-stage impedance network with eight digital capacitors, each with five control bits; a total of 40 bits resulting in 2^{40} ($\sim$ 1-trillion) states for the impedance network. Multiple capacitor states can result in the impedance required for 78 dB cancellation, and any one of those is acceptable. As it is impossible to search across such a vast space in real-time, there is a need for an efficient tuning algorithm that can run on a commodity ARM Cortex-M4 microcontroller.

We use a simulated annealing algorithm to tune the capacitors in each stage separately [86]. Simulated annealing is based on the physical process of heating, and then slowly cooling, a material to minimize defects in its structure. For every temperature value, we take ten steps. At each step, we add a random value bounded by a maximum step size to each capacitor and measure the SI using receiver RSSI measurement. We accept the new capacitor values if the SI decreases, or with a temperature-dependent probability when the SI increases. We start with a temperature equal to 512 and divide it by two each round until it reaches one. We set predefined cancellation thresholds for each stage and stop the tuning once the thresholds are met. If the first stage reaches the threshold (set to 50 dB), but the second stage fails to do so, we repeat the tuning until either it converges or reaches a timeout.

5 Implementation

We implement the FD LoRa Backscatter reader for operation in 902-928 MHz on a 3.8 in $\times$ 1.9 in, 4-layer, FR4 PCB. We place the RF components, including antenna, transmitter, receiver, and cancellation network, on the top side of the PCB, and microcontroller and power management on the bottom. We use the SX1276 as the LoRa receiver [19]. The cancellation circuit consists of the X3C09P1 90° hybrid coupler [16] and a two-stage tunable impedance network,shown in Fig. 5 (a). Variable capacitors C_1-C_8 are implemented by pSemi PE64906 tunable capacitors, with 32 linear steps from 0.9 pF - 4.6 pF [11]. We set inductors L_1, L_3 to 3.9 nH and L_2, L_4 to 3.6 nH. We set resistors R_1, R_2, and R_3 to 62 Ω, 240 Ω, and 50 Ω respectively. We use the ADF4351 synthesizer to generate the single-tone carrier, which has 23 dB better phase noise at 3 MHz offset compared to the SX1276. The output power of the carrier can be amplified up to 30 dBm using the SKY65313-21 power amplifier [12]. Our cancellation technique has an expected loss of 7-8 dB; 6 dB of which is the theoretical loss due to hybrid coupler architecture, the rest is due to component non-idealities.

We design a custom coplanar inverted-F PCB antenna. The radiating element of the antenna measures 1.9 in $\times$ 0.8 in and leverages the existing ground plane for omnidirectional radiation. We measure the performance of the antenna in an anechoic chamber, and results show a peak gain of 1.2 dB, half-power beam-width of 80°, and cumulative efficiency of 78%. The transmitter, receiver, and cancellation network are controlled using a SPI interface by an on-board ARM Cortex-M4 STM32F4 microcontroller [13]. The microcontroller implements a state machine in C to transition between tuning, downlink, and uplink operating modes. In the tuning mode, the microcontroller first configures the center frequency and power of the carrier and then tunes the impedance network to minimize SI using the simulated annealing algorithm described in §4.4. After the tuning phase, the MCU sends the downlink OOK message to wake up the backscatter tag. Then, it transitions to the uplink mode where it configures the receiver with the appropriate LoRa protocol parameters to decode backscattered packets. The MCU then repeats this cycle for the next frequency.

5.1 FD Reader Configurations

We configure the FD LoRa Backscatter reader for two different use cases; a 'base-station' setup and a 'mobile' setup. Below we describe each configuration.

Base-Station Configuration: The base-station configuration of the FD LoRa Backscatter reader uses a 8 dBc high gain patch antenna [25]. The synthesizer and PA are set to transmit at 30 dBm. These settings maximize operating range and we use this configuration for the line-of-sight and non-line-of-sight range testing. In the base-station setup method, the power amplifier, synthesizer, receiver, and MCU consume 2,580 mW, 380 mW, 40 mW, and 40 mW, respectively, resulting in total power consumption of 3.04 W. 3.04 W is not a limitation for a plugged-in device such as a smart speaker or WiFi router, but is too high for a portable device.

Mobile Configuration: For applications with lower power consumption and smaller size requirements, we configured the system as a ‘mobile’ version. We use the on-board antenna and configure the synthesizer and PA to transmit at lower power levels of 4 dBm, 10 dBm, and 20 dBm. Since the PA and synthesizer dominate power consumption, reducing transmit power greatly reduces power consumption. In this mobile configuration, power consumption is low enough to draw from conventional portable power sources like a USB battery or a laptop. It is also small enough that, if desired, we are able to attach it to an iPhone 11 Pro without increasing the phone’s footprint, shown in Fig. 11(a).

Lower transmit powers relax cancellation requirements (see §3.2), which can be leveraged to further reduce the power consumption of the synthesizer and the power amplifier. For 20 dBm output power, we can instead use an LMX2571 [8] as the synthesizer which has higher phase noise, but lower power consumption. We can also use a CC1910 [4] as the PA which operates efficiently at 20 dBm output power. Similarly, for output powers of 4 dBm and 10 dBm, we can use a CC1310 [14] as the synthesizer and eliminate the PA. These optimizations would reduce power consumption to levels shown in Table 1. Since we built our system for maximum output power and range, we did not make these hardware changes in this work, but we wish to outline the available design choices for use-cases demanding lower power consumption.

5.2 Cost Analysis

The FD LoRa Backscatter reader is designed with the goal of simplifying the deployment of backscatter technology to unleash the untapped potential of backscatter. Cost plays a critical role in achieving this objective. Table 2 outlines the cost structure of the different components of the system and compares it with a legacy HD LoRa backscatter reader. Our analysis using pricing data from Octopart [1] shows that at low volumes of 1,000 units, the FD reader costs $27.54, only 10% more than the cost of two HD readers. We believe that further optimization and leveraging economies of scale, coupled with the reuse of radios and processing power upon integration with existing devices such as IoT gateways, smartphones, and tablets, can further reduce the solution cost.

5.3 LoRa Backscatter Tag

The LoRa backscatter tag used in this work is based on the design proposed in [84]. The LoRa baseband and subcarrier chirp-spread-spectrum-modulated packets are generated using Direct Digital Synthesis (DDS) on an AGLN250 Igloo Nano FPGA [5]. The output of the FPGA is connected to SP4T ADG904 RF switch [6] to synthesize single-side-band backscatter packets. The backscatter tag design also incorporates an On-Off Keying (OOK) based wake-on radio with sensitivity down to -55 dBm and an ADG919 [7] SPDT switch to multiplex a 0 dBi omnidirectional PIFA between the receiver and the backscatter switching network. The total loss in the RF path (SPDT + SP4T) for backscatter is $\sim$ 5 dB.

Table 1: Estimated Power Consumption of FD LoRa Backscatter Reader

TX Power	Applications	Peak Power
30 dBm	Plugged-in devices	3,040 mW$^+$
20 dBm	Laptops, Tablets	675 mW
10 dBm	Phones, Battery Packs	149 mW
4 dBm	Phones, Battery Packs	112 mW

$^+$ Measured result.

Table 2: Cost Analysis of FD & HD Backscatter Hardware

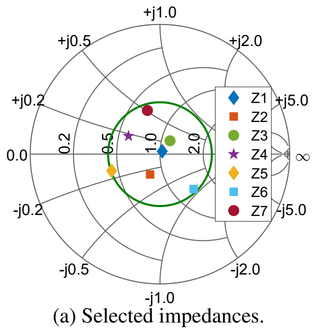
6 Evaluation

First, we validate our cancellation approach by measuring the carrier and offset cancellation of our novel two-stage impedance tuning network. Then, we measure the time overhead incurred by our tuning approach. Next, we evaluate the FD LoRa Backscatter system performance in a wired setup to neutralize multi-path effects, followed by line-of-sight and non-line-of-sight wireless deployments. Finally, we measure the performance of the mobile version of our system.

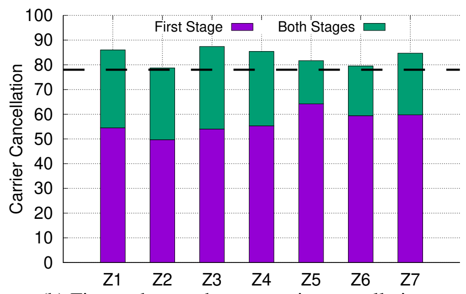
Unless mentioned otherwise, we set the subcarrier modulation frequency to 3 MHz, and configure the tag to transmit 1,000 packets with $SF = 12$, $BW = 250kHz$, (8,4) Hamming Code with an 8-byte payload, a sequence number for calculating PER, and a 2-byte CRC. Additionally, we initiate uplink by sending a downlink OOK-modulated packet at 2 kbps to wake up the tag and align the tag’s backscatter operation to the carrier. Downlink also enables channel arbitration between multiple tags, sending acknowledgments, packet re-transmissions, and other functionalities [56,84]. The evaluation of these features is beyond the scope of this work.

6.1 Cancellation Network

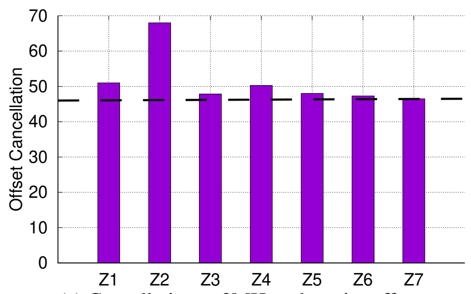
The cancellation network performance depends on the antenna impedance, which is sensitive to environmental variations (see §3.2). To demonstrate that our system can achieve the required cancellation across a range of expected antenna impedances, we simulate antenna impedances with custom circuit boards with an 0402 footprint and an SMA connector. We populate the pads with discrete passives to represent antenna impedances with $0 \leq |\Gamma| \leq 0.4$. We test seven antenna



(a) Selected impedances.



(b) First and second stage carrier cancellation.



(c) Cancellation at 3MHz subcarrier offset.

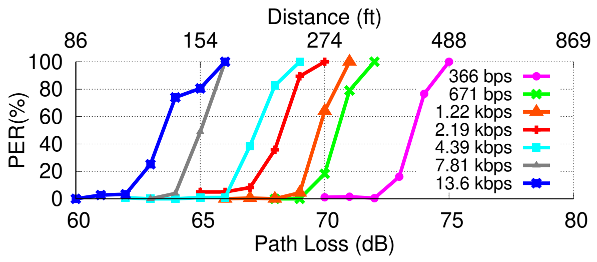

Figure 8: **Receiver Sensitivity Analysis.** We plot the PER as a function of path loss for different data rates.

impedances, as shown on the smith chart in Fig. 6 (a).

To measure cancellation, we attach a board representing an antenna impedance to the antenna port of our FD LoRa Backscatter reader with a Murata measurement probe [15]. We disconnect the receiver and attach the receiver input to a spectrum analyzer using another RF probe. We set the transmitter to 915 MHz and 30 dBm output power. Since the receiver is disconnected, we cannot measure RSSI and, therefore, cannot utilize the tuning algorithm. We manually set the capacitor states in a two-step process similar to the tuning algorithm. First, we fix the second-stage capacitors and manually tune the first stage for the best SI cancellation, then, we manually tune the second stage. Fig. 6(b) shows the SI carrier cancellation results for one- and two-stage tunable impedance networks. Results show that a single stage is insufficient to achieve 78 dB carrier cancellation, whereas the two-stage design meets the specification. Next, we measure offset cancellation by keeping the same capacitor configuration and sweeping the carrier source between 905 - 925 MHz in 100 kHz frequency increments. Fig.6(c) shows the offset cancellation for different antenna impedances at 3 MHz offset. Our results show that we achieve our target of 46.5 dB offset cancellation for all antenna impedances.

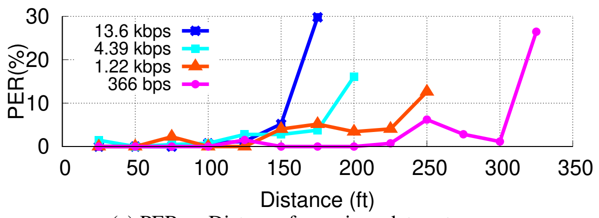
6.2 Tuning Overhead

To measure the performance of our tuning algorithm, we place the FD LoRa Backscatter reader with the PIFA on a table in a typical office environment. We collect 10,000 packets from a tag placed 20 ft away over the course of 80 minutes with multiple people sitting nearby and walking in the vicinity of the system. We modify the target SI cancellation threshold in the tuning algorithm to 70, 75, 80, and 85 dB and run experiments to measure the time required for tuning. The tuning algorithm was able to achieve the target SI in 99% cases. We plot the CDF of tuning overhead for different cancellation thresholds in Fig. 7. As expected, the tuning duration increases with the target threshold. For a threshold of 80 dB, the average tuning duration is 8.3 ms, corresponding to an overhead of 2.7%. The RSSI measurements from the SX1276 chipset are noisy, and we take the mean over 8 readings for each tuning step, which is the key limitation. Each tuning step takes about 0.5 ms, dominated by the SPI transactions and settling time of the receiver. An RF power detector, which is beyond the scope of this work, can be used to provide faster feedback at the expense of increased cost.

6.3 Receiver Sensitivity Analysis

To evaluate the receive sensitivity of the FD LoRa Backscatter system without the effect of multi-path signal propagation, we create an equivalent wired setup. We use RF cables and a variable attenuator to connect the antenna port of the FD LoRa Backscatter reader to a LoRa backscatter tag. We vary the in-line attenuator to simulate path loss, corresponding to different operating distances between the reader and the tag. We start with an attenuator value at which we receive all packets and then slowly increase the attenuation until no packets are received. We configure the SF and BW parameters to cover a range of sensitivity and data rates.

Fig. 8 plots PER as a function of path loss in a wired setup for different data rates. Since sensitivity is inversely proportional to data rate, lower data rates can operate at higher path loss, which translates to longer operating distances. For a $PER \leq 10\%$, the expected LOS range at the lowest data-



(a) PER vs Distance for various data-rates.

(b) RSSI of all measurements in the office space.

Figure 10: **Non-Line-of-Sight Wireless Tests.** We place the backscatter tag at 10 locations shown as red dots.

rate of 366 bps ($SF = 12, BW = 250\ KHz$) is 340 ft, with the range decreasing successively for higher bit rates, down to 110 ft for 13.6 kbps ($SF = 7, BW = 500\ KHz$).

6.4 Line-of-Sight (LOS) Wireless Testing

We deploy the FD LoRa Backscatter system in a nearby park to measure LOS performance. For best performance, we configure the reader as a base-station (see §5) by connecting an 8 dBiC circularly polarized patch antenna [25], placed on a 5 ft tall stand, to the antenna port and set transmit power to 30 dBm. We place the tag at the same height and move it away in 25 ft increments. Fig. 9 plots PER and RSSI as a function of distance for four different data rates. Our results show that, for $PER < 10\%$, at the lowest data rate, the system can operate at a distance of up to 300 ft with a reported RSSI of -134 dBm. For the highest data rate, the operating distance was 150 ft at -112 dBm RSSI.

A prior HD LoRa backscatter system reported a range of 475 m between the two radios [84]; this corresponds to a range of 780 ft for an FD system. Our FD system achieves a shorter range and this can be attributed to two factors. First, the HD system evaluation uses a -143 dBm sensitivity protocol at 45 bps versus the -134 dBm sensitivity at 366 bps used in this work. The 45 bps packets are 2.4 sec long, 6 $\times$ the FCC maximum channel dwell time (see §2.1). Additionally, the FD system uses a hybrid coupler architecture. This reduces cost, but incurs a 7 dB loss (see §5). So, in total, our link budget is reduced by 16 dB. This translates to a 2.5 $\times$ range reduction, close to the 300 ft range of our system.

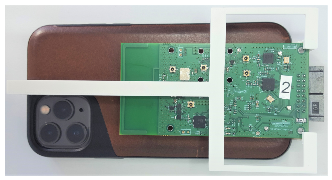
6.5 Non-Line-of-Sight (NLOS) Wireless Tests

Next, we set up in a 100 ft $\times$ 40 ft office building to evaluate performance in a more realistic NLOS scenario. We place the base-station reader in one corner of the building and move the tag to ten locations to measure performance through cubicles,multiple concrete and glass walls, and down hallways. The floor plan of the building is shown in Fig.10(a). The blue star in the lower-right corner indicates the position of the FD reader, and the red dots indicate the different locations of the tag throughout the office space. We transmit 1,000 packets at each location, and a CDF of the aggregated RSSI data from the test is shown in Fig.10(b). We observed a median RSSI of -120 dBm and PER of less than 10% at all the locations demonstrating that the FD LoRa Backscatter system is fully operational in the office space with a coverage area of 4,000 ft^2.

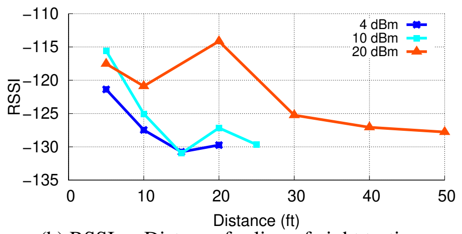
6.6 Integration with Mobile Devices

Finally, we evaluate the performance of the mobile version (see §5) of the FD reader. We attach the mobile reader to the back of an iPhone 11 Pro, as shown in Fig. 11(a) and configure the reader to transmit at 4 dBm, 10 dBm, and 20 dBm to resemble the transmit power of mobile devices. We move a backscatter tag away from the reader in 5 ft increments until PER > 10%. Fig. 11(b) plots the RSSI of the received packets as a function of distance. The plots show that at 4 dBm, the mobile reader operates up to 20 ft and the range increases beyond 50 ft (the length of the room and limit of our testing) for a transmit power of 20 dBm. These distances are sufficient for connecting peripheral, wearable, and medical devices to a smartphone using backscatter at extremely low cost, small size, and low power consumption. These experiments were done in an uncontrolled wireless environment and the variation in signal strength at different locations is due to multi-path effects, which is typical of practical wireless testing.

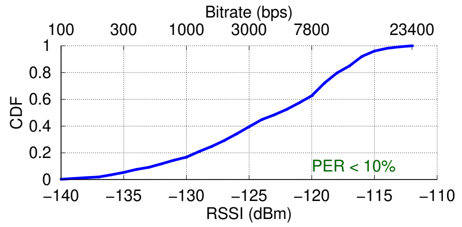
To demonstrate that our system can adapt to variations in environment and antenna impedance, we place the FD LoRa Backscatter enabled smartphone in a subject's pocket and set the transmit power to 4 dBm. We place a tag at the center of an



(a) FD LoRa Backscatter on the back of a smartphone.



(b) RSSI vs Distance for line-of-sight testing.



(c) Packet RSSI with the mobile reader in a user's pocket moving around a table.

Figure 11: Integration with Mobile Devices.

11 ft $\times$ 6 ft table, and the subject walks around the perimeter of the table, receiving more than 1,000 packets. The performance is reliable with PER < 10%, which demonstrates the efficacy of our tuning algorithm. Fig. 11(c) plots the CDF of RSSI for all the packets. The backscatter tag measures 2 in $\times$ $1\frac{1}{2}$ in, resembling the size of a pill bottle. This demonstrates that a mobile smartphone can use backscatter to communicate with a prescription pill bottle or insulin pen, allowing tracking of medication and drug delivery.

7 Applications

We demonstrate two applications for our FD system. First, we show how a mobile reader can collect data from a smart contact lens, a particularly challenging RF environment. Next, we demonstrate a precision agriculture application by mounting the reader to the bottom of a drone, which can be flown over farms and use backscatter to collect data from sensors distributed in a field. The use of a single reader coupled with a highly sensitive long-range backscatter protocol enables these applications, even in these challenging deployments.

7.1 Contact Lens

We use the mobile FD LoRa Backscatter system mounted on the back of a smartphone to communicate with a backscatter tag equipped with a smart-contact-lens-form-factor antenna. We use the same backscatter endpoint as with other tests, but we cut off the original PIFA and replace it with a small loop antenna of 1 cm diameter made with 30 AWG enameled wire. The antenna is encapsulated in two contact lenses and filled with contact lens solution to simulate the RF environment of an eye-ball, as shown in Fig. 12(a). Due to its small size and the ionic environment of the contact solution, the loop antenna has an expected loss of 15 - 20 dB.

We place the smartphone on a table and configure the mobile reader to transmit at 4, 10, and 20 dBm and move the contact lens backscatter prototype away from the smartphone. Fig. 12(b) shows the RSSI as a function of distance for various transmit powers. We show that the mobile reader at 10 dBm and 20 dBm transmit power can communicate with the contact lens at distances of 12 ft and 22 ft respectively for PER < 10%. Next, we put the mobile reader transmitting at 4 dBm in a 6 ft tall subject's pocket and hold the contact lens prototype near the subject's eye to simulate a realistic use case. Fig. 12(b) plots the CDF of the RSSI of decoded packets when the user was standing and sitting on a chair. The plot shows reliable performance with PER < 10% and a mean RSSI of -125 dBm. This demonstrates the feasibility of using backscatter to provide continuous connectivity between a user's phone and a smart contact lens. This RF-challenged application was made possible even at such a low transmit power due to the high receive sensitivity of the system.

7.2 Drone with an FD Backscatter Reader

Drones are extensively used for aerial surveillance in precision agriculture [87]. We demonstrate how one can augment a drone's functionality by adding a FD LoRa Backscatter reader to communicate with sensors distributed in a field using backscatter. We attach the mobile version of our reader to the bottom of a low-cost, commercially-available Parrot AR.Drone 2.0 quadcopter (<\$80) [24], as shown in Fig.13(a). We power the reader from the drone's battery using a USB connector to demonstrate the ease of integrating our system. We set the transmit power to 20 dBm to reduce the burden on 7.5 Whr battery of the cheap drone. We place the tag on the ground simulating an agriculture sensor and fly the drone at a height of 60 ft. Due to practical challenges in accurately positioning the drone, we allow the drone to fly laterally during the test up to 50 ft from the center, which results in 80 ft maximum separation from the tag. This corresponds to an instantaneous coverage area of 7,850 ft^2. We collect more than 400 packets over 4 minutes with the drone flying around the coverage zone while keeping its altitude constant.

Fig.13(b) plots CDF of the RSSI of the packets received by the drone over the entire duration of the test for a PER <10%. With a minimum of -136 dBm and median of -128 dBm, this demonstrates good performance for the area tested. With a flight time of 15 min and a top speed of 11 m/s, our cheap drone could, in theory, cover an area greater than 60 acres on a single charge. With a more powerful drone with higher payload capacity and longer flight time, one could integrate a higher gain antenna and transmit at higher power. This would result in a greater instantaneous coverage area and, with longer flight time, could achieve many times greater coverage on a single charge.

8 Related Work

Our work is related to prior efforts in HD backscatter, FD backscatter, and in-band FD communication.

Half-Duplex Backscatter. Our work builds on recent efforts in developing backscatter solutions that are compatible with existing wireless standards such as Bluetooth [43, 47, 53, 89], WiFi [26, 47, 56, 89, 90, 92], Zigbee [64], and LoRa [73, 84] using half-duplex architectures. The backscatter endpoint is based on prior LoRa backscatter design [84], but we take the next step of integrating the single-tone carrier source and LoRa receiver into a single device.

In addition to standards-compliant backscatter, proprietary-protocol communications [46, 78, 79, 93] (to improve data rates and throughput), applications such as wireless video streaming [49, 81], indoor localization [67, 68, 71], and human activity recognition [27, 34, 80] have been realized with HD deployments. The techniques presented in this work can be extended to build an FD version of these systems.

Full-Duplex Backscatter. A BLE monostatic/FD backscatter system was introduced in [42] that uses a 20 dB coupler, phase shifter, and variable attenuator for SI cancellation. However, due to additional losses in the coupler and limited cancellation depth, the communication range was limited to 3 m, even with 33 dBm of output power. In [30], an FD backscatter system using an SDR platform with analog and digital cancellation was introduced where WiFi packets are used as the carrier and the tag backscatters proprietary BPSK, QPSK, and 16-PSK modulated packets which were decoded by the SDR up to a distance of 7 m. Due to the wide-band nature of WiFi carrier signals, [30] needs wide-band SI cancellation. A circulator and a 10 cm $\times$ 10 cm custom PCB with 16 variable-gain delay lines are added to the SDR platform for wide-band analog cancellation, increasing both the solution cost and size. In contrast, the FD LoRa Backscatter system uses commodity LoRa radios and passive components for cancellation and can receive standard LoRa packets up to a distance of 300 ft.

RFID readers are also full-duplex devices that transmit a single-tone carrier and receive backscattered packets from RFID tags. However, EPC Gen2 readers are bulky, expensive [18, 22], and cannot compete with economies of scale of standard protocols. The operating range of passive RFID readers is determined by the power-harvesting sensitivity, not by the backscatter communication link. RFID readers operate at relatively short distances, even if the tag is powered from an alternative energy source [51], due to poor receive sensitivity (-90 dBm) [18, 22]. In contrast, our FD LoRa Backscatter system achieves much longer operating distances at significantly lower cost by leveraging a highly sensitive commodity LoRa receiver, cheap passive components, and a microcontroller for deep SI cancellation. Low-cost RFID readers based on directional couplers have also been investigated [50, 54], but they suffer from high Rx insertion loss and lower SI cancellation depth, which reduces range. In [69], a full-duplex drone relay is presented to extend the range of a fixed RFID reader. The topology requires an additional relay on a drone to extend the fixed RFID reader range to 50 m. In contrast, our FD reader can be mounted on a flying drone to cover a significantly larger area.

In-Band Full-Duplex Radios. In-band full-duplex (IBFD) radios simultaneously transmit and receive at the same frequency. Recent works have used a combination of isolation, analog cancellation, and digital cancellation techniques to suppress SI below the receiver noise floor [31, 35, 41, 62].

Existing isolation techniques use two or more physically-separated antennas [40, 41, 44, 63], discrete circulators [31, 35, 57, 62, 91], integrated circulators [39, 77], or hybrid junctions [38, 65] to isolate transmitter and receiver. The use of multiple antennas increases form factor while achieving limited isolation. Discrete circulators [9] are bulky and expensive. While recent advances in integrated circulators [39, 77] are promising, these devices are unable to handle the 30 dBm output-power requirement. Hybrid junctions, realized using couplers [50, 54] (such as the 3 dB coupler used in this work) or electrical balance duplexers (EBD) [38, 65], incur a loss, but result in small-form-factor and inexpensive solutions. However, existing solutions with COTS components cannot

Table 3: Comparison of State of the Art Analog SI Cancellation Techniques

Reference	Cancellation Technique	TX Signal	RX Signal	Analog Can.	TX Power	Active Comp.+	Size	Cost

[55]	10dB Coupler + Atten. + passive tuning network	CW	EPC Gen 2	60 dB	26 dBm	No	2.7×2.0 cm^2	Low
This Work	Hybrid Coupler + passive tuning network	CW	LoRa Backscatter	78 dB	30 dBm	No	2.5×0.8 cm^2	Low

+ Active components include phase shifters, vector modulators, amplifiers and transconductance amplifiers which can contribute additional noise.
* Custom ASICs are incompatible with COTS transceivers and are only viable and cost-efficient at scale.

achieve 78 dB of SI cancellation [42, 50, 54], whereas our proposed two-stage impedance tuning network can be used to achieve this deep cancellation required for building a cheap, low-complexity, long-range FD reader. Furthermore, [38, 65] show a path towards further reducing the cost and size at high volumes by integrating the hybrid junction in silicon.

Analog feed-forward cancellers can be combined with isolation techniques to enhance SI cancellation depth and bandwidth. Various feed-forward PCB and ASIC implementations based on vector modulation [32], finite impulse response filters [31, 38, 62, 91], frequency domain equalization based RF filters [35], N-path filters [94], and Hilbert transform equalization [82] have been proposed. However, these techniques require additional active circuitry, which has a limited power-handling capability and generates noise that increases the receiver noise floor [37]. Furthermore, COTS phase shifters [23] and vector modulators [21] are bulky and expensive, which substantially increases cost, complexity, and form factor. In this work, we utilize the two-stage tunable impedance network architecture to achieve the required 78 dB cancellation depth. Since the transmitter carrier signal is only single-tone, we do not need the feed-forward paths to improve the bandwidth.

In Table 3, we summarize the state-of-the-art techniques used for analog SI cancellation and compare them with our approach in terms of cancellation depth, transmit power-handling capability, size, and cost.

Finally, digital cancellers are often used to further suppress the SI below the receiver noise floor [31, 35, 58, 61] using both linear and non-linear cancellation techniques [52]. Digital cancellation requires access to baseband IQ samples. This function is not available on commodity radio chipsets and is typically implemented on SDRs [28, 31, 35, 83], FPGAs [85], or DSPs [29], which are prohibitively expensive. Instead, since our interference is a single-tone at a frequency offset from the receive channel, we leverage the inherent baseband filtering capabilities of the commodity receiver to suppress the SI at the offset frequency.

9 Conclusion

We present the first low-cost, long-range, small-form-factor Full-Duplex LoRa Backscatter design. We use a single-antenna, hybrid-coupler-based architecture and introduce a novel two-stage tunable impedance network to meet the stringent SI-cancellation requirements using only passive components and a microcontroller. We build hardware using COTS components and prototype proof-of-concept applications for a smart contact lens and backscatter enabled drone.

Acknowledgments

The authors would like to thank Aaron Parks, Jonathan Hamberg, and Ye Wang for their help. We would also like to thank the anonymous reviewers as well as our shepherd, Prof. Lin Zhong for their helpful feedback on the paper.

Abstract– Wireless Network-on-Chip (NoC) has emerged as a promising solution to scale chip multi-core processors to hundreds and thousands of cores. The broadcast nature of a wireless network allows it to significantly reduce the latency and overhead of many-to-many multicast and broadcast communication on NoC processors. Unfortunately, the traffic patterns on wireless NoCs tend to be very dynamic and can change drastically across different cores, different time intervals and different applications. New medium access protocols that can learn and adapt to the highly dynamic traffic in wireless NoCs are needed to ensure low latency and efficient network utilization.

Towards this goal, we present NeuMAC, a unified approach that combines networking, architecture and deep learning to generate highly adaptive medium access protocols for wireless NoC architectures. NeuMAC leverages a deep reinforcement learning framework to create new policies that can learn the structure, correlations, and statistics of the traffic patterns and adapt quickly to optimize performance. Our results show that NeuMAC can quickly adapt to NoC traffic to provide significant gains in terms of latency, throughput, and overall execution time. In particular, for applications with highly dynamic traffic patterns, NeuMAC can speed up the execution time by $1.37\times - 3.74\times$ as compared to 6 baselines.

1 Introduction

Recently, there has been an increasing interest from both industry and academia to scale network-on-chip (NoC) multicore processors to hundreds and thousands of cores [11, 21, 25, 49]. To enable such massive networks on chip, computer architects have proposed to augment NoC multicore processors with wireless links for communication between the cores [7, 9, 54, 65, 91]. The broadcast nature of wireless networks enables the NoC to significantly reduce the number of packets that the cores need to communicate to each other as well as the latency of packet delivery [1, 38]. Both aspects play a central role in scaling the number of cores on an NoC multicore processor (See Background Section 3 for details) [1, 8, 38, 50, 56]. These benefits have motivated RF circuits designers to build and test wireless NoC transceivers and antennas that can deliver multi-Gbps links while imposing a modest overhead (0.4–5.6%) on the area and power consumption of a chip multiprocessor [31, 93, 99, 100].

While the use of wireless can significantly benefit NoCs, it brings on new challenges. In particular, the wireless medium is shared and can suffer from packet collisions. Designing efficient medium access protocols for wireless NoCs is, however, difficult. The traffic patterns in NoCs tend to change drastically across applications. Even during the execution of a single application the traffic pattern can change as fast as tens of microseconds [4, 38]. As a result static MAC protocols such as TDMA, FDMA and CSMA perform poorly [17, 33, 35, 61, 70, 71, 89]. Further, due to thread synchronization primitives likes barriers and locks in parallel programming, the wireless NoC exhibits complex hard-to-model dependencies between packet delivery on the network and execution time. As a result, even adaptive protocols that try to switch between TDMA and CSMA or optimize for long-term throughput [40, 65, 66], perform poorly in the context of wireless NoCs since they remain agnostic to these domain specific and intricate dependencies. Hence, the design of efficient medium access protocols has been identified as a key bottleneck for realizing the full potential of a wireless NoC multiprocessor [6, 12].

In this paper, we present NeuMAC, a unified approach that combines networking, architecture and deep learning to generate highly adaptive medium access protocols for a wireless network on chip architecture. NeuMAC leverages a reinforcement learning framework with deep neural networks to generate new MAC protocols that can learn traffic patterns and dynamically adapt the protocol to handle different applications running on the multi-core processor. Reinforcement Learning (RL) has proved to be a very powerful tool in AI for generating strategies and policies that can optimize for complex objectives [68, 81]. RL allows NeuMAC to make better decisions by learning from experience. In particular, many basic functions, like FFT, graph search, sorting, shortest path, etc., tend to repeatedly appear in many applications. Past work also shows that a number of unique periodic traffic patterns emerge in multiple different programs, and as the number of cores increases, the traffic patterns show increasingly predictable spatiotemporal correlations and dependencies [3, 4]. NeuMAC learns these statistics and correlations in the traffic patterns, to be able to both predict future traffic patterns based on traffic history and adapt its MAC protocol to best suit the predicted future traffic. Furthermore, RL enables NeuMAC to account for hard-to-model complex dependencies between execution time and delivery of packets. In particular, we carefully engineer the reward function in RL to optimize for execution time rather than to simply improve the latency and throughput of the network.

Indeed, RL has been leveraged for wireless MAC protocols in the context of heterogenous wireless networks [43, 101], sensor networks [41], and IoT networks [62]. However, bringing these benefits to wireless networks on chip faces a number of unique challenges. First, past work runs RL inference for every packet at each time step, which is not feasible for WNoCs since the time scale of operation in a multicore processor is in the order of nanoseconds. Hence, per time-slot inference would significantly delay every packet transmission. Second, due to compute resource constraints, it is also not feasible to run RL inference at every core of the wireless NoC. While the second challenge can be addressed using a centralized controller for the RL model, it would still incur significant communication overhead and latency to collect the states from the nodes (e.g. traffic injections or buffer occupancy) and to inform the nodes when to transmit.

NeuMAC addresses these challenges by designing a framework where the controller is trained to generate high-level MAC policies simply by listening to on-going transmissions on the wireless medium. This allows NeuMAC to eliminate any communication from the cores to the controllers. Moreover, to amortize the overhead of inference and policy updates, NeuMAC only updates the cores with a new MAC policy once every interval spanning many execution cycles (e.g. ten thousand cycles). We also train NeuMAC to learn policies that are highly adaptive and simple to update, to reduce communication overhead from the controller to cores.

Finally, NeuMAC also needs to operate within the strict timing and resource constraints of the multicore processor. Modern deep neural networks, however, are designed with up to a billion tunable parameters and operate on high dimensional input spaces [47, 80]. Consequently, they require large amounts of memory and computational resources, and also suffer high inference latencies (tens of milliseconds) [46, 63]. To address this, we design NeuMAC's RL framework such that the input and output of the neural network scale linearly with the number of cores. This ensures that NeuMAC is expressive enough to service the highly dynamic network traffic while at the same time operate under the limited memory and computational resources. Specifically, NeuMAC's neural network requires three orders of magnitude less parameters, and adds a small area overhead to the multicore processor. It also has an inference latency that is small enough to meet the strict timing constraints of the multicore during run-time as we show in detail in Appendix A.

We evaluate NeuMAC by integrating it with a cycle-level architectural simulator for CPU-GPU heterogeneous computing that faithfully models the intricacies of multi-core processors [87]. We augmented the simulator with an on-chip wireless network that accurately models transmissions, collision handling and packet losses. We test NeuMAC's performance on real applications chosen from diverse domains such as graph analytics, vision and numerical simulations. We compare NeuMAC against six baselines including wired NoC, standard CSMA, TDMA, optimal CSMA protocols [79], adaptive protocols [38, 65], and an optimal oracle. Our evaluation reveals the following:

- For a 64-core NoC, NeuMAC is capable of learning traffic patterns and adapting the medium access protocol at a granularity of $10\mu s$ to achieve a median gain of $2.56\times-9.18\times$ in packet latency and $1.3\times-17.3\times$ in network throughput over different wireless NoC baselines.
- NeuMAC's throughput and latency gains translate into an average of $10\%-47\%$ speedup in execution time over wireless NoC baselines which goes up to $1.37\times-3.74\times$ for certain applications. The results also show a $3.4\times$ speedup on average over a purely wired NoC.
- NeuMAC's gains in execution time are close to the upper bound that can be achieved by a wireless network with infinite capacity and zero latency.
- As the number of cores scale up to 1024 cores, NeuMAC's performance gain increases to 3 orders of magnitude lower latency and up to $64\times$ higher throughput over baseline protocols.
- NeuMAC is robust to lossy channels, and sees minimal degradation in performance with upto 10% packet losses. We also test NeuMAC's sensitivity to noise in the observed state and show almost no loss in performance.

Contributions: We make the following contributions:

- We introduce the first MAC protocol that can learn and adapt to the highly dynamic traffic at very fine granularity in a wireless NoC processor. The protocol also accounts for non-trivial dependencies between packet delivery and computation speedups by optimizing for execution time.
- We design a lightweight deep reinforcement learning framework that introduces little overhead to the multi-core processor and can operate within tight timing, power and area constraints of chip multicore processors.
- We extensively evaluate our design and demonstrate significant improvement in network performance and reduction in the overall execution time on the multicore processor.

2 Motivation and Insights

The wireless traffic patterns on a multicore processor have been shown to vary significantly across different applications. Even for a single application, the traffic can vary across different cores (spatially) and across different time intervals (temporally) [4, 6, 12, 38, 83].

Fig. 1(a) shows examples of traffic traces captured from a cycle-level architectural simulator for three different common benchmark applications on a 16-core multiprocessor. The x-axis shows the time in clock cycles, the y-axis shows the core ID, and the scatter points show the injection of traffic at each core. For clarity, we only show a portion of the execution spanning ten thousand cycles. Some applications, like *PageRank* shown in Fig. 1(a)(i), have almost constant traffic on all cores and can benefit from a contention-free protocol like TDMA. Other applications, like computing the *Shortest Path in a Graph* shown in Fig. 1(a)(ii), have very bursty traffic and can benefit from a contention-based protocol like

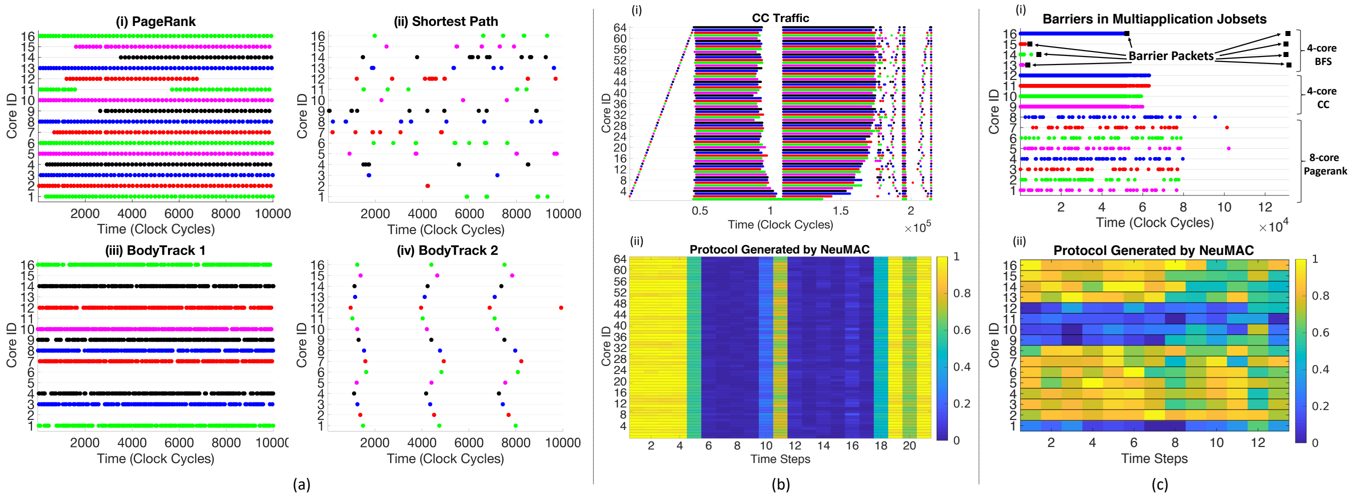

Figure 1: **Illustrative Examples: (a)** Traffic Pattern on a 16-core multiprocessor for different applications. The X-axis shows clock cycles, and the Y-axis corresponds to each of the 16 cores. The figures depict the scatter plots representing the packet injections into the buffer of each core. The different colors for packet injections are used for different cores. **(b)** NeuMAC can quickly adapt to fast changing traffic thus ensuring efficient network utilization throughout the application's execution. In the generated protocol, high probability values (closer to yellow in colormap) represent a CSMA-like protocol whereas low probability values (closer to blue) represent a TDMA-like protocol. **(c)** NeuMAC can learn and optimize for the intricate dependencies between the executions on different cores, and in turn optimize directly for end-to-end execution.

CSMA. Moreover, in most applications, the traffic pattern changes within the execution of the application. For example, Fig. 1(a)(iii)-(iv) show the traffic patterns at different times in the execution of *BodyTrack*, a computer vision application for tracking body pose. In the first time interval, since there is steady injection of packets into the network on the 10 active cores, a contention-free scheme will be optimal to minimize collisions, whereas in the second time interval, a CSMA-like based scheme for all 16 cores will perform better due to the sparse traffic injection. Next, we present concrete examples showcasing the range of protocols that NeuMAC can generate for different traffic patterns.

A. Adapting to Dynamic Traffic Patterns: To further appreciate the spatial and temporal changes across the execution of an entire application, we show the traffic trace for the application CC (Connected Components of a graph), running on a 64-core processor in Fig. 1(b)(i). Here we can see that the traffic varies significantly across the application's execution.

Fig. 1(b)(ii) presents the protocol generated by NeuMAC. At a very high level, NeuMAC's protocol is simple. Each core gets its own dedicated time slot where it can transmit with probability 1 if it has traffic. Additionally, core i can also transmit in time slots assigned to the other cores with some contention probability p_i. By setting these probability values p_i for each core, NeuMAC dictates the MAC protocol on the wireless NoC. The figure shows these contention probabilities p_i's for each core generated by NeuMAC. We present NeuMAC's protocol design in more detail in Section 4.3.

From Fig. 1(b)(ii), we can see that NeuMAC is able to adapt quickly to the changes in the traffic patterns, becoming more TDMA-like when the traffic is dense (contention probabilities p_i's are 0 and everyone transmits only in their assigned slot), and becoming more CSMA-like with sparse traffic (contention probabilities p_i's are high and cores can start transmitting in other's assigned time slots). In the case of CC, we can see that initially the traffic pattern is extremely sparse and structured such that a simple "Aloha" protocol would suffice. As a result, in the beginning the cores contend for the channel aggressively under NeuMAC's protocol. However, once the traffic pattern becomes more dense, NeuMAC adapts the protocol to be more TDMA-like, thus ensuring high network utilization. Finally, once the traffic pattern becomes less dense after $18*10^4$ cycles, the cores again start to contend for the channel with higher probability, thus emulating a CSMA-like protocol. Note that, while NeuMAC is able to quickly detect traffic changes from dense to sparse at time steps 11 and 18 (From Fig. 1(b)(ii)), it does not immediately increase contention probabilities for the cores. Instead the change is gradual, and this is because of the outstanding packets remaining in the buffers immediately after the phase with dense traffic injection. As a result, immediately switching the probabilities would lead to large number of collisions.

The above example demonstrates that NeuMAC is able to learn fine-grained highly dynamic MAC protocols that can quickly adapt to support different kinds of traffic patterns, while accounting for subtle characteristics of network operations such as buffer build-ups even though this information is not explicitly fed into NeuMAC's RL model. While there has been a lot of work on adaptive and optimal CSMA protocols [51, 73, 77, 102], these works are theoretical and make unrealistic assumptions. In particular, they optimize for long term throughput and assume that the protocol can reach a steady-state operation much faster than the variation in traffic patterns, which does not hold for wireless NoCs. As a result, these protocols perform poorly as we show in section 6.

B. Optimizing for Synchronization Primitives: Another challenge in designing efficient protocols stems from synchronization primitives. These primitives impose intricate dependencies between the execution of threads on different cores, leading to a non-trivial relationship between the delivery time of packets on the NoC and the progress of execution on each core. For example, in parallel computing it is common practice for software developers to use `barriers` for synchronization. These barriers are placed throughout the code of a multithreaded application in order to force each thread to stop at a certain point, blocking its execution until all participating threads catch up. Most standard libraries for parallel programming use barriers in many of its primitive routines in order to ensure the correctness of the program, such as OpenMP's `For` loop [23], or MPI's `Send/Recv` [45]. Therefore, there is complex but predictable structure in the traffic patterns caused by these synchronization primitives that can be exploited to improve parallel speedup and scalability of high performance applications. Hand tuning protocols to account for these dependencies is non-trivial. For example, the cores themselves do not explicitly know that they are involved in a barrier before they actually reach the barrier and execution halts. [28, 82]. Past work on designing MAC protocols mainly optimizes for throughput and latency, and is agnostic to such dependencies.

As a concrete example, consider the multiapplication jobset comprising of three concurrent applications, namely a 4-core BFS, a 4-core CC and a 8-core Pagerank, running on a 16-core multiprocessor as shown in Fig. 1(c)(i). In the traffic trace, one can observe two sets of barrier packets in the execution of BFS, denoted by black squares. The other two applications have no barriers in this portion of their executions. Here, note that core 16 has significantly more packets to transmit before arriving at its barrier, whereas core 13, 14 and 15 arrive at their barriers sooner. As a result, the execution on cores 13, 14 and 15 is blocked until core 16 clears its barrier, thus rendering the compute resources of these three cores useless as they idly wait for core 16. Additionally, at the same time core 16 also has to contend for the channel with traffic from CC, which itself has a lot of ongoing communication. Ideally, the MAC protocol in this case should prioritize traffic of the core that is falling behind, so that it arrives to the barrier and clears it as soon as possible, allowing the blocked cores to proceed execution and thus optimizing overall execution time. In Fig. 1(c)(ii), we can see that NeuMAC can learn to account and optimize for such dependencies. At the start, NeuMAC assigns high contention probabilities to cores 13 to 16 so that it can clear the barrier point at the earliest, while assigning low contention probabilities to cores 9 to 12. Once the barrier is cleared, NeuMAC increases the contention probabilities for the CC cores, so that it can transmit on the channel while the other applications go through low communication periods, thereby ensuring high network utilization.

Protocols like CSMA, TDMA and even adaptive protocols

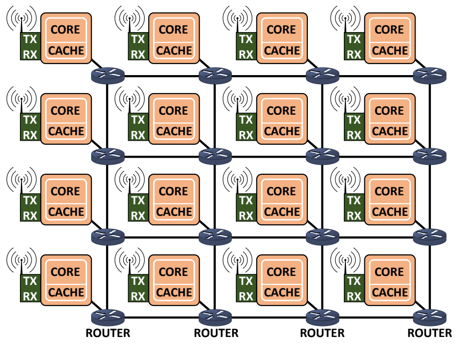

Figure 2: NoC Architecture with Wireless Links

cannot optimize for such situations as they would treat every packet in the network as equally important, thus sharing the channel equally between BFS and CC here. This would result in core 16 clearing its barrier much later, thus harming end-to-end execution time. However, since NeuMAC is trained to directly optimize the high-level objective of end-to-end execution time instead of network metrics like latency, it is able to learn to prioritize the packets of some cores over others. In this example, with NeuMAC's protocol, core 16 arrives at its barrier 2.4× faster as compared to CSMA, and 3.75× faster as compared to TDMA. This in turn leads to an overall improvement in execution time of 43% and 81% over CSMA and TDMA respectively.

3 Background

3.1 Wireless Network on Chip

Network-on-Chip (NoC) architectures have played a fundamental role in scaling the number of processing cores on a single chip which led to unprecedented parallelism and speedups in execution time [30, 75, 88, 94]. Prior to NoC, multicore processors used a shared bus architecture which had very poor scalability. As the core count increases, the power required to drive the bus grows quickly due to the increase in the capacitance of the bus wires [15]. The bus also starts to suffer from large latency [74]. As a result, shared buses become impractical for designs beyond 16 cores [59].

Unlike a shared bus, wired NoCs use packet-switched communication with every core connected to a router as shown in Fig. 2 [78]. As the packet moves from source to destination, it is buffered, decoded, processed, encoded, and retransmitted by each router along the multi-hop path. However, as we scale the number of cores, computation slows down due to the high communication latency and overhead of the network [10, 57, 97]. This problem is known as the "Coherency Wall" [58], where the execution on each core is faster than the NoC's ability to ensure that the memory caches of the cores are coherent. Hence, the speedup gained by parallelism and multithreading is outweighed by the network's communication cost for keeping the caches coherent [5, 8, 58].

Recent work proposes to augment NoC multicore processors with wireless links for communication between the cores [7, 9, 54, 65, 91]. Wireless links benefit chip multicore processors in two important aspects:[1]

- **Lower Latency:** Wireless enables every core to reach every other core in just a single hop. In contrast, in a purely wired NoC, a packet must go through multiple NoC routers, incur queuing, transmission, and processing delay at every hop which ends up taking multiple execution cycles [1]. Hence, as the number of cores increase, wireless can deliver packets with significantly lower latency and within the tight timing requirements of execution on the cores [1].
- **Broadcast:** Since wireless is a broadcast medium, transmitted packets are directly heard at all other cores which significantly simplifies the NoC's ability to ensure the coherency of the memory caches. In particular, any local changes in the memory cache of a core can instantaneously be replicated at all other cores through a single packet transmission [38]. In contrast, today's wired NoCs must send multiple parallel unicast/multicast transmissions to synchronize the caches, which leads to a large overhead that scales poorly as the number of cores increases [8, 50, 56].

Several wireless NoC transceivers and antennas have been built and shown to deliver 10 to 50-Gbps links while imposing modest overhead (0.4–5.6%) on the area and power consumption of a chip multiprocessor [31, 39, 93, 99, 100]. The wireless transceivers typically operate in the millimeter-wave and sub-THz spectrum which enables miniaturizing the antennas and avoids antenna coupling. Antennas are either planar integrated dipoles or vertical monopoles drilled through the silicon die [24, 86]. The wireless signals propagate through the enclosed chip packaging and attenuate by few tens of dBs [85, 86]. On-Off Keying (OOK) is the choice of modulation since it requires significantly lower powerand achieves a very low Bit Error Rate (BER) for on-chip wireless links [39, 60, 99]. We adopt the collision and packet loss handling protocols from past work [1, 38].

3.2 Deep Reinforcement Learning

We provide a brief primer on RL based on [84]. In RL, an *agent* interacts with an *environment*, and learns to generate a policy directly from experience as shown in Fig. 3. In our case, NeuMAC is the *agent*, the multiprocessor is the *environment*, and the generated MAC protocol is the policy.

• **Agent & Environment:** The *agent* starts with no apriori knowledge. Then, at each time step t, the agent observes the state s_t of the environment, and takes an action a_t. Following the action, the environment transitions to state s_{t+1}, and the agent receives a reward r_t. The state transitions and the rewards are stochastic and assumed to have the Markov property.

[1]Note that other technologies such as optical links have poor performance [2, 9, 37].

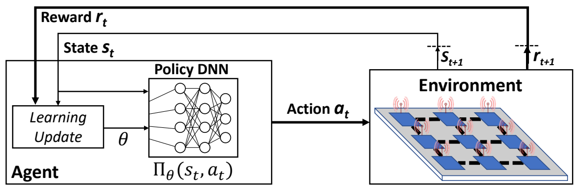

Figure 3: Deep Reinforcement Learning Framework.

During training, the *agent* gains experience by taking actions and observing the state transitions and rewards in response to these actions. The actions the *agent* takes aim to maximize an objection function known as the expected cumulative discounted reward: $\mathbb{E}\left[\sum_{t=0}^{\infty} \gamma^t r_t\right]$, where $\gamma \in (0, 1]$ is the discount factor for future rewards.

• **Policy:** The action a_t picked by the *agent* is dictated by a *policy* π, where π represents a probability distribution over the space of actions and states : $\pi(s, a) \rightarrow [0,1]$. That is, $\pi(s, a)$ is the probability that action a is taken in state s by the agent following policy π. For most large-scale practical problems, the policy π is modeled with a Deep Neural Network (DNN), as they are very powerful function approximators. The DNN is parameterized by θ, which are the learnable parameters of the model, and we represent the policy as $\pi_\theta(s, a)$. θ is also referred to as the *policy parameters*.

• **Training:** The objective of training in RL is to learn the policy parameters θ so as to maximize the expected cumulative reward received from the environment. Towards this end, we focus on a class of RL algorithms called *policy gradient algorithms*, where the learning takes place by performing *gradient descent* on the policy parameters. In practice, the training methodology follows the *Monte Carlo method* where the agent samples multiple trajectories obtained by following the policy π_θ, and uses the empirically computed cumulative discounted reward as an unbiased estimator of the expected value. This empirical value is then used to update the policy parameters via the gradient descent step. The result is a known algorithm: REINFORCE which we use in this paper. For more details, we refer the reader to [84].

4 NeuMAC Design

4.1 Overview

NeuMAC consists of two components. (1) A standard NoC multicore processor with N cores where each core has been augmented with a wireless transceiver as shown in Fig. 2. (2) A NeuMAC agent that periodically generates new medium access policies based on the traffic patterns it sees on the wireless NoC. The agent is housed in a simple neural accelerator that resides on the same chip with a small area and power overhead (See Appendix A for hardware details).

Fig. 4 shows the working of NeuMAC. The NeuMAC agent is equipped with a wireless transceiver through which it can listen on the channel, and also send protocol updates to the

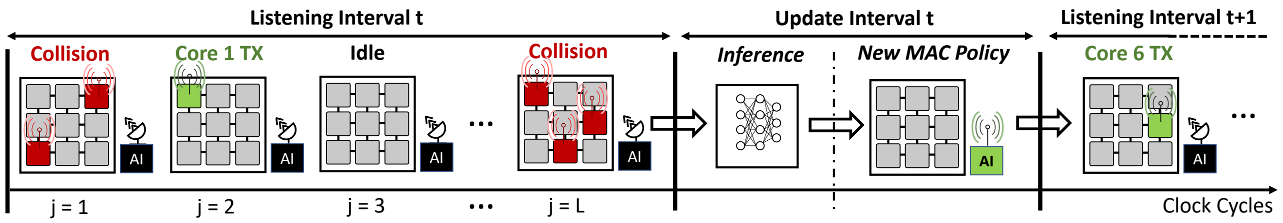

Figure 4: An Overview of NeuMAC's Protocol

cores. The NeuMAC agent listens on the wireless channel for a period called the "*Listening Interval*" where it collects traffic data about core transmissions, collisions and idle slots. It, then, feeds this data to a trained RL neural network that implicitly predicts the future traffic patterns and generates a new policy to be used as the medium access protocol during the next *Listening Interval*. NeuMAC updates the policies at the cores by sending an update message with the policy parameters. Each *Listening Interval* and *Update Interval* constitute a single step in the RL framework.

One point to note is that, although the cores share a common clock for their normal CPU operation[2], it is infeasible to coordinate medium access for each clock cycle through a shared centralized scheduler, since the exchange of control messages between the cores and the scheduler would itself incur latencies of multiple clock cycles. [6]

4.2 Design Challenges

The above design is governed by several strict timing and resource constraints of wireless NoC. In particular, it must address the below challenges while at the same time ensuring NeuMAC's ability to generate versatile and expressive medium access protocols to service the dynamic and fast-varying traffic patterns.

C1. *Centralized Agent:* Ideally, we would have wanted NeuMAC to adopt a distributed design where every core is equipped with its own NeuMAC agent that dictates its own MAC protocol. However, introducing a neural accelerator at every core would be prohibitively expensive in terms of area and power. Hence, NeuMAC is constrained to a centralized approach with a single agent.

C2. *Cores to Agent Communication Overhead:* To obtain an accurate view of traffic patterns, NeuMAC must obtain the packet injection rate and buffer occupancy across time at each core in the network. However, relaying this information from every core back to the centralized agent would result in huge communication overhead. Instead, NeuMAC leverages the broadcast nature of wireless networks to collect traffic patterns simply by listening for transmissions on the wireless medium. While the collected information is less expressive than the history of packet injection and buffer occupancy at each core, it retains sufficient information to allow NeuMAC to predict traffic patterns while at the same time completely eliminating communication overhead from the cores to the centralized agent.

C3. *Agent to Cores Communication Overhead:* One option is to have the agent tell each core whether to transmit or not at every CPU clock cycle. However, this would require running inference and relaying information to each core at every clock cycle which would lead to prohibitively large communication overhead. To address this, NeuMAC amortizes the communication overhead (*Update Interval*) from the agent to the cores by performing inference once every *Listening Interval* spanning thousands of clock cycles. In our implementation, we use an interval of $L = 10{,}000$ clock cycles ($10\mu s$) which is large enough to reduce the overhead to less than 6% and small enough to ensure that the traffic patterns remain stable and can be learned by the RL agent.

C4. *Complexity of the MAC Policy:* NeuMAC generates a policy that dictates the MAC protocol of each core for the following *Listening Interval*. Ideally, NeuMAC would generate a deterministic transmission schedule for every core to follow. Such a design is extremely expressive since it could allow NeuMAC to generate any possible schedule. However, such a design would require the RL deep neural network to output an action space with $N \times L$ dimensions where N is the number of cores and L is the number of clock cycles (e.g. 10,000). Such a neural network would be unsuitable for a resource-constraint setting like NoC. To address this, we carefully design a parameterized MAC policy that can support a flexible range of medium access protocols while ensuring that the neural network only needs to output a few parameters to dictate the desired policy.

C5. *Reward engineering:* The reward during training needs to be designed so as to guide NeuMAC towards the high-level objective. While most past work on learning link-layer and network-layer protocols only use network-level metrics such as throughput and latency for the reward signal, in our case we need to choose domain specific rewards so as to optimize for the end goal, which is application execution speedup on the multicore.

C6. *Low Footprint Neural Network:* NeuMAC's neural network must adhere to strict timing, power and area constraints of a chip multiprocessor. Thus, our design cannot simply adapt a known RL model as it would require large amounts of memory and computational resources, and would also suffer high inference latencies (tens of milliseconds) [46, 63].

[2] Unlike a distributed system of machines, a shared clock for a manycore system is feasible since all cores are housed on the same silicon die.

To address this, we design NeuMAC's RL framework such that the state space (input to the neural network) and action space (output) scale linearly with the number of cores. Our design ensures that NeuMAC is expressive enough while at the same time can operate under NoC's resource constraints.

4.3 NeuMAC's MAC Policy

As discussed above, the MAC policy that the agent dictates to the cores should have the following properties:

1. The policy should span a wide range of protocols, all the way from TDMA to CSMA.
2. It should be possible to describe the policy with few parameters to reduce the communication overhead and the output of the neural network.
3. It should allow for a simple neural network architecture to learn a mapping from observed traffic patterns to the most efficient MAC protocol.

In order to achieve these properties, we adopt a two-layer protocol design. The first layer consists of a deterministic underlying TDMA schedule, where each core is assigned a unique time slot for transmission in a round-robin fashion. For example, for time slots $j \in [1, \cdots, L]$, core i is assigned the slots $\{j \mid j \mod N = i\}$ where N is the number of cores. The second layer consists of a probabilistic transmission schedule like CSMA, where each core is assigned a contention probability. Specifically, during its assigned time slot, core i transmits on the channel with probability 1 if it has an outstanding packet in its buffer. During other cores' assigned time slots, core i can transmit with probability p_i. In the event of a collision, exponential backoff is implemented by halving p_i of the colliding cores similar to CSMA. On the other hand, if a transmission is successful, p_i is reset to it's initial value.

To generate this policy for an NoC with N cores, the RL neural network needs to output an action space that can be defined as $a_t = [a_{1,t}, a_{2,t}, \ldots, a_{N,t}]$ where $a_{i,t} \in [0, 1]$ represents the initial contention probability of core i during *"Listening Interval" t* (i.e., time step t in the RL framework). The contention probability of core i is then initialized as $p_i = a_{i,t}$. Different choices of a_t result in different protocols on the multicore. For instance, setting $a_{i,t} = 0$ for all i results in a simple TDMA protocol since every core only transmits on the channel during its assigned slot. On the other hand, $a_{i,t} = c > 0$ for all i mimics a CSMA-like protocol with varying degrees of aggressiveness on the channel. The pseudo code for NeuMAC's protocol is presented in Alg. 1.

The above formulation satisfies our design objectives. First, it enables NeuMAC to gracefully shift between a pure TDMA and a CSMA scheme, while supporting all intermediate protocols. The design also gives the flexibility to control each core individually, so that the NeuMAC can potentially increase contention probabilities for cores that observe high traffic intensity. Second, since the MAC protocol at core i is

Algorithm 1 NeuMAC Protocol

```
$L \leftarrow$ Number of Clock Cycles in Listening Interval
$[a_{1,t}, a_{2,t}, \ldots, a_{N,t}] \leftarrow$ Action space generated by RL agent at time step$t$
$[p_1, p_2, \ldots, p_N] \leftarrow [a_{1,t}, a_{2,t}, \ldots, a_{N,t}]$

At core $i$:
for $j \in \{1, \cdots, L\}$ do
    $Buffer_i(j) \leftarrow$ Outstanding packet in the buffer for core $i$
    if $Buffer_i(j) \neq \emptyset$ then
        if $j \mod N = i$ then                ▷ TDMA Slot Assigned to Core $i$
            Transmit with probability 1
        else
            Transmit with probability $p_i$
    if Transmission from Core $i$ collides then
        $p_i = p_i/2$
    else
        $p_i = a_{i,t}$
```

characterized by only one number (the contention probability $a_{i,t}$), there is very small communication overhead during the *Update Interval*, where the NeuMAC agent has to transmit a single broadcast packet with N numbers. Each core, receives the packet and extracts it own contention probability. Finally, the design keeps the action space constrained and linear in the number of cores which allows for a simple neural network that can be easily trained and is more likely to converge.

4.4 RL Formulation and Training

Given the above design, we now formalize the state space, reward, policy and training of NeuMAC's RL framework.

• **State Space Design:** The NeuMAC agent takes state information s_t as input and generates a MAC policy characterized by the action space a_t described above. The state information is generated purely by listening to ongoing transmissions on the channel. As described earlier, this allows us to eliminate all communication overhead from the cores to the RL agent. However, it only provides information about the activity on the channel rather than the traffic injection into the network. Moreover, in the event of a collision, NeuMAC cannot know which cores attempted to transmit. Despite these limitations, NeuMAC's state space retains enough information to infer traffic patterns. In particular, during each CPU cycle, NeuMAC will either detect an idle channel, a collision, or a successful transmission from some core i. We define our state at time step t, s_t, as an $(N+1) \times 1$ vector that keeps track of the number of successful transmissions from each core and the number of collisions observed during the cycles in the RL time step (*Listening Interval*). Specifically, the i^{th} element of s_t counts the number of successful packet transmissions by core i, and the $N+1^{th}$ element counts the number of collisions. The number of idle slots is implicitly encoded in the state since it is equal to $L - \sum_{i=1}^{N+1} s_{i,t}$ where L is the number of cycles in a *Listening Interval*. The state s_t is then used by the NeuMAC agent to generate the MAC protocol policy for the next time step.

• **Reward Engineering:** The reward signal is designed to guide the agent towards policies that optimize for the desired objective. Most past work that uses RL for learning networking protocols employs network-level metrics like throughput or latency as the reward signal. However, in our case, we need the reward signal to directly represent our end goal, which is to optimize for speedups in application execution time on the multicore. While network-level metrics like throughput are correlated to the execution time, they do not always capture the intricate dependencies between the execution on threads and packet delivery on the network. In Section 6, we see that there are instances where a protocol performs significantly worse in terms of average network throughput, but still has better end-to-end application execution time.

As a result, we design our reward signal to reflect our high level objective of minimizing application execution time. Specifically, for each time step t, the reward is set to $-L_t$ where L_t represents the number of clock cycles where the application was executing. Hence, for all but the last time step, the reward signal r_t is set to $-L$. For the last time step, reward is set to $-k$, where k is the number of clock cycles at which the application terminates execution. The intuition behind this choice for the reward signal is as follows. Recall that the objective of reinforcement learning is to maximize the cumulative reward, i.e. $-\sum_t L_t$. This is equivalent to minimizing $\sum_t L_t$, which ultimately means the application utilizing fewer CPU clock cycles for execution. While this choice of reward signal does correlate with improving network-level metrics such as packet latency and throughput, it is not the central objective and thus it is possible that sometimes the NeuMAC agent compromises on network performance for improvement in execution time. Note that in our formulation, we set the discount factor $\gamma = 1$.

• **Policy:** We represent our policy π as a deep neural network (also called policy network) which takes as input the state s_t, and maps it to a_t in the action space. Note that in our problem, the action space is continuous. In such cases it is common to discretize the continuous action space $a \in [0,1]^N$ similar to [52], and convert the problem into a classification problem where the agent now chooses which combination of a_i's to pick. However, an obvious issue with this approach is the curse of dimensionality. Even with 2 quantization levels for each a_i, the total number of discretized actions in $a \in [0,1]^N$ becomes 2^N. Thus the neural network architecture needs to have an output dimension of 2^N which becomes infeasible for our resource constrained environment.

Therefore, we avoid discretizing the action space and, instead, model the actions as following a Gaussian distribution with mean μ and variance σ. The deep learning model is now trained to output the parameters of this Gaussian distribution, as described in [84]. The NeuMAC agent picks the action for the next time step simply by sampling from the distribution $\mathcal{N}(\mu, \sigma)$. In NeuMAC, the policy network outputs N parameters μ_i corresponding to N distributions, one for each core i. The variance σ is set to 1 at the start of training to encourage exploration, and annealed down to 0.05 as NeuMAC's policy improves. Finally, during inference, the variance σ is set to 0.05, the action $a_{i,t}$ for core i is sampled from the corresponding distribution $\mathcal{N}(\mu_i, \sigma)$, and clipped to ensure that $a_{i,t} \in [0,1]$.

• **Training Algorithm:** We train our policy network end-to-end in an *episodic* setting. In each episode, an instance of an application is executed on the multicore, and the wireless network on chip follows the MAC protocol as dictated by the NeuMAC's policy network. The episode terminates when the application completes execution. In order to learn a policy that generalizes well, we train the network for multiple episodes with each episode observing a different application trace. For every episode, we run M separate Monte Carlo simulations to explore the probabilistic space of possible actions using the current policy, and use the resulting data to improve the policy for all applications. Specifically, we record the state, action, and reward information for all time steps of each episode. We then use this data to train our policy using the popular REINFORCE algorithm along with a baseline subtraction step, as described in [67].

4.5 Neural Network Architecture

Our network is composed of three fully connected layers with 128, 128 and 64 neurons respectively. The first two layers are followed by ReLU activation units, whereas the final layer is followed by a sigmoid unit to output the probability values a_i's between 0 and 1. During training, the weights use 16 bit floating points. Once trained, the learned weights are quantized to 8 bit fixed points for the inference stage. This is standard for run-time optimization in deep learning [53], and does not adversely affect performance.

The proposed fully connected network architecture here is simple and ties in very well with our design objectives. Recall that NeuMAC performs one inference step every 10,000 CPU clock cycles, and we require the inference step to add little overhead. The architecture here is composed of 32,000 learnable parameters, and at 8-bit quantization, it can be stored in a 32 KB on-chip SRAM cache to ensure fast memory accesses. Since inference latencies in most neural network architectures tend to be memory bound (including Fully connected and CNN architectures) [26,53], improving memory access latencies plays a big role in speeding up overall inference time. Further, the simple structure of a fully connected network allows for straightforward memory access patterns, since the inference step is a straightforward computation amounting to consecutive matrix multiplications. In Appendix A we provide energy-delay characterization of this architecture.

One point to note is that NeuMAC's deep RL agent is trained offline, and does not undergo any training during run-time since training is resource intensive. However, retraining can be triggered periodically depending on performance re-

Name	Description

quirements and this retraining will be performed offline. The updated model parameters can then be migrated to the neural hardware accelerator by simply rewriting the SRAM memory blocks on the accelerator corresponding to the neural network's model parameters. This update can happen through the multicore's wireless NoC communication channel and won't add much overhead since our model is restricted to just 32,000 parameters, each of 8 bits.

5 Implementation

Evaluation Environment: We evaluate NeuMAC on a cycle-level execution-driven architectural simulator, Multi2sim [87]. Multi2sim is a popular end-to-end heterogenous system simulator tool used in the architecture community to test and validate new hardware designs with standard benchmarks. We evaluate NeuMAC for multicores with core count $n = 64$ at 22nm technology running at 1GHz. We use the same architecture parameters as [38]. We augment Multi2sim with an on-chip wireless network that accurately models transmissions, collision handling and packet losses.

While NeuMAC could be potentially trained directly using multi2sim, it is extremely slow and would result in prohibitively large training times. Therefore, for NeuMAC's training phase, we use a light-weight custom-built Wireless Network-on-Chip simulator along with traffic traces captured from Multi2sim. Our custom simulator models the data dependencies and synchronization primitives (such as locks and barriers) in the applications, so as to faithfully mimic the behavior of multi-threaded applications.

In order to evaluate NeuMAC's generalizability and effectiveness for a broad use case, we test NeuMAC on 9 different applications chosen from diverse domains such as graph analytics, vision, and numerical simulations (Summary in Table 1). Additionally, we also test with multi-application jobsets where different groups of cores are executing different multithreaded applications. While training is performed using our custom simulator, we evaluate NeuMAC using Multi2sim. We integrate Multi2sim with NeuMAC's trained RL agent, and our evaluations account for the RL agent's DNN inference latency and communication latency between the multicore and RL agent.

Training and Evaluation Details: For each application, we collect 500 different traces, each generated with different inputs to the applications in order to capture the variations between different runs. We evaluate NeuMAC using k-fold cross validation, where we train the model on 8 applications and test performance on the ninth application. Thus, we ensure that the NeuMAC agent is never explicitly trained on the application it is being evaluated on, and our results show that NeuMAC can generalize well to different applications. We train NeuMAC for a total of 4000 episodes, and for each episode we run $M = 16$ Monte Carlo simulations in parallel. The policy network is trained using ADAM optimizer [55] with a learning rate of 0.001.

6 Evaluation Results

6.1 Baselines

We compare with the following baselines:

(1) **CSMA with Exponential Backoff:** CSMA/CA protocol from 802.11 networks, with backoff window ranging from 1 to 1024. [1, 71] use CSMA MAC in the context of WNoCs.

(2) **TDMA:** Cores are allocated fixed slots for transmission in round-robin fashion. [5, 34] evaluate TDMA for WNoCs.

(3) **Switch-thresh:** [38, 65] propose a protocol that switches between a static CSMA and a static TDMA protocol based on per-core preset thresholds for channel activity and buffer occupancy. The optimal threshold values vary across applications and we choose values that are best in the average case.

(4) **Optimal CSMA Algorithm:** There is a large body of work that designs throughput optimal CSMA algorithms. However, most of these works are theoretical, and make simplifying assumptions like ignoring collisions or static traffic arrival rates, due to which they perform significantly worse than even regular CSMA protocols in practice. Among the optimal CSMA algorithms we tested, we found queue-based algorithms to perform best. We implement an extension of the popular Q-CSMA algorithm [79], where each node uses its buffer queue buildup to infer its transmission aggressiveness on the channel. While this algorithm is not truly distributed in nature, we ignore the global communication overheads in evaluations to favor the baseline performance.

(5) **Wired Baseline:** We also compare performance against a purely wired baseline, where all cache coherency traffic is serviced through the wired network-on-chip.

(6) **Infinite Capacity Channel:** We also compare NeuMAC's performance against an oracle with infinite channel capacity where the wireless medium can support multiple concurrent transmissions without suffering collisions, and every packet can be transmitted immediately without any channel contention delays. This baseline gives us an upper bound on how much improvement in end-to-end execution time is possible from improving the wireless NoC performance.

6.2 Quantitative Results

We first evaluate NeuMAC's performance against baselines on single application executions, followed by evaluations on the more realistic scenarios where multiple applications are running on the multicore. We also test NeuMAC's performance under lossy network conditions, and conclude by presenting scaling results where we demonstrate that NeuMAC's gains increase as the multicore scales to thousands of cores.

A. Single Application Wireless Network Performance: We begin by evaluating the wireless network performance against baselines along three metrics – (i) Wireless network throughput, (ii) Packet latency on the wireless network, and (iii) Number of collisions on the channel. We note that while NeuMAC is not explicitly trained to optimize for network metrics, their performance is correlated to faster execution times on the NoC.

(i) Network Throughput: In Fig. 5, we plot the gains in average network throughput achieved by NeuMAC against the baselines. Compared to CSMA and TDMA, NeuMAC achieves a mean improvement of 1.8× and 9.63× respectively across the benchmarks, and a maximum improvement of 3.3× and 32.1× respectively. TDMA has poor performance for average network throughput since cores have to wait for their turn to transmit even when the traffic is sparse, which leads to underutilization of channel.

Compared to Switch-thresh and Q-CSMA, NeuMAC achieves a mean improvement of 1.2× and 1.33×, and a maximum improvement of 1.7× and 1.9× respectively. While these protocols are improve over CSMA and TDMA, they still cannot react and adapt quickly enough to accommodate the fast changing traffic patterns on the multicore.

(ii) Packet Latency: In Fig. 6, we plot the CDF of packet latency due to queuing in the Wireless Network-on-Chip across all applications. It is interesting to note that while at the tail TDMA performs better than CSMA, in the median case TDMA performs significantly worse than CSMA. This is because the high packet latencies at the tail are due to dense traffic in the network which TDMA is better suited for, whereas at the median where traffic is less dense, TDMA leads to much higher packet latencies. NeuMAC, on the other hand, is able to adapt to all these different scenarios and provides an improvement in packet latency across all baselines. Over CSMA and TDMA, NeuMAC improves median packet latency by 4.11× and 9.18×, and improves 90th percentile latency by 3.89× and 1.92× respectively. Over Switch-thresh and Q-CSMA, the gains respectively are 4.66× and 2.56× at the median, and 1.47× and 2.13× at 90th percentile.

(iii) Collisions on Wireless Channel: In Table 2 we show % of collisions on the wireless channel across different benchmarks. We omit TDMA here since TDMA by design does not suffer from collisions. As observed, NeuMAC has significantly fewer collisions than the CSMA algorithms. Switch-thresh is the next best performing protocol, but NeuMAC in most cases still has fewer collisions.

B. Single Application End-to-End Execution Speedup:

(i) Speedups over Purely Wired Network-on-Chip: In Table 3, we show application speed-ups achieved by NeuMAC and the Infinite Capacity baseline respectively, over the purely wired NoC. NeuMAC can speed up benchmarks by up to 9.7× for StreamCluster and 6.53× for BFS, and on average provides a speedup of 3.42× across benchmarks. Additionally, we see that NeuMAC gets very close to the upper bound of the speedup value, achieving up to 99.5% of the maximum speedup possible in the case of BFS, and 98% of the maximum speedup possible on average. This result demonstrates that NeuMAC is able to fully exploit the potential offered by the wireless NoC.

(ii) Speedups over Baselines: Fig. 7 shows execution time gains of NeuMAC over the baselines on the wireless NoC. As can be observed, there is no one baseline protocol that performs well across all applications. While in applications

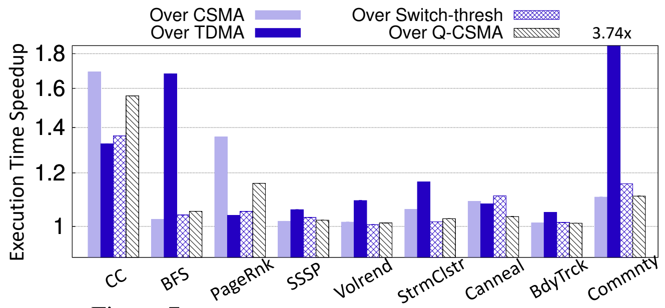

Figure 7: Execution Time Results (y axis in logscale)

Apps	NeuMAC	Inf. Cap. baseline	% Achieved
CC	1.96x	2.06x	95%
BFS	6.53x	6.56x	99.5%
Pagerank	1.07x	1.11x	96.4%
SSSP	2.24x	2.25x	99.5%
Volrend	1.32x	1.33x	99.2%
Strmclstr	9.70x	9.77x	99.28%
Canneal	1.14x	1.15x	99.13%
Bodytrack	1.37x	1.38x	99.3%
Community	3.77x	3.82x	98.6%

Table 3: Speedups over Purely Wired Network-on-Chip.

like Pagerank, TDMA performs the best, in other applications such as BFS it is significantly worse. NeuMAC, on the other hand, performs well across all benchmarks. In Table 4, we see that NeuMAC achieves a maximum of 69.18% speedup over CSMA for CC and 274.56% speedup over TDMA for Community, and compared to Switch-thresh and Q-CSMA, NeuMAC offers speedups up to 37.09%-55.94%.

C. Multi-Application Jobs: In Table. 5, we present execution time speedup results for multiapplication runs on the multicore. For each run, we randomly choose one application among the 9, and execute it using either 4, 16 or 32 threads. We choose a sufficient number of applications such that all 64 cores are utilized, and in total we test on 100 different multiapplication jobsets. Note that the NeuMAC agent was never explicitly trained on such multiapplication traffic traces. From Table. 5, we can see that NeuMAC's gains increase over the baselines compared to single benchmark experiments (Table. 4), and goes as high as 6.15× (515.04%) speedup over TDMA. These higher gains in multiapplication jobsets can be attributed to the more complex nature of packet dependencies between threads, which NeuMAC can exploit to further speed up execution time as illustrated in Section 2.

C. Lossy Networks: To evaluate NeuMAC's robustness to varying channel conditions, we conduct experiments in lossy network settings. We vary the packet loss rates in the wireless NoC from 0% up to 10%, and in the event of a loss, the packet is retransmitted. In Fig. 9, we compare the average application speedup achieved over the baselines as the loss rate increases. We observe that NeuMAC is able to generalize very well to varying channel conditions and loss rates, and

Speedups	CSMA	TDMA	Switch-thresh	Q-CSMA
Max	69.18%	274.56%	37.09%	55.94%
Min	1.26%	4.88%	0.63%	1.12%
Mean	18.21%	46.90%	9.73%	11.94%

Table 4: Summary of Execution Time Speedups by NeuMAC. The per-application speedups are shown in Fig. 7.

Speedups	CSMA	TDMA	Switch-thresh	Q-CSMA
Max	93.18%	515.04%	48.16%	26.78%
Min	13.3%	24.72%	4.41%	5.82%
Mean	33.93%	166.32%	19.97%	17.48%

Table 5: Summary of Execution Time Speedups by NeuMAC for Multiapplication runs

can maintain the same gains over the baselines throughout. Note that NeuMAC was never trained explicitly for lossy network settings. Despite this, it is able to generalize since it can implicitly infer the channel conditions from the channel activity like increased number of collisions.

We also test NeuMAC's sensitivity to errors in the observed state caused by packet losses at the NeuMAC agent's transceiver during the *"Listening Interval"*. We conduct experiments where we vary the packet loss rate from 0% to 2% in order to introduce noise in the observed state. We find that even under 2% loss rate, NeuMAC's suffers a median performance degradation of only 0.85% across all benchmarks compared to its performance with perfect state information.

D. Scaling Trends: We believe that a learning based approach like NeuMAC can greatly benefit the wireless NoC performance as the number of cores scale to thousands of cores. To demonstrate this we show the gains that NeuMAC achieves over baseline protocols for different metrics as the cores vary from 4 to 1024 in Fig. 8. Since multi2sim and other architectural simulators cannot scale beyond a hundred cores, we evaluate these results in our custom simulator by training a separate NeuMAC model for each core count. From Fig. 8, we can see that NeuMAC's gains over the baselines scale favorably with the number of cores. This is because NeuMAC is able to generate fine-grained MAC protocols by controlling the actions of each core individually, and thus can generate highly optimized protocols that improve substantially upon the baselines at high core counts.

7 Related Work

A. Wireless Network-on-Chip Protocols: The majority of past networking research on wireless NoC does not leverage the broadcast nature of wireless to enable instantaneous cache synchronization and instead focuses on using wireless only between far apart cores to reduce the latency. These complementary works focus on problems related to optimizing network topology [32,35,105], packet routing [61,90,106], flow control [18,42] and improving the reliability of the PHY layer for far apart cores [76,85,86]. However, such designs have limited gains over wired NoCs [4]. More recent work in architecture research exploits the broadcast nature of wireless to

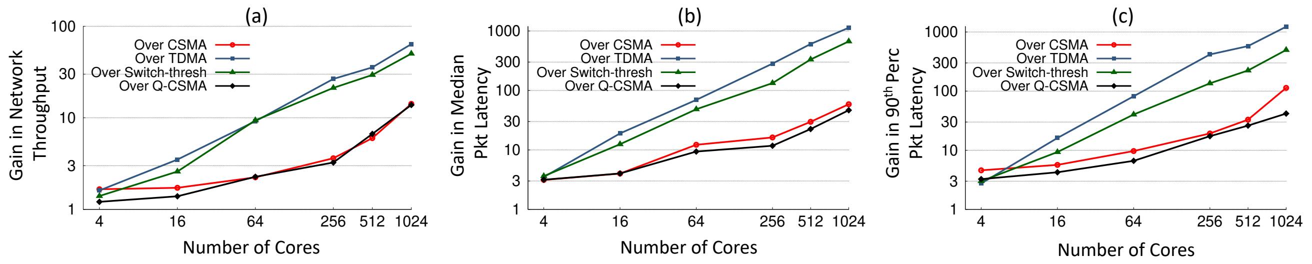

Figure 8: Scaling Trends in NeuMAC's Gains for (a) Wireless Network Throughput (b) Median Packet Latency and (c) 90^{th} Percentile Packet Latency

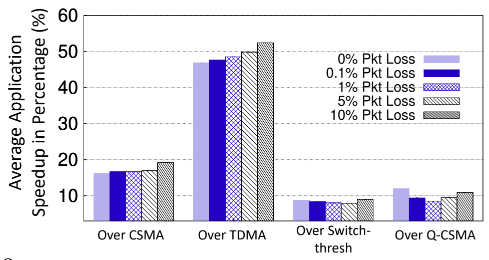

Figure 9: Effect of Packet losses on NeuMAC's application speedup performance compared to Baselines.

boost the performance of wireless enable NoCs [34,38,65,71]. These systems either use *contention-free* mechanisms such as token passing [34] or *contention-based* mechanisms such as carrier sense with exponential backoff [29,71]. The closest to our work are [38,65] which attempt to adapt to traffic patterns by switching between a CSMA or a token passing protocol based on a preset threshold. However, hand tuning the threshold values is a challenging task and does not provide the flexibility and expressibility of NeuMAC to support complex and highly variable traffic patterns.

B. Network-on-Chip Technologies: Past work on wired NoCs proposes the use of deep learning and RL to learn efficient packet routing protocols [98], learn memory access patterns to reduce cache misses [103], and reduce static and dynamic power consumption on an NoC [36]. To the best of our knowledge, ours is the first work that attempts to exploit deep reinforcement learning techniques to generate medium access protocols for Wireless NoCs.

C. Deep Learning in Wireless Networks: Deep RL has recently been applied in wireless networks to optimize duty cycling in sensor networks [64], resource allocation in cellular networks [22,27], dynamic spectrum access [72,92], rate adaptation in CSMA networks [69],and control policies at the PHY layer [52]. [104] provides an extensive survey of deep learning in wireless networks. The closest to our work are [14,16,19,101] which use reinforcement learning to modify the backoff parameters in CSMA or decide whether to transmit or not for every packet at every time step. However, such designs are not applicable in the context of wireless NoCs owing to the unique set of constraints imposed by the NoC, such as the much smaller time-scale of operation rendering neural network inference per transmission slot infeasible, the limited SRAM memory to store model parameters and the enormous action space to explore. These constraints require significant redesign to NeuMAC's deep RL framework where it has to now generate high-level, versatile and adaptable protocols that can be deployed for thousands of clock cycles, and generating such protocols cannot be reduced to a simple classification task per transmission-slot (e.g. transmit or not).

8 Limitations and Discussion

Some points are worth noting: First, given the enormous costs and engineering efforts involved in prototyping a full chip with integrated processors, memory, and NoC, it is outside the scope of this work to implement NeuMAC in hardware. As a result, we evaluate NeuMAC on a full-system cycle-accurate architectural simulator, as is the norm among computer architecture researchers. These full-system simulators exhaustively model all components of a CPU and also ensure that all timing dependencies are simulated accurately [87]. As a result, the trends and insights obtained from such architectural simulations often carry over to full fledged prototypes. Moreover, the wireless channel in this WNoC application domain is in fact very stable as opposed to WLAN channels which are extremely dynamic. This is because the multicore is isolated in a chip package, and the wireless channel can be precisely measured and characterized, thus allowing compensation for multipath fading and other artifacts. As a result, the wireless BER in these environments can be as low as 10^{-16} [33], making such a simulation based evaluation representative.

Second, in parallel programming for multicore processors, programmers today try hard to avoid broadcast transmissions as the overhead of running the cache coherency protocol is high. With wireless NoC, the overhead of broadcast traffic is now limited which opens the door to rewriting applications in a manner that embraces broadcast, and can in turn benefit even more from an adaptive protocol like NeuMAC.

Lastly, in this paper we focus on the MAC layer since it is considered a roadblock to realize the full potential of wireless NoCs. However, studying the challenges and opportunities at the other layers such as PHY remains exciting and promising avenue which we leave for future work.

Acknowledgements: We thank the shepherd and anonymous reviewers for their feedback and comments. We also thank Ameya Patil for helping guide the hardware accelerator design and characterization. The work is funded in part by NSF Award 1750725.

A Energy and Latency Overhead Characterization

It is widely acknowledged that deep learning inference has high latency and energy overheads. However, since NeuMAC needs to optimize the performance of a multicore CPU, it needs to operate at very small time scales. As a result, it is imperative that NeuMAC's inference step be efficient in time and energy. In this appendix, we characterize the overheads of running inference on NeuMAC's Deep RL agent.

Towards this end, we design an illustrative hardware macro for NeuMAC's neural accelerator (shown in Fig. 10). The trained quantized weights of NeuMAC's network are stored in the 32 KB on-chip SRAM. The primary compute elements in the macro are the (i) 128 element 8-bit multiplier, that can perform 128 parallel multiplications of 8-bit numbers, (ii) followed by a 7-layer carry save adder tree, which can add up to 128 8-bit numbers. Thus, the multiplier block and adder tree block together can implement either one 128 dimensional dot product, or two 64 dimensional dot products in a one iteration. The ReLU non-linear activation is implemented using comparators, which finally writes the result into an output buffer. It is important to note that this hardware macro is significantly simpler than a full scale neural network accelerator, such as [53].

Next, we elaborate on the pipeline for computing one inference step on NeuMAC's RL agent. Note that computing the value of one element in the first hidden layer of NeuMAC's neural network requires one 64 dimensional dot product[3]. Therefore, computing the values of all elements in the first hidden layer requires a total of 128 counts of 64 dimensional dot products. Similarly, computing the values at the second hidden layer requires 128 counts of 128 dimensional dot products, and computing the final layer requires 64 counts of 128 dimensional dot products. Hence, to compute one inference step in NeuMAC's deep network, we need to perform a total of 192 counts of 128-element dot products, and 128 counts of 64-element dot products. Further, since we can implement two 64-element dot products in parallel, one inference step requires an equivalent of 256 counts of 128 dimensional dot products to compute the output. Using this above macro design along with conservative and widely accepted hardware estimates, we next show that the design of NeuMAC's neural network architecture adds only marginal overheads, allowing it to operate under the resource constrained setting of a wireless NoC.

Latency Overhead: Here we estimate the latency of computing one inference step on NeuMAC's RL agent. The memory array is organized as 16 blocks of 64 by 256 memory elements, making a total of 32 KB storage. For 45nm technology, read access time from such memory sizes can be conservatively estimated to be around 2 ns [95]. Similarly, a 32-dimensional dot product can be computed within 2 ns [44]. Hence, we pipeline the data flow in three stages, first after the memory read, second after adding the outputs of 32 multipliers, and third at the output of the comparator bank. Hence, each stage has a maximum latency of 2 ns. As a result of such pipelining, one 128 element dot product is computed every 2 ns, that is, every 2 clock cycles[4]. As noted previously, one inference step requires 256 counts of 128 dimensional dot products. Hence, the total latency for one inference step is $256 \times 2 = 512$ *ns* (512 clock cycles). This inference latency of 512 cycles results in a small overhead of less than 6% per time step in our RL formulation. One point to note is that, the final deep network output is quantized to 8 bits. Hence, the sigmoid filter after the last layer can be implemented via a 256 element look-up table at a negligible latency overhead.

[3]Although NeuMAC's input has 65 elements, for simplicity sake we perform calculations with 64 element input.

[4]Our CPU clock is 1 GHz.

Energy Overhead: Next, we estimate energy consumption of the hardware macro. We use the energy values from the widely-cited paper [48], which approximately characterizes energy consumption of various compute elements and memory accesses. The dominant energy consumption steps are the reads from the memory array and the computations on the MAC (Multiply-ACcumulate) unit. From [48], 8 bit multiplies consume 0.2 pJ, and 8-bit additions consume 0.03 pJ. One 128 dimensional dot product on the MAC unit involves 128 multiplications and 127 additions. Thus the total energy comes to 29.41 pJ. Memory reads of 64 bits from 2 KB memory blocks requires 5 pJ. Thus, the 128 bit memory reads for each dot product requires 10 pJ. As a result, one 128 element dot product on the hardware accelerator requires 39.41 pJ, and with 256 counts, the energy consumed for a single inference step is 10088.96 pJ. Given that we require one inference every 10,000 ns, the neural accelerator consumes approximately only 1 mW of power on average. In comparison, a single transceiver on the multicore consumes 16 mW [38]. Lastly, note that the numbers in [48] are at 45 nm technology, so 1 mW is a conservative estimate.

Area Overhead: Lastly, the area overhead of the hardware macro is small. Since area is dominated by memory, the 32 KB of SRAM and few registers in the hardware accelerator impose a small overhead in comparison to the 512 KB of cache memory at each of the 64 cores. Thus we envision that such a hardware macro can reside on the same die and share the same clock as the multicore processor.

Thus, even a simple accelerator like the one demonstrated in Fig. 10 can enable NeuMAC's agent to operate under the resource constrained setting of a wireless NoC. Note that we do not employ any other advanced hardware optimization techniques and rely on reported hardware numbers that are widely accepted rather than the state-of-the-art today.

LightGuardian: A Full-Visibility, Lightweight, In-band Telemetry System Using Sketchlets

Abstract

[1] Network traffic measurement is central to successful network operations, especially for today's hyper-scale networks. Although existing works have made great contributions, they fail to achieve the following three criteria simultaneously: 1) **full-visibility**, which refers to the ability to acquire any desired per-hop flow-level information for *all* flows; 2) **low overhead** in terms of computation, memory, and bandwidth; and 3) **robustness**, meaning the system can survive partial network failures. We design LightGuardian to meet these three criteria. Our key innovation is a (small) constant-sized data structure, called *sketchlet*, which can be embedded in packet headers. Specifically, we design a novel SuMax sketch to accurately capture flow-level information. SuMax can be divided into sketchlets, which are carried in-band by passing packets to the end-hosts for aggregation, reconstruction, and analysis. We have fully implemented a LightGuardian prototype on a testbed with 10 programmable switches and 8 end-hosts in a FatTree topology, and conduct extensive experiments and evaluations. Experimental results show that LightGuardian can obtain per-flow per-hop flow-level information within $1.0 \sim 1.5$ seconds with consistently low overhead, using only 0.07% total bandwidth capacity of the network. We believe LightGuardian is the first system to collect per-flow per-hop information for all flows in the network with negligible overhead.

1 Introduction

Network traffic measurement is central to successful network operations, especially for today's hyper-scale networks with more than 10^5 devices [1–6]. Meanwhile, at end-hosts, knowing the traffic information in the core of the network can also benefit application performance [7–9]. To infer application performance and user experience, the community consensus is to measure at flow-level granularity. Thus, an ideal measurement system is expected to achieve: 1) **full-visibility**, which we define as the ability to acquire any desired per-hop flow-level information[2] for *all* flows. Typical desired information includes routing path, per-hop latency, jitters, and packet drops. 2) **lightweight** in terms of computation, memory, and bandwidth, independent of the scale of network and the traffic dynamics; 3) **robustness**: the system should survive partial network failures, including link failures, device failures, and bandwidth depletion [6, 10–12].

Although existing works have made great contributions, they fail to meet the above criteria simultaneously. We coarsely characterize them into four categories:

- **Partial/Sampling** solutions [13–17] only sample packets or flows, or collect detailed statistics based on a pre-configured list of conditionals [18, 19]. For instance, Everflow [20] samples each SYN packet, and Cisco switches use the "match" keyword to specify which network flows need to be counted. Therefore, only a subset of the network traffic is measured with questionable accuracy.
- **Probing** solutions [6,21–24] measures the states of devices or links by sending probing packets, and only these probes are measured.
- **Sketch-based** solutions [25–34] collects the information of every packet in a compact data structure, namely sketch, on network devices. Current sketches are unable to collect important flow-level information, such as jitters and packet drops, and are not robust to network failures, particularly device failures. Most prior sketches cannot be implemented on P4-capable switches (§ 2.2).
- **In-band** solutions carry information in every packet header. AM-PM [35] cannot achieve full-visibility with only one bit per packet. Although INT [36, 37] can potentially achieve full-visibility, its bandwidth and processing overhead grows quickly with the scale of the network. In both the postcard [38] (mirroring packets on each switch) or the passport [36] mode (mirroring packets on only the sink switches), the number of packets is at least doubled, which is a huge burden for the network. *Flow [39] uses a cache to group packet-level telemetry information according to the flow IDs. But its bandwidth overhead is still proportional to the number of packets.

[2]In this paper, per-hop flow-level information means per-flow per-hop information.

In summary, no existing work can achieve full-visibility without considerable performance overhead, and none focuses on lightweight and robust collection mechanism of network-wide flow-level information.

We design LightGuardian to meet the above three criteria simultaneously. Our key innovation is a (small) constant-sized data structure, called *sketchlet*. A sketchlet is a fragment of the sketch data structure on network devices (physical or virtual), carried in-band in a packet's header. At the end-host, LightGuardian collects the sketchlets, reconstructs the original sketch, and consequently obtains the accurate measurement results of all flows.

To support and make full use of sketchlets, LightGuardian incorporates three key techniques:

- **Accurate & versatile device-local sketches:** As current sketches fail to capture important flow-level statistics (per-hop latency and jitters), we design a novel sketch: the *SuMax sketch* to support common measurement tasks, as well as new tasks of operational importance. With our insight that recording both the sum and the maximum can accurately perform these tasks (§ 4.2), we design the sketch with two types of cells: the *sum cell*s and the *maximum cell*s. SuMax can be readily deployed on programmable network devices, and we have fully implemented it on a P4-capable switch (§ 7.1). Although SuMax is not the only way to measure flow-level statistics, it can support almost all measurement tasks thanks to its versatility.
- **In-band telemetry with sketchlets:** We propose a novel approach that combines in-band telemetry and device-local sketches. An INT-enabled device appends measurement data to each packet. INT alone consumes an enormous amount of bandwidth and multiplies the number of packets (§ 2.2). On the other hand, for sketch-based solutions, although sketch is a compact coding of flow-level information, the size of a sketch should be sufficiently large to ensure accuracy, thus cannot be embedded in packet headers. Combining the advantages of both approaches, our key novelty is to split the sketch with flow-level information into constant-sized sketchlets that can be embedded into selected packet headers. Since the number of flows in the network is much smaller than that of packets and the sketch is a compactly coded representation of flow-level statistics, the bandwidth overhead of sketchlets is significantly lower than that of INT, while accurate flow-level measurement can still be retrieved.
- **Incremental network-wide aggregation:** The receiving end-hosts can either forward the sketchlets to a global analyzer, or reconstruct the sketch locally to obtain measurement information of flows and devices inside the network. The information can assist end-host applications in performance optimization in a distributed fashion, which lessens the burden on the centralized network control/management plane. To guarantee robustness, we design the reconstruction algorithm to be tolerant of losses and reordering of sketchlets. Our algorithm can approximate a sketch with a subset of its sketchlets, and the reconstruction accuracy is incrementally improved with more arriving sketchlets. Our experimental results show that 80% sketchlets can achieve an accurate estimation (§ 8.1), while collecting 80% sketchlets only needs $1.0 \sim 1.5$ seconds.

To the best of our knowledge, LightGuardian is the first system to measure per-flow per-hop latency distribution and detect abnormal jitters with high accuracy for *all flows* on every participating network device, while maintaining low overhead. It also collects useful traffic data for operations and diagnostics previously unavailable in existing systems. Since LightGuardian aims to measure various per-hop flow-level information, after detecting end-to-end problems, users can use our system to locate culprit network devices. Besides, LightGuardian's on-device mechanism is not limited to physical devices, and can be readily used in cloud networking environments with virtualized network functions.

We have fully implemented a LightGuardian prototype on a testbed with 10 Tofino switches and 8 end-hosts in a FatTree topology. As a whole, our prototype can obtain per-flow per-hop information within $1.0 \sim 1.5$ seconds with consistently low overhead (0.07% of total bandwidth) on the network. We also conduct large-scale simulations using mininet [40] and P4 behavior model [41], confirming the correctness, robustness, and performance of LightGuardian. We release all source code anonymously [3].

In this paper, we make four key contributions:

We propose sketchlets and design a lightweight in-band telemetry system. Using sketchlets, our system makes the entirety of traffic information in the core of the network available at end-hosts for analytics and diagnostics. LightGuardian is lightweight, which takes up negligible bandwidth, and it can aggregate all sketchlets within 4 seconds.

We design the SuMax sketch to support common and more important measurement tasks with high accuracy. For common tasks (*e.g.*, flow size estimation), SuMax achieves 6.78 times smaller error rate. Further, LightGuardian can locate the culprit devices in the context of packet drops, inflated latency, and abnormal jitters, achieving almost 100% accuracy with less than 0.5MB memory.

We design an incremental reconstruction algorithm to achieve robustness and failure tolerance. Our experimental results show that, even when 50% end-hosts fail, the analyzer can still reconstruct 89% of all sketches. In addition, device and link failures do not affect the reconstruction of sketches of other devices (§ 8.3.2).

We implement a LightGuardian prototype and make it open-source. We also build a testbed and conduct extensive experiments, which confirms that our system can reach the design criteria.

2 Background and Related Work

2.1 Measurement Tasks

Existing measurement tasks can be classified into two categories: device-local measurement tasks and network-wide measurement tasks. Device-local measurement tasks refer to measuring flow-level information in a single node (an end-host, a switch or a router), and there have been various sketch-based solutions, such as sketches of CM [25], CU [26], Count [27], UnivMon [28], Elastic [29], SketchLearn [30], SketchVisor [42], and more [32–34, 43–48]. However, there are very few sketches designed for network-wide measurement tasks. This paper focuses on the following four network-wide measurement tasks.

1) Estimating Latency: We aim to estimate per-flow per-hop latency distribution. Existing works acquire end-to-end latency by sending probing packets. And they monitor specific flows by tracking their packets [49]. However, these solutions can hardly locate the victim flows and the culprit devices simultaneously. In contrast, per-flow per-hop latency distribution can help a lot but is more challenging.

2) Detecting Packet Drops: There are three causes of packet drops: random drops, loops, and blackholes. For random drops, the state-of-the-art LossRadar [50] uses a Bloom filter [51] and an Invertible Bloom Lookup Table (IBLT) [52] to accurately find drops. LossRadar works excellently in many cases. However, it consumes a lot of memory when a large flow drops many packets, which frequently happens when there are network misconfigurations [53]. For loops and blackholes, the state-of-the-art FlowRadar [54] also uses a Bloom filter and an IBLT, sharing the same advantages and shortcomings as that of LossRadar.

3) Detecting Abnormal Jitters: Jitters refer to drastic changes of packet inter-arrival time of a given flow. We aim to find abnormal jitters in the per-flow per-hop manner. Jitters are often caused by queuing, congestion, high bandwidth load, or network attacks. It can significantly affect the performance of streaming media (*e.g.*, audio, video, music). To detect jitters, end-to-end methods [55–57] have been proposed. However, they cannot work in the per-flow per-hop manner.

4) Tracing Forwarding Path: We aim to trace the forwarding path of any flow. Given a flow, tracing forwarding path can check whether the actual forwarding path is consistent with expectation. It can help test and/or debug new network protocols and network architectures, solutions for network congestion, load balance, and flow scheduling. Existing works for tracing forwarding path include FlowRadar [54], SwitchPointer [58], Service traceroute [59], and more [60–63].

2.2 Related Work

As shown in Table 1, compared with the state-of-the-art solutions, only our system supports device-local and network-wide measurement tasks, and it is implemented in both RMT switches (*e.g.*, Tofino) and P4 behavior model, achieving per-flow per-hop measurements. In this section, we mainly introduce the following four categories of measurement solutions. For other measurement solutions, please refer to references [64–72].

Partial/Sampling Solutions. Many measurement systems [14–17, 20, 46, 73–76] are developed by sampling packets. Sampling can significantly reduce the overhead of both time and space, but inevitably sacrifices accuracy and misses important events. Typical systems include NetFlow [73], sFlow [74], OpenSketch [46], OpenSample [17], Everflow [20], NitroSketch [77], and more [14–16, 76]. The state-of-the-art UnivMon [28] obtains elegant theoretical guarantees using a multiple sample solution at the cost of high time complexities. Sampling solutions probably miss many small flows, and thus cannot achieve the ideal goal of fully-visibility.

Probing Solutions. These solutions monitor the network by sending tailored packets. Typical systems include Pingmesh [78], NetBoncer [6], NetSonar [22], NetNorad [23], and more [24, 79–82]. Recently, AM-PM [35] gains wide recognition in industry. AM-PM divides packet streams into time periods, and the middle packet in each period is essentially a probing packet. Therefore, it only records per-period packet information, but is unaware of flow-level information. Probing solutions cannot achieve the ideal goal of fully-visibility because they cannot measure per-flow information.

Sketch-based Solutions. There are a great number of sketch-based solutions, which can be further divided into three categories. First, design and optimization of sketch algorithms. Typical solutions include sketches of CM [25], CU [26], Count [27], Elastic [29], and more [28, 30–32, 34]. But they cannot measure the latency and jitters. Some are implemented in P4 behavior model, but only a very few (BeauCoup [33], Elastic [29]) are fully implemented in real programmable switches . Due to the limitations of RMT (Re-configurable Match Tables) based programmable switches, *e.g.*, limited concurrent memory access, single stage memory access, and *etc.*, the implementation in real switches is significantly more challenging. Thus, we aim to design a new sketch to support both device-local and network-wide measurement tasks, while can be easily implemented in RMT switches. Second, measurement systems with dedicated sketches. Typical solutions include FlowRadar [54], SketchLearn [30], NitroSketch [77], and more [33, 46, 50]. The dedicated sketches can barely achieve fully-visibility. Third, measurement systems with shining features. Typical solutions include Marple [83], Sonata [84], DREAM [85], Scream [86], and OmniMon [87]. By carefully designing the resource manager and telemetry operator, OmniMon [87] achieves both resource efficiency and high accuracy. Our SuMax sketch can also be applied in OmniMon. All existing solutions do not focus on the overhead with aggregating sketches all over the network.

In-band Telemetry Solutions. They insert packet-level information into every packet. Well-known solutions include INT [36] and its successor PINT [88]. INT is considered as the most promising solution for network measurement because of two reasons. First, it can achieve fully-visibility because it is flexible to carry any desired packet-level information. Second, it can be implemented in RMT switches in a per-packet manner. However, its bottleneck lies in the aggregation of INT information. The INT information is distributed in every network packet, and it is obviously very challenging to aggregate that per-packet information. INT has two aggregation strategies: postcard and passport, which mirror every packet with only INT information in each switch or only the sink switches. Although the INT information in each packet is small (*e.g.*, 100 bytes), the total bandwidth overhead is huge. What is worse, the number of packets in the network will be doubled, which is a heavy burden for packet processing. Another in-band telemetry solution *Flow [39] uses a cache to group packet-level telemetry information according to the flow IDs. In this way, some information (*e.g.*, 5-tuple flow ID) in one group is recorded only once. However, its bandwidth overhead is still proportional to the number of packets.

3 LightGuardian Overview

As shown in Figure 1, LightGuardian captures flow-level statistics on each participating network device (physical or virtual)[4] using sketches. The devices periodically split the sketches into sketchlets and send the sketchlets to the end-hosts by piggybacking them in headers of appropriate packets. Then at the receiving end, the end-hosts batch the sketchlets into groups and send them to a global analyzer when the network load is low. Finally, the analyzer reconstructs the sketches and perform analysis.

1) Capture flow-level statistics with novel sketches. LightGuardian captures flow-level statistics by deploying our SuMax sketch on each participating device. Every packet is processed into the sketch *without sampling*. Typical collected statistics include the flow size (number of packets/bytes), per-hop delay distribution, the arrival time of the last packet, and the maximum inter-arrival time. The above statistics are used for detecting packet drops and measuring per-hop latency and maximum inter-arrival time, which are essential tasks for industrial community. To support more tasks, we can also include more collected statistics, *e.g.*, the number of out-of-order packets, the highest sequence number, and *etc.*

2) Split sketches into sketchlets and send them to the end-hosts. The participating devices periodically split their

[4]Since most legacy switches and routers do not have programmable dataplane capabilities, they cannot participate in LightGuardian (and their existence in the network will not hinder the functions of LightGuardian).

sketches into sketchlets and send them to the end-hosts. Specifically, at the start of each measurement interval, the devices initiate a new SuMax sketch to record the flow-level statistics. In the end, the sketches are divided into sketchlets of several bytes (24 bytes in our implementation). Each sketchlet is one column[5] (or several columns) of the sketch. Each switch then attaches these sketchlets to appropriate incoming packets. Specifically, we choose the packets that have not yet carried a sketchlet with a fixed probability (*e.g.*, 0.05).

3) [Optional] Batch sketchlets and forward to a global analyzer. LightGuardian has two working modes: 1) Local analysis mode, where each end-host uses local sketchlets to perform analysis for local applications; 2) Global analysis mode, where a global analyzer collects all sketchlets and performs analysis for network operators. If an end-host does not want to perform local analysis, it can choose to forward sketchlets to a global analyzer. A system daemon process running on each end-host strips sketchlets off the packets, and maintains the received sketchlets. When the process has collected enough sketchlets, it batches the received sketchlets into groups and forward them to the global analyzer. For LightGuardian, more than 350 sketchlets are grouped into a UDP packet and share 42 bytes packet header, which significantly reduces the number of additional packets for measurement.

4) Reconstruct sketches and perform analysis. The end-host or the global analyzer (or end-hosts) can reconstruct the sketchlets into sketches and perform further analysis. The process of reconstructing sketches proceeds simultaneously with the process of collecting sketchlets. After collecting enough sketchlets, the analyzer can perform accurate estimation using the partially reconstructed sketch. According to our experiments, after receiving 55% sketchlets, our LightGuardian reports 90% valid results, while the average relative error (ARE) is only 0.088. Further, the estimation results are incrementally refined with more and more sketchlets collected, the ARE reduces to 1×10^{-2}, 1×10^{-3}, 2×10^{-4} when 80%, 90%, and 100% sketchlets are received, respectively.

In this way, LightGuardian well achieves the three mentioned design goals. For full-visibility, LightGuardian deploys SuMax sketch on each network device to monitor various per-flow per-hop information for all flows. For low overhead, LightGuardian uses small and constant-sized sketchlets to transmit measurement information, which makes the in-band overhead grow sub-linearly with the network/traffic scale. For robustness, the reconstruction process of LightGuardian does not require collecting all sketchlets whereas providing desirable accuracy. Besides, any end-host with limited computation resources can play the role of the global analyzer, which makes our system robust.

[5]A sketch consists of multiple bucket arrays, and a column refers to the buckets with the same index in each array.

4 Device-local Sketch Design: SuMax

4.1 Motivation

We design the SuMax sketch to achieve accurate measurement of flow-level information on network devices of different platforms: software (CPU, or OVS [89]), P4 behavior model [41], programmable switches. To make LightGuardian widely applicable, this paper focuses on P4 behavior model and programmable switch platforms, as the software implementation is straightforward. Using P4 also ensures our implementation can be compiled to available and future P4 back-ends, such as SmartNIC, FPGA and GPU.

UnivMon [28] and HashPipe [90] are implemented in P4 behavior model, but can hardly be implemented in RMT switches. To address these issues, Basat *et al.* proposed using a recirculate method [91], inevitably incurring complexities and degradation of switch throughput. BeauCoup [33] and Elastic [29] have been implemented in RMT switches (*i.e.*, Tofino switches) by complicated designs and programs. Further, the above four sketches cannot be directly used for network-wide measurement tasks, such as estimating latency and jitters. We found CM [25] is the most friendly sketch for programmable switches. On the one hand, we optimize its accuracy under the constraints of programmable switches. On the other hand, we extend its functions to support both device-local and network-wide tasks. In the meantime, we try to keep the designed sketches as simple as possible.

4.2 Rationale and Design Space for Sketches

We first introduce the well-known CM sketch [25]. It is a typical sketch algorithm that sums packet attributes (*e.g.*, packet number, bytes number). It uses d counter arrays $\mathcal{A}_0, \cdots, \mathcal{A}_{d-1}$. For each array, it has a hash function $\mathcal{H}_i(\cdot)$ to map a flow[6] uniformly and randomly into a counter. When a packet of flow f with attribute value α arrives, CM selects the counter $\mathcal{A}_i[\mathcal{H}_i(f)]$ for each array $\mathcal{A}_i$ and increments these counters by α. To query the attribute sum of flow f, CM returns the minimum value among $\mathcal{A}_0[\mathcal{H}_0(f)], \cdots, \mathcal{A}_{d-1}[\mathcal{H}_{d-1}(f)]$, which is still a sum of attributes of some flows. Therefore, CM has only over-estimation errors. Similarly, the CU sketch [26] increments only the smallest counter(s), significantly improving the accuracy but not supporting pipeline implementation.

We propose to record both of the sum value and the maximum value[7] to support versatile tasks. We insist that all packet attributes can be accurately estimated by keeping only the sum and maximum values. We also insist that either sum or maximum value is indispensable. For example, sketches of CM, CU, Count, FlowRadar cannot be used to find maximum latency or inter-arrival time and last arrival time, because they only record the sum value without maximum value.

[6]A flow has many packets sharing the same flow ID, which can be any combination of 5-tuple: source IP address, source port, destination IP address, destination port, protocol type.

[7]Note that [92] also suggests that the sketch algorithm can be used to find the maximum value in a sequence.

Table 2: Symbols frequently used in this paper.

Symbol	Meaning
f	An arbitrary flow
α	An attribute that needs to be recorded in the sum cell (*e.g.*, packet size)
β	An attribute that needs to be recorded in the maximum cell (*e.g.*, arrival time)
d	SuMax consists of d bucket arrays
w	Each array consists of w buckets
$\mathcal{A}_i$	The i-th bucket array
$\mathcal{A}_i^{sum}[\cdot]$	The *sum cell* in a bucket
$\mathcal{A}_i^{max}[\cdot]$	The *maximum cell* in a bucket
$\mathcal{H}_i$	A hash function from a flow to $\{0,\cdots,w\}$

4.3 Data Structure and Operations

Data Structure (Figure 2): Our SuMax consists of d bucket arrays $\mathcal{A}_0,\cdots,\mathcal{A}_{d-1}$. Each array $\mathcal{A}_i$ contains w buckets $\mathcal{A}_i[0],\cdots,\mathcal{A}_i[w-1]$. Each bucket has two cells: a *sum cell* and a *maximum cell*, recording the sum value and the maximum value of attributes, respectively. Each array $\mathcal{A}_i$ is associated with a hash function $\mathcal{H}_i(.)$ that maps a flow into one of its buckets. To support various tasks, we may need more than one sum value or maximum value in each bucket. For convenience, we only show using one sum value and one maximum value. Table 2 lists the frequently used symbols in this paper.

Insertion: To achieve high accuracy and support pipeline implementation, we propose an approximate conservative update strategy as follows. To record a packet of flow f with attribute α and β ($\langle f,\alpha,\beta\rangle$, α will be accumulated and β will be compared with the maximum), we first maintain a current minimum value ω and initialize it to ∞. For each array $\mathcal{A}_i$, we select a bucket $\mathcal{A}_i[\mathcal{H}_i(f)]$ by computing the hash function $\mathcal{H}_i(f)$. For each selected bucket $\mathcal{A}_i[\mathcal{H}_i(f)]$, we check its *sum cell* $\mathcal{A}_i^{sum}[\mathcal{H}_i(f)]$ and update it as follows:

- If $\mathcal{A}_i^{sum}[\mathcal{H}_i(f)]+\alpha<\omega$, update the current minimum value $\omega=\mathcal{A}_i^{sum}[\mathcal{H}_i(f)]+\alpha$, and set the cell to ω.
- If $\mathcal{A}_i^{sum}[\mathcal{H}_i(f)]+\alpha\geqslant\omega$, and $\mathcal{A}_i^{sum}[\mathcal{H}_i(f)]<\omega$, set the cell to ω.
- If $\mathcal{A}_i^{sum}[\mathcal{H}_i(f)]\geqslant\omega$, we keep the cell unchanged.

For the *maximum cell* $\mathcal{A}_i^{max}[\mathcal{H}_i(f)]$, we just set it to $\max\{\mathcal{A}_i^{max}[\mathcal{H}_i(f)],\beta\}$. The pseudo-code of the insertion operation is shown in Algorithm 1 in Appendix A.

Query: Given a flow f, SuMax returns two results: one sum value estimation and one maximum value estimation. The sum estimation is the minimum value among $\mathcal{A}_0^{sum}[\mathcal{H}_0(f)]$ $,\cdots,$ $\mathcal{A}_{d-1}^{sum}[\mathcal{H}_{d-1}(f)]$. The maximum value estimation is the minimum value among $\mathcal{A}_0^{max}[\mathcal{H}_0(f)]$ $,\cdots,$ $\mathcal{A}_{d-1}^{max}[\mathcal{H}_{d-1}(f)]$.

Example (Figure 2): To record a packet $\langle f,\alpha=3,\beta=4\rangle$, SuMax updates the d ($d=3$) buckets $\mathcal{A}_0[\mathcal{H}_0(f)]$, $\mathcal{A}_1[\mathcal{H}_1(f)]$, $\mathcal{A}_2[\mathcal{H}_2(f)]$ as follows. For the bucket $[6,3]$, we increase 6 to 9, set ω to 9, and set 4 to $\max\{4,3\}$. For the bucket $[9,7]$, as $9\geqslant\omega$ and $7\geqslant 4$, we keep this bucket unchanged. For the bucket $[3,5]$, as $3+\alpha<\omega$, we update ω to 6 and update 3 to

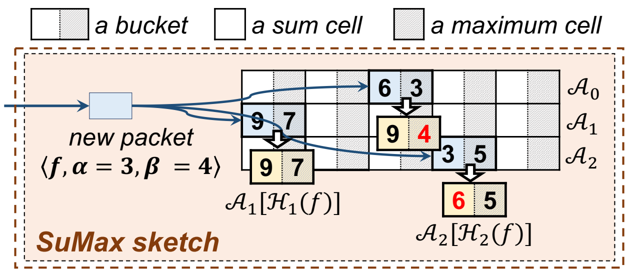

Figure 2: An example of SuMax.

$\omega=6$; as $4<5$, we do not change the maximum cell. After the insertion, when query flow f, SuMax returns $\min\{9,9,6\}=6$ as the sum estimation, and returns $\min\{4,7,5\}=4$ as the maximum value estimation.

Analysis: Our SuMax uses an approximate conservative update strategy to achieve both accuracy and pipeline friendly. Note that the conservative update strategy (CU) cannot be implemented in the pipeline because it needs the traceback operations to only increase the smallest counter(s). Our idea is to use the current minimum value to approximate the global minimum value. In each insertion process, with more and more counters accessed, the current minimum value will be closer and closer to the global minimum value, and thus the updated counter will be closer and closer to CU. Actually, the first array is updated following the rule of CM, and the last array is updated following the rule of CU. Since the counters in the last few arrays tend to have smaller values, they are more likely to be returned as query results. Therefore, SuMax can be viewed as an intermediate between CM and CU, and its error is also bounded between them, but closer to CU. As there are no tracebacks in our SuMax, it can be easily implemented in the switch pipeline.

4.4 Configuration of SuMax Sketch

In current implementation, we design each bucket as follows. Each bucket consists of four parts:

- a *flow-size cell* (sum cell) recording the flow size;
- λ_d *delay cells* (sum cells) recording the per-hop delay distribution, each one of which is associated with a predefined delay time interval;
- an *interval cell* (maximum cell) recording the maximum inter-arrival time;
- a *last-time cell* (maximum cell) recording the arrival time of the last packet of a flow.

All cells are initialized to zero. When the cells of a bucket are going to update, they should be updated as follows. Let t_{now} be the ingress timestamp of this packet, t_{last} be the value of the *last-time cell*, and $t_{interval}=t_{now}-t_{last}$. When $t_{last}=0$, we consider the current packet as the first packet of a flow, and set $t_{interval}=0$. First, we increment the *flow-size cell* by 1. Second, we select one cell from the λ_d *delay cells* according to the packet delay, and increment this cell by 1. Third, we compare the value in the *interval cell* with $t_{interval}$ and update it accordingly. Fourth, we update the *last-time cell* to t_{now}.

5 Transmission of Sketchlets

In this section, we show the transmission procedure of sketchlets in each participating network device. First, we split sketches into sketchlets. Second, we sample packets to carry sketchlets. Third, we select a sketchlet to be carried using our selection strategy and insert it into the packet.

5.1 Splitting the Sketch into Sketchlets.

LightGuardian deploys two SuMax sketches (one active and one idle) on each device. The active sketch is used to record flow-level information, while the idle sketch is split into sketchlets for transmission. After a fixed time interval (*e.g.*, 5s), we interchange these two sketches. We use an *active-bit* to indicate which sketch is active. The *active-bit* is flipped periodically, and the current interval is set to 5 seconds.

We split the idle sketch column by column, so that each sketchlet contains a column of buckets. Each sketchlet is associated with **1)** a *Sketchlet ID* indicating the column index; **2)** a *Device ID*; and **3)** the *active-bit* indicating which one of the two sketches it belongs to. The analyzer will sort the received sketchlets (bucket columns) according to the *Device ID*, *active-bit*, and *Sketchlet ID*.

5.2 Probabilistically Carrying Sketchlets.

Given an incoming packet, the device first checks the packet header: if it has already carried a sketchlet, no more sketchlets will be carried. Otherwise, the device calculates a fixed carrying probability λ_c (*e.g.*, 0.05) to determine whether this packet should carry a sketchlet. Each device samples only a part of the packets to carry sketchlets with λ_c, so that every device has a similar opportunity for packet transmission.

The packet format is shown in Figure 1. If a packet is selected to carry sketchlet, we insert the sketchlet between the TCP header and the application-layer message. First, we use a bit in the TCP header (*carry-bit*) to indicate whether this TCP packet carries a sketchlet. Second, we add a field to record the device ID (16 bits). Third, we add a field to record the sketchlet ID and the *active-bit*.

5.3 Sketchlets Selection: *K+chance Selection*.

Once the device determines the incoming packet should carry a sketchlet, we need an algorithm to choose a sketchlet. In-band telemetry solutions will lose measurement information when packet drops happen. To address this issue, we can send a sketchlet several times at the cost of more bandwidth usage. An effective solution is to use a counter array. Specifically, each counter corresponds to a sketchlet, indicating the number of times this sketchlet has been carried. For the incoming packet, we locate several counters by computing hash functions, find the smallest counter among them, and choose the corresponding sketchlet to carry. As mentioned above, similar to the CU sketch, this solution cannot be implemented in current P4-programmable switches, and thus we propose a new algorithm namely *k+chance selection*.

The *k+chance selection* uses k arrays, each of which is an N-bit array. For each array, each bit corresponds to a sketchlet. All bits are initialized to 0. Whenever we need to select one of the N sketchlets, we access the k arrays one by one. For each array, we randomly choose a bit: if it is zero, we choose the corresponding sketchlet and set this bit to 1; Otherwise, we access the next array. In the worst case, we do not find a zero bit after accessing all the k arrays, and we randomly choose one sketchlet to transmit. In this way, we only need to record an array ID in each sketchlet, which just takes $\lceil \log(k+1) \rceil$ bits (2∼3 bits). By contrast, when using the simple round-robin, we need to record the column ID (usually 32 bits) in each sketchlet. *K+chance selection* is an approximately fair selection algorithm for hardware platforms. Our experiments show that *k+chance selection* works well (§ 8.1).

6 Reconstruction and Analysis

In this section, we first describe the two modules at the end-hosts: forwarding module and reconstruction module. These two modules can work in isolation or in parallel. Then we elaborate on how to obtain device-local measurements and network-wide analysis using SuMax.

6.1 End-host Modules

Reconstruction Module. This module dynamically classifies the received sketchlets into groups according to their device IDs and *active-bit*s, and sorts the sketchlets in each group by their sketchlet IDs. In this way, the end-host reconstructs a sketch for each group. Note that the reconstructed sketches might be incomplete because some sketchlets are still in the network or missing. Fortunately, an incomplete sketch can also be used to answer queries: each query will access d buckets, some of which may not have been received yet. We consider the values in these buckets as invalid, and report the minimum value among the other valid buckets. As long as one of the d buckets is valid, we can report a valid result. Otherwise, we report the result of invalid. In this way, after some sketchlets are collected, the end-host then uses these reconstructed sketches to perform further analysis. Our experimental results (see § 8.1) show that 55% sketchlets can report 90% valid results and achieve accurate estimation ($ARE < 0.1$). The following theorem provides theoretical guarantees for the reconstruction process.

Theorem 6.1 *After receiving sketchlets with a ratio of* θ, *SuMax can report valid results with a ratio of* $(1-(1-\theta)^d)$. *Specifically, when the result is valid, the estimated flow size has the following error bounds.*

$$\Pr\left\{|\hat{n}_f - n_f| > \varepsilon\right\} < \frac{\left(\frac{m\theta}{w\varepsilon} + 1 - \theta\right)^d - (1-\theta)^d}{1-(1-\theta)^d}$$

where d and w are parameters of SuMax (see Table 2), n_f and $\hat{n}_f$ are the real and estimated flow size, and m is the number of inserted packets.

The module can reconstruct the following four widely-studied [28, 29, 54] device-local measurements:

- *Flow Size Estimation.* We return the minimum value of the d mapped flow-size cells.
- *Flow Size Distribution.* We use the MRAC [93] algorithm with the first bucket array in SuMax as input.
- *Entropy.* We compute $-\sum(n_i \cdot \frac{i}{m} \log \frac{i}{m})$ based on the flow size distribution, where n_i is the number of flows with size of i, and $m = \sum(i \cdot n_i)$.
- *Cardinality.* We calculate the number of flows using the method of linear counting [94].

We believe the main advantage of this approach is that the measurement is done in a distributed fashion, without a centralized control or management plane.

Forwarding Module. End-hosts use this module to forward sketchlets to a global analyzer for network-wide analysis. Each end-host groups the received sketchlets into batches. The end-host will send a batch of sketchlets to the analyzer when appropriate. 1) When the bandwidth usage is high, the end-host does not send sketchlets. 2) When the number of the accumulated sketchlets reaches a threshold, or the end-host has not sent any sketchlets for a certain period, it will send all the accumulated sketchlets to the network-wide analyzer. The network-wide analyzer reconstructs the sketches as the end-hosts do, and then performs the network-wide analysis.

6.2 Network-wide Analysis with SuMax

For the following four network-wide analysis tasks, we need to access different SuMax cells for different tasks. To perform network-wide analysis tasks, we have two steps. First, the network operator detects abnormal end-to-end incidents (*e.g.*, TCP duplicate ACKs, TCP timeout[8]), and report the victim flows to the network-wide control plane analyzer. Second, based on the network topology, the analyzer further investigates the sketches on the switches in the forwarding path of the victim flow as to locate the specific culprit device or link.

Locating Inflated Latency. Locating inflated latency refers to finding out the culprit switch, and the victim flow when inflated end-to-end latency occurs. First, the end-host detects abnormal incidents of inflated end-to-end latency, and reports the ID of the victim flow. Second, the analyzer queries the per-hop latency distribution of this flow by accessing the delay cells in the corresponding reconstructed sketches. In this way, it can easily locate the culprit switches with inflated latency (*e.g.*, a switch on which 80% packets have $> 10\mu s$ latency).

Locating Packet Drops. As mentioned above, there are three main packet drops behaviors: random drops, loops, and black-holes. Random drops may result from hardware failures (*e.g.*, faulty interfaces in switches). Loops may result from the mis-configuration of the forwarding table, which leads the packets of the victim flows forever loop among several switches. Blackholes may result from forwarding entries corruption in culprit switches. After detecting end-to-end packet drops from TCP re-transmission, timeout, or ping probe loss, the end-host (sender) reports the flow ID to the analyzer. To locate the culprit switch, the analyzer queries the victim flow in every sketch on the forwarding path by accessing the flow-size cells. **1)** If the flow size suddenly drops to 0 after passing a switch, we report the switch as a blackhole. For example, suppose there are five switches ($s_1 \sim s_5$) on the forwarding path. If the estimated flow sizes on the five switches are $100, 100, 100, 0, 0$, respectively, we report s_4 as a blackhole. **2)** If the flow size is abnormally large on several switches, we infer a loop happens on them. For the same example with five switches, if the flow sizes are $100, 100, 5000, 5000, 0$, respectively, we infer that s_3 and s_4 probably be involved in a loop. **3)** If the flow size slightly decreases after passing a switch, we infer that the switch suffers random packet drops. For the same example, if the flow sizes are $100, 100, 95, 95, 95$, we infer random packet drops happen on s_3.

Locating Abnormal Jitters. After detecting end-to-end variation in the packet inter-arrival time of a flow, the end-host reports the flow ID to the analyzer. The analyzer queries the maximum inter-arrival time of that flow, and finds out the culprit switches on which the result is abnormally large.

Finding Abnormal Forwarding Path. When an end-host receives a packet which carries a sketchlet not belonging to the switches on the expected forwarding path, we report this packet suffers abnormal forwarding.

7 Prototype Implementation

In this section, we first describe the workflow and difficulties we face when implementing a LightGuardian prototype on a programmable switch (Tofino-40GbE). On each switch, we develop SuMax and the sketchlet transmission mechanism using P4 [96]. Then we overview the components in the end-hosts: the kernel modules to collect and forward the sketchlets.

7.1 SuMax on Programmable Switches

All existing sketches can be implemented in the software (*e.g.* middleboxes, virtual network appliances, *etc.*), but most of them cannot be deployed on programmable switches, which limits their applicability outside of cloud networking environments. For LightGuardian, since deployability is crucial to achieving full-visibility in all network environments, we first show that SuMax can be deployed on programmable switches by implementing it on a Tofino-40GbE switch.

7.1.1 Workflow

On the switch, we design the workflow (relevant to LightGuardian) (Figure 3) as follows: we put Decision Making Stage in the ingress pipeline, and Sketching Stage and Sketchlet Generation Stage are placed in the egress pipeline.

The **Decision Making Stage** decides the following:

[8]Some tools provided by the OS (*e.g.*, ePBF [95]) can help operators to easily detect these abnormal incidents.

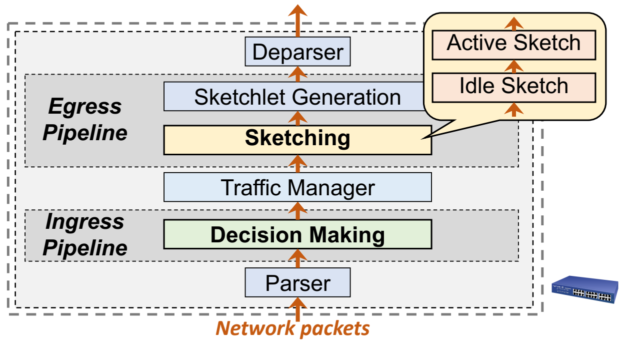

Figure 3: Workflow on an RMT switch.

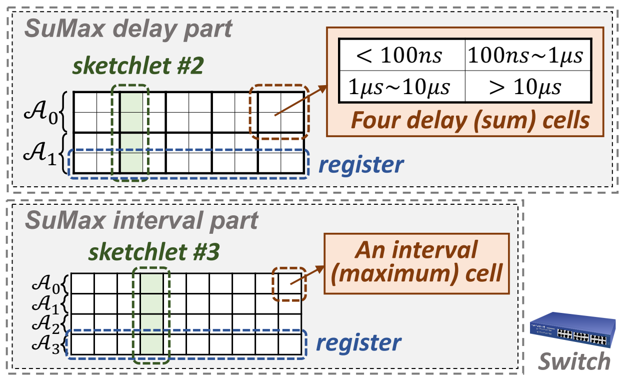

Figure 4: Sketch implementation on an RMT switch.

- **Active sketch**, *i.e.* which sketch should be inserted into. As mentioned in § 5.1, we deploy two SuMax sketches on each switch, and use the *active-bit* to identify the *active* sketch. Note that the data plane of the switch *cannot* periodically update the active-bit. Therefore, we run a process in the switch control plane to periodically flip it. As the flipping is asynchronous, we forbid carrying sketchlets in the last second in each measurement interval.
- **Fitness for sketchlets**, *i.e.* whether the packet should carry a sketchlet. The fitness conditions are: 1) the packet is not carrying a sketchlet; 2) For each packet, we use its 5-tuple and its ingress timestamp to calculate a 16-bit hash value (CRC16), and only when the value falls within $[0, \lambda_c 2^{16})$, the packet is selected to carry a sketchlet. λ_c is a pre-configured parameter, and the second condition is approximately allowing a packet to carry sketchlet with a probability of λ_c
- **Sketchlets selection.** As described in § 5.3, we use the *k+chances selection* algorithm to select a sketchlet to carry. Thus, we need to randomly select a bit for each bit array. In Tofino switches, we can only achieve pseudo-randomness: we still use CRC16 to generate approximately random numbers, and choose reasonable polynomials of CRC16 to generate multiple approximately independent random numbers. Due to limitation of Tofino switch, we set $k = 1$.

In the **Sketching Stage**, we place two sketches: one idle and one active. Their status is periodically flipped. These two sketches are two match-action tables placed in the egress pipeline, so each packet will pass them sequentially. For each packet, the sketch table checks the active-bit. If the active-bit indicates the current sketch is active, we hash the flow ID to update the corresponding cells to record packet information. The update procedures of SuMax are challenging on Tofino, and we highlight the difficulties below (§ 7.1.2).

The **Sketch Generation Stage** reads the selected sketchlet and writes it into the metadata if the packet is selected.

7.1.2 Challenge of Sketching Stage

SuMax records multiple packet attributes (*e.g.*, flow size, delay distribution, last arrival time, maximum inter-arrival time). This requires multiple cells in each bucket. In Tofino switches, the cells in SuMax are stored in *registers*. A switch has 12 *Match-Action Units* (MAU), each of which contains up to two 256KB registers. Since 6 MAUs are used in other stages, only 6 MAUs (12 registers) can be used in the Sketching stage. The main challenge is that, each incoming packet can only access each register exactly once, and each access can only read/write up to 64 consecutive bytes.

Thus, we have to assign the cells in a single bucket to multiple registers. In other words, we need to divide SuMax into parts. We use two examples, the measurement of latency distribution (sum) and that of maximum packet inter-arrival time, to illustrate our solution.

Latency distribution. We use the delay part of SuMax to perform this task. As shown in Figure 4, this part consists of $d = 2$ bucket arrays, each of which has $w = 2^{15}$ buckets. Each bucket has $\lambda_d = 4$ sum cells (32-bit), each of which corresponds to a predefined delay range. To make full use of the registers, we observe that:

- The four cells in each bucket should not be assigned to a single register. Since each 256KB register stores up to 2^{16} 32-bit cells, using a single register will limit the size of the sketch (up to 2^{14}), which compromises the accuracy.
- Using four registers to store the four cells in each bucket cannot be implemented on Tofino switch. As each switch has two sketches, each of which contains at least two bucket arrays, so we need at least 16 registers, while at most 12 registers are available in the Sketching stage.

Thus, we propose to use one register to store two cells in each bucket, as shown in Figure 4. We divide each bucket array into two registers, the first contains the first two cells of each bucket, and the second contains the remaining two cells. We group 4 cells in the same column into a sketchlet. In this way, either the active or the idle sketch is updated, each register is accessed *only once* for a packet.

Packet inter-arrival time is a task of measuring the maximum value, and its implementation is much easier. As shown in Figure 4, we set $d = 4$ and $w = 2^{16}$. For each bucket array, all 32-bit interval-cells are assigned to one register. We still group the 4 interval-cells in the same column into a sketchlet.

7.2 End-host Components

LightGuardian needs to implement three functions on the end-hosts: sending packets, receiving packets, reconstruction and performing analysis.

Sending packets: In the current implementation, LightGuardian inserts sketchlets between the Ethernet header and the IP header. However, we should emphasize that this is mainly due to hardware limitation: TCP checksum recalculation on Tofino is unreliable currently.

We also add the *carry-bit* after the Ethernet header, because there is no space in the Ethernet header. To implement this design, we program a Linux kernel module on the end-host, which registers a new packet type `ETH_P_SKETCHLET` in the Layer-3 protocol stack and modifies the Ethernet type of each packet to be sent to `ETH_P_SKETCHLET`, and allocates extra space for the *carry-bit*.

Receiving packets: We implement another Linux kernel module to handle `ETH_P_SKETCHLET` packets. This module decides whether the packet carries a sketchlet by checking the *carry-bit*, and records the sketchlet in the `stderr`.

Reconstruction and Forwarding We implement a forwarding module for end-hosts to forward the sketchlets to a centralized analyzer. It reads `stderr` every 1 millisecond. When the process finds the number of sketchlets in the log exceeds a threshold (dependant on Maximum Transmission Unit (MTU) of the network), or when a timeout is reached, the module generates a packet containing all the received sketchlets of the current interval, and sends it to the central analyzer. For example, when MTU is 9KB, the threshold is set to 350 packets ($\sim$8.4KB). We set the timeout to 100 milliseconds.

Finally, analysis can be performed on the end-host or the centralized analyzer with the same sketch reconstruction algorithm described in § 6.1.

8 Experimental Results

We conduct extensive experiments on a testbed and using mininet [40]. We focus on the following four key issues.

- **How accurate can our SuMax sketch measure per-flow statistics?** We implement our SuMax sketch using C++, and use the CAIDA datasets to evaluate the accuracy of SuMax for seven measurement tasks.
- **How much is the overhead of sending and aggregating sketchlets?** We generate network traffic following the widely used traffic distributions (WEB [97] and DCTCP [98]). We evaluate the aggregation time, the bandwidth overhead, and the impact on network performance (*e.g.*, RTT, FCT).
- **How accurate can LightGuardian detect network anomalies?** We use mininet to simulate a network, and evaluate the accuracy of LightGuardian in locating blackholes, loops, and abnormal jitters.
- **Is LightGuardian resilient to network failures?** We evaluate the performance of LightGuardian when end-hosts fail, or some sketchlets are missing.

We conduct the experiments using the following metrics: **ARE**, **RR**, **PR**, F_1 **Score**, **RE**, and **WMRE**. We explain the details of these metrics in Appendix C.

8.1 Experiments on SuMax

We use the anonymized IP traces collected in 2018 from CAIDA [99]. The dataset contains 6M packets belonging to 0.9M different flows. We set $d = 3$ by default, which means there are 3 bucket arrays in SuMax.

Flow size estimation (Figure 5a): We find that the accuracy of SuMax is higher than CM and close to CU. When using 96KB of memory, the ARE of SuMax is 6.78 times lower than CM, and 1.75 times higher than CU. We further study how the flow sizes affect the accuracy (see Figure 11a in Appendix D.1), and find that the results hold for both large and small flows.

Robustness (Figure 5b-5c): We find that partially reconstructed SuMax can provide accurate estimation. We set the memory to 768KB and measure the valid query rate and the ARE of the largest 1K flows. The results show that 55% reconstructed SuMax can report >90% valid results with <0.1 ARE, and 80% reconstructed SuMax can report >99% valid results with <0.01 ARE.

Other device-local tasks (Figure 5d-5e): We find that besides flow size estimation, SuMax also achieves good performance in other device-local measurement tasks, including estimating cardinality, flow size distribution (see Figure 11c in Appendix D.1), and entropy.

Delay distribution (Figure 5f): We find that the accuracy of SuMax is higher than CM and close to CU. We generate the delay of each packet according to the *chi-square distribution*. We set $\lambda_d = 8$ and vary w from 2^{10} to 2^{17}. For other delay distribution, please refer to Figure 12a-12e in Appendix D.1.

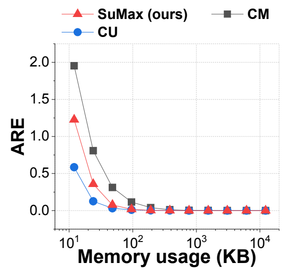
Maximum inter-arrival time (Figure 5g): We find that SuMax achieves <10 ARE when using more than 6MB of memory, and <0.3 ARE when using more than 12MB of memory. Since when abnormal incidents happen, the maximum inter-arrival time will rapidly increase dozens or hundreds times, <10 ARE is accurate enough to locate problems. We further study how the flow sizes affect the accuracy (see Figure 12h in Appendix D.1), and find that the results hold for both large and small flows.

***k+chance* Selection (Figure 5h):** We find that *k+chance Selection* can effectively reduce the number of packets required by the reconstruction process. According to the results, a larger k goes with fewer required packets, which demonstrates the effectiveness of our algorithm. We also find that the larger the w, the better the optimization effect.

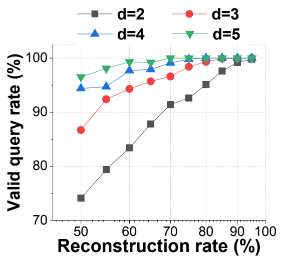
We further study the memory overhead of SuMax, and find that its memory overhead grows sub-linearly with the network scale, which guarantees the scalability of LightGuardian (see Figure 11b and Table 3 in Appendix D.1).

8.2 Testbed Experiments

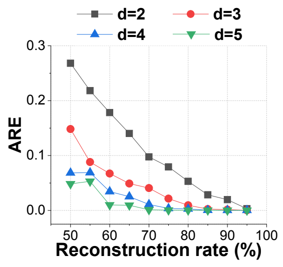
We evaluate LightGuardian on the testbed described in § 7. Take the delay distribution measurement task as an instance, the SuMax sketch we used contains $d = 2$ bucket arrays, each of which has $w = 2^{15}$ buckets, and each bucket contains 4



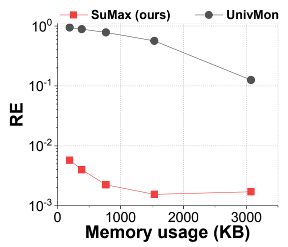
(a) Flow size estimation.



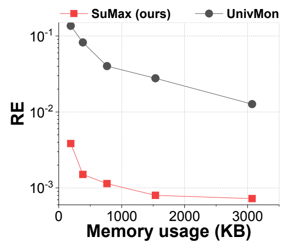
(b) Valid query rate.



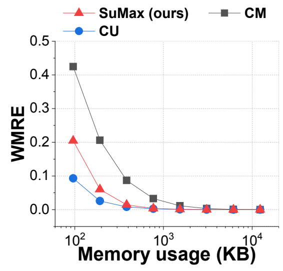
(c) ARE.



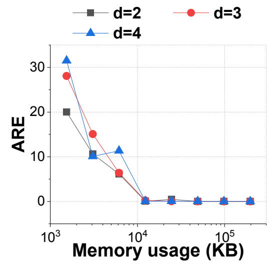
(d) Cardinality.



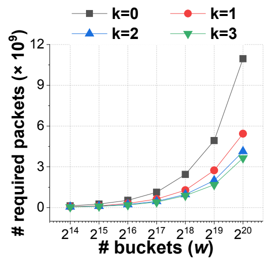
(e) Entropy.



(f) Delay distribution.



(g) Max inter-arrival time.



(h) *K+chance Selection.*

Figure 5: Experimental results on SuMax and the selection algorithm.

delay cells. This sketch also supports locating packet drops and all the mentioned local measurement tasks. Similarly, we can use another SuMax to locate abnormal jitters. By default, we set the carrying probability λ_c to $\frac{1}{16}$, and set $k = 1$ for *k+chance selection*. We use two traffic distributions W1 (DCTCP [98]) and W2 (WEB [97]), which are widely used in existing works [8, 100–102]. On each switch, the number of the sketchlets is 2^{16}, and each sketchlet is 24 bytes.

Bandwidth overhead *v.s.* traffic load (Figure 6a): We find that our system saves substantial bandwidth than INT. We compare LightGuardian with a kind of INT that inserts 20-bytes per-packet information into the packet headers at each hop. The results show that the bandwidth overhead of LightGuardian ranges from 13.8Mbps to 25.7Mbps, which is only about 0.07% of the total bandwidth. The bandwidth overhead of INT ranges from 211Mbps to 394Mbps. Compared with INT, our LightGuardian saves more than 93.5% bandwidth. We also study how the carrying probability λ_c affects the bandwidth usage (see Figure 13a-13c in Appendix D.3).

FCT *v.s.* traffic load (Figure 6b): We find that LightGuardian has little impact on the network. We vary the bandwidth usage from 50% to 90%, and measure the average Flow Completion Time (FCT) before and after deploying LightGuardian. Under workload W1, after deploying LightGuardian, the average FCT increases by 8.3% at 50% traffic load, and 1.8% at 90% traffic load. Under workload W2, after deploying LightGuardian, the average FCT increases by 16.3% at 50% traffic load, and 5.6% at 90% traffic load. Even under 90% traffic load, LightGuardian still achieves <5ms FCT. We also study the impact of the flow size on the average FCT (see Figure 14b in Appendix D.3).

Per-hop latency *v.s.* traffic load (Figure 6c): We find that LightGuardian has little impact on the network. We test the per-hop latency before and after deploying LightGuardian in the network. We vary the bandwidth usage from 0% to 90%, and measure the average per-hop latency of 10^4 packets using the `ping -f` instruction. The results show that at 0% traffic load, after deploying LightGuardian, per-hop latency increases $1.6\mu s$. At 90% load, per-hop latency increases at most $3.1\mu s$.

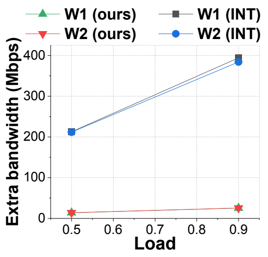
Reconstruction rate *v.s.* time (Figure 6d): We find that the sketches in LightGuardian can be quickly reconstructed. We use 90% of the total bandwidth and measure the reconstruction rate on each switch over time. The results show that under workload W1, the analyzer aggregates 90% sketchlets on the *edge switches*, the *aggregation switches*, and the *core switches* in 1.3, 1.7 and 2.1 seconds, respectively; and it aggregates 99% sketchlets in 2.1, 2.8 and 3.6 seconds, respectively. The results under workload W2 (as shown in Figure 14a in Appendix D.3) are similar. Other results related to sketch reconstruction are shown in Figure 14c-14d in Appendix D.3.

8.3 Simulations

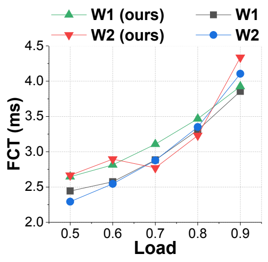
8.3.1 Simulations on Mininet

We evaluate LightGuardian's performance in locating blackholes, loops, and abnormal jitters through Mininet case studies. Our setup in Mininet consists of 16 hosts, 20 switches, and 48 links in a Fat-Tree topology. We only show the results as F1 scores. For more specific PR and RR results, please refer to Appendix D.2.

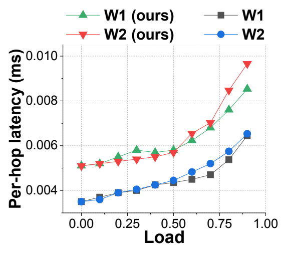
Locating blackholes (Figure 7a): We find that LightGuardian achieves high accuracy in locating blackholes. We randomly generate 10M packets belonging to 0.1M different flows. We create two blackholes by shutting down two links. And we reconstruct the sketchlets in a fixed time interval (5s) into sketches. For each flow, we query it in the reconstructed sketches to locate the culprit switches where the ratio $\frac{\mathcal{P}}{\mathcal{L}}$ is below a threshold. Here, for any switch, $\mathcal{P}$ is the estimated flow size, and $\mathcal{L}$ is the estimated flow size in the last-hop switch. The results show that when using 0.8MB of memory (2^{16} buckets), F1 score can reach 0.99.



(a) Bandwidth *v.s.* load.



(b) FCT *v.s.* load.



(c) Per-hop latency *v.s.* load.

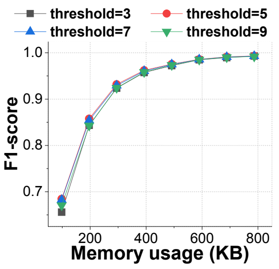
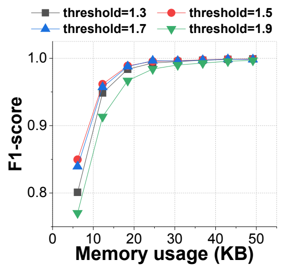
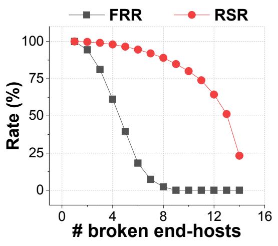
(a) Blackhole detection.



(b) Loop detection.



(c) Jitter detection.



(d) FRR/RSR *v.s.* λ_b.

Figure 7: Simulations results on Mininet.

Locating loops (Figure 7b): We find that LightGuardian achieves high accuracy in locating loops. We randomly generate 10M packets belonging to 0.1M different flows, and let 10% flows loop between two randomly selected adjacent switches. For each flow, we query it in the reconstructed sketches and locate the switches where $\frac{\varphi}{L}$ exceeds a threshold. The results show that when using 0.8MB of memory, F1 score reaches about 0.99.

Locating abnormal jitters (Figure 7c): We find that LightGuardian achieves high accuracy in locating abnormal jitters. We randomly generate 10M packets belonging to 10K different flows. To simulate jitters on the switch, we randomly choose two links, and split each of them into two parallel links with different speed. In this way, the flows passing through the slow link will suffer jitters, which leads to a sharp increase in their inter-arrival time in the next-hop switch. The results show that when using more than 20KB of memory, the F1 score is close to 1.

8.3.2 Simulations for Robustness

Next, we focus on the robustness of LightGuardian. The network topology here is the same as Mininet. We set $w = 2^{16}$. And in each experiment, we randomly select λ_b end-hosts and shut them down[9]. Then we observe how many sketches can be fully-reconstructed (recovered) in the global analyzer. The metrics we used here are: 1) *Full-Recovery Rate (FRR)*: the probability of recovering all sketches; 2) *Recovering-Sketch Rate (RSR)*: the ratio of the number of recovered sketches to the number of all sketches; From Figure 7d, we find that our system is robust to survive several device failures. When $\lambda_b = 4$, the FRR is still >60%. Even if half of the end-hosts break down ($\lambda_b = 8$), the analyzer still stands a chance of recovering all sketches (FRR > 0). And the RSR slowly decreases as λ_b increases. When $\lambda_b = 7$, the analyzer can reconstruct more than 90% sketches.

[9]Normal end-hosts still send packets to broken end-hosts, but broken end-hosts cannot send packets to others.

9 Conclusion and Future Work

In this paper, we present LightGuardian, a full-visibility, lightweight, in-band network telemetry system. LightGuardian designs the SuMax sketch to capture per-flow per-hop statistics on the programmable data plane, and use the constant-sized sketchlet to aggregate the statistics to any end-host, which can then perform both the device-local and the network-wide analysis. Experiments on a testbed and mininet simulations show that our system is able to perform 4 local measurement tasks, 3 network-wide tasks, and 3 anomalies locating tasks with high accuracy and consistently low overhead.

In the future work, we plan to design a mechanism to automatically adjust the system parameters according to the current traffic characteristics; we plan to conduct large-scale simulations; we plan to design and evaluate other methods of transferring sketches; we plan to offload the reconstruction and forwarding modules in end-host to smart NIC; we plan to deploy our system in cloud networking; and we also plan to use our measurement results to further improve the performance of congestion control, load balancing, and traffic scheduling.

Acknowledgment

We would like to thank the anonymous reviewers and our shepherd, Z. Morley Mao, for their thoughtful suggestions. This work is supported by National Natural Science Foundation of China (NSFC) (No. U20A20179), and the project of "FANet: PCL Future Greater-Bay Area Network Facilities for Large-scale Experiments and Applications" (No. LZC0019).

APPENDIX

A Algorithm

Algorithm 1: Insertion of SuMax sketch

```
Input: A new packet $\langle f, \alpha, \beta \rangle$.
$\omega \leftarrow +\infty$;
for $i = 0 \rightarrow d-1$ do
    if $\mathcal{A}_i^{sum}[\mathcal{H}_i(f)] + \alpha < \omega$ then
        $\omega \leftarrow \mathcal{A}_i^{sum}[\mathcal{H}_i(f)] + \alpha$ ;
        $\mathcal{A}_i^{sum}[\mathcal{H}_i(f)] \leftarrow \omega$;
    else if $\mathcal{A}_i^{sum}[\mathcal{H}_i(f)] < \omega$ then
        $\mathcal{A}_i^{sum}[\mathcal{H}_i(f)] \leftarrow \omega$;
    end
    $\mathcal{A}_i^{max}[\mathcal{H}_i(f)] \leftarrow \max\{\beta, \mathcal{A}_i^{max}[\mathcal{H}_i(f)]\}$;
end
```

B Proof of Theorem 6.1

Theorem B.1 *After receiving sketchlets with a ratio of θ, SuMax can report valid results with a ratio of $(1-(1-\theta)^d)$. Specifically, when the result is valid, the estimated flow size has the following error bounds.*

$$\Pr\left\{|\hat{n}_f - n_f| > \varepsilon\right\} < \frac{\left(\frac{m\theta}{w\varepsilon} + 1 - \theta\right)^d - (1-\theta)^d}{1-(1-\theta)^d},$$

where d and w are parameters of SuMax (see Table 2), n_f and $\hat{n}_f$ are the real and estimated flow size, and m is the number of inserted packets.

Proof B.1 *Let $\mathcal{A}_1[\mathcal{H}_1(f)], \cdots \mathcal{A}_d[\mathcal{H}_d(f)]$ be the values of d mapped buckets. Let $\mathcal{V}_1, \cdots, \mathcal{V}_d$ be d indicating random variables, where $\mathcal{V}_i$ indicates whether the i-th mapped bucket is received. Since the reported result of SuMax is valid as long as at least one buckets is received, the probability of acquiring a valid result is:*

$$\Pr\left\{\texttt{valid}\right\} = \Pr\left\{\mathcal{V}_1 = 1 \vee \cdots \vee \mathcal{V}_d = 1\right\}$$
$$= 1 - \prod_{i=1}^{d} \Pr\left\{\mathcal{V}_i = 0\right\} = 1-(1-\theta)^d$$

The expected number of packets mapped to each bucket is $\frac{m}{w} + n_f$. Since SuMax uses a conservative update method, not every packet increments the value of the bucket. Thus the value of each bucket satisfies:

$$\mathbb{E}\left(\mathcal{A}_i[\mathcal{H}_i(f)]\right) < \frac{m}{w} + n_f$$

According to the Markov inequality, we can derive that:

$$\Pr\left\{\left|\mathcal{A}_i[\mathcal{H}_i(f)] - n_f\right| > \varepsilon\right\} < \frac{\mathbb{E}\left(\mathcal{A}_i[\mathcal{H}_i(f)] - n_f\right)}{\varepsilon} < \frac{m}{w\varepsilon}$$

According to the total probability rule, we have

$$\Pr\left\{|\hat{n}_f - n_f| > \varepsilon\right\} = \sum_{i=1}^{d} \Pr\left\{\zeta_i\right\} \cdot \Pr\left\{|\hat{n}_f - n_f| > \varepsilon \mid \zeta_i\right\}$$
$$< \sum_{i=1}^{d} \frac{\binom{d}{i}\theta^i(1-\theta)^{d-i}}{1-(1-\theta)^d} \cdot \left(\frac{m}{w\varepsilon}\right)^i = \frac{\left(\frac{m\theta}{w\varepsilon} + 1 - \theta\right)^d - (1-\theta)^d}{1-(1-\theta)^d}$$

where ζ_i indicates that there are i valid buckets after the reconstruction process.

C Evaluation Metrics

1) Average Relative Error (ARE): $\frac{1}{|\Psi|}\sum_{f_i \in \Psi} \frac{|n_i - \hat{n}_i|}{n_i}$, where n_i is the real statistics of flow f_i, $\hat{n}_i$ is the estimated statistics of flow f_i, and Ψ is the flow set.
2) Recall Rate (RR): The ratio of the number of correctly reported instances to the number of all correct instances.
3) Precision Rate (PR): The ratio of the number of correctly reported instances to the number of all reported instances.
4) F_1 Score: $\frac{2 \times PR \times RR}{PR + RR}$.
5) Relative Error (RE): $\frac{|Est. - True|}{True}$, where $Est.$ and $True$ are the estimated and true statistics, respectively.
6) Weighted Mean Relative Error (WMRE) [42, 93]: $\frac{\sum_{i=1}^{z}|n_i - \hat{n}_i|}{\sum_{i=1}^{z}\frac{n_i + \hat{n}_i}{2}}$, where n_i and $\hat{n}_i$ are the real and estimated event probabilities respectively, and z is the number of events.

D Additional Experimental Results

D.1 Experiments on SuMax

Flow size estimation (Figure 11a): We find that the ARE of SuMax is higher to CM and close to CU. When using 768KB of memory, for the largest 500 flows, the ARE of SuMax is 17.1 times lower than CM and only 0.1 times higher than CU.
Memory overhead (Figure 11b): We find that the memory overhead of SuMax grows sub-linearly with the number of generated packets, which guarantees the scalability of LightGuardian. We conduct this experiment in the flow size estimation task. We vary the number of generated packets in the network, and record how much memory SuMax needs to achieve 0.01 ARE. Table 3 further studies the memory overhead of SuMax in various tasks.
Delay distribution (Figure 12a-12e): We find that for different datasets, SuMax always achieves performance similar to CU. Figure 12a-12b show that the WMRE of SuMax is lower than CM and close to CU, which means SuMax has a stable performance. Figure 12c-12e show that when using 6MB of memory and varying the top-k flows, the WMRE of SuMax is similar to CU and lower than CM.
Last arrival time (Figure 12f-12g): We find that when using 768KB of memory, the Average Absolute Error (AAE) is less than 12ms; and when using 3MB of memory, the AAE is less than 1.5ms. Figure 12g further illustrated that when using

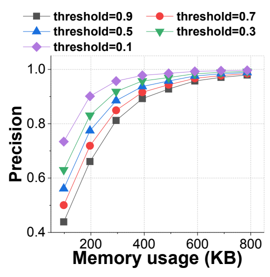
768KB of memory, the estimated results are absolutely correct for 87% packets.

Table 3: Memory usage of SuMax in various tasks.

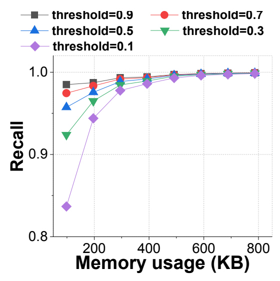
Task	Target error	Memory (MB)
Flow size estimation	0.01	~ 0.1
Flow size distribution	0.05	~ 0.4
Cardinality	0.005	~ 0.2
Entropy	0.001	~ 0.8
Delay distribution	0.05	~ 0.8
Max inter-arrival	0.01	~ 50
Last arrival time	0.01	~ 0.8

D.2 Simulations on Mininet

We demonstrate the specific PR and RR experimental results in § 8.3.



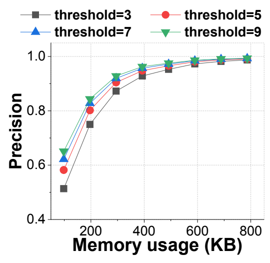
(a) PR *v.s.* memory usage.



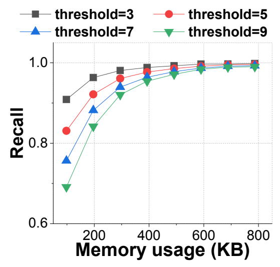
(b) RR *v.s.* memory usage.

Figure 8: Accuracy of locating blackholes.

Locating blackholes (Figure 8a-8b): We find that LightGuardian achieve high accuracy in locating blackholes. The results show that higher threshold goes with lower PR and higher RR. When using 800KB of memory (2^{16} buckets), the PR and RR reach $0.982 \sim 0.997$ and $0.998 \sim 0.999$ respectively.



(a) PR *v.s.* memory usage.

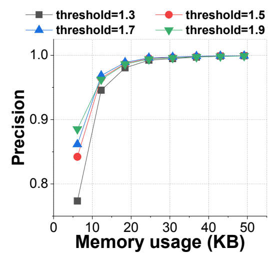


(b) RR *v.s.* memory usage.

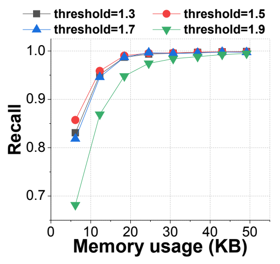
Figure 9: Accuracy of locating loops.

Locating loops (Figure 9a-9b): We find that LightGuardian achieve high accuracy in locating loops. The results show that higher threshold goes with higher PR and lower RR. When using 800KB of memory, the PR and RR reaches $0.988 \sim 0.994$ and $0.993 \sim 0.998$ respectively.

Locating abnormal jitters (Figure 10a-10b): We find that LightGuardian achieve high accuracy in locating jitters. The results show that higher threshold goes with higher PR and



(a) PR *v.s.* memory usage.



(b) RR *v.s.* memory usage.

Figure 10: Accuracy of locating abnormal jitters.

lower RR. When using more than 500KB of memory, both PR and RR are close to 1.0. When using 50KB of memory (2^{12} buckets), the PR and RR reach $0.998 \sim 0.999$ and $0.994 \sim 0.999$ respectively.

D.3 Testbed Experiments

We further extend the experiments in § 8.2.

Bandwidth overhead *v.s.* λ_c (Figure 13a): We find that the bandwidth overhead of LightGuardian can be dynamically adjusted by the carrying probability λ_c. We vary the carrying probability λ_c from $\frac{1}{64}$ to $\frac{8}{64}$, and measure the bandwidth overhead. The results show that compared with INT, LightGuardian only uses 1.5% to 12.4% bandwidth. When the average packet size becomes smaller (*e.g.*, when encountering DDos attacks) and the number of the packets increases, our LightGuardian can adjust the bandwidth overhead by reducing λ_c. INT does not have this ability.

Required time (RT) *v.s.* λ_c (Figure 13b): We find that the time required to construct the sketches can be dynamically adjusted by the carrying probability λ_c. We generate 36Gbps traffic between two end-hosts in the same rack, and vary λ_c from $\frac{1}{64}$ to $\frac{8}{64}$. The results show that as λ_c increases, the required time decreases.

Required packets (RP) *v.s.* λ_c (Figure 13c): We find that the packets required to reconstruct the sketches can be dynamically adjusted by the carrying probability λ. The results show that the packets required to aggregate 90% and 99% sketchlets is negatively correlated to λ_c.

FCT *v.s.* flow size (Figure 14b): We find that LightGuardian has little impact on the FCT for the flows of any size. We measure the average FCT of flows of different sizes under 90% traffic load. We divide the flows into five groups according to their sizes: (0, 0.01MB), (0.01, 0.1MB), (0.1MB, 1MB), (1MB, 10MB) and (10MB, 100MB), and calculate the average FCT of each group. The results show that even for the flows of 100MB, the average FCT is no more than 40ms.

RP/RT *v.s.* w (Figure 14c-14d): We find that the required packets and the required time to reconstruct the sketches can be dynamically adjusted by w. We vary the number of sketchlets on the TOR switch from 2^{12} to 2^{16} and measure the number of the required packets and the required time to achieve certain reconstruction rates. The results show that both the required time and the required packets grow linearly with the number of sketchlets.

Abstract

Bandwidth testing measures the access bandwidth of end hosts, which is crucial to emerging Internet applications for network-aware content delivery. However, today's bandwidth testing services (BTSes) are slow and costly—the tests take a long time to run, consume excessive data usage at the client side, and/or require large-scale test server deployments. The inefficiency and high cost of BTSes root in their methodologies that use excessive temporal and spatial redundancies for combating noises in Internet measurement.

This paper presents FastBTS to make BTS fast and cheap while maintaining high accuracy. The key idea of FastBTS is to accommodate and exploit the noise rather than repetitively and exhaustively suppress the impact of noise. This is achieved by a novel statistical sampling framework (termed *fuzzy rejection sampling*). We build FastBTS as an end-to-end BTS that implements fuzzy rejection sampling based on elastic bandwidth probing and denoised sampling from high-fidelity windows, together with server selection and multi-homing support. Our evaluation shows that with only 30 test servers, FastBTS achieves the same level of accuracy compared to the state-of-the-art BTS (`SpeedTest.net`) that deploys ∼12,000 servers. Most importantly, FastBTS makes bandwidth tests 5.6× faster and 10.7× more data-efficient.

1 Introduction

Access link bandwidth of Internet users commonly constitutes the bottleneck of Internet content delivery, especially for emerging applications like AR/VR. In traditional residential broadband networks, the access bandwidth is largely stable and matches ISPs' service plans [9, 14, 15]. In recent years, however, it becomes less transparent and more dynamic, driven by virtual network operators (VNOs), user mobility, and infrastructure dynamics [21].

To effectively measure the access bandwidth, bandwidth testing services (BTSes) have been widely developed and deployed. BTSes serve as a core component of many applications that conduct network-aware content delivery [1, 31]. BTSes' data are cited in government reports, trade press [37], and ISPs' advertisements [29]; they play a key role in ISP customers' decision making [39]. During COVID-19, BTSes are top "home networking tips" to support telework [11, 12]. The following lists a few common use cases of BTSes:

[*] Co-primary authors. Zhenhua Li is the corresponding author.

- VNO has been a popular operation model that resells network services from base carrier(s). The shared nature of VNOs and their complex interactions with the base carriers make it challenging to ensure service qualities [69, 72, 78]. Many ISPs and VNOs today either build their own BTSes [2], or recommend end users to use public BTSes. For example, `SpeedTest.net`, a popular BTS, serves more than 500M unique visitors per year [4].
- Wireless access is becoming ubiquitous, exhibiting heterogeneous and dynamic performance. To assist users to locate good coverage areas, cellular carriers offer "performance maps" [16], and several commercial products (*e.g.,* WiFiMaster used by 800M mobile devices [31]) employ crowd-sourced measurements to probe bandwidth.
- Emerging bandwidth-hungry apps (*e.g.,* UHD videos and VR/AR), together with bandwidth-fluctuating access networks (*e.g.,* 5G), make BTSes an integral component of modern mobile platforms. For example, the newly released Android 11 provides 5G apps with a bandwidth estimation API that offers "a rough guide of the expected peak bandwidth for the first hop of the given transport [20]."

Most of today's BTSes work in three steps: (1) setup, (2) bandwidth probing, and (3) bandwidth estimation. During the setup process, the user client measures its latency to a number of candidate test servers and selects one or more servers with low latency. Then, it probes the available bandwidth by uploading and downloading large files to and from the test server(s) and records the measured throughput as samples. Finally, it estimates the overall downlink/uplink bandwidth.

The key challenge of BTSes is to deal with *noises* of Internet measurements incurred by congestion control, link sharing, *etc.* Spatially, the noise inflates as the distance (the routing hop count) increases between the user client and test server. Temporally, the throughput samples may be constantly fluctuating over time—the shorter the test duration is, the severer impact on throughput samples the noise can induce. An effective BTS needs to accurately and efficiently measure the access bandwidth from noisy throughput samples.

Today's BTSes are slow and costly. For example, a 5G bandwidth test using `SpeedTest.net` for a 1.15 Gbps downlink takes 15 seconds of time and incurs 1.94 GB of data usage on end users in order to achieve satisfying test accuracy. To deploy an effective BTS, hundreds to thousands of test servers are typically needed. Such a level of cost (both at the client and server sides) and long test duration prevent BTSes from being a foundational, ubiquitous Internet service for high-speed, metered networks. Based on our measurements and reverse engineering of 20 commercial BTSes (§2), we find that the inefficiency and cost of these BTSes fundamentally root in their methodology of relying on temporal and/or spatial redundancy to deal with noises:

- Temporally, most BTSes rely on a *flooding-based* bandwidth probing approach, which simply injects an excessive number of packets to ensure that the bottleneck link is saturated by test data rather than noise data. Also, their test processes often intentionally last for a long time to ensure the convergence of the probing algorithm.
- Spatially, many BTSes deploy dense, redundant test servers close to the probing client, in order to avoid "long-distance" noises. For example, `FAST.com` and `SpeedTest.net` deploy $\sim$1,000 and $\sim$12,000 geo-distributed servers, respectively, while WiFiMaster controversially exploits a large Internet content provider's CDN server pool.

In this paper, we present FastBTS to make BTS fast and cheap while maintaining high accuracy. Our key idea is to accommodate and exploit the noise through a novel statistical sampling framework, which eliminates the need for long test duration and exhaustive resource usage for suppressing the impact of noise. Our insight is that the workflow of BTS can be modeled as a process of *acceptance-rejection sampling* [43] (or *rejection sampling* for short). During a test, a sequence of throughput samples are generated by bandwidth probing and exhibit a measured distribution $P(x)$, where x denotes the throughput value of a sample. They are filtered by the bandwidth estimation algorithm, in the form of an acceptance-rejection function (ARF), which retains the accepted samples and discards the rejected samples to model the target distribution $T(x)$ for calculating the final test result.

The key challenge of FastBTS is that $T(x)$ cannot be known beforehand. Hence, we cannot apply traditional rejection sampling algorithm that assumes a $T(x)$ and uses it as an input. In practice, our extensive measurement results show that, while the noise samples are scattered across a wide throughput interval, the true samples tend to concentrate within a narrow throughput interval (termed as a *crucial interval*). Therefore, one can reasonably model $T(x)$ using the crucial interval, as long as $T(x)$ is persistently covered by $P(x)$. We name the above-described technique *fuzzy rejection sampling*.

FastBTS implements fuzzy rejection sampling with the architecture shown in Figure 1. First, it narrows down $P(x)$ as the boundary of $T(x)$ to bootstrap $T(x)$ modeling. This is done by an Elastic Bandwidth Probing (EBP) mechanism to tune the transport-layer data probing rate based on its deviation from the currently-estimated bandwidth. Second, we design a Crucial Interval Sampling (CIS) algorithm, acting as the ARF, to efficiently calculate the optimal crucial interval with throughput samples (*i.e.,* performing denoised sampling from high-fidelity throughput windows). Also, the Data-driven Server Selection (DSS) and Adaptive Multi-Homing (AMH) mechanisms are used to establish multiple parallel connections with different test servers when necessary. DSS and AMH together can help saturate the access link, so that $T(x)$ can be accurately modeled in a short time, even when the access bandwidth exceeds the capability of each test server.

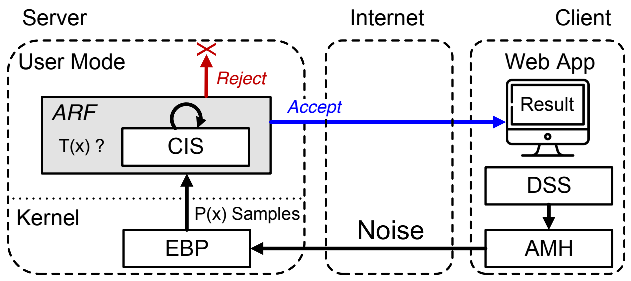

Figure 1: An architectural overview of FastBTS. The arrows show the workflows of a bandwidth test in FastBTS.

We have built FastBTS as an end-to-end BTS, consisting of the FastBTS app for clients, and a Linux kernel module for test servers. We deploy the FastBTS backend using 30 geo-distributed budget servers, and the FastBTS app on 100+ diverse client hosts. Our key evaluation results are[1]:

- On the same testbed, FastBTS yields 5%–72% higher average accuracy than the other BTSes under diverse network scenarios (including 5G), while incurring 2.3–8.5$\times$ shorter test duration and 3.7–14.2$\times$ less data usage.
- Employing only 30 test servers, FastBTS achieves comparable accuracy compared with the production system of `SpeedTest.net` with $\sim$12,000 test servers, while incurring 5.6$\times$ shorter test duration and 10.7$\times$ less data usage.
- FastBTS flows incur little ($<$6%) interference to concurrent non-BTS flows—EBP only ramps up fast when the data rate is well below the available bandwidth; it slowly grows the data rate when it is about to hit the bottleneck bandwidth.

To benefit the community, we have released all the source code at `https://FastBTS.github.io` and an online prototype system at `http://FastBTS.thucloud.com`.

2 Understanding State-of-The-Art BTSes

2.1 Methodology

We measure a BTS using the following metrics: (1) *Test Accuracy* measures how well the result (r) reported by a BTS matches the ground-truth bandwidth R. We calculate the accuracy as $\frac{r}{R}$. In practice, we observe that all BTSes (including FastBTS) tend to underestimate the bottleneck bandwidth due to factors like TCP slow start and congestion control, so the accuracy values are less than 1.0. (2) *Test Duration* measures

[1]In this work, we focus on the downlink bandwidth test due to its importance to a typical Internet user compared to the uplink.

the time needed to perform a bandwidth test—from starting a bandwidth test to returning the test result. (3) *Data Usage* measures the consumed network traffic for a test. This metric is of particular importance to metered LTE and 5G links.

Obtaining ground truth. Measuring test accuracy requires ground-truth data. However, it is challenging to know all the ground-truth bandwidths for large measurements. We use best possible estimations for different types of access links:

- *Wired LANs for in-lab experiments.* We regard the (known) physical link bandwidth, with the impact of (our injected) cross traffic properly considered, as the ground truth.
- *Commercial residential broadband and cloud networks.* We collect the bandwidth claimed by the ISPs or cloud service providers from the service contract, denoted as T_C. We then verify T_C by conducting long-lived bulk data transfers (average value denoted as T_B) before and after a bandwidth test. In more than 90% of our experiments, T_B and T_C match, with their difference being less than 5%; thus, we regard T_C as the ground truth. Otherwise, we choose to use T_B.
- *Cellular networks (LTE and 5G).* Due to a lack of T_C and the high dynamics of cellular links, we leverage the results provided by SpeedTest.net as a baseline reference. Being the state-of-the-art BTS that owns a massive number of (∼12,000) test servers across the globe, SpeedTest.net's results are widely considered as a close approximation to the ground-truth bandwidth [33, 36, 38, 41, 50, 73].

2.2 Analyzing Deployed BTSes

We study 20 deployed BTSes, including 18 widely-used, web-based BTSes and 2 Android 11 BTS APIs.[2] We run the 20 BTSes on three different PCs and four different smartphones listed in Table 1 (WiFiMaster and Android APIs are only run on smartphones). To understand the implementation of these BTSes, we jointly analyze: (1) the network traffic (recorded during each test), (2) the client-side code, and (3) vendors' documentation. A typical analysis workflow is as follows. We first examine the network traffic to reveal which server(s) the client interacts with during the test, as well as their interaction durations. We then inspect the captured HTTP(S) transactions to interpret the client's interactions with the server(s) such as server selection and file transfer. We also inspect client-side code (typically in JavaScript). However, this attempt may not always succeed due to code obfuscation used by some BTSes like SpeedTest. In this case, we use the Chrome developer tool to monitor the entire test process in the debug mode.

[2]The 18 web-based BTSes are ATTtest [2], BWP [5], CenturyLink [6], Cox [7], DSLReports [8], FAST [10], NYSbroadband [17], Optimum [19], SFtest [13], SpeakEasy [22], Spectrum [23], SpeedOf [24], SpeedTest [25], ThinkBroadband [28], Verizon [30], Xfinity [32], XYZtest [26], and WiFi-Master [31]. They are selected based on Alexa ranks and Google page ranks. In addition, we also study two BTS APIs in Android 11: `getLinkDownstreamBandwidthKbps` and `testMobileDownload`.

Device	Location	Network	Ground Truth
PC-1	U.S.	Residential broadband	100 Mbps
PC-2	Germany	Residential broadband	100 Mbps
PC-3	China	Residential broadband	100 Mbps
Samsung GS9	U.S.	LTE (60Mhz/1.9Ghz)	60–100 Mbps
Xiaomi XM8	China	LTE (40Mhz/1.8Ghz)	58–89 Mbps
Samsung GS10	U.S.	5G (400Mhz/28Ghz)	0.9–1.2 Gbps
Huawei HV30	China	5G (160Mhz/2.6Ghz)	0.4–0.7 Gbps

Table 1: Client devices used for testing the 20 BTSes. The test results are obtained from SpeedTest.net.

With the above efforts, we are able to "reverse engineer" the implementations of all the 20 BTSes.

Our analysis shows that a bandwidth test in these BTSes is typically done in three phases: (1) setup, (2) bandwidth probing, and (3) bandwidth estimation. In the setup phase, the BTS sends a list of candidate servers (based on the client's IP address or geo-location) to the client who then PINGs each candidate server over HTTP(S). Next, based on the servers' PING latency, the client selects one or more candidate servers to perform file transfer(s) to collect throughput samples. The BTS processes the samples and returns the result to the user.

2.3 Measurement Results

We select 9 (out of 20) representative BTSes for more in-depth characterizations, as listed in Table 2. These 9 selected BTSes well cover different designs (in terms of the key bandwidth test logic) of the remaining 11 ones. We deploy a large-scale testbed to comprehensively profile 8 representative BTSes, except Android API-A (we will discuss it separately). Our testbed is deployed on 108 geo-distributed VMs from multiple public cloud services providers (CSPs, including Azure, AWS, Ali Cloud, Digital Ocean, Vultr, and Tencent Cloud) as the client hosts. Note that we mainly employ VMs as client hosts because they are globally distributed and easy to deploy. Per their service agreements, the CSPs offer three types of access link bandwidths: 1 Mbps, 10 Mbps, and 100 Mbps (36 VMs each). The ground truth in Figure 2c is obtained according to the methodology in §2.1. We denote one *test group* as using one VM to run back-to-back bandwidth tests across all the 8 BTSes in a random order. We perform in one day 3,240 groups of tests, *i.e.,* 108 VMs × 3 different time-of-day (0:00, 8:00, and 16:00) × 10 repetitions.

We summarize our results in Table 2. We discover that all but one of the BTSes adopt *flooding-based* approaches to combat the test noises from a temporal perspective, leading to enormous data usage. Meanwhile, they differ in many aspects: (1) bandwidth probing mechanism, (2) bandwidth estimation algorithm, (3) connection management strategy, (4) server selection policy, and (5) server pool size.

2.4 Case Studies

We present our case studies of five major BTSes with the largest user bases selected from Table 2.

BTS	# Servers	Bandwidth Test Logic	Duration	Accuracy (Testbed / 5G)	Data Usage (Testbed / 5G)
TBB*	12	average throughput in all connections	8 s	0.59 / 0.31	42 MB / 481 MB
SpeedOf	116	average throughput in the last connection	8–230 s	0.76 / 0.22	61 MB / 256 MB
BWP	18	average throughput in the fastest connection	13 s	0.81 / 0.35	74 MB / 524 MB
SFtest	19	average throughput in all connections	20 s	0.89 / 0.81	194 MB / 2,013 MB
ATTtest	75	average throughput in all connections	15–30 s	0.86 / 0.53	122 MB / 663 MB
Xfinity	28	average all throughput samples	12 s	0.82 / 0.67	107 MB / 835 MB
FAST	∼1,000	average stable throughput samples	8–30 s	0.80 / 0.72	45 MB / 903 MB
SpeedTest	∼12,000	average refined throughput samples	15 s	0.96 / 0.92	150 MB / 1,972 MB
Android API-A	0	directly calculate using system configs	< 10 ms	NA / 0.09	0 / 0

Table 2: A brief summary of the 9 representative BTSes. “Testbed” and “5G” denote the large-scale cloud-based testbed and the 5G scenario, respectively. * means that WiFiMaster and Andriod API-B share the similar bandwidth test logic with ThinkBroadBand (TBB).

ThinkBroadBand [28]. The ThinkBroadBand BTS first selects a test server with the lowest latency to the client among its server pool. Then, it starts an 8-second bandwidth test by delivering a 20-MB file towards the client; if the file transfer takes less than 8 seconds, the test is repeated to collect more data points. After the 8 seconds, it calculates the average throughput (*i.e.,* data transfer rate) during the whole test process as the estimated bandwidth.

WiFiMaster [31]. WiFiMaster’s BTS is largely the same as that of ThinkBroadBand. The main difference lies in the test server pool. Instead of deploying a dedicated test server pool, WiFiMaster exploits the CDN servers of a large Internet content provider (Tencent) for frequent bandwidth tests. It directly downloads fixed-size (∼47 MB) software packages as the test files and measures the average download speed as the estimated bandwidth.

Our measurements show that the accuracy of ThinkBroadBand and WiFiMaster is low. The accuracy is merely 0.59, because the single HTTP connection during the test can easily be affected by network spikes and link congestion which lead to significant underestimation. In addition, using the average throughput for bandwidth estimation cannot rule out the impact of slow start and thus requires a long test duration.

Android APIs [1,3]. To cater to the needs of bandwidth estimation for bandwidth-hungry apps (*e.g.,* UHD videos and VR/AR) over 5G, Android 11 offers two “Bandwidth Estimator” APIs to “make it easier to check bandwidth for uploading and downloading content [1]”.

API-A, `getLinkDownstreamBandwidthKbps`, statically calculates the access bandwidth by “taking into account link parameters (radio technology, allocated channels, *etc.*) [20]”. It uses a pre-defined dictionary (`KEY_BANDWIDTH_STRING_ARRAY`) to map device hardware information to bandwidth values. For example, if the end-user’s device is connected to the new-radio non-standalone mmWave 5G network, API-A searches the dictionary which records `NR_NSA_MMWAVE:145000,60000`, indicating that the downlink bandwidth is 145,000 Kbps and the uplink bandwidth is 60,000 Kbps. This API provides a static “start-up on idle” estimation [1]. We test the performance of API-A in a similar manner as introduced in §2.3 with the 5G phones in Table 1. The results show that API-A bears rather poor accuracy (0.09) in realistic scenarios.

API-B, `testMobileDownload`, works in a similar way as ThinkBroadBand. It requires the app developer to provide the test servers and the test files.

FAST [10] is an advanced BTS with a pool of about 1,000 test servers. It employs a two-step server selection process: the client first picks five nearby servers based on its IP address, and then PINGs these five candidates to select the latency-wise nearest server for the bandwidth probing phase.

FAST progressively increases the concurrency according to the client network condition during the test. The client starts with a 25-MB file over a single connection. When the throughput reaches 0.5 Mbps, a new connection is created to transfer another 25-MB file. Similarly, at 1 Mbps, a third connection is established. For each connection, when the file transfer completes, it repeatedly requests another 25-MB file (the concurrency level never decreases).

FAST estimates the bandwidth as follows. As shown in Figure 2a, it collects a throughput sample every 200 ms, and maintains a 2-second window consisting of 10 most recent samples. After 5 seconds, FAST checks whether the in-window throughput samples are stable: $S_{max} - S_{min} \leq 3\% \cdot S_{avg}$, where S_{max}, S_{min}, and S_{avg} correspond to the maximum, minimum, and average value across all samples in the window, respectively. If the above inequality holds, FAST terminates the test and returns S_{avg}. Otherwise, the test will continue until reaching a time limit of 30 seconds; at that time, the last 2-second window’s S_{avg} will be returned to the user.

Unfortunately, our results show that the accuracy of FAST is still unsatisfactory. The average accuracy is 0.80, as shown in Table 2 and Figure 2c. We ascribe this to two reasons: (1) Though FAST owns ∼1,000 servers, they are mostly located in the US and Canada. Thus, FAST can hardly assign a nearby server to clients outside North America. In fact, FAST achieves relatively high average accuracy (0.92) when serving the clients in North America; however, it has quite low accuracy (0.74) when measuring the access link bandwidth of the clients in other places around the world. (2) We observe that FAST’s window-based mechanism for early generation of the test result is vulnerable to throughput fluctuations. Under unstable network conditions, FAST can only use throughput samples in the last two seconds (rather than the entire

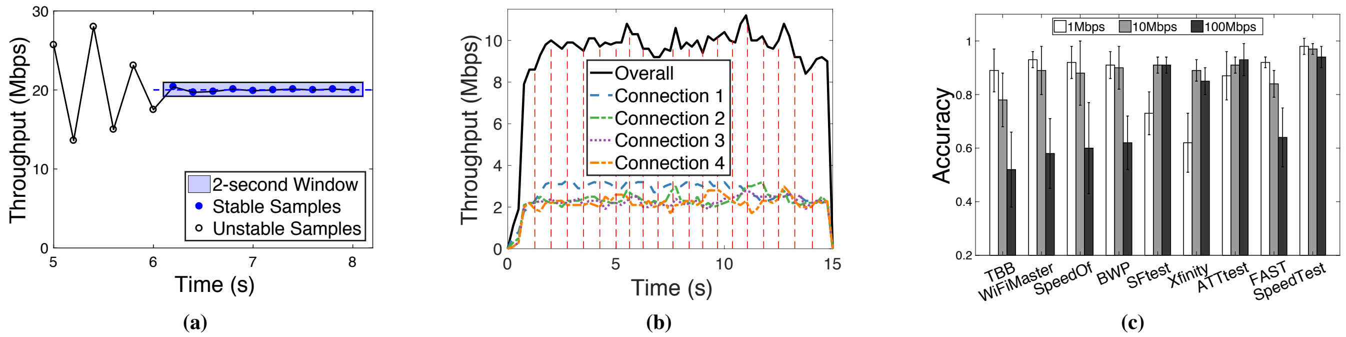

Figure 2: (a) Test logic of FAST. (b) Test logic of SpeedTest. (c) Test accuracy of nine commercial BTSes.

30-second samples) to calculate the test result.

SpeedTest [25] is considered the most advanced industrial BTS [33, 36, 41, 50, 73]. It deploys a pool of ∼12,000 servers. Similar to FAST, it also employs the two-step server selection process: it identifies 10 candidate servers based on the client's IP address, and then selects the latency-wise nearest from them. It also progressively increases the concurrency level: it begins with 4 parallel connections for quickly saturating the available bandwidth, and establishes a new connection at 25 Mbps and 35 Mbps, respectively. It uses a fixed file size of 25 MB and a fixed test duration of 15 seconds.

SpeedTest's bandwidth estimation algorithm is different from FAST's. During the bandwidth probing phase, it collects a throughput sample every 100 ms. Since the test duration is fixed to 15 seconds, all the 150 samples are used to construct 20 slices, each covering the same traffic volume, illustrated as the area under the throughput curve in Figure 2b. Then, 5 slices with the lowest average throughput and 2 slices with the highest average throughput are discarded. This leaves 13 slices remaining, whose average throughput is returned as the final test result. This method may help mitigate the impact of throughput fluctuations, but the two fixed thresholds for noise filtering could be deficient under diverse network conditions.

Overall, SpeedTest exhibits the highest accuracy (0.96) among the measured BTSes. A key contributing factor is its large server pool, as shown in §5.2.

3 Design of FastBTS

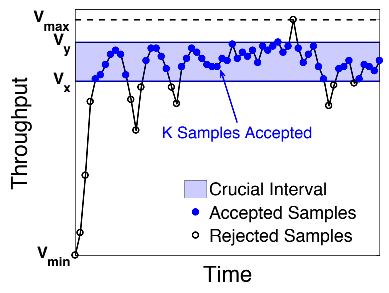
FastBTS is a fast and lightweight BTS with a fundamentally new design. FastBTS *accommodates and exploits* noises (instead of suppressing them) to significantly reduce the resource footprint and accelerate the tests, while retaining high test accuracy. The key technique of FastBTS is *fuzzy rejection sampling* which automatically identifies true samples that represent the target distribution and filters out false samples due to measurement noises, without apriori knowledge of the target distribution. Figure 1 shows the main components of FastBTS and the workflow of a bandwidth test.

- *Crucial Interval Sampling (CIS)* implements the acceptance rejection function of fuzzy rejection sampling. CIS is built upon a key observation based on our measurement study (see §2.3 and §2.4): *while the noise samples may be widely scattered, the desired bandwidth samples tend to concentrate within a narrow throughput interval*. CIS searches for a *dense* and *narrow* interval that covers the majority of the desirable samples, and uses computational geometry to drastically reduce the searching complexity.
- *Elastic Bandwidth Probing (EBP)* generates throughput samples that persistently[3] obey the distribution of the target bandwidth. We design EBP by optimizing BBR's bandwidth estimation algorithm [42] – different from BBR's static bandwidth probing policy, EBP reaches the target bandwidth much faster, while being non-disruptive.
- *Data-driven Server Selection (DSS)* selects the server(s) with the highest bandwidth estimation(s) through a data-driven model. We show that a simple model can significantly improve server selection results compared to the de-facto approach that ranks servers by round-trip time.
- *Adaptive Multi-Homing (AMH)* adaptively establishes multiple parallel connections with different test servers. AMH is important for saturating the access link when the last-mile access link is not the bottleneck, *e.g.,* 5G [67].

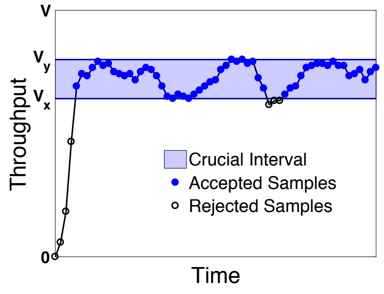
3.1 Crucial Interval Sampling (CIS)

CIS is designed based on the key observation: while noise samples are scattered across a wide throughput interval, the desirable samples tend to concentrate within a narrow interval, referred to as the *crucial interval*. As shown in Figure 3, in each subfigure, although the crucial interval is narrow, it can cover the vast majority of the desirable samples. Thus, while the target distribution $T(x)$ is unknown, we can approximate $T(x)$ with the crucial interval. Also, as more noise samples accumulate, the test accuracy would typically increase as

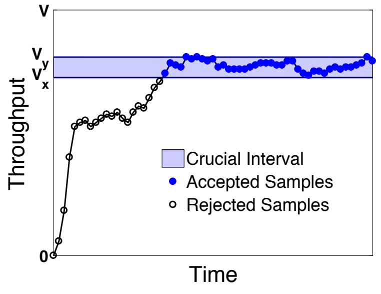
[3]Here "persistently" means that a certain set (or range) of samples constantly recur to the measurement data during the test process [45].



(a) SpeedTest

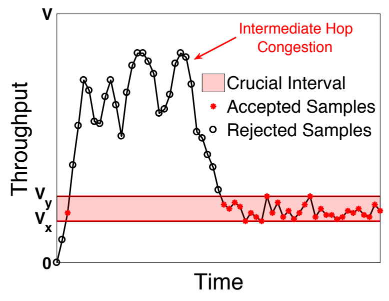


(b) ATTtest, BWP, XFinity, Android API-B

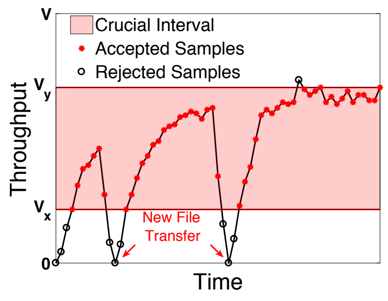


(c) FAST

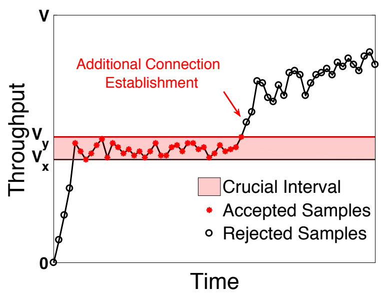
Figure 3: Common scenarios where the true samples fall in a crucial interval. In our measurement, > 96% cases fall into the three patterns.



(a) Slow start effect of sequential file transfer in SpeedOf and TBB



(b) WiFiMaster when an intermediate hop suffers a temporary congestion



(c) SpeedTest when another connection is established to saturate the access link

Figure 4: Pathological scenarios where the true samples are not persistently covered by the crucial interval (less than 4% in our measurements).

randomly scattered noise samples help better "contrast" the crucial interval, leading to its improved approximation.

Crucial Interval Algorithm. Based on the above insights, our designed bandwidth estimation approach for FastBTS aims at finding this crucial interval ($[V_x, V_y]$) that has both *a high sample density* and *a large sample size*. Assuming there are N throughput samples ranging from V_{min} to V_{max}, our aim is formulated as maximizing the *product of density and size*. We denote the size as $K(V_x, V_y)$, *i.e.,* the number of samples that fall into $[V_x, V_y]$. The density can be calculated as the ratio between $K(V_x, V_y)$ and $N' = N(V_y - V_x)/(V_{max} - V_{min})$, where N' is the "baseline" corresponding to the number of samples falling into $[V_x, V_y]$ *if* all N samples are uniformly distributed in $[V_{min}, V_{max}]$. To prevent a pathological case where the density is too high, we enforce a lower bound of the interval: $V_y - V_x$ should be at least L_{min}, which is empirically set to $(V_{max} - V_{min})/(N-1)$. Given the above, the objective function to be maximized is:

$$F(V_x, V_y) = Density \times Size = C \cdot \frac{K^2(V_x, V_y)}{V_y - V_x}, \qquad (1)$$

where $C = (V_{max} - V_{min})/N$ is a constant. Once the optimal $[V_x, V_y]$ is calculated, we can derive the bandwidth estimation by averaging all the samples falling into this interval.

FastBTS computes the crucial interval as bandwidth probing (§3.2) is in progress, which serves as the acceptance-rejection function (ARF) of rejection sampling. When a new sample is available, the server computes a crucial interval by maximizing Equation (1). It thus produces a series of intervals $[V_{x3}, V_{y3}]$, $[V_{x4}, V_{y4}]$, $\cdots$ where $[V_{xi}, V_{yi}]$ corresponds to the interval generated when the i-th sample is available.

Searching Crucial Interval with Convex Hull. We now consider how to actually solve the maximization problem in Equation (1). To enhance the readability, we use L to denote $V_y - V_x$, use K to denote $K(V_x, V_y)$, and let the maximum value of $F(V_x, V_y)$ be F_{max}, which lies in $(0, \frac{C \cdot N^2}{L_{min}}]$.

Clearly, a naïve exhaustive search takes $O(N^2)$ time. Our key result is that this can be done much more efficiently in $O(N \log N)$ by strategically searching on a convex hull dynamically constructed from the samples. Our high-level approach is to perform a binary search for F_{max}. The initial midpoint is set to $\lfloor \frac{C \cdot N^2}{2 \cdot L_{min}} \rfloor$. In each binary search iteration, we examine whether the inequality $\frac{C \cdot K^2}{L} - m \geq 0$ holds for any interval(s), where $0 < m \leq F_{max}$ is the current midpoint. Based on the result, we adjust the midpoint and continue with the next iteration.

We next see how each iteration is performed exactly. Without loss of generality, we assume that the throughput samples are sorted in ascending order. Suppose we choose the i-th and j-th samples ($i < j$) from the N sorted samples as the end-

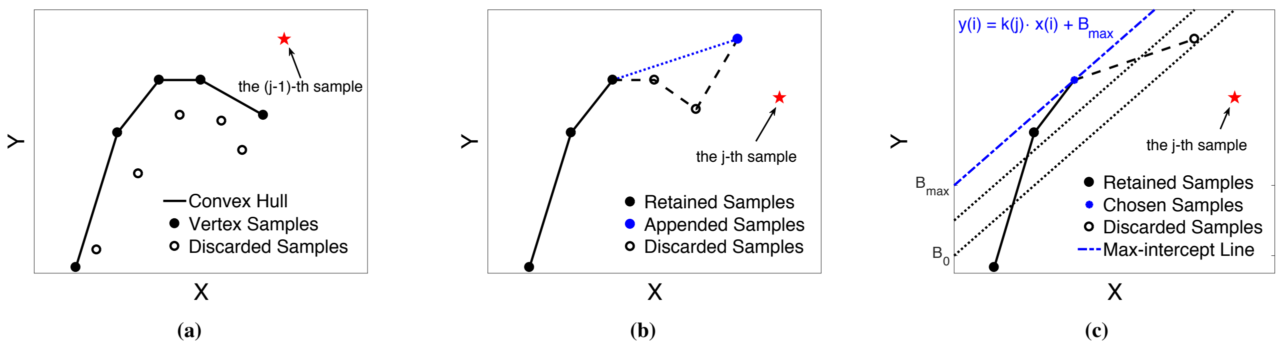


Figure 5: (a) The current convex hull under transformed coordinates, where the axes X and Y correspond to $x(i)$ and $y(i)$ in Equation (4) respectively. (b) Updating the convex hull with the $(j-1)$-th sample. (c) Searching for the max-intercept line.

points of the interval $[V_i, V_j]$. Then the inequality $\frac{C \cdot K^2}{L} - m \geq 0$ can be transformed as:

$$\frac{C \cdot (j-i+1)^2}{V_j - V_i} - m \geq 0. \tag{2}$$

We further rearrange it as:

$$i^2 - 2i + \frac{m}{C}V_i - 2ij \geq \frac{m}{C}V_j - 2j - j^2 - 1. \tag{3}$$

It is not difficult to discover that the right side of the inequality is only associated with the variable j, while the left side just relates to the variable i except the term $-2ij$. Therefore, we adopt the following coordinate conversion:

$$\begin{cases} k(j) = 2j \\ b(j) = \frac{m}{C}V_j - 2j - j^2 - 1 \\ x(i) = i \\ y(i) = i^2 - 2i + \frac{m}{C}V_i \end{cases} \tag{4}$$

With the above-mentioned coordinate conversion, the inequality (3) can be transformed as: $y(i) - k(j) \cdot x(i) \geq b(j)$. Then, determining whether the inequality holds for at least one pair of (i, j) is equivalent to finding the maximum of $f(i) = y(i) - k(j) \cdot x(i)$ for each $1 < j \leq N$.

As depicted in Figure 5a, we regard $\{x(i)\}$ and $\{y(i)\}$ as coordinates of N points on a two-dimensional plane (these points do not depend on j). It can be shown using the linear programming theory that for any given j, the largest value of $f(i)$ always occurs at a point that is on the convex hull formed by $(x(i), y(i))$. This dictates an algorithm where for each $1 < j \leq N$, we check the points on the convex hull to find the maximum of $f(i)$.

Since i must be less than j, each time we increment j (the outer loop), we progressively add one point $(x(j-1), y(j-1))$ to the (partial) convex hull, which is shown in Figure 5b. Then among all existing points on the convex hull, we search backward from the point with the largest $x(i)$ value to the smallest $x(i)$ to find the maximum of $f(i)$, and stops searching when $f(i)$ starts to decrease since the points are on the convex hull (the inner loop).

As demonstrated in Figure 5c, an analytic geometry explanation of this procedure is to determine a line with a fixed slope $y = k(j)x + B$, *s.t.* the line intersects with a point on the convex and the intercept B is maximized, and the maximized intercept corresponds to the maximum of $f(i)$.

Also, once the maximum of $f(i)$ is found at $(x(i'), y(i'))$ for a given j, all points that are to the right of $(x(i'), y(i'))$ can be removed from the convex hull – they must not correspond to the maximum of $f(i)$ for all $j' > j$. This is because (1) the slope of the convex hull's edge decreases as i increases, and (2) $k(j)$ increases as j increases. Therefore, using amortized analysis, we can show that in each binary search iteration, the overall processing time for all points is $O(N)$ as j grows from 1 to N. This leads to an overall complexity of $O(N \log N)$ for the whole algorithm.

Fast Result Generation. FastBTS selects a group of samples that well fit $T(x)$ as soon as possible while ensuring data reliability. Given two intervals $[V_{xi}, V_{yi}]$ and $[V_{xj}, V_{yj}]$, we regard their similarity as the Jaccard Coefficient [60]. FastBTS then keeps track of the similarity values of consecutive interval pairs *i.e.,* $S_{3,4}, S_{4,5}, \ldots$ If the test result stabilizes, the consecutive interval pairs' similarity value will keep growing from a certain value β, satisfying $\beta \leq S_{i,i+1} \leq \cdots \leq S_{i+k,i+k+1} \leq 1$. If the above sequence is observed, FastBTS determines that the result has stabilized and reports the bottleneck bandwidth as the average value of the throughput samples belonging to the most recent interval. The parameters β and k pose a tradeoff between accuracy and cost in terms of test duration and data traffic. Specifically, increasing β and k can yield a higher test accuracy while incurring a longer test duration and more data usage. Currently, we empirically set β=0.9 and k=2, which are found to well balance the tradeoff between the test duration and accuracy. Nevertheless, when dealing with those relatively rare cases that are not covered by this paper, BTS providers are recommended to do pre-tests in order to find the suitable parameter settings before putting CIS mechanism into actual use.

Solutions to Caveats. There do exist some "irregular" bandwidth graphs in prior work [37, 48, 56] where CIS may lose efficacy. For instance, due to in-network mechanisms like data aggregation and multi-path scheduling, the millisecond-level throughput samples can vary dramatically (*i.e.,* sometimes the throughput is about to reach the link capacity, and sometimes the throughput approaches zero). To mitigate this issue, we learn from some BTSes (*e.g.,* SpeedTest) and use a relatively large time interval (50 ms) to smooth the gathered throughput samples. However, even with smoothed samples, it is still possible that CIS may be inaccurate if the actual access bandwidth is outside the crucial interval, or the interval becomes too wide to give a meaningful bandwidth estimation. In our experiences, such cases are rare (less than 4% in our measurements in §2.3). However, to ensure that our tests are stable in all scenarios, we design solutions to those pathological cases.

Figure 4 shows all types of the pathological cases of CIS we observe, where $P(x)$ deviates from $T(x)$ over time. FastBTS leverages three mechanisms to resolve these cases: (1) elastic bandwidth probing (§3.2) reaches bottleneck bandwidth in a short time, effectively alleviating the impact of slow-start effect in Figure 4a; (2) data-driven server selection (§3.3) picks the expected highest-throughput server(s) for bandwidth tests, minimizing the requirement of additional connection(s) in Figure 4c; (3) adaptive multi-homing (§3.4) establishes concurrent connections with different servers, avoiding the underestimations in Figures 4b and 4c. We will discuss these mechanisms in §3.2 – §3.4.

3.2 Elastic Bandwidth Probing (EBP)

In rejection sampling, $P(x)$ determines the boundary of $T(x)$. A bandwidth test measures $P(x)$ using bandwidth probing based on network conditions. It shares a similar principle as congestion control at the test server's transport layer—the goal is to accommodate diverse noises over the live Internet, while saturating the bandwidth of the access link. FastBTS employs BBR [42], an advanced congestion control algorithm, as a starting point for probing design. Specifically, FastBTS uses BBR's built-in bandwidth probing for bootstrapping.

On the other hand, bandwidth tests have different requirements compared with congestion control. For example, congestion control emphasizes stable data transfers over a long period, while a BTS focuses on obtaining accurate link capacity as early as possible with the lowest data usage. Therefore, we modify and optimize BBR to support bandwidth tests.

BBR Prime. BBR is featured by two key metrics: bottleneck bandwidth $BtlBw$ and round-trip propagation time RT_{prop}. It works in four phases: Startup, Drain, ProbeBW (probing the bandwidth), and ProbeRTT. A key parameter *pacing_gain* (PG) controls TCP pacing so that the capacity of a network path can be fully utilized while the queuing delay is minimized. BBR multiplies its measured throughput by PG to determine the data sending rate in the subsequent RTT. After a connection is established, BBR enters the Startup phase and exponentially increases the sending rate (*i.e.,* $PG = \frac{2}{ln2}$) until the measured throughput does not increase further, as shown in Figure 6. At this point, the measured throughput is denoted as B_0 and a queue is already formed at the bottleneck of the network path. Then, BBR tries to Drain it by reducing PG to $\frac{ln2}{2} < 1$ until there is expected to be no excess in-flight data. Afterwards, BBR enters a (by default) 10-second ProbeBW phase to gradually probe $BtlBw$ in a number of cycles, each consisting of 8 RTTs with $PGs = \{\frac{5}{4}, \frac{3}{4}, 1, 1, 1, 1, 1, 1\}$. We plot in Figure 6 four such cycles tagged as ①②③④. Finally (10 seconds later), the *maximum* value of the measured throughput samples is taken as the network path's $BtlBw$ and BBR enters a 200-ms ProbeRTT phase to estimate RT_{prop}.

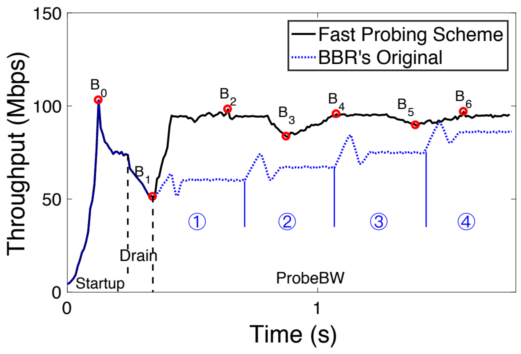

Figure 6: Elastic bandwidth probing vs. BBR's original scheme.

Limitations of BBR. Directly applying BBR's $BtlBw$-based probing method to BTSes is inefficient. First, as illustrated in Figure 6 (where the true $BtlBw$ is 100 Mbps), BBR's $BtlBw$ probing is conservative, making the probing process unnecessarily slow. A straightforward idea is to remove the 6 RTTs with $PG = 1$ in each cycle. Even with that, the probing process is still inefficient when the data (sending) rate is low. Second, when the current data rate (*e.g.,* 95 Mbps) is close to the true $BtlBw$ (*e.g.,* 100 Mbps), using the fixed PG of $\frac{5}{4}$ causes the data rate to far overshoot its limit (*e.g.,* to 118.75 Mbps). This may not be a severe issue for data transfers, but may significantly slow down the convergence of $BtlBw$ and thus lengthen the test duration. Third, BBR takes the maximum of all throughput samples in each cycle as the estimated $BtlBw$. The simple maximization operation is vulnerable to outliers and noises (this is addressed by CIS in §3.1).

Elastic Data-rate Pacing. We design *elastic pacing* to make bandwidth probing faster, more accurate, and more adaptive. Intuitively, when the data rate is low, it ramps up quickly to reduce the probing time; when the data rate approaches the estimated bottleneck bandwidth, it performs fine-grained probing by reducing the step size, towards a smooth convergence. This is in contrast to BBR's static probing policy.

We now detail our method. As depicted in Figure 6, once entering the ProbeBW phase, we have recorded B_0 and B where B_0 is the peak data rate measured during the Startup phase and B is the current data rate. Let the ground-truth bottleneck bandwidth be B_T. Typically, B_0 is slightly higher than B_T due to queuing at the bottleneck link in the end of the Startup phase (otherwise it will not exit Startup); also, B is lower than B_T due to the Drain phase. We adjust the value of B by controlling the *pacing gain* (PG) of the data sending rate, but the pivotal question here is the adjustment policy, *i.e.,* how to make B approach B_T quickly and precisely.

Our idea is inspired by the spring system [51] in physics where the restoring force of a helical spring is proportional to its elongation. We thus regard PG as the restoring force, and B's deviation from B_0 as the elongation (we do not know B_T so we approximate it using B_0). Therefore, the initial PG is expected to grow to:

$$PG_{grow-0} = (PG_m - PG_0) \times \left(1 - \frac{B}{B_0}\right) + PG_0, \quad (5)$$

where $1 - \frac{B}{B_0}$ denotes the normalized distance between B_0 and B, and PG_0 represents the default value (1.0) of PG. We set the upper bound of PG (PG_m) as $\frac{2}{ln2}$ that matches BBR's PG in the (most aggressive) Startup phase. As Equation (5) indicates, the spring system indeed realizes our idea: it increases the data rate rapidly when B is well below B_0, and cautiously reduces the probing step as B grows.

To accommodate a corner scenario where B_0 is lower than B_T ($< 1\%$ cases in our experiments), we slightly modify Equation (5) to allow B to overshoot B_0 marginally:

$$PG_{grow-0} = max\{(PG_m - PG_0') \times \left(1 - \frac{B}{B_0}\right) + PG_0', PG_0'\}, \quad (6)$$

where PG_0' equals $1 + \varepsilon$, with ε being empirically set to 0.05.

When the data rate overshoots the bottleneck bandwidth (*i.e.,* the number of in-flight bytes exceeds the bandwidth-delay product), we reduce the data rate to suppress the excessive in-flight bytes. This is realized by inverting PG to $PG_{drop-0} = \frac{1}{PG_{grow-0}}$. This process continues until no excessive in-flight data is present. At that moment, B will again drop below B_T, so we start a new cycle to repeat the aforementioned data rate growth process.

To put things together, in our design, the ProbeBW phase consists of a series of cycles each consisting of only two stages: *growth* and *drop*. Each stage has a variable number of RTTs, and the six RTTs with $PG = 1$ in the original BBR algorithm are removed. The transitions between the two stages are triggered by the formation and disappearance of excessive in-flight bytes (*i.e.,* the queueing delay). In the i-th cycle, the PGs for the two stages are:

$$\begin{cases} PG_{grow-i} = max\{(PG_m - PG_0') \times \left(1 - \frac{B}{B_i}\right) + PG_0', PG_0'\}, \\ PG_{drop-i} = \frac{1}{PG_{grow-i}}, \end{cases} \quad (7)$$

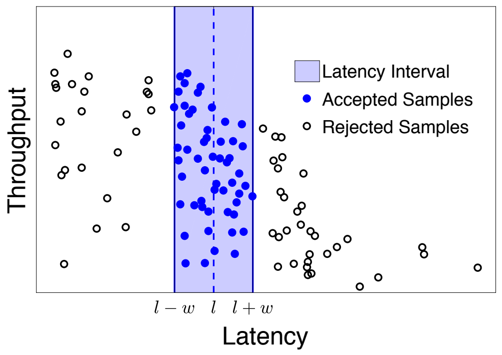

Figure 7: Data-driven server selection that takes both historical latency and throughput information into account.

where B is the data rate at the beginning of a growth stage, and B_i is the peak rate in the previous cycle's growth stage. Interestingly, by setting $B_0 = +\infty$, we can make the growth and drop stages identical to BBR's Startup and Drain phases, respectively. Our final design thus only consists of a single phase (ProbeBW) with two stages. The ProbeRTT phase is removed because it does not help our bandwidth probing.

Compared with traditional bandwidth probing mechanisms, EBP can saturate available bandwidth more quickly as it ramps up the sending rate when the current rate is much lower than the estimated bandwidth. Meanwhile, when the sending rate is about to reach the estimated bandwidth, EBP carefully increases the rate in order to be less aggressive to other flows along the path than other bandwidth probing mechanisms.

3.3 Data-driven Server Selection (DSS)

FastBTS includes a new server selection method. We find that selecting the test server(s) with the lowest PING latency, widely used in existing BTSes, is ineffective. Our measurement shows that latency and the available bandwidth are not highly correlated—the servers yielding the highest throughput may not always be those with the lowest PING latency.

FastBTS takes a *data-driven approach* for server selection (DSS): each test server maintains a database (model) containing {latency, throughput} pairs obtained from the setup and bandwidth probing phases of past tests. Then in a new setup phase, the client still PINGs the test servers, while each server returns an expected throughput value based on the PING latency by looking up the database. The client will then rank the selected server(s) based on their expected throughput values.

As demonstrated in Figure 7, the actual DSS algorithm is conceptually similar to CIS introduced in §3.1, whereas we empirically observe that only considering the density can yield decent results. Specifically, given a latency measurement l, the server searches for a width w that maximizes the density defined as $K(l,w)/2w$, where $K(l,w)$ denotes the number of latency samples falling in the latency interval $[l-w, l+w]$. The expected throughput is calculated as an average of all samples in $[l-w, l+w]$. In addition, the server also returns the maximum throughput (using the 99-percentile value) belonging to $[l-w, l+w]$ to the client. Both values will be used in the bandwidth probing phase (§3.4). During bootstrapping when servers have not yet accumulated enough samples, the client can fallback to the traditional latency-based selection strategy. To keep their databases up-to-date, servers can maintain only most recent samples.

3.4 Adaptive Multi-Homing (AMH)

For high-speed access networks like 5G, the last-mile access link may not always be the bottleneck. To saturate the access link, we design an adaptive multi-homing (AMH) mechanism to dynamically adjust the concurrency level, *i.e.,* the number of concurrent connections between the servers and client.

AMH starts with a single connection to cope with possibly low-speed access links. For this single connection C_1, when CIS (§3.1) has accomplished using the server S_1 (the highest-ranking server, see §3.3), the reported bottleneck bandwidth is denoted as BW_1. At this time, the client establishes another connection C_2 with the second highest-ranking server S_2 while retaining C_1. C_2 also works as described in §3.2. Note we require S_1 and S_2 to be in different ASes to minimize the likelihood that S_1 and S_2 share the same Internet-side bottleneck. Moreover, we pick the server with the second highest bandwidth estimation as S_2 to saturate the client's access link bandwidth with the fewest test servers. After that, we view C_1 and C_2 together as an "aggregated" connection, with its throughput being $BW_2 = BW_{2,1} + BW_{2,2}$, where $BW_{2,1}$ and $BW_{2,2}$ are the real-time throughput of C_1 and C_2 respectively.

By monitoring $BW_{2,1}$, $BW_{2,2}$, and BW_2, FastBTS applies intelligent throughput sampling and fast result generation (§3.1) to judge whether BW_2 has become stable. Once BW_2 stabilizes, AMH determines whether the whole bandwidth test process should be terminated based on the relationship between BW_1 and $BW_{2,1}$. If for C_1 the bottleneck link is not the access link, $BW_{2,1}$ should have a value similar to or higher than BW_1 (assuming the unlikeliness of C_1 and C_2 sharing the same Internet-side bottleneck [53]). In this case, the client establishes another connection with the third highest-ranking server S_3 (with a different AS), and repeats the above process (comparing $BW_{3,1}$ and BW_1 to decide whether to launch the fourth connection, and so on). Otherwise, if $BW_{2,1}$ exhibits a noticeable decline (empirically set to $> 5\%$) compared to BW_1, we regard that C_1 and C_2 saturate the access link and incur cross-flow contention. In this case, the client stops probing and reports the access bandwidth as $max(BW_1, BW_2)$.

4 Implementation

As shown in Figure 1, we implement *elastic bandwidth probing* (EBP) and *crucial interval sampling* (CIS) on the server side, because EBP works at the transport layer and thus requires OS kernel modifications, and CIS needs to get fine-grained throughput samples from EBP in real time. We implement EBP and CIS in C and Node.js, respectively.

We implement *data-driven server selection* (DSS) and *adaptive multi-homing* (AMH) on the client side. End users can access the FastBTS service through REST APIs. We implement DSS and AMH in JavaScript to make them easy to integrate with web pages or mobile apps.

The test server is built on CentOS 7.6 with the Linux kernel version of 5.0.1. As mentioned in §3.2, we develop EBP by using BBR as the starting point. Specifically, we implement the calculation of *pacing_gain* according to Equation (7) by modifying the `bbr_update_bw` function; we also modify `bbr_set_state` and `bbr_check_drain` to alter BBR's original cycles in the ProbeBW phase, so as to realize EBP's two-stage cycles. EBP is implemented as a loadable kernel module. CIS is a user-space program. To efficiently send in-situ performance statistics including throughput samples, *Btlbw*, and RT_{prop} from EBP to CIS (both EBP and CIS are implemented on the server side in C and Node.js), we use the Linux Netlink Interface in `netlink.h` to add a raw socket and a new packet structure `bbr_info` that carries the above performance information. The performance statistics are also sent to the client by piggybacking with probing traffic, allowing users to examine the real-time bandwidth test progress.

5 Evaluation

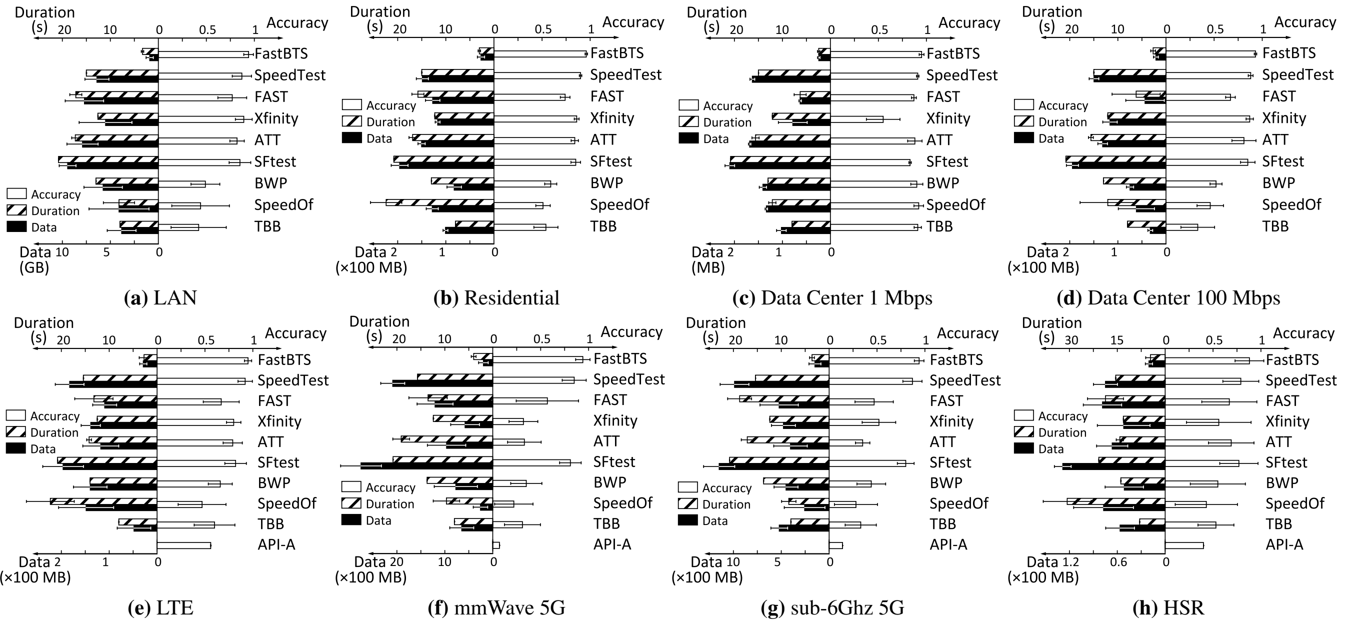
5.1 Experiment Setup

We compare FastBTS with the 9 state-of-the-art BTSes studied in §2. For fair comparisons, we re-implement all the BTSes based on our reverse engineering efforts and use the same setup for all these re-implemented BTSes. To do so, we built the following testbeds.

Large-scale Testbed. We deploy a total of 30 test servers on 30 VMs across the globe (North America, South America, Asia, Europe, Australia, and Africa) with the same configurations (dual-core Intel CPU@2.5 GHz, 8-GB DDR memory, and 1.5+ Gbps outgoing bandwidth). The size of the server pool (30) is on par with 5 out of the 9 BTSes but is smaller than those of FAST and SpeedTest (Table 2), which we assume is a representative server pool size adopted by today's commercial BTSes. We deploy 100+ clients including 3 PCs, 4 smartphones, and 108 VMs (the same as those adopted in §2). For a fair comparison with FastBTS, we replicate the 9 other popular BTSes: SpeedOf, BWP, SFtest, ATTtest, Xfinity, FAST, SpeedTest, TBB, and Android API-A (see §2.3) and deploy them on the 30 test servers and the 100+ clients. We deploy API-A (Android specific) on 4 phones.

Tested Networks. We conduct extensive evaluations under heterogeneous networks. We detail their setups below.

- *Residential Broadband.* We deploy three PCs located in China, U.S., and Germany (Table 1). All the PCs' access links are 100 Mbps residential broadband. The three clients



(a) LAN **(b)** Residential **(c)** Data Center 1 Mbps **(d)** Data Center 100 Mbps

(e) LTE **(f)** mmWave 5G **(g)** sub-6Ghz 5G **(h)** HSR

Figure 8: Duration and test accuracy of FastBTS, compared with 9 BTSes under various networks. "API-A" refers to Android API-A (§2.4).

communicate with (a subset of) the aforementioned 30 test servers to perform bandwidth tests. We perform in one day 90 groups of tests, consisting of 3 clients $\times$ 3 different time-of-day (0:00, 8:00, and 16:00) $\times$ 10 repetitions.

- *Data Center Networks.* We deploy 108 VMs belonging to different commercial cloud providers as the clients (§2.3). We perform a total number of 108 VMs $\times$ 3 time-of-day $\times$ 10 repetitions = 3,240 groups of tests.
- *mmWave 5G* experiments were conducted at a downtown street in a large U.S. city, with a distance from the phone (Samsung GS10, see Table 1) to the base station of 30m. This is a typical 5G usage scenario due to the small coverage of 5G base stations. The phone typically has line-of-sight to the base station unless being blocked by passing vehicles. The typical downlink throughput is between 0.9 and 1.2 Gbps. We perform in one day 120 groups of tests, consisting of 4 clients $\times$ 3 time-of-day $\times$ 10 repetitions.
- *Sub-6Ghz 5G* experiments were conducted in a Chinese city using an HV30 phone over China Mobile. The setup is similar to that of mmWave. We run 120 groups of tests.
- *LTE* experiments were conducted in both China (a university campus) and U.S. (a large city's downtown area) using XM8 and GS9, respectively, each with 120 groups of tests.
- *HSR Cellular Access.* We also perform tests on high-speed rail (HSR) trains. We take the Beijing-Shanghai HSR line (peak speed of 350 km/h) with two HV30 phones. We measure the LTE bandwidth from the train. We run 2 clients $\times$ 50 repetitions = 100 groups of tests.
- *LAN.* Besides the deployment of 30 VMs, we also create an in-lab LAN testbed to perform controlled experiments, where we can craft background traffic. The testbed consists of two test servers (S_1, S_2) and two clients (C_1, C_2), each equipping a 10 Gbps NIC. They are connected by a commodity switch with a 5 Gbps forwarding capability, thus being the bottleneck. When running bandwidth tests on this testbed, we maintain two parallel flows: one 1 Gbps background flow between S_1 and C_1, and a bandwidth test flow between S_2 and C_2.

We use the three metrics described in §2.1 to assess BTSes: test duration, data usage, and accuracy. Also, the methodology for obtaining the ground truth is described in §2.1.

5.2 End-to-End Performance

LAN and Residential Networks. As shown in Figure 8a and 8b, FastBTS yields the highest accuracy (0.94 for LAN and 0.96 for residential network) among the 9 BTSes, whose accuracy lies within 0.44–0.89 for LAN, and 0.51–0.9 for residential network. The average test duration of FastBTS for LAN and residential network is 3.4 and 3.0 seconds respectively, which are 2.4–7.4$\times$ shorter than the other BTSes. The average data usage of FastBTS is 0.9 GB for LAN and 27 MB for residential network, which are 3.1–10.5$\times$ less than the other BTSes. The short test duration and small data usage are attributed to EBP (§3.2), which allows a rapid data rate increase when the current data rate is far lower than the bottleneck bandwidth, as well as fast result generation, which strategically trades off accuracy for a shorter test duration.

Data Center Networks. Figure 8c and 8d show the performance of different BTSes in CSPs' data center networks with the bandwidth of $\{1, 100\}$ Mbps (per the CSPs' service agreements). FastBTS outperforms the other BTSes by yielding the highest accuracy (0.94 on average), the shortest test duration (2.67 seconds on average), and the smallest data usage (21 MB on average for 100-Mbps network). In contrast, the other BTSes' accuracy ranges between 0.46 and 0.91; their test duration is also much longer, from 6.2 to 20.8 seconds, and they consume much more data (from 44 to 194 MB) compared to FastBTS. In particular, we find that on low-speed network (1 Mbps), some BTSes such as Xfinity and SFtest establish too many parallel connections. This leads to poor performance due to the excessive contention across the connections. FastBTS addresses this issue through AMH (§3.4) that adaptively adjusts the concurrency level according to the network condition. The results of networks with 10 Mbps bandwidth are similar to those of 100 Mbps networks.

LTE and 5G Networks. We evaluate the BTSes' performance on commercial LTE and 5G networks (both mmWave and sub-6Ghz for 5G). Over LTE, as plotted in Figure 8e, FastBTS owns the highest accuracy (0.95 on average), the smallest data usage (28.23 MB on average), and the shortest test duration (2.73 seconds on average). The other 9 BTSes are far less efficient: 0.62–0.92 for average accuracy, 41.8 to 179.3 MB for data usage, and 7.1 to 20.8 seconds for test duration. For instance, we discover that FAST bears a quite low accuracy (0.67) because its window-based mechanism is very vulnerable to throughput fluctuations in LTE. SpeedTest, despite having a decent accuracy (0.92), incurs quite high data usage (166.3 MB) since it fixes the bandwidth test duration to 15 seconds regardless of the stability of the network.

Figure 8f shows the results for mmWave 5G. It is also encouraging to see that FastBTS outperforms the 9 other BTSes across all three metrics (0.94 vs. 0.07–0.87 for average accuracy, 194.7 vs. 101–2,749 MB for data usage, and 4.0 vs. 8.9–26.2 seconds for test duration). Most of the BTSes have low accuracy (< 0.6); Speedtest and SFtest bear relatively high accuracy (0.81 and 0.85). However, the high data usage issue due to their flooding nature is drastically amplified in mmWave 5G. For example, Speedtest incurs very high data usage—up to 2,087 MB per test. The data usage for FAST is even as high as 2.75 GB. FastBTS addresses this issue through the synergy of its key features for fuzzy rejection sampling such as EBP and CIS. We observe similar results in the sub-6Ghz 5G experiments as shown in Figure 8g.

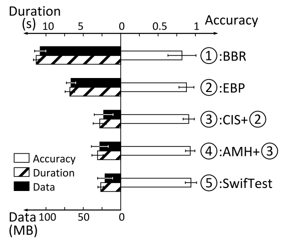
HSR Cellular Access. We also benchmark the BTSes on an HSR train running at a peak speed of 350km/h from Beijing to Shanghai. As shown in Figure 8h, the accuracy of all 10 BTSes decreases. This is attributed to two reasons. First, on HSR trains, the LTE bandwidth is highly fluctuating because of, *e.g.,* frequent handovers caused by high mobility and the contention traffic from other passengers. Second, given such fluctuations, performing bulk transfer before and after a bandwidth test can hardly capture the ground truth bandwidth, which varies significantly during the test. Nevertheless, compared to the other 9 BTSes, FastBTS still achieves the best performance (0.88 vs. 0.26–0.84 for average accuracy, 20.3 vs. 16–155 MB for data usage, and 4.6 vs. 10.6–32.4 seconds for test duration). The test duration is longer than the stationary scenarios because under high mobility, network condition fluctuation makes crucial intervals converge slower.

5.3 Individual Components

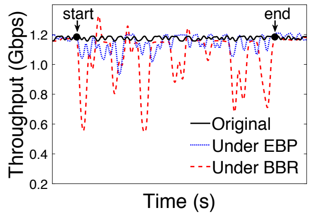
We evaluate the benefits of each component of FastBTS by incrementally enabling one at a time. When EBP is not enabled, we use BBR. When CIS is not enabled, we average the throughput samples to calculate the test result. When DSS is not enabled, test server(s) are selected based on PING latency. When AMH is not enabled, we apply SpeedTest's (single-homing) connection management logic.

Bandwidth Probing Schemes. We compare BBR-based FastBTS and SpeedTest under mmWave 5G. The average data usage of BBR per test (735 MB) is 65% less than that of our replicated SpeedTest (2,087 MB). Meanwhile, the accuracy of BBR slightly reduces from 0.85 to 0.81. The results indicate that BBR's *BtlBw* estimation mechanism better balances the tradeoff between accuracy and data usage compared to flooding-based methods. We next compare BBR and EBP. We find that our EBP brings further improvements over BBR: under mmWave, EBP achieves an average data usage of 419 MB (compared 735 MB in BBR, a 42% reduction) and an average accuracy of 0.87 (compared to 0.81 in BBR, a 7% improvement). The advantages of EBP come from its elastic PG setting mechanism that is critical for adaptive bandwidth probing. Next, we compare BBR and EBP under data center networks. As shown in Figure 9a, compared to BBR, EBP reduces the average test duration by 40% (from 11.3 to 6.6 seconds) and the data usage by 38% (from 107 to 66 MB), while improving the average accuracy by 6%.

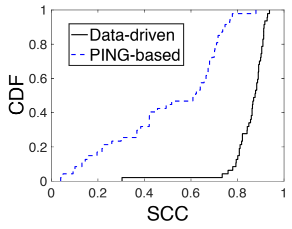
Probing Intrusiveness. We evaluate the probing intrusiveness of vanilla BBR and EBP using the LAN testbed (§5.1). Recall that we simultaneously run a 1 Gbps background flow and the bandwidth test flow that shares a 5 Gbps bottleneck at the switch. Ideally, a BTS should measure the bottleneck bandwidth to be 4 Gbps without interfering with the background flow, whose average/stdev throughput is thus used as a metric to assess the intrusiveness of BBR and EBP. Our test procedure is as follows. We first run the background flow alone for 1 minute and measure its throughput as R_{Origin}= 1 Gbps. We then run BBR and EBP with the background flow and measure the average (standard deviation) of the background flow throughput as R_{BBR} (S_{BBR}) and R_{EBP} (S_{EBP}), respectively, during the test. We demonstrate the three groups' throughput samples with their timestamps normalized by BBR's test duration in Figure 9b. EBP incurs a much smaller impact on the background flow compared to BBR, with R_{EBP} and R_{BBR} measured to be 0.97 Gbps and 0.90 Gbps, respectively.



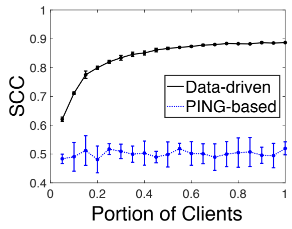
(a)



(b)



(c)



(d)

Figure 9: (a) Impact of individual modules of FastBTS in 100-Mbps data center networks. (b) Comparing intrusiveness between EBP and BBR. (c) Distributions of SCC_{gp} (PING-based) and SCC_{gd} (Data-driven) when P=20%; (d) P (portion of clients) vs. SCC_{gp} and SCC_{gd}.

Also, under EBP, the background flow's throughput variation is lower than under BBR: S_{EBP}/R_{EBP} and S_{BBR}/R_{BBR} are calculated to be 0.03 and 0.15, respectively. This suggests that when probing the bandwidth, EBP is less intrusive than BBR. We repeat the above test procedure under other settings, with the background flow's bandwidth varying from 0.5 to 4 Gbps, and observe consistent results. The lower intrusiveness of EBP compared with vanilla BBR probably lies in that when the sending rate is about to hit the access link bandwidth, EBP tends to carefully reclaim the available bandwidth; however, vanilla BBR still increases the sending rate with a fixed step, which is more aggressive than EBP in this scenario.

Crucial Interval Sampling (CIS). We further enable CIS. As shown in Figure 9a, by strategically removing outliers, CIS increases the average accuracy from 0.87 (EBP only) to 0.91. Due to the fast result generation mechanism, the test duration is reduced from 6.8 seconds to 2.8 seconds and the data usage is reduced by 2.8× (compared with EBP only).

We next compare CIS with the sampling approaches used by the other 9 BTSes (§5.1), which use a total of five bandwidth sampling algorithms because SFtest, ATTtest, and Xfinity employ the same trivial approach of simply averaging the throughput samples. To fairly compare them with CIS, we take a replay-based approach. Specifically, we select one "template" BTS from which we collect the network traces during the bandwidth probing phase; the time series of the aggregated throughput across all connections is then obtained from the traces and fed to all the sampling algorithms. We exclude SpeedOf and BWP from this experiment because they calculate the bandwidth based on the last or fastest connection that cannot be precisely reconstructed by our replay approach. We next show the results by using SpeedTest as the template BTS. The simplest algorithm (averaging) bears the lowest accuracy (0.81) because it is poor at eliminating the noises caused by, for example, TCP congestion control; the accuracy values of FAST, and SpeedTest are 0.82 and 0.84, respectively. In contrast, CIS owns the highest accuracy (0.91). This confirms the effectiveness of CIS's sampling approach. The efficiency and effectiveness of CIS lies in that, instead of incurring much redundancy in test duration and data usage to achieve a decent test accuracy, CIS keeps calculating the crucial interval of the gathered throughput samples. Once the crucial interval stabilizes, CIS immediately stops the test, thus significantly saving test duration and data usage.

Adaptive Multi-Homing (AMH). When AMH is further enabled, the test accuracy increases from 0.91 (EBP+CIS) to 0.93 (EBP+CIS+AMH), as shown in Figure 9a. Meanwhile, since testing over more connections takes additional time, AMH slightly lengthens the average test duration from 2.8 to 3.1 seconds, with the average data usage increased from 23 MB to 28 MB. We repeat the above experiments over mmWave 5G networks where the bottleneck is more likely to shift to the Internet side. The results show that AMH improves the average accuracy from 0.84 to 0.91, while incurring moderate overhead by increasing the average data usage from 148 MB to 206 MB and the average test duration from 3.3 to 4.1 seconds. The results suggest that AMH is essential for high-speed networks such as mmWave 5G.

Data-driven Server Selection (DSS). We employ *cross-validation* for a fair comparison between the PING-based method and DSS in three steps: (1) We do file transfers between every server and a randomly selected portion (P) of all clients to gather throughput samples. (2) Each client C runs a bandwidth test towards every server. In each test, the clients' historical test records (excluding the record of C) gathered in the previous step is utilized by each server to calculate the expected bandwidth, which is then returned to C. (3) Each client calculates three rankings of the servers based on the server-returned expected bandwidth: $Rank_g$, $Rank_p$, and $Rank_d$. $Rank_g$ refers to the server ranking based on the ground truth. $Rank_p$ is the ranking calculated based on PING latency; and $Rank_d$ is the ranking computed by DSS. We use the *Spearman Correlation Coefficient* (SCC [59]) to calculate the similarity SCC_{gp} between $Rank_g$ and $Rank_p$, as well as the similarity SCC_{gd} between $Rank_g$ and $Rank_d$.

The distributions of SCC_{gp} and SCC_{gd} when $P = 20\%$ are shown in Figure 9c. We find that SCC_{gd} is much higher than SCC_{gp} in terms of the median (0.81 *vs.* 0.63), average (0.80 *vs.* 0.50), and maximum (0.93 *vs.* 0.88) values. Further, Figure 9d shows that SCC_{gd} drops as P decreases; however, even when P decreases to 5%, SCC_{gd} (0.62) is still 24% larger than SCC_{gp} (0.5). These results show that even with limited historical data, DSS works reasonably well. We enable DSS in our experiments of Figure 9a with $P = 20\%$. Compared to EBP+CIS+AMH, enabling DSS improves the average accuracy from 0.93 to 0.94; the test duration slightly reduces.

Overall Runtime Overhead. The client-side overhead of FastBTS is negligible based on our measurement on Samsung Galaxy S9, S10, Xiaomi M8, and Huawei Honor V30. On the server side, the incurred overhead is also low. When *Btlbw* is 100 Mbps, the CPU overhead is measured to be lower than 5% (single core, tested on Intel CPU@2.5 GHz, 8-GB memory). The CPU overhead is only 12% when *Btlbw* is 5 Gbps.

6 Related Work

Bandwidth Measurement. Bandwidth measurement is an essential component for many networked systems that empower many important applications and use cases [46, 61, 62, 75]. Apart from the BTSes described in §2, other bandwidth measurement methods mostly target specific types of networks (*e.g.,* datacenter [44], LTE [56, 71], and wireless [74, 77]) and require special support from the deployed infrastructure. For example, AuTO [44] conducts bandwidth estimation over DCTCP in data centers; it needs switch support to tag ECN marks on the data packets, and thus is challenging to be applied in WAN. Huang et al. [56] propose to deploy monitors inside the cellular core network for bandwidth measurement. Dischinger et al. [47] devise a bandwidth measurement tool which concurrently leverages multiple packet trains with different sending rates to measure the link bandwidth of residential broadband network.

While almost all commercial BTSes employ flooding-based methods to combat measurement noises, there exists quite a few non-flooding methods [55, 65, 68, 70] in academia, which indirectly infer the available bandwidth based on timing information of crafted packets (including packet pairs and packet trains). Unfortunately, these methods are highly sensitive to timing information, and thus can be easily disrupted by many factors like packet loss [54, 64], queueing [54], and data/ACK aggregation [64], especially in high-speed networks.

Designed as a generic network service for Internet users, FastBTS differs from and complements the above work. FastBTS targets at conducting fast and light bandwidth tests especially for high-speed wide-area networks (*e.g.,* 5G), significantly reducing data usage and test duration for clients. It does not require any hardware support at the client side. On the server side, we show that FastBTS requires a much smaller deployment to achieve the same level of effectiveness of existing large-scale commercial BTSes (*e.g.,* SpeedTest).

Congestion Control. FastBTS's elastic bandwidth probing is inspired by congestion control algorithms [63, 66, 79]. We categorize congestion control algorithms based on the congestion indicators: (1) *Loss-based CCs* (*e.g.,* BIC-TCP [76] and CUBIC [52]) which take packet loss as the indicator. They are vulnerable to bufferbloat and random losses [34]. (2) *Delay-based CCs* (*e.g.,* TCP FAST [58] and TCP Vegas [40]) which take transmission delay as the indicator. They are known to under-utilize the available bandwidth as the Internet latency is inherently noisy and fluctuating. (3) *Rate-based CCs* (*e.g.,* BBR [42], PCC [48] and PCC Vivace [49]) which directly estimate the available bandwidth and accordingly adjust data sending rate, typically via a feedback loop. We choose to design elastic bandwidth probing based on BBR, because BBR is mature with large-scale deployment on WAN [18], edge [27, 57], and cellular networks [35].

7 Concluding Remarks

We present FastBTS, a novel bandwidth testing system, to make bandwidth testing fast and light as well as accurate. By accommodating and exploiting the test noises, FastBTS achieves the highest level of accuracy among commercial BTSes, while significantly reducing data usage and test duration. Further, FastBTS only employs 30 servers, 2–3 orders of magnitude fewer than the state of the arts.

Despite the above merits, FastBTS still bears several limitations at the moment. First, when testing a client's uplink bandwidth, FastBTS requires extra deployment efforts (in particular a kernel module of EBP, as demonstrated in Figure 1) at the client side. Second, the performance of the data-driven server selection (DSS) mechanism can be affected by its cold start phase as well as the specific deployment of test servers. Third, when the selected test servers cannot saturate the client's downlink bandwidth, the adaptive multi-homing (AMH) mechanism may need several rounds to make the bandwidth probing process converge, thus leading to a relatively long test duration. We have been exploring practical ways to overcome these limitations.

Abstract

Sketch algorithms have been extensively studied in the area of network measurement, given their limited resource usage and theoretically bounded errors. However, error bounds provided by existing algorithms remain too coarse-grained: in practice, only a small number of flows (e.g., heavy hitters) actually benefit from the bounds, while the remaining flows still suffer from serious errors. In this paper, we aim to design a nearly-zero-error sketch that achieves negligible per-flow error for almost all flows. We base our study on a technique named compressive sensing. We exploit compressive sensing in two aspects. First, we incorporate the near-perfect recovery of compressive sensing to boost sketch accuracy. Second, we leverage compressive sensing as a novel and uniform methodology to analyze various design choices of sketch algorithms. Guided by the analysis, we propose two sketch algorithms that seamlessly embrace compressive sensing to reach nearly zero errors. We implement our algorithms in OpenVSwitch and P4. Experimental results show that the two algorithms incur less than 0.1% per-flow error for more than 99.72% flows, while preserving the resource efficiency of sketch algorithms. The efficiency demonstrates the power of our new methodology for sketch analysis and design.

1 Introduction

Sketch algorithms have been widely adopted in flow-level monitoring. They maintain compact data structures that sacrifice a small portion of accuracy to be readily deployable in commodity network devices. Given their limited overheads and provable high accuracy, numerous sketch algorithms are designed to monitor various flow statistics, such as per-flow counting [49], heavy hitters [19, 25], denial-of-service victims [26,84] and traffic distributions [46]. These flow statistics form essential building blocks for network management.

Despite the sound theoretical bounds on the errors, existing sketch algorithms remain far from perfect for providing comprehensive guarantees for all flows. Ideally, it is expected to monitor *every* flow with *minimum* errors, which empowers various fine-grained network management operations such as responsive diagnosis [17, 51, 67] and precise failure localization [3, 50]. However, the bounds in existing algorithms are designed for specific traffic statistics such as heavy hitters or flow distributions. They are too coarse-grained when applied to all flows. As a result, *only a small portion of flows actually benefit from the provable error bounds*. For instance, for byte counting, many sketch algorithms guarantee an upper bound of per-flow error. Heavy hitters whose size is much larger than the bound can certainly achieve high accuracy as the maximum possible error is limited compared to their size. Nonetheless, such a bound is still unacceptable for most small flows that still suffer from poor accuracy.

In this paper, our goal is to explore nearly-zero-error (NZE) per-flow monitoring. We aim to achieve a negligibly small error (e.g., >99.99% flows are reported, and the estimated size of any reported flow has a <0.1% relative error compared to the true size). We base our study on a signal processing technique named *compressive sensing*. Our key insight is that: (1) compressive sensing provides near-perfect signal recovery with limited resources, which inspires us to apply it to flow monitoring; (2) compressive sensing is built on various matrix properties such as sparsity, which provides a powerful tool to study sketch algorithms, given that most sketch algorithms exhibit the same mathematical form as compressive sensing [21]. Even though some telemetry solutions also adopt compressive sensing [7, 16, 21, 35, 44, 83], our work addresses the design of NZE sketch, which is never studied.

In particular, we exploit compressive sensing in two lines. In the *first line*, we incorporate the near-perfect recovery technique of compressive sensing by regarding flow statistics as signals. However, our preliminary experiments show that it is non-trivial to adopt compressive sensing directly. This motivates the *second line* of our work that examines the suitability of compressive sensing for sketch algorithms and then designs new algorithms accordingly. Specifically, we leverage compressive sensing to propose a novel and uniform methodology to study sketch techniques: we formulate various sketch algorithms in forms of matrices and then quantitatively analyze their suitability to compressive sensing. Thus, instead of designing from scratch, we use the analysis results as a guideline for the algorithm design.

In summary, we not only propose new algorithms but also provide a new methodology to study sketch techniques from a perspective of compressive sensing. We make the following contributions:

- We investigate the feasibility of applying compressive sensing to flow monitoring. We evaluate two simple methods and show that simple utilization either suffers from poor scalability or fails to reach the expected accuracy level.
- We dissect existing sketch algorithms based on compres-

sive sensing theory. We formulate each sketch algorithm by inducing a matrix for it. We examine a fundamental matrix property namely *orthonormality* that ensures the correctness of compressive sensing. We find that induced matrices of existing algorithms fail to be orthonormal.

- We study the common approaches to build sketch algorithms from a perspective of matrix analysis. We analyze the impact of these approaches on the orthonormality of their induced matrices. We reveal the limitations of existing algorithms when combining with compressive sensing.
- We design two new algorithms that efficiently utilize the common approaches to embrace compressive sensing seamlessly. The two algorithms target suitability to compressive sensing to achieve nearly-zero errors, while prior algorithms provide only coarse-grained error bounds. Further, their design choices can be interpreted by matrix analysis, while existing algorithms are built on statistical analysis or empirical observations on hash conflicts. To our best knowledge, both the two aspects are never explored before.
- We implement our proposed algorithms atop both OpenVSwitch [62] and P4 [63]. Our evaluation results demonstrate that our algorithms achieve less than 0.1% relative error for more than 99.72% flows, while incurring zero false negatives and zero false positives, while consuming limited resources compared to state-of-the-art algorithms. We release our source code at **`https://github.com/N2-Sys/NZE-Sketch`**.

2 Problem

2.1 Sketch-based Flow Monitoring

We follow the line of approximate flow-level measurement [4, 35, 37, 49, 53, 54, 80, 82]. Flow-level monitoring defines a flow as a sequence of packets with the same *flow ID*, and computes its *flow values* based on the packet sequence. We focus on sketch algorithms that outperform sampling in accuracy [49] and hence have been extensively used in flow monitoring. A sketch algorithm records information of *every* packet in a *compact* data structure, so as to achieve high accuracy yet be readily deployed in commodity measurement points.

In a nutshell, a sketch algorithm comprises a collection of counters. It supports two operations: *update* and *query*. The update operation is performed in the data plane. For each packet, it selects several counters with hash functions and updates the selected counters to reflect the changes of flow values. The query operation is invoked by the control plane. The control plane periodically collects sketch structures from each measurement point, and performs the query operation to extract flow IDs and flow values from the structure.

Sketch algorithms allow a small but bounded accuracy drop to reduce resource overheads. Specifically, in a sketch algorithm, a counter is typically shared by multiple flows, which inevitably incurs some errors due to flow conflicts. Each sketch algorithm mitigates the errors with its specific algorithmic design. Backed by sound mathematical analysis, sketch algorithms usually provide theoretical bounds on the errors.

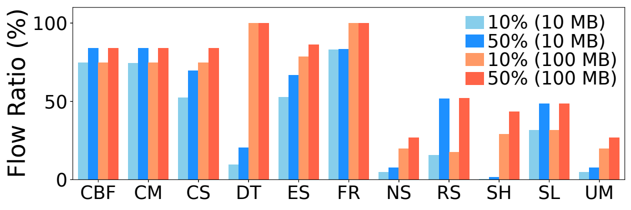

Figure 1: Fractions of flows that reach <10% and <50% per-flow errors in existing sketch algorithms.

2.2 Limitation

However, the theoretical guarantees provisioned by existing sketch algorithms are limited. Existing algorithms are typically designed to provide guarantees for specific flows (e.g., heavy hitters [8, 19, 25, 68] or super-spreaders [84]) and/or aggregated flow statistics (e.g., cardinality [28] or traffic distribution [46]). With regard to the specific scope, it is sufficient for a sketch algorithm to mitigate the overall hash conflicts only because bounding per-flow error is not a primary goal. Nonetheless, when extending an algorithm to the entire network traffic, the derived bounds are too coarse-grained to work for all flows. This leads to a considerable gap between theoretical analysis and practical results: only a small portion of flows actually benefit from the theoretical bounds, while the remaining flows still exhibit poor accuracy.

We consider an example of CountMin [20] to illustrate it. A CountMin sketch consists of r rows, each of which has w counters. When applying it to count per-flow bytes, it guarantees that the per-flow counting error is at most $\frac{2U}{w}$ with a high probability $1-\frac{1}{2^r}$, where U is the total byte count of all flows. Now we consider an interval with U =10 GB traffic, and configure $w = 10^5$ and a sufficiently large r such that the probability $1-\frac{1}{2^r}$ is close to one. In this case, the error bound is around 210 KB. For extremely large flows, such a bound guarantees a small error (e.g., <2% relative error for a flow of 10 MB). However, the error is awfully huge for small flows whose byte counts are below the bound. Given the heavy-tailed traffic distribution, most flows are small. Thus, most flows suffer from low accuracy due to the loose bound.

We justify this observation via trace-driven experiments. We consider 11 sketch algorithms for per-flow packet counting: Counting Bloom Filter (CBF) [27], CountMin (CM) [20], CountSketch (CS) [15], Deltoid (DT) [19], ElasticSketch (ES) [80], FlowRadar (FR) [49], NitroSketch (NS) [53], RevSketch (RS) [68], SeqHash (SH) [8], SketchLearn (SL) [37], and UnivMon (UM) [54]. We use Caida [9] traces and partition our traces in two 2-second intervals where each interval contains 100 K flows. We employ two configurations for each algorithm: one with 10 MB memory that is around the maximum available memory in commodity switches [43, 56], and the other with 100 MB that indicates an ideal scenario that has plenty of memory resources. We set parameters as suggested in the original papers. Figure 1 presents the fractions of flows whose per-flow error is below 10% and 50%. With 10 MB, less than half flows can reach a per-flow error below 10% in most algorithms. The low accuracy is caused by the serious hash conflicts in these sketches. With 100 MB, the overall accuracy is improved. However, such huge memory consumption is not affordable in commodity switches.

3 Overview

Goals. We explore the methodology to design NZE sketch algorithms. Specifically, we expect that: (1) flow IDs are extracted with a negligible error probability (e.g., both false positive rate and false negative rate are below 0.01%), and (2) per-flow error is small (e.g., <0.1%) for almost all (e.g., >99%) flows. At the same time, we also aim to limit the resource usage such that the algorithms can be readily deployed.

The NZE monitoring forms the basis for various flow statistics, such as flow cardinality [28], super-spreaders and DDoS victims [30, 86], heavy hitters/changes [45], flow distributions [46], and entropy [34]. For each type of statistics, a lot of specific algorithms have been proposed. However, to our best knowledge, none of existing algorithms provide comprehensive and strict accuracy guarantees for all flows. Prior studies advocate that: (1) it is sufficient to address large flows, and (2) approximate monitoring is acceptable. Nevertheless, NZE monitoring for even small flows greatly benefits network management. For example, single-packet TCP flows typically indicate unsuccessful connection attempts, caused by DDoS attacks, service crashes, or software bugs. Without accurate monitoring for small flows, it is difficult to rapidly react to such events. On the other hand, NZE monitoring allows administrators to deal with the reported anomalies without concerns on false alarms or undetected events.

Key idea. Our study addresses three questions. (1) Is NZE monitoring theoretically feasible? (2) What are the key factors to achieve NZE monitoring? (3) How do the key factors be efficiently realized in practice?

To answer these questions, we base our work on compressive sensing [11–13, 24]. Compressive sensing is a signal processing technique that acquires high-dimensional signals with limited resources. Classical compressive sensing has two procedures. The *sensing procedure* records a signal by multiplying the signal with a matrix, while the *recovery procedure* reconstructs the signal with an optimization-based approach. We exploit compressive sensing in two aspects:

- We aim to incorporate the optimization-based recovery of compressive sensing to achieve near-zero errors. This is motivated by the sound theoretical guarantees provisioned by compressive sensing on its overheads and correctness. It has been demonstrated that the optimization-based approach can recover signals nearly perfectly in many areas such as image compression [11, 12]. Thus, similar results are expected if we regard flow values as signals.
- We also leverage compressive sensing to guide the design of NZE sketch. Here, compressive sensing serves as a general framework to study various sketch algorithms. In particular, compressive sensing exhibits the same mathematical form as sketch algorithms: prior works [18, 21, 55] show that sketch algorithms can be viewed as variants of compressive sensing. Even though each sketch algorithm exhibits its unique design that is quite different from classical compressive sensing, it can be formulated by a matrix (§4.3) and analyzed via matrix analysis.

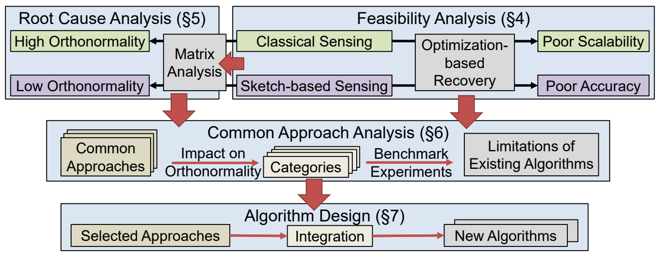

Figure 2: Workflow.

Assumptions. Our study makes two assumptions. First, network traffic is sparse. By sparsity, we mean that even though there are enormous possible flows (e.g., 2^{64} possible 2-tuple flows), the number of active flows is much smaller. This assumption has been justified in many measurement studies [5, 66] and utilized in various recent works [35, 83]. Second, we assume that a sketch algorithm contains a linear part in which each counter is updated linearly by a packet. Previous studies [18, 21] show that basic sketch algorithms, including CM, CS, and CBF, are linear structures; while we observe that many other sketches (e.g., UM, FR, ES, and SL) are built atop these basic sketches. We discuss how to handle the non-linear portion of a sketch in §4.3.

Workflow. Figure 2 outlines the workflow of our study.

- **Feasibility analysis (§4):** We investigate the feasibility of applying compressive sensing to flow monitoring. We consider two methods. The first method directly adopts classical compressive sensing, including its sensing and recovery procedures. The second method employs sketch algorithms to record per-packet information (referred to as *sketch-based sensing*). Then it formulates each sketch algorithm as a matrix and invokes the optimization-based recovery of classical compressive sensing. However, we find that the first method suffers from a scalability problem, while the second method has very low accuracy. This motivates us to dive into the fundamental theory of compressive sensing and design new algorithms.
- **Root cause analysis (§5):** We examine the root cause that leads to the poor accuracy when combining sketch-based

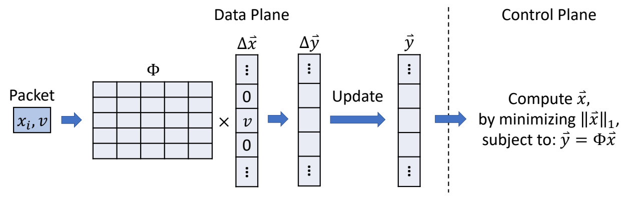

Figure 3: Utilization of compressive sensing for network monitoring.

sensing with the optimization-based recovery. Our study compares the matrices formulated by sketch algorithms with those in classical compressive sensing. We address a critical matrix property *orthonormality* (§1) that ensures the correctness of classical compressive sensing. Our benchmark experiments show that the matrices formulated by sketch algorithms lack sufficient orthonormality.

- **Common approach analysis (§6):** We identify common approaches to improve matrix orthonormality for sketch algorithms. Even though the approaches are also used in existing algorithms, we revisit these approaches in a novel methodology of matrix analysis. We group the approaches into four classes. For each class, we theoretically analyze the impact on matrix orthonormality. We also perform benchmark experiments to validate our analysis. Our analysis points out that the current utilization of these approaches is not efficient to combine with the optimization-based recovery of compressive sensing.
- **Algorithm design (§7):** We propose two algorithms that seamlessly combine sketch with the compressive sensing recovery. Based on the results of common approach analysis, we select appropriate approaches and efficiently integrate them to form the data plane of the two algorithms. Each design choice can be fully interpreted by matrix analysis. In the control plane, the two algorithms recover flow IDs and flow values by solving an optimization problem.

Discussion. Some recent studies have also applied compressive sensing in network measurement [7, 16, 21, 35, 44, 83]. However, they focus on recovering missing values in specific scenarios such as traffic matrices [16, 83] or network tomography [7]. In contrast, we utilize compressive sensing to (i) comprehensively dissect sketch algorithms, and (ii) guide the full design of NZE sketch.

Note that there are numerous variants of compressive sensing that reconstruct signals in different manners (e.g., LASSO [47] or using L_0 norm). In this paper, we focus on the original reconstruction approach that is based on matrix orthonormality [11, 12], given their simplicity and sound guarantees.

4 Feasibility Analysis

We introduce the fundamental concepts of compressive sensing in §4.1. Then we study two methods that apply compressive sensing to flow monitoring in §4.2 and §4.3, respectively.

4.1 Preliminary

Compressive sensing represents a signal as a *signal vector* $\vec{x}$ of length n. It includes two procedures to acquire $\vec{x}$.

Sensing procedure. The sensing procedure is responsible for recording $\vec{x}$ in a lightweight manner. Since the length n is usually a large number, compressive sensing linearly maps $\vec{x}$ into a *measurement vector* $\vec{y}$ of length m, where m is much smaller than n. Formally, the mapping can be represented as an $m \times n$ *sensing matrix* Φ, while $\vec{y}$ is computed as:

$$\vec{y} = \Phi \times \vec{x} \tag{1}$$

Recovery procedure. The recovery procedure is to reconstruct the signal vector $\vec{x}$ with Φ and $\vec{y}$. However, Equation (1) is an underdetermined system. It includes m linear equations for the n unknown variables in $\vec{x}$: the i-th element in $\vec{y}$ (denoted by y_i) and the i-row of Φ form a linear equation: $\sum_{j=1}^{n} \Phi_{i,j} \cdot x_j = y_i$. Since the number of variables n is much larger than the number of equations m, the number of possible solutions is infinite.

Compressive sensing addresses the underdetermined problem by introducing some prior knowledge. It assumes that $\vec{x}$ is sparse[1]. Then compressive sensing formulates an optimization problem:

$$\begin{aligned} \text{minimize:} \quad & \|\vec{x}\|_1, \\ \text{subject to:} \quad & \vec{y} = \Phi\vec{x} \end{aligned} \tag{2}$$

Here, compressive sensing chooses to minimize the L_1 norm of $\vec{x}$ because L_1 norm penalizes against the lack of sparsity [11, 12]. Therefore, a sparse vector satisfying Equation (1) is obtained. Theoretical analysis shows that the solution is close to the true $\vec{x}$ if some specific properties hold in Φ [11–13, 24]. We will study the properties in §5.

Utilization. Figure 3 depicts how to map the concepts of compressive sensing to those in network monitoring. Let n be the number of possible flows. For each type of flow statistic, all flow values form a vector $\vec{x}$ of length n. An element x_i indicates the value of the flow i. A measurement point maintains $\vec{y}$ in its memory. For each packet, it identifies the flowkey i such that the packet can be considered as a change to $\vec{x}$ denoted by $\Delta\vec{x}$. The measurement point multiplies $\Delta\vec{x}$ with the matrix Φ to form the update to $\vec{y}$ (denoted by $\Delta\vec{y}$). Then it applies the update to $\vec{y}$. The control plane collects $\vec{y}$ and invokes the optimization-based recovery in Equation (2) to reconstruct $\vec{x}$. Note that we do not need to explicitly maintain Φ, $\vec{x}$, $\Delta\vec{x}$, and $\Delta\vec{y}$ in memory. Instead, we compute their elements on demand. For example, we compute an element $\Phi_{k,i}$ when we update the k-th counter in $\vec{y}$ with flow indexed by i.

In practice, network administrators can directly utilize a classical matrix Φ [12, 75]. They can also propose their own method and formulate it in the form of Equation (1). We study

[1]For non-sparse $\vec{x}$, it needs to be transformed to another sparse vector first. We omit this case because network traffic exhibits high sparsity (§3).

the classical methods in §4.2 and formulate sketch algorithms using compressive sensing in §4.3.

4.2 Method 1: Classical Sensing

Accuracy. We first consider a method that direct utilizes classical sensing matrix Φ. We evaluate the accuracy of the classical sensing method via experiments with the same setup as that in §2.2. We employ four types of commonly used sensing matrices Φ: (1) Gaussian Matrix (GM) [75], (2) Bernoulli Matrix (BM) [12], (3) Incoherence Matrix (IM) [12], and (4) Fourier Matrix (FM) [12]. To reconstruct $\vec{x}$, we leverage two algorithms: the L_1 minimization approach that solves the optimization problem with the simplex method [22], and a greedy algorithm named Orthogonal Matching Pursuit (OMP) [64]. The four types of sensing matrices and two recovery algorithms produce eight approaches in total. The results show that all the eight approaches can recover flow IDs and flow values perfectly: zero false positives, zero false negatives, and zero per-flow error. Our results show that 400 KB memory is sufficient to achieve perfect recovery, which is much smaller than sketch algorithms (§2.2). The detailed accuracy trend with different memory settings is in Table 3 in Appendix.

Scalability problem. However, the classical sensing method suffers from a scalability problem. The classical sensing matrices are dense matrices in which all elements are non-zero. Thus, each packet needs to update m (above 10^4) counters in $\vec{y}$. This is infeasible for commodity devices. In software switches, updating so many counters fails to keep pace with packet streams with the slow CPUs. In hardware switches, the updates far exceed the available computational units. Thus, classical sensing can only accommodate limited flows.

Note that the scalability problem does not occur in other compressive sensing applications in which $\vec{x}$ does not vary (e.g., image compression). In those scenarios, $\vec{y}$ is computed only once using the constant $\vec{x}$.

4.3 Method 2: Sketch-based Sensing

Matrix formulation. Sketch algorithms incur limited per-packet operations, which addresses the scalability problem in §4.2. we follow prior studies [18, 21] that regard sketch as *linear* mapping and formulate it in the form of $\vec{y} = \Phi\vec{x}$. Let m be the number of linear counters. For $\vec{y}$, we index the m counters and stack them as a vector $\vec{y}$ of length m. For Φ, we form Φ with m rows and n columns, where each column represents a flow while each row represents one counter in $\vec{y}$. Each element $\Phi_{i,j}$ implies that the counter y_i is incremented by $\Phi_{i,j}$ if the value x_j of flow j changes by one.

Examples. We present an example of CountMin in Figure 4. We consider four flows, i.e., $\vec{x}$ has its length n=4. We employ two rows and configure three counters in each row in the sketch. Hence, $\vec{y}$ has length $m = 6$. In each row, a packet (k, v)

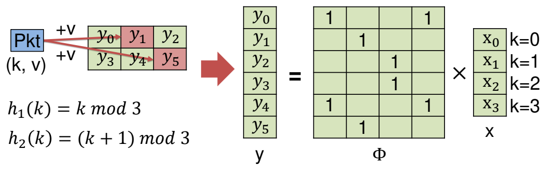

Figure 4: Matrix formulation of CountMin.

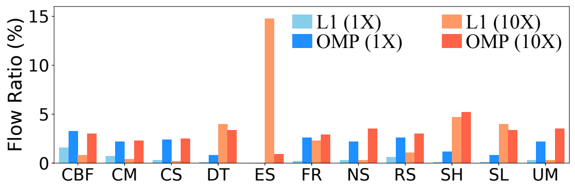

Figure 5: Ratio of flows that reach <50% per-flow errors in sketch-based sensing.

selects one counter with a hash function and increments it by v. Thus, we have $\Phi_{i,k} = 1$ if flow k is hashed to counter i, and $\Phi_{i,k} = 0$ otherwise. For each more flow, we may add a column to Φ and derive the column elements in the same method. We present more examples in Appendix.

Nonlinear structures. Not all components in a sketch are linear mapping. These components cannot be formulated by matrices. For example, FlowRadar maintains a set of counters that encode flow IDs via XOR operations [49]. We do not incorporate such nonlinear components in the optimization problem when reconstructing $\vec{x}$. Instead, we employ them to verify the correctness of the reconstructed $\vec{x}$. Specifically, we recompute these nonlinear structures with the reconstructed $\vec{x}$ and compare them with the original ones. For example, in FlowRadar, we encode all recovered flow IDs via the same XOR operations. We compare the new encoded results with the original XOR results to validate the correctness.

Results. We evaluate the sketch-based sensing method. We consider the sketch algorithms in §2.2. For each algorithm, we perform both L_1 minimization and OMP for the recovery. We employ two memory configurations: one with the same amount of memory as classical sensing, and the other with 10× memory. Figure 5 presents the ratio of flows whose error is below 50%. We see that even with 10× memory, all algorithms suffer from extremely low accuracy when using the optimization-based recovery. The results are even worse than those using their original query operations (see §2.2). The reason is that the matrices derived from existing sketch algorithms do not exhibit the required properties of compressive sensing although they exhibit the same form (see 5). This suggests us to explore new methods to boost sketch-based sensing to embrace compressive sensing, provided by the extensive study on the accuracy of compressive sensing [11–13, 24].

5 Root Causes

We examine the root cause of the poor accuracy in §4.3. Our methodology is to examine whether key properties of classical

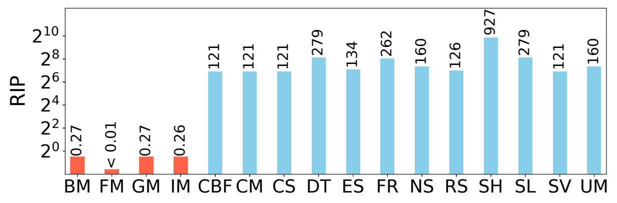

Figure 6: RIP of classical and sketch-based sensing.

sensing hold in sketch-based sensing.

Key properties. Compressive sensing guarantees its correctness by two properties: the *sparsity* of $\vec{x}$ and the *orthonormality* of Φ. Specifically, any orthonormal matrix Φ preserves the norms (and hence differences) for sparse vectors: given arbitrary two different sparse vectors $\vec{x}_1$ and $\vec{x}_2$, their mappings under matrix Φ (i.e., $\Phi\vec{x}_1$ and $\Phi\vec{x}_2$) remain distinct. Thus, when a sparse vector $\vec{x}^*$ that satisfies $\Phi\vec{x}^* = \vec{y}$ is found, it is must be equal to the desired $\vec{x}$ (otherwise two different vectors $\vec{x}^*$ and $\vec{x}$ have the same mapping, which compromises the property of the orthonormal matrix Φ) [12]. Since $\vec{x}$ is already sparse (§3), we only address whether Φ is orthonormal.

Orthonormal matrix and RIP. Unfortunately, orthonormality cannot hold in Φ, because an orthonormal matrix is requires to be a square matrix, but the number of rows is smaller than the number of columns in Φ. Compressive sensing deals with this issue with a notion of *restricted isometry property (RIP)* [10], which serves as an approximation of being fully orthonormal. RIP characterizes the extent to which Φ preserves the norm of sparse signals.

At a high level, for any sparse vector $\vec{x}$, $\Phi\vec{x}$ is its mapping under the matrix Φ. If Φ is highly orthonormal, the norm of $\Phi\vec{x}$ (denoted by $||\Phi\vec{x}||_2$) must be close to that of $\vec{x}$ (denoted by $||\vec{x}||_2$). Therefore, RIP evaluates the difference between $||\vec{x}||_2$ and $||\Phi\vec{x}||_2$. Since Φ should work for an arbitrary sparse vector $\vec{x}$, RIP is calculated as a sequence of *isometry constants* $\{\delta_S\}$. Each δ_S in the sequence is the maximum relative difference between the norms of $\Phi\vec{x}$ and $\vec{x}$ among all S-sparse signals:

$$\delta_S = \sup\{\frac{|\,||\Phi\vec{x}||_2 - ||\vec{x}||_2\,|}{||\vec{x}||_2} \text{ for any S-Sparse } \vec{x}\} \qquad (3)$$

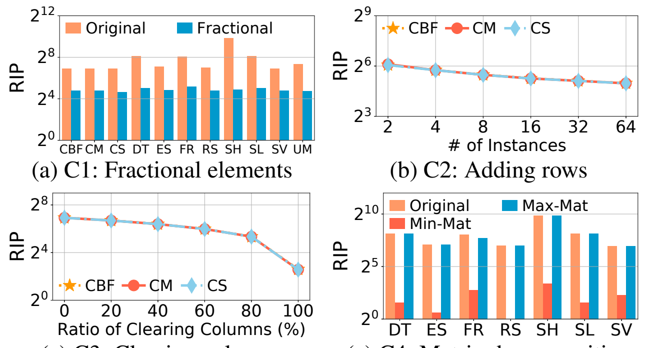
Benchmark results. We measure the RIP of both classical sensing matrices (§4.2) and the matrices induced by sketch algorithms (§4.3). We present RIP as δ_S, the isometry constant for S-sparse vectors, where S is the number of actual flows in each interval. Figure 6 shows that classical sensing matrices have RIP below 0.3. In contrast, RIP is above 120 in all sketch-induced matrices. The large RIPs degrade the efficiency of compressive sensing reconstruction.

6 Common Approach Analysis

We examine common approaches in general sketch design. Based on their impacts on matrix orthonormality, we categorize the approaches into four classes. For each class, we analyze its matrix property and use RIP as the metric to quantify the effectiveness. Although some approaches have been used in existing sketch algorithms (see Table 1), we study them from novel perspectives. First, we target the suitability of these approaches to compressive sensing, while existing algorithms study them for specific purposes. Second, we quantify the efficiency of these approaches via matrix analysis, while previous algorithms address probabilistic error bounds.

Algorithm	**C1**	**C2**	**C3**	**C4**
CU Sketch [25]	Conservative update			
Deltoid [19]		Multiple CM instances		Flow extraction
ElasticSketch [80]				Traffic splitting
FlowRadar [49]		Multiple Bloom Filters	Bloom Filter	Flow extraction
NitroSketch [53]	Sampling	Multiple CS instances	Heap	
RevSketch [68]				Flow extraction
SeqHash [8]		Multiple CM instances		Flow extraction
SketchLearn [37]		Multiple CM instances		Flow extraction
SketchVisor [35]				Traffic splitting
UnivMon [54]		Multiple CS instances	Heap	
SeqSketch	Fractional update		Bloom Filter + Controller	Splitting + Controller
EmbedSketch	Fractional update		Bloom Filter + controller	Extraction + Controller

Table 1: Common approaches in sketch algorithms.



(a) C1: Fractional elements (b) C2: Adding rows

(c) C3: Clearing columns (c) C4: Matrix decomposition

Figure 7: Impact of common approaches.

6.1 Class 1 (C1): Fractional Elements

Matrix analysis. We observe that elements in sketch-based sensing matrices are integers, which leads to the norm of matrix columns above one. However, an orthonormal matrix requires column vectors with norm one. Thus, the first class is to employ fractional matrix elements whose values are less than one, such as to reduce the norm of each column.

Benchmark results. Figure 7(a) evaluates the impact of fractional elements in existing sketch algorithms. For a sketch, we replace each element with a randomized value $1/\sqrt{t} + \sigma$, where σ is sampled from a Gaussian distribution with its mean equal to zero. Thus the mean of elements in the matrix is $1/\sqrt{t}$. Here, t is the number of counters accessed by a packet. Thus, the expected norm of each column vector is one. We see that RIP is decreased by 40% in all cases.

Approaches. In existing algorithms, there are two approaches producing fractional elements.

- **Sampling:** Sampling techniques [69, 70] discard some packets. For each flow, only partial packets contribute to $\vec{y}$. Thus, the elements in Φ are less than one. NitroSketch [53] has combined an adaptive sampling in its design.
- **Conservative updates:** In general, a packet incurs several updates in a sketch algorithm. Conservative update [25] preserves only the smallest update and drops the others. This also leads to smaller elements in Φ because not all updates are included.

Limitation. However, sampling and conservative updates are hard to be formulated as matrices. To obtain the exact fractional elements in Φ, it needs to track exact per-flow packet loss or update drops, which inevitably incurs excessive overheads and cancels out the benefit of sketch.

6.2 Class 2 (C2): Adding Rows

Matrix analysis. The second class is to add more rows to the matrix Φ. Ideally, two columns are orthonormal if and only if their nonzero elements occur in different positions. This implies that the two flows have no conflicts in all counters. Since each counter contributes one row in Φ (§4.3), adding rows means to configure more counters to reduce flow conflicts. Hence, column vectors become more orthonormal.

Approaches. In addition to simply allocating more counters to a single sketch, a common approach is to use multiple instances of sketch structures. For instance, FlowRadar [49] contains two Bloom Filters; UnivMon [54] employs multiple CS instances and filters flows for each instance; Deltoid [19] and SketchLearn [37] maintain multiple CM instances while each instance is updated based on the bits of flow IDs.

Benchmark results. Figure 7(b) shows RIP with respect to various number of sketch instances. We consider three commonly used basic sketch algorithms: CM, CS, and CBF. We see that the RIP decreases as the number of instances grows. With 64 instances, RIP is reduced by nearly 75%.

Limitation. However, the resulting RIP is still much higher than that of classical sensing matrices (§5). Although we can further reduce RIP with more instances, adding instances consumes more memory. It also incurs excessive usage of computational resources to update multiple instances.

6.3 Class 3 (C3): Clearing Columns

Matrix analysis. The third class is to clear elements of some columns. Recall that a column indicates the contribution of an unknown variable (§4.3). Clearing one column means to exclude a variable, which simplifies the optimization problem and hence improves accuracy.

Approaches. Identifying columns that can be cleared is equivalent to detecting flow IDs that never occur, such that discarding the flows does not compromise the results. Two approaches can track flow IDs in existing algorithms.

- **Heap:** CountMin [20], UnivMon [54] and NitroSketch [53] use a heap to store flow IDs whose flow values satisfy specific conditions (e.g., above a pre-defined threshold).
- **Bloom Filter:** Bloom Filter records Flow IDs compactly with bit arrays. An example is FlowRadar [49] that uses Bloom Filter to avoid duplicate flow IDs.

Benchmark results. Figure 7(c) measures how RIP varies as the ratio of cleared useless columns. Due to the interest of space, we present three sketches here and put the remaining results in Appendix. With no columns cleared, RIP is above 120 for all the three sketch algorithms. RIP significantly decreases as the number of cleared columns grows. It becomes 6 when all useless columns are cleared.

Limitation. However, tracking all Flow IDs with existing approaches is bounded by resource restrictions in switches. For the heap-based approach, per-flow tracking is infeasible due to the memory usage of heap. For BF, since it only examines the occurrence of flow IDs, extra resources are needed to store flow IDs (e.g., XOR arrays in FlowRadar [49]). For the controller-based approach, it needs careful design to avoid bandwidth exhaustion.

6.4 Class 4 (C4): Matrix Decomposition

Matrix analysis. The final class decomposes Φ as the sum of several component matrices. The decomposition distributes non-zero elements in Φ into different components. Thus, their conflicts are alleviated and hence each component becomes more likely to be orthonormal.

Approaches. There are two possible approaches to distribute flows and hence decompose matrix Φ.

- **Traffic splitting:** Traffic splitting employs multiple algorithmic parts in the data plane and splits traffic into different parts. Each part can produce a component matrix individually. For example, SketchVisor [35] maintains a fast path and a normal path, and directs traffic into either path based on real-time workloads. ElasticSketch [80] consists of a heavy part and a light part: traffic that is evicted from the heavy part enters the light part.
- **Flow extraction:** We can also form a component matrix by extracting flows from the sketch structure. These algorithms usually embed specific features in the sketch structures for the extraction. For example, FlowRadar [49] estimates the number of distinct flows in each counter (i.e., a row in Φ) and iteratively extracts from the counters with exactly one flow. Deltoid [19] and SketchLearn [37] extract from rows with large corresponding flow values.

Benchmark results. Figure 7(d) compares RIP before and after the decomposition. We present the component matrices with the minimum RIP (Min-Mat) and maximum RIP (Max-Mat). We observe that the orthonormality is significantly improved in each Min-Mat. For example, the original RIP of DT is nearly 1000, but it is reduced to 2.92 in Min-Mat.

Limitation. However, Max-Mat still exhibits high RIP in all algorithms. For some algorithms, the RIP of Max-Mat is close to that in the original matrix. We find that the decomposed traffic is limited because it needs extra structures to split traffic or extract flows. When resources are bounded, limited traffic can be decomposed.

7 New Algorithms

Motivation. §6 points out that existing algorithms fail to produce highly orthonormal matrices. The key issue is that they are not tailored for compressive sensing. On the one hand, the four classes C1-C4 are not realized efficiently. On the other hand, they do not collectively combine the approaches for compressive sensing. Thus, we need new algorithms that realize and combine the common approaches more efficiently.

Design choices. To better embrace compressive sensing, we examine each class in §6 to employ appropriate approaches to combine with compressive sensing.

- **C**1: As both sampling and conservative updates are hard to formulate, we realize a novel method of fractional updates. Specifically, for a packet (k,v), we use an additional hash function $g(\cdot)$ to change its value from v to $v \cdot g(k)$. Here, $g(\cdot)$ generates a value with its mean equal to $\frac{1}{\sqrt{r}}$ where r is the number of rows in the sketch. Thus, the expected norm of column vectors is reduced to one.
- **C**2: We discard C2 because of its excessive resource usage.
- **C**3: We employ a control-based approach to enhance Bloom Filter. Specifically, we store flow IDs in the controller. Since the controller has enough memory, the flow IDs can be recorded with zero errors. To reduce bandwidth usage, we employ a Bloom Filter to eliminate duplicate transfers.
- **C**4: We separate large flows as key-value pairs and small flows in the sketch with fractional values (referred to as fractional sketch). It has been proved that such separation can be realized with limited overheads [35,71,80]. To make *each* decomposed component matrix highly orthonormal, we also leverage the controller to steer the traffic in key-value pairs and the fractional sketch.

In summary, we maintain three types of components in the data plane: (1) key-value pairs to track large flows, (2) fractional-valued sketch to record small flows and (3) a Bloom Filter. We propose two algorithms that combine them in different manners. The first algorithm SeqSketch arranges the components sequentially, while the second algorithm EmbedSketch embeds the key-value table and Bloom Filter into the sketch arrays such that key-value pairs can be extracted

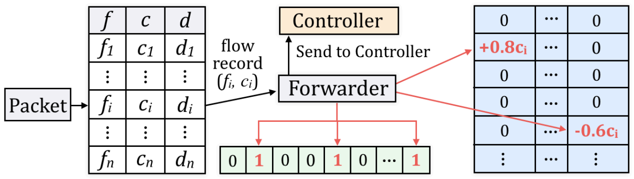


Figure 8: Structure of SeqSketch.

Algorithm 1 SeqSketch Data Plane

```
Input: Packet $(k,v)$
 1: procedure UPDATE$(k,v)$
 2:     $j = \text{hash}(k)$
 3:     if $H[j]$ is $\emptyset$ then
 4:         $H[j].f = k$, $H[j].c = v$, and $H[j].d = 0$
 5:     else if $H[j].f == k$ then
 6:         $H[j].c = H[j].c + v$
 7:     else
 8:         $H[j].d = H[j].d + v$
 9:         if $H[j].d > H[j].c$ then
10:             Send $(H[j].f, H[j].c)$ to controller
11:             $H[j].f = k$, $H[j].c = v$, and $H[j].d = 0$
12:         else
13:             for all row $i$ in $FS$ do
14:                 Compute $j = h_i(k)$
15:                 Increment counter $(i,j)$ by $g_i(k) \cdot v$
16:             if $k \notin BF$ then
17:                 Send $k$ to controller
18:                 Insert $k$ to $BF$
```

from sketch buckets. SeqSketch consumes less memory, while EmbedSketch needs fewer computational units. Network administrators can select the more suitable algorithm based on their resource budget.

7.1 SeqSketch

Data structure. Figure 8 presents an overview of SeqSketch. SeqSketch organizes its key-value pairs in a hash table H, and employs a *forwarder* to connect the hash table, Bloom Filter BF and fractional sketch FS. Every packet first enters the hash table H. Each tuple in H has three fields to identify large flows: apart from flow ID f, two counters c and d record flow values belonging and not belonging to f, respectively. The hash table evicts records of potential small flows based on the two counters when conflicts occur. The forwarder transfers an evicted record if it is a new flow, or sends it to the fractional sketch. It uses the Bloom Filter to record all occurred flows and examine new flows. The eviction is cheap because it incurs limited operations for each evicted record. Given the heavy-tailed distribution of network traffic, the hash table H absorbs a large portion of traffic, which alleviates the memory usage of BF and FS. Thus, SeqSketch is memory efficient.

Data plane. Algorithm 1 outlines how SeqSketch processes

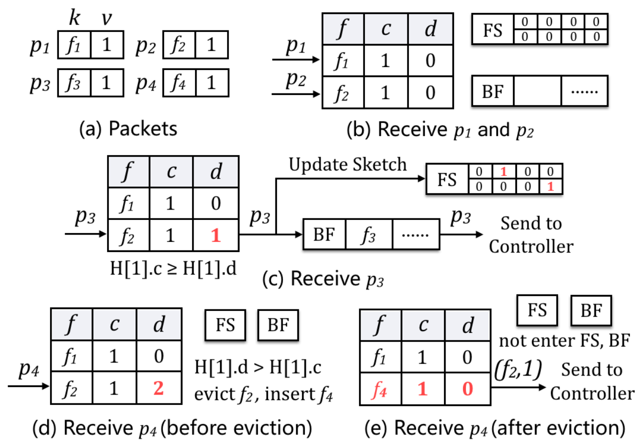

Figure 9: Example of SeqSketch.

a packet. When a packet (k, v) arrives, we first compute its position in the hash table H (Line 2). If its hashed entry is empty, a new record is created for this packet (Lines 3-4). If the entry already exists, there are two cases. First, if the existing entry has the same ID as the packet, the counter c is incremented (Lines 5-6). Second, if f and k are different, we add d by v (Line 8). At the same time, we need to evict the flow record of f or the packet (k, v) (Lines 9-18). When d is larger than c, we send the record to the controller (Line 10), and insert a flow record for k (Line 11). Otherwise, we evict (k, v) to FS (Line 13-15). In this case, the forwarder queries its Bloom Filter to examine whether the flow ID appears before. If it is a new flow, the ID is also forwarded to the controller (Line 16-18). Note that we increment each counter in FS with a fractional value instead of v (Lines 14-15).

Example. Figure 9 presents an example with two buckets in H. H directly inserts the first two packets p_1 and p_2 (Figure 9(b)). For the third packet p_3, H maps it to $H[1]$ that already records another flow f_2 . To deal with the conflict, H increments $H[1].d$. Since $H[1].d$ does not exceed $H[1].c$, p_3 is delivered to FS and BF. FS updates its counters with p_3, while BF transfers its flow ID to the controller because it is a new flow (Figure 9(c)). Finally, p_4 enters H and is also hashed to $H[1]$. Since p_4 does not belong to f_2, H increments $H[1].d$ by one. Since $H[1].d$ exceeds $H[1].c$ (Figure 9(d)), we evict $H[1]$ and insert p_4 (Figure 9(e)).

Control plane. We recover flow IDs and flow values by formulating an optimization problem. There are three portions of traffic: that in the hash table H, that transferred to the controller, and that in FS. Denote flow values in the three portions by $\vec{x}_H$, $\vec{x}_C$ and $\vec{x}_S$, respectively. Since $\vec{x}_H$, $\vec{x}_C$ can be obtained directly, we only need to solve $\vec{x}_S$ by formulating the per-flow update of FS as Φ and its counters as $\vec{y}$:

$$\begin{aligned} \text{minimize:} \quad & \|\vec{x}_S\|_1, \\ \text{subject to:} \quad & \vec{y} = \Phi \vec{x}_S \end{aligned} \tag{4}$$

Algorithm 2 EmbedSketch Data Plane

```
Input: Packet $(k, v)$
1: function UPDATEBUCKET($k$, $v$, $i$, $j$)
2:     $V_{i,j} = V_{i,j} + g_i(k)$
3:     if $f_{i,j}$ is empty then
4:         $f_{i,j} = k$, $c_{i,j} = v$, $d_{i,j} = 0$
5:     else if $f_{i,j}$ is $k$ then
6:         $c_{i,j} = c_{i,j} + v$
7:     else
8:         $d_{i,j} = d_{i,j} + v$
9:         if $d_{i,j} > c_{i,j}$ then
10:            Send $(f_{i,j}, c_{i,j})$ to controller
11:            $f_{i,j} = k$, $c_{i,j} = v$, $d_{i,j} = 0$
12:        else
13:            if $k \notin BF_{i,j}$ then
14:                Send $k$ to controller
15:                Insert $k$ to $BF_{i,j}$
16:
17: procedure UPDATE($k, v$)
18:     for row $i = 1, 2, ..., r$ do
19:         $j = h_i(k)$
20:         UPDATEBUCKET($k$, $v$, $i$, $j$)
```

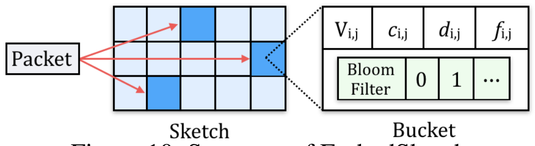

Figure 10: Structure of EmbedSketch.

7.2 EmbedSketch

Data structure. Figure 10 depicts EmbedSketch. It maintains a sketch with r rows. Each row i has two hash functions (h_i to select counters and g_i to generate fractional values) and w buckets. A bucket (i, j) in EmbedSketch consists of: (i) a counter $V_{i,j}$, which denotes the total values hashed to this bucket, (ii) $f_{i,j}$, which denotes the flow ID of the candidate for the largest flow in the bucket, (iii) $c_{i,j}$, which denotes the aggregated value of f, (iv) $d_{i,j}$, which denotes the total value of other flows in the bucket, and (v) a Bloom Filter $B_{i,j}$ that records flow IDs in this bucket. Essentially, EmbedSketch distributes monitoring operations in its buckets. This mitigates per-bucket hash conflicts. Thus, one hash function in each bucket is sufficient (see §7.4).

Data plane. Algorithm 2 details how EmbedSketch processes a packet (k, v). For each row i, EmbedSketch computes a bucket with $h_i(k)$ and updates the bucket (Lines 18-20). To update a bucket (i, j), EmbedSketch first increments $V_{i,j}$ by $g_i(k) \cdot v$ (Line 2). If the existing candidate $f_{i,j}$ equals to k, $c_{i,j}$ is also incremented (Lines 5-6). Otherwise, EmbedSketch increments $d_{i,j}$ (Line 8) and determines to evict either $f_{i,j}$ (Lines 9-11) or k (Lines 13-15). If $f_{i,j}$ is evicted, a record $(f_{i,j}, c_{i,j})$ is transferred to the controller (Line 10). At the same time, EmbedSketch uses k as the new candidate and sets $c_{i,j} = v$ and $d_{i,j} = 0$ (Line 11). Otherwise, if k is evicted, EmbedSketch queries its local Bloom Filter $B_{i,j}$ (Line 13). If k is a new ID, EmbedSketch forwards it to the controller and updates $B_{i,j}$ to include k (Lines 14-15).

Control plane. We form $\vec{y}$ with all $r \times w$ counters of $V_{i,j}$ in EmbedSketch. Traffic in $V_{i,j}$ comprises three portions: (1) each $f_{i,j}$ contains its value $c_{i,j}$, (2) per-flow values transferred to the controller, and the remaining traffic in $V_{i,j}$. Thus, we denote per-flow values in the three portions by $\vec{x}_f$, $\vec{x}_C$ and $\vec{x}_R$, respectively. Since only $\vec{x}_R$ is unknown, we build the following optimization problem:

$$\begin{aligned} \text{minimize:} \quad & \|\vec{x}_R\|_1, \\ \text{subject to:} \quad & \vec{y} = \Phi(\vec{x}_f + \vec{x}_C + \vec{x}_R) \end{aligned} \tag{5}$$

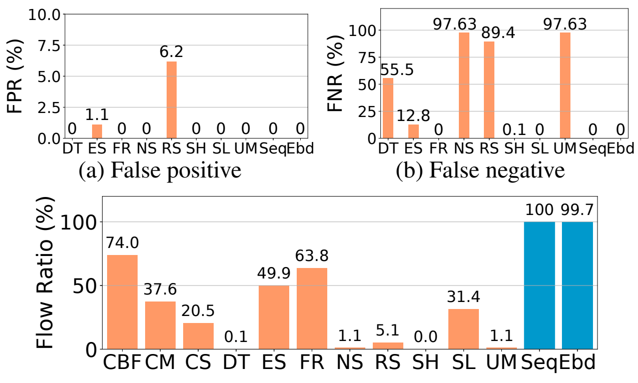
7.3 Parameters

We need to configure the three components: the fractional sketch (FS), the Bloom Filter (BF), and key-value pairs (KV).

Fractional sketch. For FS, two rows are sufficient as our optimization-based recovery does not need many rows to alleviate hash conflicts. However, compressive sensing theory requires a minimum amount of counters: $C \cdot S \log_2(n/S)$ (c.f. Equation(13) in [13]), where n is the number of possible flows, S is the expected number of actual flows, and C is a small positive number. In practice, we can select a proper C to make memory usage fits the device. For example, to monitor around S=100K 2-tuple flows ($n = 2^{64}$), setting C=0.1 leads to around 472K counters. If we employ 32-bit counters, the total memory of FS is 1888 KB.

Bloom Filter. The Bloom Filter BF determines the accuracy of the received flow IDs in the control plane. A false flow ID indicates 100% relative error for that flow, which seriously compromises the recovery accuracy. Thus, we need to carefully configure BF. The size of BF depends on the expected number of flows S. According to [18] (c.f. §5.2.5), the false positive rate of Bloom Filter is $(0.6185)^{m/S}$ where m is the length of Bloom Filter, if we set the number of hash functions to its optimal value $\frac{m}{S} \ln 2$. In our case, a false positive in Bloom Filter means wrongly clearing a column in Φ. To achieve our goal of $< 1\%$ error probability for flow ID extraction, we need to bound the false positive rate of the Bloom Filter below 1%. This requires $m = 9.6S$. For $S = 100$ K flows, this leads to a Bloom Filter with 120 KB. For SeqSketch, we employ the optimal number of hash functions: $9.6 \ln 2 \approx 7$. For EmbedSketch, since the Bloom Filter is distributed across buckets, one hash suffices to achieve low error probability.

Key-value pairs. In EmbedSketch, each bucket maintains one key-value pair by design. For SeqSketch, it can employ the same amount for simplicity.



(a) False positive (b) False negative

(c) Fractions of flows with relative errors less than 0.1%

Figure 11: (Experiment 1) Accuracy.

7.4 Evaluation

Setup. We implement both software version and hardware version of the two algorithms (see Appendix). We evaluate them via trace-driven experiments. We use the CAIDA-2018 backbone trace [9] and two data center traces [5]. We present 2-tuple flows and count their packets, while other flow definitions (e.g., 5-tuple) and statistics have similar results. We partition each trace into equal-length intervals. Due to the interest of space, we present the results with 2-second intervals, each of which has around 100 K flows. More results are in Appendix. We present the average results across all intervals. Here, we omit the standard deviations because the standard deviations are negligible. When measuring accuracy (Experiments 1 and 2), we run both update and query operations in a server with 36 CPU cores (2.6GHz each) and 128 GB memory to process the traces. When measuring resource overheads (Experiments 3 to 6), we build a testbed with 16 servers and a Barefoot Tofino switch [79]. Each server has a 40Gbps NIC for traffic transfers and a 10Gbps NIC to connect to the controller. We deploy our algorithms in the switch. Each server replays our traces and evenly sends the traces to others. We follow §7.3 to configure key-value pairs (KV), the Bloom Filter BF, and the fractional sketch FS.

Experiment 1: Accuracy (Figure 11). We compare the accuracy of SeqSketch (Seq) and EmbedSketch (Ebd) with 11 sketch algorithms. Every algorithm has its suggested theoretical configuration (see Appendix). However, they fail to achieve NZE even when we allocate 100 MB memory (§2.2). Thus, for a fair comparison, each algorithm is allocated with the same amount of memory as ours for a stress test. In Figure 11(a) and Figure 11(b), we exclude CBF, CM, and CS because they cannot extract flow IDs by design. We find that more than half existing algorithms have nearly zero false positive rate and false negative rate. However, none of existing algorithms achieve high accuracy for all flows. Recall §2.2, even when we allocate more memory (10 MB) and relax the desired per-flow error to 50%, the ratio of accurate flows in existing algorithms is less than 85%. In contrast, EmbedS-

(c) EmbedSketch w.r.t. FS size (d) EmbedSketch w.r.t. BF size

Figure 12: (Experiment 2) Robustness to various memory configurations.

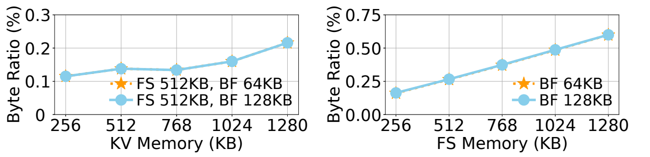
Name	PHV (Bytes)	VLIW	ALU	Stage
ElasticSketch	163 (21.22%)	13 (3.39%)	9 (18.75%)	10 (83.33%)
FlowRadar	134 (21.22%)	11 (2.86%)	15 (31.25%)	10 (83.33%)
SketchLearn	156 (20.31%)	11 (2.86%)	33 (68.75%)	8 (83.33%)
UnivMon	132 (17.19%)	13 (3.39%)	33 (68.75%)	12 (100%)
SeqSketch	151 (19.66%)	12 (3.12%)	13 (27.08%)	8 (66.67%)
EmbedSketch	137 (17.84%)	10 (2.60%)	6 (12.50%)	8 (66.67%)

Table 2: (Experiment 3) Switch resource usage.

ketch bounds the error below 0.1% for more than 99.72% and SeqSketch covers all flows. The reason is that existing algorithms depend on a large amount of memory to fully resolve hash conflicts. However, our algorithms recover flow values by solving an optimization problem based on compressive sensing, which is not so sensitive to hash conflicts.

Experiment 2: Robustness (Figure 12). We measure the ratio of flows with an error less than 0.1% in different configurations. To study the accuracy as memory changes, we fix two components and vary the size of the remaining one. For SeqSketch in Figure 12(a), when FS has 256KB, only 68% flows reach the accuracy level because the memory is far smaller than a reasonable size. However, the ratio increases to nearly 100% as the sketch size increases. Figure 12(b) shows that the accuracy remains stable for different BF configurations. Even with 32 KB (25% of the expected memory as §7.3), more than 96% flows remain per-flow error below 0.1%. In EmbedSketch, since each bucket of FS embeds one KV pair, we either fix BF and vary FS (Figure 12(c)) or vice versa (Figure 12(d)). We observe similar trends: the accuracy is low with 256 KB FS but grows as the size of FS, while remaining stable for various BF size.

We also find that SeqSketch is more memory efficient than EmbedSketch. For SeqSketch, 832 KB memory (512 KB FS, 64 KB BF, and 256 KB KV) is sufficient to achieve near-zero error. In contrast, EmbedSketch requires around 2.5 MB memory to reach the same level of accuracy, including at least 512 KB FS, 64 KB BF and 2048 KB KV. Here, the 2048 KB KV comes from the per-bucket key-value pairs. Recall that



(a) SeqSketch (b) EmbedSketch

Figure 13: (Experiment 4) Bandwidth usage.

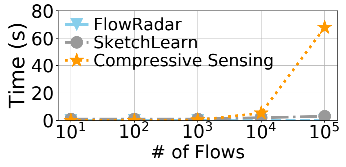


Figure 14: (Experiment 5) Recovery time.

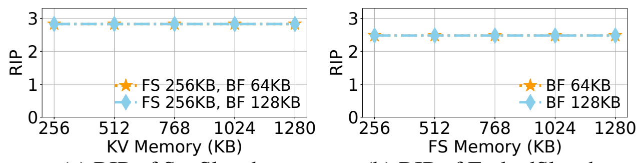
each key-value pair occupies 16 bytes, which is 4× of a FS counter. Thus, KV consumes as 4× memory as FS. The root cause for different memory usage is that in SeqSketch, there are no duplicate flow IDs in the hash table, while a flow may be tracked multiple times in EmbedSketch.

Experiment 3: Resource usage in Tofino (Table 2). We compare SeqSketch and EmbedSketch with four state-of-the-art sketch algorithms. We consider four types of resources: stages, ALUs, and VLIW are used for updating sketch values, while PHV carries data across stages. We find that our algorithms consume fewer stages, ALUs, and VLIW than FR, SL, and UM. The reason is that the three algorithms need to update multiple instances (Table 1), while the components in our algorithms require only simple operations. SeqSketch incurs more resource usage than ES because it needs to update additional Bloom Filter and transfer flow records to the controller for evicted entries. EmbedSketch requires fewer resources than others because updating local structures is much simpler (e.g., fewer hash functions for BF).

Experiment 4: Bandwidth usage (Figure 13). We measure the ratio of incurred traffic to the traffic in a time interval. The incurred traffic compromises two parts: the evicted flow records and flow IDs during per-packet updates, and the transfer of the sketch at the end of each interval. We see that achieving NZE monitoring incurs less than 0.7% additional bandwidth consumption. Note that existing sketch algorithms only transfer the sketch structures. Although our algorithms additionally transfer flow IDs, the overall bandwidth usage remains limited for two reasons. First, the sketch structures are quite small. Second, we only send evicted flow records that aggregate a considerable number of packets to the controller. When an individual packet is evicted, it will be absorbed by FS. Further, BF avoids duplicate transfers of flow IDs.

Experiment 5: Recovery time (Figure14). We measure the recovery time for different number of flows. Currently, we use a single thread for recovery. The time is around 60 seconds in the worst case, which is much worse than sketch algorithms. We can optimize it by assigning recovery operations in different CPU cores. Recall that the time interval containing 100 K flows is around 2.5 seconds. Our 36-core server is sufficient



(a) RIP of SeqSketch (b) RIP of EmbedSketch

Figure 15: (Experiment 6) RIP.

to handle all recovery operations. Further, we can speed up with recent distributed machine learning architectures such as TensorFlow. Since solving optimization problem is not our focus, we leave it in the future work.

Experiment 6: RIP (Figure 15). We further examine the RIP of the two algorithms in Figure 15(a) and Figure 15(b), respectively. We observe that RIP remains below 3 in all cases, which is much smaller than that in existing algorithms (§6). The results reveal that SeqSketch and EmbedSketch produce highly orthonormal matrices, which lead to high accuracy when applying compressive sensing reconstruction.

More results. In Appendix, we also present the throughput in software (Experiment 7). We also present the complete accuracy results under different configurations.

7.5 Discussion

Correctness. The correctness of both SeqSketch and EmbedSketch can be derived from compressive sensing. Since we recover per-flow values with standard compressive sensing, the recovered results are close to the true values given the orthonormal matrices produced by the two algorithms (Experiment 3). We leave the formal proof in our future work.

Comparison to existing algorithms. Both the sequential design and embedding design have been used in prior algorithms. For example, ElasticSketch [80] evicts records from a hash table to a sketch; MV-Sketch [77] embeds heavy flows in buckets. Our algorithms are different in four aspects. First, our recovery is based on an optimization framework of compressive sensing. Second, we employ a fractional sketch that increments each counter by a fractional value. Third, we maintain a Bloom Filer to track all flow IDs. Finally, we leverage the controller to reduce the overheads in the data plane. With these design choices, our algorithms achieve near-zero errors.

8 Related Work

Measurement algorithms. Hash tables [1,2,52,59] achieve zero errors but incur excessive resource usage. Some approximate techniques reduce memory usage by addressing only heavy hitters [4,25,33,71]. Sampling techniques [14,41,69,70,74] selectively discard a portion of traffic to improve resource efficiency. Sketch algorithms [20,36,37,49,53,54,68,80,85] employ a compact structure in which multiple flows share a counter. These approximate algorithms usually provide theoretical guarantees to bound the incurred errors. However, the bounds are too loose to apply to all flows, leading to poor accuracy in practice (see §2).

Measurement systems. OpenSketch [82], SCREAM [58] and SketchVisor [35] enhance sketch algorithms in different aspects. Some systems boost performance with TCAM [40,57,60]. PacketHistory [32] and Planck [65] mirror traffic to the controller. EverFlow [87] and dShark [81] filter out uninterested traffic with pre-defined rules. mOS [38] and Confluo [42] address monitoring at edges. Studies on query languages [29,31,61,73,78] empower more fine-grained expressions to tune measurement tasks. TPP [39], MOZART [52], and SwitchPointer [76] combine software and hardware devices to provide both flexibility and programmability for network measurement. Different from these works, our work addresses the algorithmic design for flow monitoring. It is complementary to above system studies.

Compressive sensing for network measurement. CounterBraids [55] demonstrates that sketch and compressive sensing are thematically related, but does not actually apply compressive sensing. [48] applies Least Linear Square method to reconstruct flow values from CountMin Sketch, but does not consider other sketch techniques. [21] shows that sketch algorithms can be formulated as a special kind of compressive sensing. [16,44,83] leverage compressive sensing to restore missing values in traffic matrices. [7] uses compressive sensing for tomography. SketchVisor [35] merges its two paths with compressive sensing. In contrast, this paper leverages compressive sensing for NZE monitoring.

9 Conclusion

This paper revisits the theoretical bounds provided by sketch algorithms. We observe that the bounds in existing algorithms are too loose to achieve high accuracy for all flows. We address this problem with compressive sensing. We formulate sketch algorithms as matrices and study their suitability to compressive sensing. The results guide us to design two new algorithms accordingly. The efficiency of the two algorithms demonstrates the power of our methodology. We expect that more algorithms can be designed in the future.

(b) Count Bloom Filter

Figure 16: Matrix formulation of CS and CBF.

Appendix A: Sketch-based Sensing

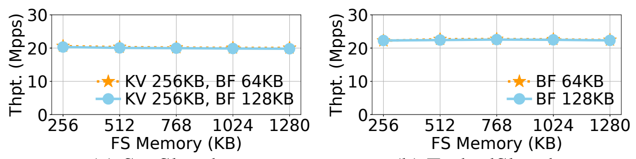
Examples. Figure 16 presents another two examples of the sensing matrices for CS and CBF. As §4.3, we also consider four flows. Figure 16(a) shows a CountSketch (CS). CS has the same structure as CM. However, a packet (k, v) increments its hashed counter in row t by $g_t(k) \cdot v$, where $g_t(k)$ is another function that maps a flow ID to $\{-1, 1\}$. Thus, $\Phi_{i,k}$ is either 1 or -1 if flow k hits counter i. Figure 16(b) presents a Bloom Filter. Note that the original Bloom Filter is not a linear mapping, because it maintains an array of bits and performs bitwise OR operations. We extend it to a Counting Bloom Filter (CBF) that replaces the bit array with a counter array. Each counter is updated by v for a packet (k, v) hashed to it. Thus, we set $\Phi_{i,k} = 1$ if flow k hashes to counter i.

Appendix B: Implementation

Software version. The software version integrates OpenVSwitch (OVS) [62]. We target two implementations of OVS: one resides in the kernel space, and the other bypasses the kernel via DPDK [23]. In each implementation, we intercept packets in the forwarding module. We put the packet headers in a region of shared memory. A dedicated thread reads the shared memory and updates the sketch (either SeqSketch or EmbedSketch) accordingly.

Hardware version. We implement the hardware version in P4 [63] and target PISA [6] switches. We place the data structures in switch registers, and invoke stateful ALUs to update register values for each packet. However, the limited memory access model of PISA raises two challenges. The first challenge is that each memory access can only manipulate at most 64-bit variables, but in our algorithms, we need to update more than 64 bits of data each time. Second, PISA partitions hardware resources into several stages, each of which is associated with its own ALUs and registers. An ALU can only access the registers belonging to its same stage.

To this end, we tailor SeqSketch and EmbedSketch to fit them into PISA switches. For the first challenge, we sepa-



(a) SeqSketch. (b) EmbedSketch.

rate different types of variables across stages, such that the size of accessed variables in each stage does not exceed the 64-bit limit. For the second challenge, we introduce a few intermediate variables to break the inter-dependencies among variables. More precisely, we store only f and c in the same stage, but replace the variable d with a new variable d'. The new variable d' resides in a stage before f and c. It counts all incoming flows (i.e. $d' = c + d$) and records its value in a metadata field such that it can be shared across stages. The later stage (i.e., that actually maintains f and c) reads d' from the metadata, and determines to perform an eviction operation based on whether $d' - c > c$.

Appendix C: more experiments

Experiment 7: Throughput in software switches (Figure17). We measure the throughput of the two algorithms. We observe that both algorithms keep stable throughput. The throughput of EmbedSketch is higher than that of SeqSketch because its local structures are simpler (see Experiment 3).

Complete results. Table 3 provides the results of classical compressive sensing under different memory settings. Table 4 shows the theoretical configurations of state-of-the-art algorithms with 1% threshold, 1% relative error, and 5% error probability. Table 5, Table 6 Table 7, and Table 8 show the complete results of SeqSketch and EmbedSketch.
