6.3 Cameo: Internal Evaluation

We next evaluate Cameo's internal properties.

LLF vs. EDF vs. SJF. We implement three scheduling policies using the Cameo context API and evaluate using Section 6.1's workload. The three scheduling policies are: Least Laxity First (LLF, our default), Earliest Deadline First (EDF), and Shortest Job First (SJF). Figure 11 shows that SJF is consistently worse than LLF and EDF (with the exception of query IPQ4– due to the lack of queuing effect under lighter workload). Second, EDF and LLF perform comparably.

In fact we observed that EDF and LLF produced similar schedules for most of our queries. This is because: i) our operator execution time is consistent within a stage, and ii) operator execution time is $\ll$ window size. Thus, excluding operator cost (EDF) does not change schedule by much.

Scheduling Overhead. To evaluate Cameo with many small messages, we use one thread to run a no-op workload (300-350 tenants, 1 msg/s/tenant, same latency needs). Tenants are increased to saturate throughput.

Figure 12 (left) shows breakdown of execution time (inverse of throughput) for three scheduling schemes: FIFO, Cameo without priority generation (overhead only from priority scheduling), and Cameo with priority generation and the LLF policy from Section 4 (overhead from both priority scheduling and priority generation). Cameo's scheduling overhead is $<15\%$ of processing time in the worst case, comprising of 4% overhead from priority-based scheduling and 11% from priority generation.

In practice, Cameo encloses a columnar batch of data in each message like Trill [30]. Cameo's overhead is small compared to message execution costs. In Figure 12 (right), under Section 6's workload, scheduling overhead is only 6.4% of execution time for a local aggregation operator with batch size 1. Overhead falls with batch size. When Cameo is used as a generalized scheduler and message execution costs are small (e.g., with <1 ms), we recommend tuning scheduling quantum and message size to reduce scheduling overhead.

In Figure 13, we batch more tuples into a message, while maintaining same overall tuple ingestion rate. In spite of decreased flexibility available to the scheduler, group 1 jobs' latency is unaffected up to 20K batch size. It degrades at higher batch size (40K), due to more lower priority tuples blocking higher priority tuples. Larger messages hide scheduling overhead, but could starve some high priority messages.

Varying Scope of Scheduler Knowledge. If Cameo is unaware of query semantics (but aware of DAG and latency constraints), Cameo conservatively estimates t_{M_F} without dead-

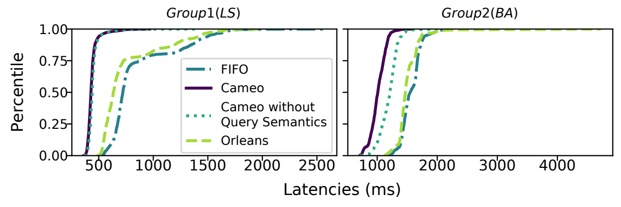

Figure 14: *Benefit of Query Semantics-awareness in Cameo.*

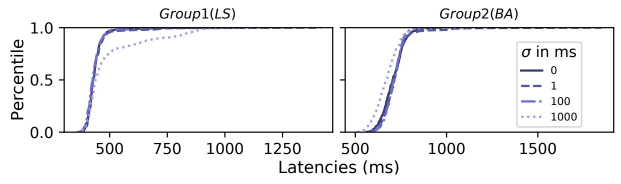

Figure 15: *Profiling Inaccuracy. Standard deviation in ms.*

line extension for window operators, causing a tighter ddl_M. Figure 14 shows that Cameo performs slightly worse without query semantics (19% increase in group 2 median latency). Against baselines, Cameo still reduces group 1 and group 2's median latency by up to 38% and 22% respectively. Hence, even without query semantic knowledge, Cameo still outperforms Orleans and FIFO.

Effect of Measurement Inaccuracies. To evaluate how Cameo reacts to inaccurate monitoring profiles, we perturb measured profile costs (C_{O_M} from Equation 3) by a normal distribution (μ=0), varying standard deviation (σ) from 0 to 1 s. Figure 15 shows that when σ of perturbation is close to window size (1 s), latency is: i) stable at the median, and ii) modestly increases at tail, e.g., only by 55.5% at the 90th percentile. Overall, Cameo's performance is robust when standard deviation is $\leq$ 100ms, i.e., when measurement error is reasonably smaller than output granularity.

7 Related Work

Streaming system schedulers. The first generation of Data Stream Management Systems (DSMS) [15, 32], such as Aurora [28], Medusa [23] and Borealis [14], use QoS based control mechanisms with load shedding to improve query performance at run time. These are either centralized (single-threaded) [28], or distributed [14, 23] but do not handle timestamp-based priorities for partitioned operators. TelegraphCQ [31] orders input tuples before query processing [21, 79], while Cameo addresses operator scheduling within and across query boundaries. Stanford's STREAM [71] uses chain scheduling [22] to minimize memory footprints and optimize query queues, but assumes all queries and scheduler are execute in a single-thread. More recent works in streaming engines propose operator scheduling algorithms for query throughput [20] and latency [41, 64]. Reactive and operator-based policies include [20, 64], while [41] assumes arrivals are periodic or Poisson—however, these works do not build a framework (like Cameo), nor do they handle per-event semantic awareness for stream progress.

Modern stream processing engines such as Spark Streaming [90], Flink [27], Heron [57], MillWheel [18], Naiad [72], Muppet [59], Yahoo S4 [73]) do not include *native* support for multi-tenant SLA optimization. These systems also rely on coarse-grained resource sharing [13] or third-party resource management systems such as YARN [84] and Mesos [47].

Streaming query reconfiguration. Online reconfiguration has been studied extensively [48]. Apart from Figure 3, prior work addresses operator placement [39, 76], load balancing [56, 66], state management [29], policies for scale-in and scale-out [44–46, 67]. Among these are techniques to address latency requirements of dataflow jobs [44, 67], and ways to improve vertical and horizontal elasticity of dataflow jobs in containers [87]. The performance model in [60] focuses on dataflow jobs with latency constraints, while we focus on interactions among operators. Online elasticity was targeted by System S [40, 80], StreamCloud [42] and TimeStream [78]. Others include [35, 53]. Neptune [38] is a proactive scheduler to suspend low-priority batch tasks in the presence of streaming tasks. Yet, there is no operator prioritization *within* each application. Edgewise [37] is a queue-based scheduler based on operator load but not query semantics. All these works are orthogonal to, and can be treated as pluggables in, Cameo.

Event-driven architecture for real-time data processing. This area has been popularized by the resource efficiency of serverless architectures [4, 5, 7]. Yet, recent proposals [17, 26, 58, 70] for stream processing atop event-based frameworks do not support performance targets for streaming queries.

8 Conclusion

We proposed Cameo, a fine-grained scheduling framework for distributed stream processing. To realize flexible per-message scheduling, we implemented a stateless scheduler, contexts that carry important static and dynamic information, and mechanisms to derive laxity-based priority from contexts. Our experiments with real workloads, and on Microsoft Azure, showed that Cameo achieves $2.7\times - 4.6\times$ lower latency than competing strategies and incurs overhead less than 6.4%.

***Abstract*—** Today's data analytics frameworks are compute-centric, with analytics execution almost entirely dependent on the predetermined physical structure of the high-level computation. Relegating intermediate data to a second class entity in this manner hurts flexibility, performance, and efficiency. We present WHIZ, a new analytics execution framework that cleanly separates computation from intermediate data. This enables runtime visibility into intermediate data via programmable monitoring, and data-driven computation where data properties drive when/what computation runs. Experiments with a WHIZ prototype on a 50-node cluster using batch, streaming, and graph analytics workloads show that it improves analytics completion times 1.3-2× and cluster efficiency 1.4× compared to state-of-the-art.

1 Introduction

Many important applications in diverse settings rely on analyzing large datasets, including relational tables, event streams, and graph-structured data. To analyze such data, several execution frameworks have been introduced [4, 7, 15, 24, 36, 42–45, 50, 51]. These enable data parallel computation, where an analytics job's logic is run in parallel on data shards spread across cluster machines.

Almost all these frameworks build on the *MapReduce execution engine* [21]. Like MapReduce, they leverage *compute-centric* execution (§2). Their execution engines' focus is on splitting a job's computational logic, and distributing it across *tasks* to be run in parallel. All aspects of the subsequent execution of the job are rooted in the job's computational logic, and its task-level computation distribution. These include the fact that compute logic running inside tasks is static and/or predetermined; intermediate data is partitioned and routed to where it is consumed based on the task-level structure; and dependent tasks are launched when a fraction of upstream tasks they depend on finish. These attributes of job execution are not related to, or driven by, the properties of intermediate data, i.e., how much and what data is generated. Thus, intermediate data is a *second-class citizen*.

[†]These authors contributed equally to this work.
[*]Work done while at University of Wisconsin–Madison.

Compute-centricity was a natural early choice: knowing job structure beforehand simplifies carving containers to execute tasks; compute-centricity provided clean mechanisms to recover from failures – only tasks on a failed machine needed to be re-executed; and job scheduling became simple because of having to deal with static inputs, i.e., fixed tasks/dependency structures.

Unfortunately, today, compute-centricity severely hinders analytics performance and cluster efficiency due to four fundamental issues (§2, §9): (1) Intermediate data-unawareness means there is no way to quickly adapt job execution based on changing run-time data properties (e.g., volume, key distribution, etc.) to ensure performance- and resource-optimal data processing. (2) Likewise, static parallelism and intermediate data partitioning inherent to compute-centricity prevent adaptation to intermediate data skew and resource flux which are difficult to predict ahead of time, yet, common to modern datasets [30] and multi-tenancy. (3) Execution schedules being tied to compute structure can lead to resource waste while tasks wait for input data to become available - an effect that is exacerbated under multi-tenancy. (4) The skew due to compute-based organization of intermediate data can result in storage hotspots and poor cross-job I/O isolation; it also curtails data locality.

We observe that the above limitations arise from (1) tight *coupling* between intermediate data and compute, and (2) *intermediate data agnosticity* in today's execution frameworks. To improve analytics performance, efficiency, isolation, and flexibility, we develop a new execution framework, WHIZ, that eschews compute-centricity, cleanly separates computation from all intermediate data, and treats both intermediate data and compute as equal first-class entities during analytics applications' execution. WHIZ applies equally to batch analytics, streaming and graph processing.

In WHIZ, intermediate data is written to/read from a *logically* separate distributed key-value datastore. The store offers programmable visibility – applications can provide custom routines for monitoring runtime data properties. The store notifies an execution layer when an application's runtime data satisfies predicates based on data properties. Decoupling, monitoring, and predicates enable *data-driven incremental computation*: based on data properties, WHIZ decides on the fly *what logic* to launch in order to further process the data generated, *how many parallel tasks* to launch, *when/where to launch* them, and *what resources* to allocate to tasks.

We make the following contributions in designing WHIZ: (1) We present a scalable approach for programmable intermediate data monitoring which forms the basis for data-driven actions. (2) We show how to organize intermediate data from multiple jobs in the datastore so as to achieve data locality, fault tolerance, and cross-job isolation. Since obtaining an optimal data organization is intractable, we develop novel heuristics that carefully trade-off among these objectives. (3) We build an execution layer that incrementally decides all aspects of the job execution based on data property predicates being satisfied. We develop novel iterative heuristics for the execution layer to decide, for each ready-to-run analytics stage, task parallelism, task placement, and task sizing. This minimizes runtime skew in the data processed, lowers data shuffle cost and ensures optimal efficiency under resource dynamics. The execution layer also decides the optimal per-task logic to use at run-time.

We build a WHIZ prototype using Tez [47] and YARN [52] (15K LOC). We conduct experiments on a 50 machine cluster in CloudLab [6]. We compare against several state-of-the-art compute-centric (CC) batch, stream and graph processing approaches. Using data-driven incremental computation, WHIZ improves median (95%-ile) job completion time (JCT) $1.3-1.6\times$ $(1.5-2.2\times)$ and cluster efficiency $1.4\times$ by launching the right number of appropriately-sized tasks only when predicates are met. We observe up to $2.8\times$ improvement in efficiency due to WHIZ's ability to change processing logic on the fly. Furthermore, we observe that the impact on JCT under failures is minimal due to WHIZ's data organization. We observe that WHIZ's gains relative to CC improve with contention due to data-driven execution and better data management which mitigate I/O hotspots and minimize resource wastage.

2 Compute-Centric vs. Data-Driven

We begin with an overview of existing data analytics frameworks (§2.1). We then discuss the key design principles of WHIZ (§2.2). Finally, we list the performance issues arising from *compute-centricity* and show how the *data-driven* design adopted by WHIZ overcomes them (§2.3).

2.1 Today: Compute-Centric Engines

Frameworks for batch, graph and streaming analytics rely on execution engines [2, 57]; the engine can be an internal component of the framework or a stand-alone one that the system leverages. The engine is responsible for orchestrating the execution of the analytics job across the cluster.

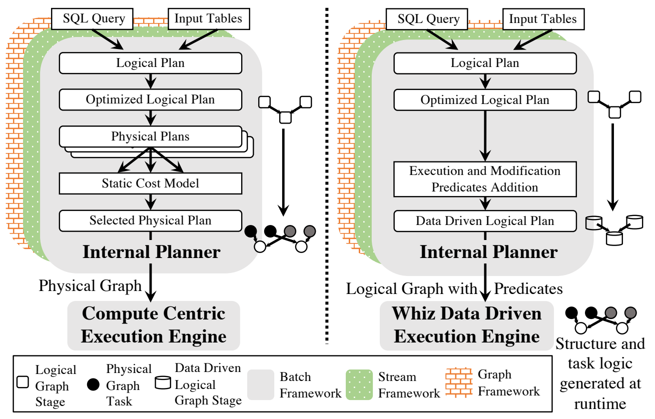

Figure 1: Job Execution Pipelines: Today frameworks hand over physical graphs to the underlying CC execution engine. With WHIZ, *the framework instead hands down a data-driven logical graph and* WHIZ *decides the physical graph at runtime.*

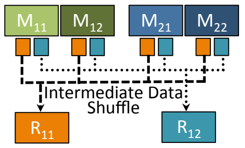
Users submit their jobs to these frameworks (Figure 1) via high-level interfaces (e.g., SQL-like query in case of batch analytics). On submission, the high-level job is handed over to the *internal planner* of the framework which decides the execution plan of the job (expressed in the form of a directed graph). Specifically, the high-level job is translated to a *logical graph* in which different vertices represent different compute *stages* of the overall job and edges represent the dependencies. The logical graph may optionally undergo further optimizations (e.g., to decide the execution order of the stages) and is finally converted to a *physical graph* by undergoing physical optimizations during which low-level execution details such as number of *tasks* per stage (parallelism), dependencies between tasks, resource needs and exact task processing logic are decided.

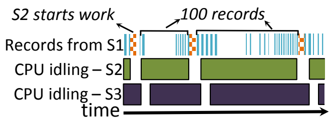
The execution engine takes the physical graph and orchestrates its execution starting with root stages' tasks processing input data to generate *intermediate data*, which is consumed by downstream stages' tasks.

We explain how the execution engine orchestrates the physical graph and its interplay with intermediate data for different analytics. Figure 2a is an example of a simple *batch analytics* job. Here, two tables need to be filtered based on provided predicates and joined to produce a new table. There are 3 stages: two maps for filtering and one reduce to perform the join. Execution proceeds as follows: (1) Map tasks from both the stages execute first with each task processing a partition of the corresponding input table. (2) Map intermediate results are written to local disk by each task, split into files, one per consumer reduce task. (3) Reduce tasks are launched when the map stages are nearing completion; each reduce task *shuffles* relevant intermediate data from all map tasks' locations, and generates output.

A *stream analytics* job (e.g., Figure 2b) has a similar model [11,37,58]; the main difference is that tasks in all stages are always running. A *graph analytics job*, in a framework



(a) A batch analytics job. Intermediate data is partitioned into two key ranges, one per reduce task, and stored in local files at map tasks.



(b) Data flow in a streaming job. Tasks in all stages are always running. Output of a stage is immediately passed to a task in downstream stage. However, CPU is idle until task in Stage 2 receives 100 records after which computation is triggered.

Figure 2: Simplified examples of existing analytics systems.

that relies on the popular message passing abstraction [42], has a similar but simplified model: the different stages are iterations in a graph algorithm, and thus all stages execute the same processing logic (with the input being the output of the previous iteration).

Compute-centricity: Today's execution engines *early-bind* to a physical graph at job launch-time. Their primary goal is to split up and distribute computation across machines. The composition of this distributed computation, in terms of physical tasks and their dependencies, is a first class entity. The exact computation in each task is assumed to be known beforehand. The way in which intermediate data is partitioned and routed to consumer tasks, and when and how dependent computation is launched, are tied to compute structure. We use the term *compute-centric* to refer to this design pattern. Here, intermediate data is a second class entity as important aspects of job execution such as parallelism, processing and scheduling logic are decided without taking it into account (§2.3).

2.2 Whiz: A Data-Driven Framework

Whiz is an *execution engine* that makes intermediate data a first class citizen and supports diverse analytics. Whiz adopts the following design principles:

1. Decoupling compute and data: Whiz decouples compute from intermediate data, and the data from all stages across all jobs is written/read to/from a logically separate key-value (KV) datastore (§4), i.e, the datastore resides across the same set of machines on which computations take place. The store is managed by a distinct data management layer called the data service (DS). Similarly, an execution service (ES) manages compute tasks.

2. Programmable data visibility: The above separation enables low-overhead and scalable approaches to gain visibility into *all* runtime data (§5.1). Whiz DS allows gathering custom runtime properties of intermediate data, via narrow, well-defined APIs.

3. Runtime physical graph generation: During the job execution pipeline, Whiz skips physical optimization (Figure 1) and thus, *does not early-bind* to a physical graph. Instead, the framework's internal planner performs *data-driven embellishment* on the logical graph to give a *data-driven logical graph*. This embellishment adds predicates to decide when and what logic should be used to process data of each stage, and gives Whiz the ability to incrementally generate the physical graph at runtime (§6).

4. Data-driven computation: Building on data visibility and data-driven logical graphs, Whiz initiates data-driven computation by notifying applications when intermediate data predicates within each stage are satisfied (§5.2). Data properties drive all further aspects of computation: task logic, parallelism and sizing (§6).

2.3 Overcoming Compute-centricity Issues

We contrast Whiz with compute-centricity along flexibility, performance, efficiency, placement, and isolation.

Data opacity, and compute rigidity: In compute-centric frameworks, there is no visibility into intermediate data of a job and the tasks' computational logic are decided a priori. This prevents adapting the tasks' logic based on their input data. Consider the job in Figure 2a. Existing frameworks determine the type of join for the *entire* reduce stage based on coarse statistics [3]; unless one of the tables is small, a sort-merge join is employed to avoid out-of-memory (OOM) errors. On the other hand, having fine-grained visibility into input data for each task enables dynamically determining the type of join to use for *different* reduce tasks. A task can use hash join if the total size of *its* input is less than the available memory, and merge join otherwise. Whiz enables deciding the logic at runtime through its ability to provide visibility and incrementally generate the physical graph (§6.1).

Static Parallelism, Partitioning: Today, jobs' per-stage parallelism, inter-task edges and intermediate data partitioning strategy are decided independent of runtime data and resource dynamics. In Spark [57] the number of tasks in a stage is determined a priori by the user application or by SparkSQL [10]. A hash partitioner is used to place an intermediate (k, v) pair into one of $|tasks|$ buckets. Pregel [42] vertex-partitions the input graph; partitions do not change during the execution of the algorithm.

This limits adaptation to *resource flux* and *data skew*. A running stage cannot utilize newly available compute resources [26, 27, 41] and dynamically increase its parallelism. If some key in a partition has an abnormally large number of records to process, then the corresponding task is significantly slowed down [14], affecting both stage and overall job completion times.

By not early-binding, Whiz can decide task parallelism and task size based on resources available and data volume. This controls data skew, and provisions task resources proportional to the data to be processed (§6.2).

Idling due to compute-driven scheduling: Modern schedulers [23, 52] decide when to launch tasks for a stage based on the static computation structure. When a stage's computation is commutative+associative, schedulers launch its tasks once 90% of all tasks in upstream stages complete [5]. But the remaining 10% of producers can take long to complete [14], resulting in tasks idling.

Idling is worse in streaming, where consumer tasks are continuously waiting for data from upstream tasks. E.g., consider the streaming job in Figure 2b. Stage 2 computes and outputs the median for every 100 records received. Between computation, S2's tasks stay idle. As a result, the tasks in the downstream S3 stage *also* stay idle. To avoid idling, tasks should be scheduled *only when, and only as long as, relevant input is available*. In our example, computation should be launched only after $\geq$ 100 records have been generated by an S1 task. Likewise, in batch analytics, if computation is commutative+associate, it is beneficial to "eagerly" launch tasks to process intermediate data whenever enough data has been generated to process in one batch, and exit soon after it's done.

Idling is easily avoided with WHIZ as it does data-driven scheduling: launches tasks only when predicates are met, i.e, relevant data has been generated (§5.2).

Placement, and storage isolation: Because intermediate data is spread across producer tasks' locations, it is impossible to place *consumer tasks* in a data-local fashion. Such tasks are placed at random [21] and forced to engage in expensive shuffles that consume a significant portion of job runtimes ($\sim$30% [20]).

Also, when tasks from multiple jobs are collocated, it becomes difficult to isolate their hard-to-predict intermediate data I/O. Tasks from jobs generating large intermediate data may occupy much more local storage and I/O bandwidth than those generating less.

Since the WHIZ store manages data from all jobs, it can enforce policies to organize data to meet *per-job* objectives, e.g., data locality for *any* stage (not just input-reading stages), and to meet *cluster* objectives, such as I/O hotspot avoidance and cross-job isolation (§4).

3 WHIZ Overview

We now describe the end-to-end control flow in WHIZ. The end-user submits the job through a high-level interface exposed by the application-specific framework. The framework's internal planner converts the job into a data-driven logical graph through *data-driven embellishment* during which each stage in the graph is annotated with *execution predicates* and *modification predicates*.

Execution predicates determine when data generated by the current stage can be consumed by its downstream stages (e.g., start downstream processing when number of records cross a threshold). Modification predicates determine which processing logic should be chosen at runtime (e.g., decide the join algorithm for the task, say, sort-merge join or hash join) based on data properties.

This data-driven logical graph (e.g., directed acyclic graph in case of batch analytics) , that is expressed via WHIZ APIs (Appendix. A), is submitted to WHIZ via a client (Figure 3).

Figure 3: WHIZ *control flow.*

The WHIZ client is the primary interface between the framework running atop WHIZ and the core WHIZ services - the DS and the ES. The client provides the DS with details regarding data properties to be collected and execution predicates. The client also transfers the logical graph and modification predicates to the ES (step 1).

The ES runs the first stage(s) of the logical graph and writes its output to the datastore (step 2). The DS stores the received data and when the execution predicate corresponding to the stage(s) is met, it notifies the ES. The DS piggybacks data statistics (e.g., per-key counts) on this notification to the ES (step 3). On receiving the notification, the ES checks the modification predicates to decide the processing logic and then processes the data. This process repeats. Interactions between the ES, DS and the client are transparent to the framework.

The DS organizes data from all jobs and ensures both per-job and cross-job objectives are met (§4) while simultaneously enabling data visibility through programmable monitoring (§5). The ES, in addition to deciding the processing logic, also determines task parallelism, location and resource use at runtime (§6). In this manner end-users are no longer required to specify low-level details such as task parallelism and data partitioning strategy. In the rest of the paper, we focus on how WHIZ handles data-driven logical graphs and plan to explore designing data-driven embellishers (responsible for embellishment of logical graphs with predicates) that can be added to existing frameworks in the future.

4 Data Store

In WHIZ, all jobs' intermediate data is written to/read from a logically separate datastore (managed by the DS), where it is structured as <key,value> pairs. In batch/stream analytics, the keys are generated by the stage computation logic itself; in graph analytics, keys are identifiers of vertices to which messages (values) are destined for processing in the next iteration. The DS via a cluster-wide master **DS-M** organizes data in the store.

An ideal data organization should achieve three goals: (1) *load balance* and spread all jobs' data, specifically, avoid hotspots and *improve cross-job isolation*, and *minimize within-job skew* in tasks' data processing. (2) maximize job *data locality* by co-locating as much data having the same key as possible. (3) be *fault tolerant* - when a storage node fails, recovery should have minimal impact on job runtime. Our data storage granularity, described next, forms the basis for meeting our goals.

Figure 4: Data organization flow when a stage starts generating data.

4.1 Capsule: A Unit of Data in WHIZ

WHIZ groups intermediate data based on keys into groups called *capsules*. A stage's intermediate data is organized into some large number N capsules; crucially N is *late-bound* as described below, which helps meet our goals above. Intermediate data key range is split N-ways, and each capsule stores all <k, v> data from a given range. WHIZ strives to materialize all capsule data on one machine; rarely (e.g., when there is less space left on a machine), a capsule may be spread across a small number of machines. This materialization property of capsules forms the basis for consumer task data locality.

Furthermore, WHIZ capsule key ranges are *late-bound*: we first determine the set of machines on which capsules from a stage are to be stored; machines are chosen to maximally support isolation, load balance, locality and fault tolerance; the choice of machines then determines the number N for a stage's capsules (§4.2).

Given these machines and N, as the stage produces data at runtime, N capsules are materialized, and dynamically allocated to right-sized tasks; this enables the ES to preserve data-local processing, lower skew, and optimally use compute resources (§6).

4.2 Fast Capsule Allocation

We consider how to place multiple jobs' capsules on machines to avoid hotspots, ensure data locality and minimize job runtime impact on data loss. We formulate an ILP to this end (see Table 7 in Appendix. B). However, solving this ILP at scale can take several tens of seconds delaying capsule placement. WHIZ instead uses a practical approach for the capsule placement problem. First, instead of jointly optimizing global placement decisions for all the capsules, WHIZ solves a "local" problem of placing capsules for each stage independently while still considering inter-stage dependencies; when new stages arrive, or when existing capsules may exceed job quota on a machine, new locations for some of these capsules are determined (see Figure 4). Second, instead of solving a multi-objective optimization, WHIZ uses a linear-time rule-based heuristic to place capsules; the heuristic prioritizes load and locality (in that order) in case machines satisfying all objectives cannot be found. Isolation is always enforced.

Capsule location for new stages (Figure4): When a job j is

h1	*// Q_j: max storage quota per job j and machine m.* Based on fairness considerations across all runnable jobs J.
h2	*// M_v: number machines (out of M) to organize data that //generated by v of j.* a. Count number machines M_{j75} where j is using $< 75\%$ of Q_j; b. $M_v = max(2, M_{j75} \times \frac{M\_M_{j75}}{M})$.
h3	*// Given M_v, compute list of machines $\overrightarrow{M_v}$.* Considers only machines where j is using $< 75\%$ of Q_j; a. Pick machines that provide load balance (LB), data locality (DL) and maximum possible fault tolerance (FT); b. If $\lvert\overrightarrow{M_v}\rvert < M_v$, relax FT guarantees and pick machines that provide LB and DL; c. If $\lvert\overrightarrow{M_v}\rvert$ is still $< M_v$, pick machines that just provide LB.
h4	*// Given M_v, compute total capsules N.* $N = G$ X M_v, where G = capsules per machine
h5	*// Which machines are at risk of violating Q_j?* $\overrightarrow{M_j}$: machines which store data of j and j is using $\geq 75\%$ of Q_j.
h6	*// Which capsules are hot on $\overrightarrow{M_j}$?* Significantly larger in size or have a higher increasing rate than others.

Table 1: Heuristics employed in data organization.

ready to run, **DS-M** invokes an admin-provided heuristic h1 (Table 1) that assigns job j a quota Q_j per machine. Setting up quotas helps ensure isolation across jobs.

When a stage v of job j starts to generate intermediate data, **DS-M** invokes h2 to determine the number of machines M_v for organizing v's data. h2 picks M_v between 2 and a fraction of the total machines which are $\leq 75\%$ of the quota Q_j for job j. $M_v \geq 2$ ensures opportunities for data parallel processing; a bounded M_v (Table 1) controls the ES task launch overhead (§6.2).

Given M_v, **DS-M** invokes h3 to generate a list of machines $\overrightarrow{M_v}$ to materialize data on. It starts by creating three sub-lists: (1) For load balancing (LB), machines are sorted lightest-load-first, and only ones which have $\leq 75\%$ quota usage for the corresponding job are considered. (2) For data locality (DL), we prefer machines which already materialize other capsules for this stage v, or capsules from other stages whose output will be consumed by same downstream stage as v (e.g., two map stages in Figure 2a). (3) For fault tolerance (FT), we strive to place dependent capsules on different machines to minimize failure recovery time. We pick machines where there are no capsules from any of v's k upstream stages in the job, sorted in descending order of k. Thus, for the largest value of k, we have all machines that do not store data from *any* of v's ancestors; for $k = 1$ we have nodes that store data from the immediate parent of v.

We pick machines from the sub-lists to maximally meet our objectives in 3 steps: (1) Pick the least loaded machines that are data local and offer as *high fault tolerance as possible* (machines present in all three sub-lists). Note that as we go down the fault tolerance list in search of a total of M_v machines, we trade-off fault tolerance. (2) If despite reaching the minimum possible fault tolerance, i.e., reaching the bottom of the fault tolerance sub-list – the number of machines picked falls below M_v, we completely trade-off fault tolerance and pick the least loaded machines that are data local. (3) If still the number of machines picked falls below M_v, we simply pick the least-loaded machines and trade-off data locality too.

Finally, given $\overrightarrow{M_v}$, **DS-M** invokes h4 and instantiates a fixed number (G) of capsules per machine leading to total capsules per-stage (N) to be $G \times M_v$. While a large G would aid us in better handling of skew and computation as the capsules can be processed in parallel, it comes at the cost of significant scheduling and storage overheads. We empirically study the sensitivity to G (in §9.4); based on this, our prototype uses $G = 24$.

New locations for existing capsules: Data generation patterns can vary across different stages, and jobs, due to heterogeneous compute logics and data skew. Thus a job j may run out of its Q_j on machine m, leaving no room to grow already-materialized capsules of job j on m. **DS-M** reacts to such dynamics by determining, $\forall j$: machines where job j is using $\geq 75\%$ Q_j (h5), closing capsules that are significantly larger or have a higher growth rate than others on such machines (h6), and invokes heuristic h3 to compute the machines to spread these capsules. This focuses on capsules that contribute most load to machines at risk of being overloaded and thus bounds the number of capsules that will spread out.

5 Data Visibility

We now describe how WHIZ offers programmable data monitoring via the DS (§5.1), and how it initiates data-driven computations using execution predicates (§5.2).

5.1 Data Monitoring

Given that intermediate data properties form the basis of data-driven computation, native support for data monitoring is extremely crucial. The DS through its data organization simplifies monitoring as it consolidates a capsule at one or a few locations rather than it being spread across the cluster (§4.1). WHIZ achieves scalable monitoring via per-job masters **DS-JMs** which track light-weight properties related to their capsules.

WHIZ supports *built-in* and *custom* monitors that gather properties per capsule. They are periodically sent to the relevant **DS-JM**. Built-in monitors constantly collect *coarse-grained* properties such as current capsule size, total or number of unique (k,v) pairs, location(s) and rate of growth; apart from being used for data-driven computation, these are used in runtime data organization (§4.2).

Custom monitors are UDFs (user defined functions) that are used to get *fine-grained* data properties per the job specification. We restrict UDFs to those that can execute in linear time and O(1) state, such as (a) number of entries s.t. values are $<, =,$ or $>$ than a threshold; (b) min, max, avg. of keys; and (c) whether data is sorted or not.

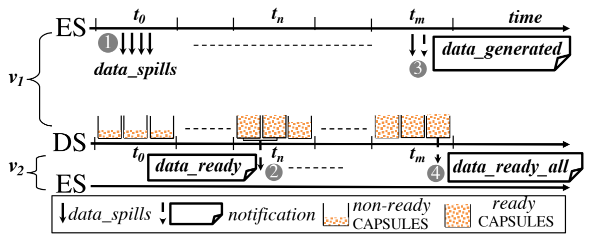

Figure 5: Data-driven computation facilitated by notifications. (1) Intermediate data (v_1) batches sent from ES to DS. (2) DS detects that 2 capsules are ready and sends data_ready notification from DS to ES leading to downstream computation (v_2). (3) ES sends data_generated notification to DS when entire output of v_1 pushed to DS. (4) DS sends data_ready_all notification to ES indicating that all data_ready notifications have been sent.

Getting visibility into intermediate data through monitors enables data-driven computation as we describe next.

5.2 Indicating Data Readiness

The DS is responsible for initiating data-driven computation. The DS achieves this via two key abstractions: *notifications* and *execution predicates*. The decoupled DS and ES interact via notifications which enable, and track progress of, data-driven computation. Execution predicates enable the **DS-JM** to decide when capsules can be deemed ready for corresponding computation to be run on them.

Notifications: WHIZ introduces 3 types of notifications: (1) A *data_ready* notification is sent by the **DS-JM** to the ES whenever a capsule becomes ready (as per the execution predicate) to trigger corresponding computation. (2) A *data_generated* notification is sent by the ES to the **DS-JM** when a stage finishes generating all its intermediate output. This notification is required because the **DS-JM** is unaware of the number of tasks that the ES launches corresponding to a stage, and thus cannot determine when a stage is completed. (3) A *data_ready_all* notification is sent by the **DS-JM** to the ES when a stage has received all its input data (occurs when *data_ready* notifications regarding all ready input capsules are sent). This notification is required because the ES is unaware of the total number of capsules that the DS deems ready.

The use of these notifications is exemplified in Figure 5. Here: ❶ when a stage v_1 generates a batch of intermediate data, a *data_spill* containing the data is sent to the data store, which accumulates it into capsules (t_0 through t_m). ❷ Whenever the **DS-JM** determines that a collection of v_1's capsules (2 capsules in Figure 5 at t_n) are ready for further processing, it sends a *data_ready* notification per capsule to the ES; the ES launches tasks of a consumer stage v_2 to process such capsules. This notification carries per-capsule information such as: a list of machine(s) on which each capsule is spread, and a list of statistics collected by the data monitors. ❸ Finally, a *data_generated* notification – from the ES, generated upon v_1 computation completion – notifies the **DS-JM** that v_1 finished generating *data_spills*. ❹ Subsequently, **DS-JM** notifies the ES via the *data_ready_all* event, that all capsules corresponding to v_1 have sent their data_ready events (at t_m). This enables the ES to determine when the immediate downstream stage v_2, that is reading the data generated by v_1, has received all of its input data.

Execution predicates: The interaction between ES and DS via notifications is initiated by execution predicates whose logic is based on the properties collected by the monitors. Each job stage is typically associated with an execution predicate as indicated by the input program, which is transferred to the **DS-JM** by the WHIZ client. If not, default analytics-specific predicates are applied. WHIZ supports diverse execution predicates such as:

1. Data Generated: This predicate deems capsules ready when the computation generating them is done; this is the default predicate for batch and graph analytics in WHIZ; akin to a barrier in batch systems today and bulk synchronous execution in graph analytics.

2. Record Count $\geq X$: The vanilla version of this predicate deems a capsule ready when it has $\geq X$ records from producers tasks; this is the default predicate for streaming systems in WHIZ; akin to micro-batching in existing streaming systems [58], with the crucial difference that the micro-batch is not wall clock time-based, but is based on the more natural intermediate data count.

This predicate can be extended to support pipelining via *ephemeral compute*, i.e, compute is launched once there is partial data and just for the processing duration. The ability to launch compute ephemerally is particularly useful under heavy resource contention. Ephemeral compute can be used to speed up jobs across analytics if they contain commutative+associative operations (§9).

For example, consider the partial execution of a batch (or graph) analytics job, consisting of the first two logical stages (likewise, first two iterations) $v_1 \rightarrow v_2$. If the processing logic in v_2 contains commutative+associative operations, it can start processing its input before all of it is in place. Using this predicate, a capsule generated by v_1 is ready whenever the number of records in it reaches a threshold X. This enables the ES to overlap v_2's computation with v_1's data generation as follows: (1) Upon receiving a *data_ready* notification from the **DS-JM** for capsules which have $\geq X$ records, the ES launches ephemeral tasks of v_2. (2) Tasks read the current data, compute the associative+commutative function on the (k,v) data read, push the result back to data store (in the same capsules advertised through the received *data_ready* notification) and immediately quit. (3) The **DS-JM** waits for each capsule to grow back beyond threshold X for generating subsequent *data_ready* notifications leading to ephemeral tasks being launched again. (4) Finally, when a *data_generated* notification is received from v_1, the **DS-JM** triggers a final *data_ready* notification for all the capsules generated by v_1, and a subsequent *data_ready_all* notification, to enable v_2's final output to be written in capsules and fully consumed by a downstream stage, say v_3 (similar to Figure 5).

This predicate can be further extended to *across* capsules, i.e., the **DS-JM** could deem all capsules ready when the number of entries generated across all capsules cross a threshold. In streaming, such predicates help improve efficiency and performance as ephemeral tasks are launched only when the required input records have streamed into the system and quit post processing (§9.1.3). On the other hand, systems today lack support for ephemeral compute and are forced to deploy long-standing tasks.

3. Special Records: This predicate deems all output capsules of a stage ready on observing a special record in any one capsule. Stream processing systems often rely on "low watermark" records to ensure event-time processing [19, 40], and to support temporal joins [40]. Such predicates can be used to launch, *on demand*, temporal operators whenever a low watermark record is observed at any of a stage's output capsules. In contrast, systems today have the operators always running and this leads to compute idling when there are no records to process.

6 Execution Service

While the DS initiates data-driven computation by notifying when data is ready for processing, the ES carries out all other data-driven execution aspects by *incrementally generating the physical graph*. It does so via a per-job master **ES-JM** that given ready capsules, and available resources[1]: (a) determines the appropriate processing logic to use (§6.1); (b) determines optimal parallelism and deploys tasks to minimize skew and shuffle; (c) maps capsules to tasks in a resource-aware fashion (§6.2).

6.1 Selecting Compute Logic

Upon detecting a ready capsule, the **DS-JM** sends the *data_ready* notification, with capsule properties (including fine-grained ones) piggybacked, to the **ES-JM**. The **ES-JM** then uses modification predicates associated with this stage to determine the exact processing logic.

Modification predicates give the ability to decide processing logic at runtime based on the received data properties and available resources. Importantly, WHIZ also provides jobs with the flexibility to use *different* processing logic for different input capsules of the same stage. For e.g., consider a batch analytics job that involves joining two tables.[2] In such

[1]Similar to existing frameworks, a cluster-wide Resource Manager decides available resources as per cross-job fairness.

[2]DS via per-job quotas ensures that the input tables use the same # of capsules and because both tables use the same key, i.e., the join key, while

h7	*// $\overrightarrow{C}$: subsets of unprocessed capsules.* a. $CaMax = 2 \times \lvert c \rvert$, c is largest capsule $\in C$; b. Group all capsules $\in C$ into subsets in strict order: i. data local capsules together; ii. each spread capsule, along data-local capsules together; iii. any remaining capsules together; subject to: iv. each subset size $\leq CaMax$; v. conflicting capsules don't group together; vi. troublesome capsules always group together.
h8	*// $\overrightarrow{M}$: preferred machines to process each subset $\in \overrightarrow{C}$.* c. no machine preference for troublesome subsets $\in \overrightarrow{C}$ d. for every other subset $\in \overrightarrow{C}$ pick machine m such that: i. all capsules in the subset are only materialized at m; ii. otherwise m contains the largest materialization of the subset.
h9	Compute $\overrightarrow{R}$: resources to execute each subset $\in \overrightarrow{C}$: e. $\overrightarrow{A}$ = available resources for j on machines $\overrightarrow{M}$; f. $F = \min\left(\frac{\overrightarrow{A}[m]}{\text{total size of capsules allocated to } m}, \text{ for all } m \in \overrightarrow{M}\right)$; g. for each subset $i \in \overrightarrow{C}$: $\overrightarrow{R}[i] = F \times$ total size of capsules allocated to $\overrightarrow{C}[i]$.

Table 2: Heuristics to group capsules and assign them to tasks.

a scenario, the SQL framework running atop sets the modification predicates of the join stage to choose the appropriate join algorithm between, say, sort-merge join[3] and hash join[4] as follows: (a) if both capsules are already sorted, and the max value in the first capsule is less than the min value in the other capsule (no intersection), then skip unnecessarily launching a task to do the join; (b) if the size of one capsule is significantly smaller than the other one (and data is not sorted), then use hash join (as it is typically less expensive to create a hash table of the smaller capsule, than sorting the large one); and (c) if data is sorted or (a)–(b) don't satisfy, then default to sort-merge join.

Crucially, such predicates enable stream jobs submitted to WHIZ, to change their processing logic *over time*, as opposed to being early bound to processing logic (status-quo today). For e.g., predicates allow a job involving temporal join to change its join algorithm over time and choose the appropriate one, from the three choices (a)–(c) above, based on data properties and available resources.

6.2 Task Parallelism, Placement, and Sizing

Given a set of ready capsules (C) for a stage, the ES-JM needs to map capsules to tasks, and determine their location (across machines M) and sizes (resources) so as to minimize cross-task skew and shuffle while taking available resources into account. To do so, we propose an *iterative procedure* that applies a set of heuristics (Table 2) repeatedly until tasks for all ready capsules are allocated, and their locations and sizes determined.

The iterative procedure consists of 3 steps: (a) generate optimal subsets of capsules to minimize cross-subset skew (using h7), (b) decide on which machine should a subset be processed to minimize shuffle (h8), and (c) determine resources required to process each subset (h9).

First, we group capsules C into a collection of *subsets* $\overrightarrow{C}$ using h7. We then try to assign each group to a task. Our grouping into subsets attempts to ensure that data in a subset is spread on just one or a few machines (lines (b.i-b.iii)), which minimizes shuffle, and that the data is spread roughly evenly across subsets (line (b.iv)) making cross-task performance uniform. We place a bound $CaMax$, equaling twice the size of the largest capsule, on the total size of a subset (see line (a)). This ensures that multiple (at least 2) capsules are present in each subset and allows mitigating stragglers by *only* assigning the yet-to-be-processed capsules to the speculative task.[5]

Second, we determine a preferred machine to process each subset using h8; this is a machine where most if not all capsules in the subset are materialized (line (d)). Choosing a machine in this manner minimizes shuffle.

Finally, given available resources across the preferred machines (from the cluster-wide resource manager [52]) we need to allocate tasks to process subsets. But some machines may not have resource availability. For the rest of this iteration, we ignore such machines and the subsets of capsules that prefer such machines.

Given machines with resources $\overrightarrow{A}$, we assign a task for each subset of capsules which can be processed, and allocate task resources *altruistically* using h9. That is, we first compute the minimum resource available to process unit data (F; line (f)). Then, for each task, the resource allocated (line (g)) is F times the total data in the subset of capsules allocated to the task ($\lvert\overrightarrow{C}[i]\rvert$).

Allocating task resources proportional to input size ensures that tasks have similar finish times. Allocating resources corresponding to the minimum available helps further: if a job gets more resources than what is available for the most constrained subset, then it does not help the job's completion time (which is determined by the most constrained subset's processing). Altruistically "giving back" such resources speeds up other jobs/stages.

The above 3 steps repeat whenever new capsules are ready, or existing ones can't be scheduled. Similar to delay scheduling [56], we attempt several tries to execute a group which couldn't be scheduled on its preferred machine due to resource unavailability, before marking capsules *conflicting*. These are

writing to the store, key-range split for both tables is the same.

[3]This (a) sorts the two input capsules on the join key and (b) merges them by comparing the records.

[4]This (a) builds a hash table on the join key using the smaller capsule and (b) probes for matches using the other capsule.

[5]Speculative tasks today [12–14, 38, 59] reprocess the entire input leading to duplicate work and resource wastage.

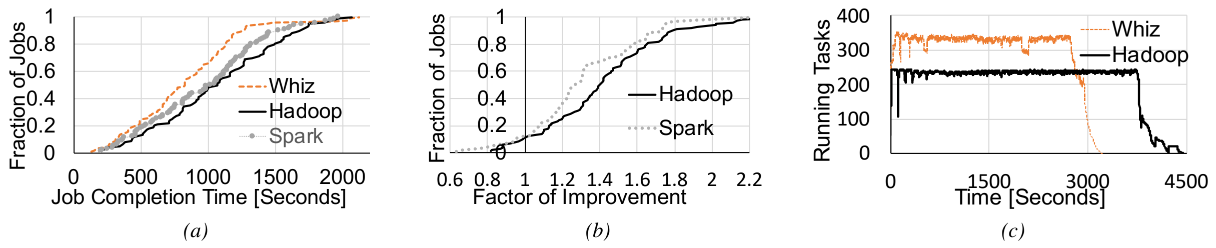

Figure 6: [Batch Analytics] (a) CDF of JCT; (b) CDF of factors of improvement of individual jobs using Whiz *w.r.t. baselines; (c) Snapshot of running tasks during one of the experiments. Gains are lower w.r.t. Spark due to our Hadoop-based implementation, and thus using a non-optimized in-memory store.*

re-grouped in the next iteration (line (b.v)). Finally, capsules that cannot be executed under any grouping are marked troublesome (line (b.vi)) and processed on any machine (line (d.ii)).

7 Fault Tolerance

Task Failure. When a task fails due to a machine failure, only the failed tasks need to be re-executed if the input capsules are not lost. But, this will result in duplicate data in all capsules for the stage leading to data inconsistencies. To address this, we use checksums at the consumer task-side Whiz library to suppress duplicate data.

However, if the failed machine also contains the input capsules of the failed task, then the **ES-JM** triggers the execution of the upstream stage(s) to regenerate the input capsules of the failed task. Recall that Whiz's fault tolerance-aware capsule storage (§4) helps control the number of upstream (ancestor) stages that need to be re-executed in case of data loss.

DS-M/DS-JM/ES-JM. Whiz maintains replicas of DS-M/DS-JM daemons using Apache Zookeeper [28], and fails over to a standby. Given that Whiz generates the physical graph of a job at runtime in a data-driven manner, upon ES-JM failure, we simply need to restart it so that it can resume handling notifications from the DS. During this time already launched tasks continue to run.

8 Implementation

We prototyped Whiz by modifying Tez [5] and leveraging YARN [52]. The DS, implemented from scratch, has three kinds of daemons (managed via YARN): cluster-wide master **DS-M**, per-job masters **DS-JM** and workers **DS-W**. DS-M does data organization across DS-Ws. DS-JMs collect statistics and notify ES-JM when execution predicates are met. DS-Ws run on cluster machines and do node-level management: (a) store data received from ES/other DS-Ws in local in-memory file system (`tmpfs` [48]) and transfer data to other DS-Ws per DS-M directives; (b) report statistics to DS-M/DS-JMs via heartbeats; and (c) provide ACK to tasks for data written.

The ES was implemented by modifying Tez. It consists of per-job masters **ES-JM** which are responsible for generating the physical graph at runtime. ES tasks are modified Tez tasks that have an interface to the local DS-W as opposed to local disk or cluster-wide storage. The Whiz client is a standalone process per-job.

All communication (asynchronous) between DS, ES and client is through RPCs in YARN using Protobuf [8]. We also use RPCs between the YARN Resource Manager (RM) and ES-JM to propagate resource allocations (§6).

9 Evaluation

We evaluated Whiz on a 50-machine cluster deployed on CloudLab [6] using publicly available benchmarks – *batch* TPC-DS jobs, PageRank for *graph analytics*, and synthetic *streaming* jobs. Unless otherwise specified, we set Whiz to use default execution predicates, equal storage quota ($Q_j = 2.5GB$) and 24 capsules per machine.

9.1 Experiment Setup

Workloads: We consider a mix of jobs, all from TPC-DS (**batch**), or all from PageRank (**graph**). For **streaming**, we use a variety of different queries described in detail later. In each experiment, jobs are randomly chosen and follow a Poisson arrival distribution with average inter-arrival time of 20s. Each job lasts up to 10s of minutes, and takes as input tens of GBs of data. We run each experiment thrice and present the median.

Cluster, baseline, metrics: Machines have 8 cores, 64GB memory, 256GB storage, and a 10Gbps NIC. We compare Whiz as follows: (1) **Batch**: *vs.* Tez [5] running atop YARN [52], for which we use the shorthand "Hadoop" or "CC"; and *vs.* SparkSQL [15]; (2) **Graph**: *vs.* Giraph (i.e., open source Pregel [42]); and *vs.* GraphX [24]; (3) **Streaming**: *vs.* SparkStreaming [58].

For a fair comparison, we ensure Hadoop/Giraph use `tmpfs`. We study the relative improvement in the average job completion time (JCT), or $JCT_{CC}/JCT_{\text{WHIZ}}$. We measure efficiency using *makespan*.

9.1.1 Batch Analytics

Performance and efficiency: Figure 6a shows the JCT distributions of Whiz, Hadoop, and Spark for the TPC-DS work-

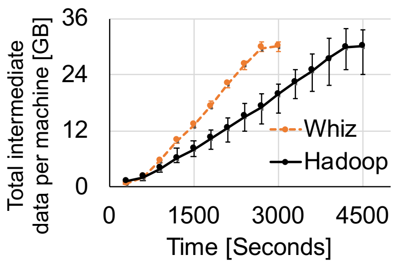

Figure 7: Cross-job average, min *and* max *intermediate data per machine during one of our batch analytics experiments.*

load. Only 0.4 (1.2) highest percentile jobs are worse off by $\leq 1.06\times$ ($\leq 1.03\times$) than Hadoop (Spark). WHIZ speeds up jobs by **1.4×** (**1.27×**) on average, and **2.02×** (**1.75×**) at 95*th* percentile w.r.t. Hadoop (Spark). Also, WHIZ improves makespan by **1.32×** (**1.2×**).

Figure 6b presents improvement for individual jobs. For more than 88% jobs, WHIZ outperforms Hadoop and Spark. **Only 12**% jobs slow down to $\leq 0.81\times$ ($0.63\times$) using WHIZ. Gains are $> 1.5\times$ for $> 35\%$ jobs.

Sources of improvements: We observe that *more rapid processing* due to *data-driven execution*, and *better data management* contribute most to benefits.

First, we snapshot the number of running tasks across all the jobs in one of our experiments when running WHIZ and Hadoop (Figure 6c). WHIZ has 1.45× more tasks scheduled over time which translates to jobs finishing 1.37× faster. It has **1.38×** better cluster efficiency than Hadoop. Similar observations hold for Spark (omitted).

The main reasons for rapid processing/high efficiency are: (1) The DS ensures that most tasks are data local (**76**% in our expts). This improves average *consumer* task completion time by 1.59×. Resources thus freed can be used by other jobs' tasks. (2) Based on DS-provided properties, ES's data-driven actions provide similar input sizes for tasks in a stage – within 14.4% of the mean.

Second, Figure 7 shows the size of the cross-job total intermediate data per machine. We see that Hadoop generates heavily imbalanced load spread across machines. This creates many storage hotspots and slows down tasks competing on those machines. Spark is similar. WHIZ mitigates hotspots (§4) improving overall performance.

We observe jobs generating less intermediate data are more prone to performance losses in WHIZ, especially under ample resource availability as WHIZ strives for capsule-local task execution (§6.2). If resources are unavailable, WHIZ will assign the task to a data-remote node, or get penalized waiting for data-local placement.

9.1.2 Graph Processing

We run multiple PageRank (40 iterations) jobs on the Twitter Graph [17, 18]. In each iteration, vertices run the processing logic and exchange their output as messages with each other. WHIZ groups messages into capsules based on vertex ID. We use an *execution predicate* that deems a capsule ready when ≥ 1000 messages are present.

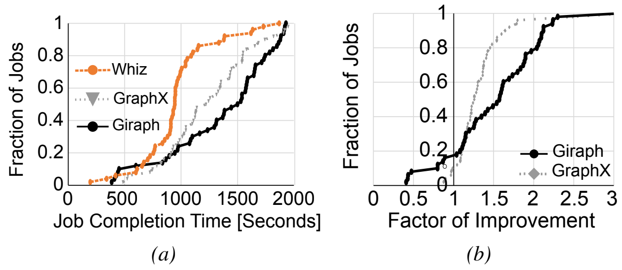

Figure 8: [Graph Analytics] (a) CDF of JCT using WHIZ, *GraphX and Giraph; (b) CDF of factors of improvement of individual jobs using* WHIZ *w.r.t. GraphX and Giraph.*

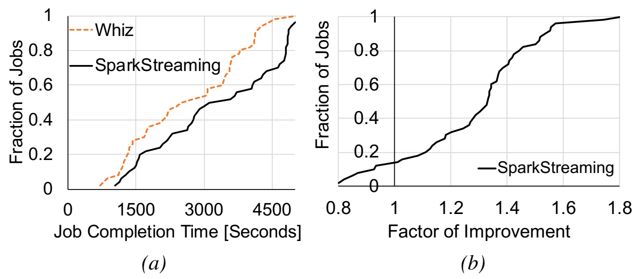

Figure 9: [Stream Analytics] (a) CDF of JCT using WHIZ *and SparkStreaming; (b) CDF of factors of improvement of individual jobs using* WHIZ *w.r.t. SparkStreaming.*

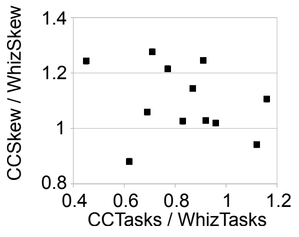
Figure 8a shows the JCT distribution of WHIZ, GraphX and Giraph. WHIZ speeds up jobs by **1.33×** (**1.57×**) on average and **1.57×** (**2.24×**) at the 95*th* percentile w.r.t. GraphX (Giraph) (Figure 8b). Gains are lower w.r.t. GraphX, due to its efficient implementation atop Spark. However, **< 10**% jobs are slowed down by $\leq 1.13\times$.

Improvements arise for two reasons. First, WHIZ is able to *deploy appropriate number of ephemeral tasks*: execution predicates immediately indicate data availability, and runtime parallelism (§6.2) allows messages to high-degree vertices [24] to be processed by more than one task. Also, WHIZ has 1.53× more tasks (each runs multiple vertex programs) scheduled over time; rapid processing and runtime adaptation to data directly leads to jobs finishing faster. Second, because of ephemeral compute, WHIZ doesn't hold resources for a task if not needed, resulting in **1.25×** better cluster efficiency.

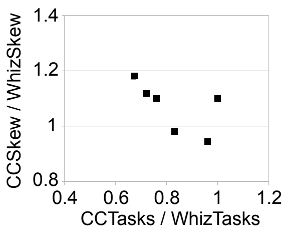
9.1.3 Stream Processing

We run multiple stream jobs, each calculating top 5 common words for every 100 distinct words from synthetic streams replaying GBs of text data from HDFS.

Spark Streaming discretizes the records stream into time-based micro-batches and processes every micro-batch duration. We configure the micro-batch interval to 1 minute. With WHIZ, given the semantics of the processing logic, we use an



(a)



(b)

Figure 10: Hadoop w.r.t. WHIZ *fraction of tasks allocated vs. the fraction of skew in a given stage: (a) for a job with* 12 *stages where* WHIZ *improves JCT by* $1.6\times$*; (b) for a job with* 6 *stages, where* WHIZ *improves JCT by* $1.2\times$. $\frac{CCSkew}{WhizSkew} > 1$ *means* WHIZ *has less skew;* $\frac{CCTasks}{WhizTasks} < 1$ *means Hadoop under-parallelizes.*

execution predicate to enable computation whenever ≥ 100 distinct records are present.

Figures 9a, 9b show our results. WHIZ speeds up jobs by **1.33×** on average and **1.55×** at the 95*th* %-ile. Also, 15% of the jobs are slowed down to around **0.8×**.

The gains are due to *data-driven computation* via execution predicates; WHIZ does not have to delay execution till the next micro-batch if data can be processed now. A Spark Streaming task has to wait as it has no data visibility. In our experiments, more than **73%** executions happen at less than 40*s* time intervals with WHIZ.

Additionally, we evaluate the role of modification predicates in streaming in §9.2.

9.1.4 WHIZ Overheads

CPU, memory overhead: We find that DS-W (§8) processes inflate the memory and CPU usage by a negligible amount even when managing data close to storage capacity. DS-M and DS-JM have similar resource profiles.

Latency: We compute the average time to process heartbeats from various ES/DS daemons, and WHIZ client. For 5000 heartbeats, the time to process each is $2-5ms$. We implemented the WHIZ client and ES-JM logic atop Tez AM. Our changes inflate AM decision logic by $\leq 14ms$ per request with negligible increase in AM memory/CPU.

Network overhead from events/heartbeats is negligible.

9.2 Benefits of Data-driven Computation

The overall benefits above included the effects of execution predicates and incrementally generating the physical graph. We now delve deeper to further shed light into late-binding benefits.

Skew and parallelism: Figure 10 shows fractions of skew and parallelism as generated by Hadoop w.r.t. WHIZ for two TPC-DS jobs from one of our runs. WHIZ's ability to dynamically change parallelism at runtime, driven by the number of capsules for each vertex, leads to significantly less data skew than Hadoop. When Hadoop is under-parallelizing, the skew is significantly higher than WHIZ (up to 1.43×). Over-parallelizing does not help either; Hadoop incurs up to 1.15× larger skew, due to its rigid data partitioning and tasks allocation schemes. Even when WHIZ incurs more skew (up to 1.26×), corresponding tasks will get allocated more resources to alleviate this overhead (§6.2).

% Skew	Improvement Factor
10%	1.1
30%	1.47
50%	1.87
70%	2.48
90%	2.67

Table 3: Improvement in cumulative time using modification predicates w.r.t no predicates. Predicate chooses hash join if the ratio of input capsules' sizes is ≥ 3.

Modification predicates: To evaluate the benefits enabled by WHIZ's ability to late-bind processing logic, we pick a query from our TPC-DS workload which has a join and run it with and without modification predicates while varying the skew between the input tables. Modification predicates allow the job to pick the join algorithm between sort-merge join and hash join (see §6.1) for the different tasks. Table 3 shows the relative improvement in cumulative time (summation over duration of all tasks of the job) with and without predicates (sticks to sort-merge join). We see that predicates improve the cumulative time **1.1×–2.8×** as the skew in capsule sizes increases. This is because with modification predicates, WHIZ chooses to use the hash join when skew between the task inputs exists as building a hashmap on the smaller input is typically cheaper than sorting the other input (occurs when sort-merge join is used instead). Gains increase with skew as the join performance difference also increases.

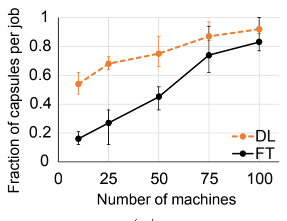
We also quantify the benefits of modification predicates for stream processing. We run a stream query that performs event-time temporal join over 3 minute intervals (execution predicate indicates to wait for watermark) with and without the above modification predicates. We change skew-% randomly (from 10%, 20%,..., 90%) between the two input sources over the same time interval and observe that using modification predicates leads to 1.7× average improvement in cumulative time.

Additionally, we run microbenchmarks to delve further into WHIZ's data-driven benefits (results in Appendix C).

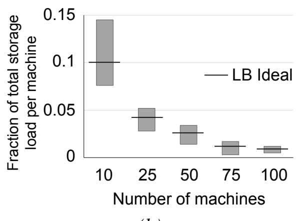
9.3 Load Balancing, Locality, Fault Tolerance

To evaluate DS load balancing (LB), data locality (DL) and fault tolerance (FT), we stressed the data organization under different cluster load. We used job arrivals and all stages' capsule sizes from one of our TPC-DS runs.

Figure 11 shows that: (1) WHIZ prioritizes load balancing and data locality over fault tolerance across cluster loads (§4.2); (2) when the available resources are scarce (5× higher load than initial), all three metrics suffer. However, the maxi-



(a)



(b)

Figure 11: (a) Average, min and max fraction of capsules which are data local (DL) respectively fault tolerant (FT) across all the jobs for different cluster load; (b) Max, min and ideal storage load balance (LB) on every machine for different cluster load.

% Machines Failed	JCT [Seconds] Avg	Min	Max
None	725	215	2100
10%	740	250	2320
25%	820	310	2360
50%	1025	350	2710
75%	1600	410	3300

Table 4: JCT under random machine failures.

mum load imbalance per machine is $< 1.5\times$ than the ideal, while for any job, $\geq 47\%$ of the capsules are data local. Also, on average 16% of the capsules per job are fault tolerant; (3) less cluster load ($0.6\times$ lower than initial) enables more opportunities for DS to maximize all of the objectives: $\geq 84\%$ of the per-job capsules are data local, 71% are fault tolerant, with at most $1.17\times$ load imbalance per machine than the ideal.

Failures: Using the same workload, we also evaluated the performance impact in the presence of machine failures (Table 4). We observe that WHIZ does not degrade job performance by more than $1.13\times$ even when 25% of the machines fail. This is mainly due to DS's ability to organize capsules to be fault tolerant across ancestor stages and avoid data recomputations. Even when 75% of the machines fail, the maximum JCT does not degrade by more than $1.57\times$, mainly due to capsules belonging to some ancestor stages still being available, which leads to fast recomputation for corresponding downstream vertices.

9.4 Sensitivity Analysis

Impact of Contention: We vary storage load, and hence resource contention, by changing the number of machines while keeping the workload constant; half as many servers lead to twice as much load. We see that at $1\times$ cluster load, WHIZ improves over Hadoop by $1.39\times$ ($1.32\times$) on average in terms of JCT (makespan). Even *at high contention* (up to $4\times$), WHIZ's gains keep increasing $1.83\times$ ($1.42\times$). This is because of data-driven execution and better data management which minimizes resource wastage, time spent in shuffling, and leads to few hotspots.

Multiple of Original Load	# Capsules 8	16	20	24	28	32	36	40
1	1.07	1.33	1.46	1.52	1.57	1.63	1.54	1.46
2	1.10	1.16	1.53	1.58	1.56	1.61	1.47	1.31
4	0.85	1.12	1.34	1.39	1.32	1.16	0.95	0.74

Table 5: Factors of improvement w.r.t. Hadoop for different number of capsules per machine and cluster load.

Impact of G (number of capsules per machine): We now provide the rationale for picking $G = 24$. Table 5 shows the factors of improvements w.r.t. Hadoop for different values of G and levels of contention.

The main takeaways are as follows: for $G = 8$ the performance gap between WHIZ and Hadoop is low ($< 1.1\times$). This is expected because small number of capsules results in less data locality (each capsule is more likely to be spread). Further, the gap decreases at high resource contention. In fact, at $4\times$ the cluster load, Hadoop performs better ($0.85\times$). At larger values of G the performance gap increases. For example, at $G = 24$, WHIZ gains are the most (between $1.39\times$ and $1.58\times$). This is because larger G implies (1) more flexibility for WHIZ to balance the load across machines; (2) more likely that few capsules are spread out; (3) lesser data skew and more predictable per task performance. However, a very large G does not necessarily improve performance, as it can lead to massive task parallelism. The resulting scheduling overhead degrades performance, especially at high load.

Altruism: Assigning resources altruistically is beneficial as it improves median (95*th* %-ile) JCT by $1.48\times$ ($4.8\times$) for our TPC-DS runs w.r.t a greedy approach where tasks use all of their available resources. Only 16% jobs are slowed down by $\leq 0.6\times$.

10 Related Work

We now discuss the various related efforts to overcome the various limitations of compute-centricity. WHIZ, with its clean separation of compute and intermediate data, overcomes the various limitations of compute-centricity in a unified manner while prior related efforts propose point-fixes to a subset of the limitations that plague compute-centric execution engines.

Data opacity: Almost all database and bigdata SQL systems [10, 12, 54] use statistics computed ahead of time to optimize execution. Adaptive query optimizers (QOs) [22] use dynamically collected statistics and re-invoke the QO to re-plan queries top-down. In contrast, WHIZ alters the query plans on-the-fly at the *execution layer* based on *run-time* data properties, thereby circumventing additional expensive calls to the QO. Tukwila [30] reformulates queries by using run-time visibility in a limited fashion to fix poor statistics maintenance in QOs. WHIZ instead enables much richer visibility and supports a richer set of actions that enable true data-centric behavior. RoPE [12] leverages historical statistics from prior plan executions in order to tune future executions. WHIZ, instead uses runtime properties.

CIEL [45] is an execution engine that provides support for data-dependent iterative or recursive algorithms by dynamically deciding the execution graph as tasks execute. However, low-level execution aspects such as per-stage parallelism are decided beforehand. Optimus [33] extends frameworks such as CIEL [45] and Dryad [29] to enable runtime logic rewriting and parallelism selection by using streaming-based algorithms to collect aggregated statistics on intermediate data. RIOS [39] is an optimizer for Spark that solely focuses on optimizing joins by deciding the join order and stage-level join implementation using the approximate statistics collected at runtime. While Optimus and RIOS attempt to provide data visibility, neither of them does a clean separation of compute and data; this limits data-local processing and imposes I/O interference as intermediate data organization is determined by the compute structure. Moreover, both still resort to compute-driven scheduling and do not use data visibility to decide if/when tasks should be scheduled. Further, RIOS adopts static per-stage parallelism, and cannot make fine-grained logic changes (e.g., task-level) as table-level statistics are aggregated by a separate Spark job and then sent to the Spark driver which is responsible for making runtime changes. Overall, WHIZ is a general approach to data-driven computation that subsumes all prior efforts, and enables new data-driven execution benefits; its clean separation of data enables data-locality and I/O isolation management.

Skew and parallelism: Some parallel databases [25, 34, 55] and big data systems [38] dynamically adapt to data skew for single large joins. In contrast, WHIZ holistically solves data skew for all joins across multiple jobs. [25, 38] deal with skew in MapReduce by dynamically splitting data for slow tasks into smaller partitions and processing them in parallel. But, they can cause additional data movement from already slow machines leading to poor performance. Hurricane [16] mitigates skew via an adaptive task partitioning scheme by cloning slow tasks at runtime and performing data organization such that all tasks, be it the primary task or its clones, can access data that requires processing. However, Hurricane can lead to additional processing overheads as it does not take data locality into account while organizing data (data corresponding to the same key can be spread across multiple machines) and also involves an additional merge step that combines the partial outputs of the clones using the end-user provided merging logic. Moreover, Hurricane does not have fine-grained visibility into intermediate data and thus cannot do fine-grained task logic changes and still adopts compute-driven scheduling. Henge [32] supports multi-tenant streaming by deciding parallelism based on SLOs. However, it still adopts compute-driven scheduling.

Decoupling: Naiad [44] and StreamScope [53] also decouple intermediate data. They tag intermediate data with vector clocks which are used to trigger compute in the correct order. Both support ordering driven computation, orthogonal to data-driven computation in WHIZ. Also, StreamScope is not applicable to batch/graph analytics. Crail [49] decouples intermediate data from compute so that various execution engines can easily leverage modern storage hardware (including tiered storage) to perform intermediate data management. However, the compute structure still decides the number of partitions across which data is organized. Additionally, it adopts a similar data storage abstraction as well as data placement policy to Hurricane and thus incurs additional overheads as it does not take data locality into account. Moreover, Crail recommends replicating data in case fault tolerance is required which can further lead to additional overheads. Instead, WHIZ provides fault tolerance by intelligent placement of intermediate data so as to minimize recovery time. Also, similar to Hurricane, it does not have fine-grained data visibility to drive all aspects of execution.

Storage inefficiencies: For batch analytics, [31,46] addresses storage inefficiencies by pushing intermediate data to the appropriate external data services (like Amazon S3 [1], Redis [9]) while remaining cost efficient and running on serverless platforms. Similarly, [35] is an elastic data store used to store intermediate data of serverless applications. However, since this data is still opaque, and compute and storage are managed in isolation, these systems cannot support data-driven computation or achieve data locality and load balancing simultaneously.

11 Summary

The compute-centric nature of existing data analytics frameworks hurts flexibility, performance, efficiency, and job isolation. With WHIZ, analytics undergo data-driven execution aided by a clean separation of compute from intermediate data. WHIZ enables monitoring of data properties and using these properties to decide all aspects of execution - what to launch, where to launch, and how many tasks to launch, while ensuring isolation. Our evaluation using batch, stream and graph workloads shows that WHIZ significantly outperforms state-of-the-art.

A Whiz APIs

Table 6 shows the various APIs exposed by Whiz that are used by frameworks running atop Whiz to submit programs. Similar to APIs today, (1)–(3) APIs are job composition APIs to create logical directed graphs (Whiz has similar APIs to load a graph). Crucially, Whiz *does not require* the frameworks to specify low-level details like parallelism and partitioning strategy. The *addCustomMonitor* API is used by the framework to submit UDFs to collect custom statistics (apart from the built-in monitors that Whiz supports).

During the data embellishment phase, the framework annotates the logical graph with execution and modification predicates using *addExecutionPredicate* API and *addModificationPredicate* API respectively. The framework provides the predicates based on data properties via a UDF.

We now show how to write execution and modification predicates for a number of applications used in our testbed experiments (§9).

Figure 12a shows the execution predicate used to run the PageRank algorithm. Specifically, the UDF specifies that as soon as 1000 messages corresponding to a vertex are received, the data is ready to be processed. Similarly, Figure 12b shows the execution predicate used to run the streaming job that returns the top 5 words when we see 100 distinct words. This predicate indicates that as soon as 100 unique key records globally have been received, the data is ready to be processed.

Lastly, Figure 12c shows how to specify modification predicates to decide the join algorithm on the fly for a batch SQL query as well as a streaming query involving a temporal join. This predicate takes as input the properties collected of the two capsules (from the two input tables) and chooses the join algorithm based on the amount of skew. If the amount of skew is less than the threshold specified by the framework, then sort-merge join is used; otherwise hash join is chosen.

B Allocating Capsules to Machines ILP

We consider how to place multiple jobs' capsules to avoid hotspots, reduce per-capsule spread (for data locality) and minimize job runtime impact on data loss. We formulate a binary integer linear program (see Table 7) to this end. The indicator decision variables, x_i^k, denote that all future data to capsule g_k is materialized at machine M_i. The ILP finds the best x_i^k's that minimizes a multi-part weighted objective function, one part each for the three objectives mentioned above.

The first part (O_1) represents the maximum amount of data stored across all machines across all capsules. Minimizing this ensures load balance and avoids hotspots. The second part (O_2) represents the sum of *data-spread penalty* across all capsules. Here, for each capsule, we define the primary location as the machine with the largest volume of data for that capsule. The total volume of data in non-primary locations is the data-spread penalty, incurred from shuffling the data prior to processing it. The third part (O_3) is the sum of fault-tolerance penalties across capsules. Say a machine m storing intermediate for current stage s fails; then we have to re-execute s to regenerate the data. If the machine also holds data for ancestor stages of s then multiple stages have to be re-executed. If we ensure that data from parent and child stages are stored on different machines, then, upon child data failure only the child stage has to be executed. We model this by imposing a penalty whenever a capsule in the current stage is materialized on the same machine as the parent stage. Penalties O_2, O_3 need to be minimized.

Finally, we impose isolation constraint (C_1) requiring the total data for a job to not exceed an administrator set quota Q_j. Quotas help ensure isolation across jobs.

However, solving this ILP at scale can take several tens of seconds delaying capsule placement. Thus, Whiz uses a linear-time rule-based heuristic to place capsules (as described in §4).

C Whiz Microbenchmarks

Apart from the experiments on the 50-machine cluster (§9), we also ran several microbenchmarks to delve deeper into Whiz's data-driven benefits. The microbenchmarks were run on a 5 machine cluster and the workloads consists of the following jobs: $\mathbb{J}_1$ ($v_1 \rightarrow v_2$) and $\mathbb{J}_2$ ($v_1 \rightarrow v_2 \rightarrow v_3$). These patterns typically occur in TPC- DS queries.

Skew and parallelism: Figure 13a shows the execution of one of the $\mathbb{J}_2$ queries from our workload when running Whiz and CC. Whiz improves JCT by 2.67× over CC. CC decides stage parallelism tied to the number of data partitions. That means stage v_1 generates 2 intermediate partitions as configured by the user and 2 tasks of v_2 will process them. However, execution of v_1 leads to data skew among the 2 partitions ($1GB$ and $4GB$).On the other hand, Whiz ends up generating capsules that are approximately equal in size and decides at runtime a max. input size per task of $1GB$ (twice the largest capsule). This leads to running 5 tasks of v_2 with equal input size and 2.1× faster completion time of v_2 than CC.

Over-parallelizing execution does not help. With CC, v_2 generates 12 partitions processed by 12 v_3 tasks. Under resource crunch, tasks get scheduled in multiple waves (at 570s in Figure 13a) and completion time for v_3 suffers (85s). In contrast, Whiz assigns at runtime only 5 tasks of v_3 which can run in a single wave; v_3 finishes 1.23× faster.

Straggler mitigation: We run an instance of $\mathbb{J}_1$ with 1 task of v_1 and 1 task of v_2 with an input size of $1GB$. A slowdown happens at the v_2 task, which was assigned 2 capsules by Whiz.

In CC (Figure 13b), once a straggler is detected (v_2 task at 203s), it is allowed to continue, and a speculative task v_2' is launched that duplicates v_2's work. The work completes when v_2 *or* v_2' finishes (at 326s). In Whiz, upon straggler detection, the straggler (v_2) is notified to finish processing the current capsule; a task v_2' is launched and assigned data

	API	Description
1	createJob(name:Str, type:Type)	Creates a new job which can be of type BATCH, STREAM or GRAPH.
2	createStage(j:Job, name:Str, impl:StageImpl, prop:StageProperties)	Adds a logical stage of to a Job with a default processing logic. StageProperties specifies properties of the logic (e.g., if it is commutative+associative).
3	addDependency(j: Job, s1: Stage, s2: Stage)	Adds a starts before relationship between stages s1 and s2.
4	addCustomMonitor(j:Job, s:Stage, impl:DataMonitorImpl)	Adds a custom data monitor to compute statistics over data generated by stage *s*. DataMonitorImpl is a UDF.
5	addExecutionPredicate(j:Job, s:Stage, predicates:ExecutionPred)	Decides when downstream stages can consume current stage's data based on the predicates specified by ExecutionPred. ExecutionPred is used by DS to decide when data is ready for processing.
6	addModificationPredicate(j:Job, s:Stage, predicates:ModifyPred)	Decides processing logic for the input capsules that are ready based on the predicates specified by ModifyPred. ModifyPred is used by the ES to decide which processing logic to use based on the data properties from the DS.

Table 6: WHIZ *APIs - Used by the frameworks running atop* WHIZ *to translate the high-level job submitted by end users to* WHIZ*-compatible data-driven logical graphs.*

```
def ExecutionPredicate():
  for key in keys:
    if (DS.monitor.num_entries(key) >= 1000):
      return true

```

Figure 12: Examples of predicates. (a) Execution predicate for the PageRank algorithm - deem capsule ready when it has 1000 messages, (b) Execution predicate for the streaming application - deem capsules ready when we see 100 unique entries and (c) Modification predicate for changing join algorithm on the fly.

Objectives (to be minimized):

O_1	$\max_i \left(\sum_k (b_i^k + x_i^k e^k)\right)$
O_2	$\sum_k \left(P^k - \left(\sum_{i\in I^k_-} x_i^k\right) b^k_{\hat{i}(k)} + \sum_{i\in I^k_+} x_i^k \left(b_i^k + e^k\right)\right)$
O_3	$\sum_k \left((1-f^k)\sum_{i\in I^\circ} x_i^k\right)$

Constraints:

C_1	$\sum_{k:J(g_k)=j} \left(b_i^k + x_i^k e^k\right) \leq Q_j, \quad \forall j,i$

Variables:

x_i^k	Binary indicator denoting capsule g_k is placed on machine i

Parameters:

b_i^k	Existing number of bytes of capsule g_k in machine i
e^k	Expected number of remaining bytes for capsule, g_k
P^k	$e^k + \sum_i b_i^k$
$J(g_k)$	The job ID for job g_k
$\hat{i}(k)$	$\text{argmax}_i \quad b_i^k$
I^k_-, I^k_+	$\{i : b_i^k \leq b^k_{\hat{i}(k)} - e^k\}$, $\{i : b_i^k > b^k_{\hat{i}(k)} - e^k\}$
f^k	Binary parameter indicating that capsules for same stage as g_k share locations with capsules for preceding stages
I°	Set of machines where capsules of preceding stages are stored
Q_j	Administrative storage quota for job, j.

Table 7: Binary ILP formulation for capsule placement.

from v_2's unprocessed capsule. v_2 finishes processing the first capsule at 202s; v_2' processes the other capsule and finishes 1.7× faster than v_2' in CC.

Modification Predicates: We consider a job which processes words and, for words with < 100 occurrences, sorts them by frequency. The program structure is $v_1 \to v_2 \to v_3$, where v_1 processes input words, v_2 computes word occurrences, and v_3 sorts the ones with < 100 occurrences. In CC, v_1 generates $17GB$ of data organized in 17 partitions; v_2 generates $8GB$ organized in 8 partitions. Given this, 17 v_2 tasks and 8 v_3 tasks execute, leading to a CC JCT of 220s. Here, the entire data generated by v_2 has to be analyzed by v_3. In contrast, WHIZ uses modification predicates for v_3 as follows - (a) if all the # entries of all keys in the capsule is > 100, then we unnecessarily don't launch a task; (b) otherwise we launch the task to do the sort. We observe that WHIZ ignores processing two capsules at runtime, and 6 tasks of v_3 (instead of 8) are executed; JCT is 165s (1.4× better).

Pushing the Physical Limits of IoT Devices with Programmable Metasurfaces

Lili Chen[2,1,*], Wenjun Hu[4], Kyle Jamieson[3], Xiaojiang Chen[2], Dingyi Fang[2] and Jeremy Gummeson[1]

[1]Univ. of Massachusetts Amherst, [2]Northwest Univ. (China), [3]Princeton Univ., [4]Yale Univ.

Abstract

Small, low-cost IoT devices are typically equipped with only a single, low-quality antenna, significantly limiting communication range and link quality. In particular, these antennas are typically linearly polarized and therefore susceptible to polarization mismatch, which can easily cause $10-15$ dB of link loss when communicating with such devices. In this work, we highlight this under-appreciated issue and propose the augmentation of IoT deployment environments with programmable, RF-sensitive surfaces made of metamaterials. Our smart metasurface mitigates polarization mismatch by rotating the polarization of signals that pass through or reflect from the surface. We integrate our metasurface into an IoT network as LLAMA, a Low-power Lattice of Actuated Metasurface Antennas, designed for the pervasively used 2.4 GHz ISM band. We optimize LLAMA's metasurface design for both low transmission loss and low cost, to facilitate deployment at scale. We then build an end-to-end system that actuates the metasurface structure to optimize for link performance in real time. An empirical evaluation demonstrates gains in link power of up to 15 dB, and wireless capacity improvements of 100 and 180 Kbit/s/Hz in through-surface and surface-reflective scenarios, respectively, attributable to the polarization rotation properties of LLAMA's metasurface.

1 Introduction

Internet of Things (IoT) devices have achieved widespread adoption due to shrinking hardware costs and software management tools that ease installation by the end user. In recent years, a wide range of IoT devices have resulted in diverse systems including mobile devices such as smartwatches [31] and health trackers or statically deployed devices including sensors, cameras, voice assistants, and other appliance automation [14, 15]. One key property these devices share is low-cost hardware, in particular low-cost radios, allowing for a minimal consumer price point. Such devices are typically

[*]Work conducted on internship at Univ. of Massachusetts Amherst.

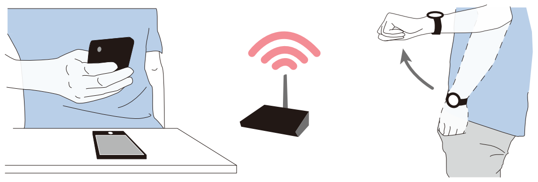

Figure 1: Low-cost IoT devices and wearables suffer from polarization mismatch when their antennas become oriented perpendicularly with respect to an AP's antenna.

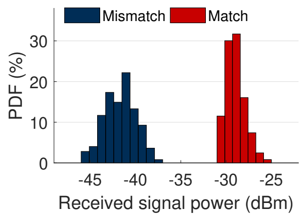
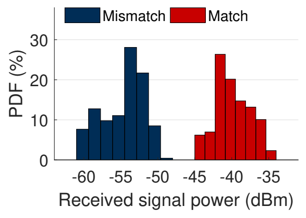
deployed by non-experts who understand neither their home's wireless environment nor the deployment considerations that govern wireless performance. Devices are typically deployed in a configuration that is well-suited for a particular application or use-case, but may not be the ideal placement in terms of communications performance. This combination of cheap hardware and non-ideal network topology results in significant opportunities to improve wireless performance.

One source of performance degradation in such deployments is a significant power loss caused by a *polarization mismatch* [13, 32] between a low-cost dipole antenna on an IoT device and antennas on a Wi-Fi access point (AP)—in higher performance devices (*i.e.*, mobile handsets) this loss is usually mitigated through the use of circularly polarized or dynamically-switched linearly polarized antennas in different orientations. Low-cost IoT devices instead use one cheap, linearly polarized dipole antenna that results in weak, fragile links between transmitters and receivers. In addition to misaligned stationary devices, mobile devices such as wearables can suffer from dynamic antenna misalignment as a user swings their arm, for example, as Figure 1 illustrates. This effect can be significant: microbenchmark experiments show that moving between orthogonal and aligned relative antenna polarization results in ≈ 10 dB of power variation at the receiver, for both the low power Wi-Fi link between an Arduino equipped with an ESP8266 module [19] and an 802.11g Wi-Fi AP [5] shown in Figure 2 (a), and for a Bluetooth link between a smartwatch [1] and a Raspberry Pi 3 [36]



(a) Wi-Fi communication (802.11g) between an AP [5] and a cheap ESP8266-based Arduino [19].



(b) Bluetooth communication between a Huawei Watch [1] and a Raspberry Pi 3 [36].

Figure 2: *Impact of polarization mismatch.* Received signal power distributions for matching and mismatching antenna orientations between IoT transmitter-receiver pairs. Polarization mismatch significantly reduces link signal power.

shown in Figure 2 (b).

In this work, we specifically investigate how to change the effective relative orientation of antennas at the communication endpoints, without hardware modifications to the endpoints themselves. Achieving this objective would allow us to maintain a low bill of materials cost for IoT wireless communications components, and significantly improve the performance for existing off-the-shelf devices. Our approach to changing effective polarization alignment hinges instead, on changing the radio propagation environment itself, with a ***Low-Power Lattice of Actuated Metasurface Antennas*** (*LLAMA*), a tunable smart surface made with inexpensive metamaterials [39, 41]. LLAMA is deployed in the radio environment near the IoT endpoints, and is able to change the polarization of incident waves as they travel from sender to receiver. As we show in this paper, the LLAMA substrate can be programmed dynamically to effect just the right amount of polarization rotation needed to help the ongoing communication between nearby endpoints. LLAMA follows the PRESS [43] approach, which was the first to outline a vision of programmable radio environments along with a preliminary experimental setup that validates the feasibility of change the perceived channel at the communication endpoints.

Designing a metasurface in the 2.4 GHz ISM band requires us to overcome significant challenges. First, longer wavelengths in the 2.4 GHz band require larger and thicker metasurface substrates, which can attenuate the incident signal significantly. While an inefficient structure could rotate polarization, losses would dominate and the structure would attenuate the incident signal, hampering communication. Therefore, the metasurface structure needs to be optimized for low transmission loss. Second, since we aim to realize pervasive deployments of these structures, we need to develop materials that are low cost, avoiding high performance but relatively expensive RF materials commonly used in other implementations of metasurfaces. Overcoming both of these challenges results in a pervasively deployable substrate that can compensate for losses between different endpoint pairs.

Indeed, naively replacing a high performance substrate (*i.e.*, Rogers 5880 [38]) with a low-cost substrate (*i.e.*, FR4 [20]) results in higher transmission loss due to FR4's inherent physical properties; this in turn significantly attenuates power at the receiver, reducing link throughput and communication distance. To deal with this problem, we optimize the metasurface structure to ensure the overall system has both low transmission loss, as well as a scalable price point. Specifically, we choose a cheap material (FR4) as the substrate, use a minimum number of substrate layers for the required bandwidth, and minimize the thickness of each layer to significantly reduce the losses associated with FR4.

To enable real-time polarization optimization, a receiver must report received power to a controller which in turn rotates polarization by modifying a pair of bias voltages. We provide a novel method to estimate the polarization rotation angle induced by the metasurface which can vary with link distance—understanding this mapping can enable rotation sensing and tracking.

Contributions. To summarize, LLAMA is the first system that leverages an inexpensive RF substrate to optimize the radio environment in real time, thereby avoiding signal losses caused by polarization mismatch, and thus enables higher quality communication links between IoT devices. In this work, we optimize a metasurface structure based on microwave attenuation theory and achieve comparable polarization tunability to a similar system that uses relatively expensive materials. We validate a proof-of-concept implementation of LLAMA for both communication and sensing with comprehensive experiments. Our results show that LLAMA enables polarization rotation within $3^\circ - 45^\circ$, improves the signal strength by 15 dB (transmission) and 17 dB (reflection) with respect to mismatched antenna polarizations. LLAMA also holds great potential to enhance sensing applications, as demonstrated in § 5.2.2.

2 A Polarizing View of Wireless

Electromagnetic polarization describes the parametric trajectory of the electric and magnetic field vectors of a planar electromagnetic wave as it propagates through space. The polarization of RF wave propagation is a fundamental characteristic of wireless communication, but it has not received as much attention as issues like multipath fading and interference. An antenna constrains outgoing or incoming RF propagation to a particular plane. Therefore, communication is only possible if the signal propagation planes at both the transmitter and the receiver are well aligned.

Polarization loss. One challenge in mobile wireless communication links is the significant power loss due to polarization mismatch. Three examples of various transmitter antennas and their associated far-field electric fields are depicted in

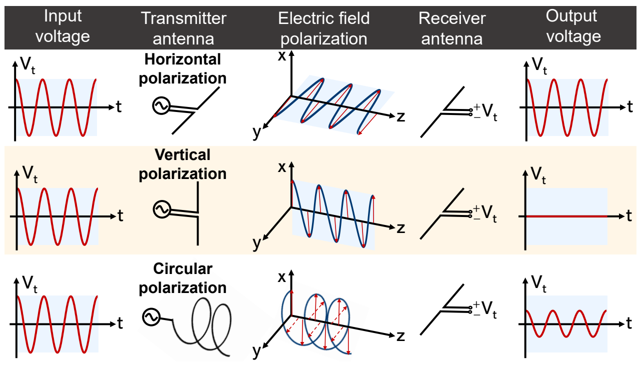


Figure 3: Signal transmission loss under different antenna polarization combinations between transmitter and receiver [13].

Figure 3. If the signal is being received by a horizontally polarized receiver antenna, it will be polarization matched to the transmitter antenna with horizontal linear polarization and the power received will primarily be a function of the transmit power and free space path loss. If the transmitter antenna is rotated in space, the received signal will continue to degrade due to polarization mismatch to the point where the very little signal is received when the antennas are completely mismatched with orthogonal polarizations. The signal loss is less when one of the antennas is circularly polarized [1].

As shown in Figure 2, polarization mismatch can be debilitating for IoT devices. Higher performance devices such as mobile phones use switched antennas or circular polarized antennas to mitigate polarization mismatch, but low-cost IoT devices like smartwatches typically have a single low-quality antenna.

Correcting polarization mismatch. Intuitively, polarization mismatch can be corrected by rotating the polarization of the signal before it arrives at the receiver. Here we show the mathematical foundation of polarization rotation.

In general, the polarization state of radio waves can be described by a 2×1 Jones vector J. Consider a plane perpendicular to the direction of signal propagation. Any polarization state can be represented by two orthogonal components in that plane (*i.e.*, projected onto the X and Y axes) with different amplitude and phase. The *Jones vector* is [28]:

$$J = \left[\begin{array}{c} a^x \\ a^y e^{j\pi/2} \end{array} \right], \quad (1)$$

where a^x and a^y represent the X and Y polarized signal components respectively.

When a manipulation surface is aligned with the x-y coordinate axis, the *Jones matrix* is defined as [28]:

$$M = e^{j\alpha} \left[\begin{array}{cc} 1 & 0 \\ 0 & e^{j\pi/2} \end{array} \right], \quad (2)$$

[1] A theoretical 3 dB degradation in coupling due to polarization mismatch will also occur when one of the antennas is circularly polarized while the other is linearly polarized.

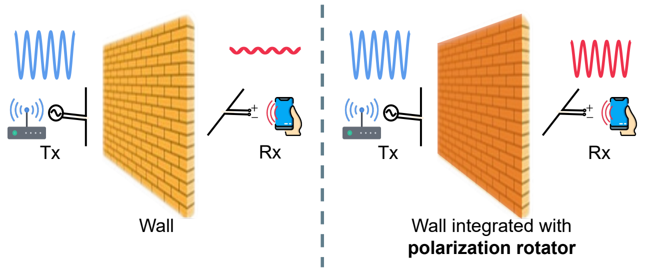

Figure 4: Wireless communication system without/with polarization rotator between mismatched transmitter (Tx) and receiver (Rx).

where α is a phase delay between the X and Y axes. If the surface is rotated counterclockwise by a degree of θ, the Jones matrix becomes [28]:

$$M_\theta = R(\theta) M R^T(\theta), \qquad R(\theta) = \left[\begin{array}{cc} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{array} \right], \quad (3)$$

where $R(\theta)$ is a rotation matrix.

In systems with multiple layers of polarization manipulation surface between the incident wave and outgoing wave, the outgoing Jones vector J_{out} is obtained by multiplying the Jones vector of incident wave with the Jones matrix of each surface layer [28]:

$$J_{out} = M_N ... M_2 M_1 J_{in}, \quad (4)$$

where M_N is a 2×2 Jones matrix, representing the N^{th} surface.

3 System Design

In this section, we introduce the LLAMA architecture (§ 3.1) and illustrate the properties of the metasurface hardware with HFSS simulation results (§ 3.2). Next, we illustrate our approach towards actuating polarization angle in real-time by manipulating bias voltages for the polarization rotator (in § 3.3). While the primary goal of LLAMA is to enhance signal quality between two endpoints, it can also be used for orientation sensing, which requires estimating relative polarization rotation between endpoint; § 3.4 describes a technique for this purpose.

3.1 System Overview

LLAMA is a low power system that is designed to reduce significant wireless signal loss caused by polarization mismatch between the transmitter and receiver. As shown in Figure 4, the signal from a mismatched transmitter arrives at the receiver with a lower loss when the intermediate wall includes a polarization rotator. LLAMA has the ability to improve the communication quality and extend the sensing range in the widely used ISM frequency band.

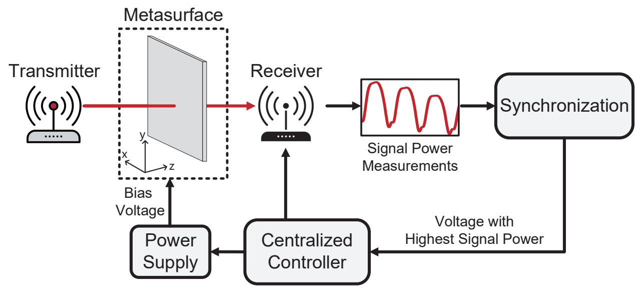

Figure 5: LLAMA system architecture, showing transmitter and receiver endpoints, the LLAMA substrate deployed in the environment, and control signal flow.

An overview of our system architecture is depicted in Figure 5 and consists of these four elements:

Metasurface. The metasurface used in LLAMA is a polarization rotator implemented using a low-cost FR4 substrate; the polarization rotator is tunable and uses biasing voltages within phase shifters in both the X and Y axes to define a rotation angle. The metasurface is deployed in a structural element (*i.e.*, wall) and influences wireless signals that reflect from or propagate through the metasurface.

Centralized controller. A centralized controller observes the power measured at a receiver and uses a search algorithm to determine a set of bias voltages that maximize received signal power by finding the optimal rotation angle that achieves a polarization match between the antennas at the endpoints.

Power supply. The bias voltages used to tune the metasurface are set with a programmable DC power supply. By synchronizing the power supply output with the receiver, we can manipulate the polarization rotator with an optimal rotation angle in real time, with a rotation that maximizes signal power. Two bias voltages are needed for the phase shifters in the X and Y axes; while bias voltages as high as 30 V are needed, the metasurface draws only 15 nA of current. In future implementations, a circuit that generates these bias voltages could be integrated directly on the metasurface.

Endpoints. The endpoint receiver reports its received signal strength to the controller, which then determines how to actuate the metasurface by manipulating the two bias voltages.

3.2 Metasurface Architecture

Tunable metasurfaces are implemented as layered structures that consist of copper patterns printed on controlled dielectric substrates; these layers perform different functions that reflect, bias, or guide EM waves. A transmissive metasurface uses a biasing network sandwiched between or adjacent to waveguide layer(s) to modify the transmissive signal properties in a controlled manner. In contrast, a reflective metasurface uses a metallic plane as one of its layers, where the signal passes through a wave guide layer and a biasing layer, and reflects from the metallic plane in the same relative direction with a different angle of departure. Depending on the bias voltages used LLAMA can operate in either a transmissive or reflective mode.

Cost-effective metasurface design. Our design was inspired by a 10 GHz design [45], and we calculate the correct geometries of circuit elements for 2.4 GHz instead based on the impedance matching.

To achieve polarization rotation for both x-polarized and y-polarized waves, we construct a polarization rotator consisting of a tunable birefringent structure (BFS) placed between two quarter wave plates (QWP) [17]. The QWPs are rotated by $+45^\circ$ and -45° with respect to the BFS, which causes the phase delays for two orthogonal polarizations differ by 90°. The Jones matrices of the two QWPs can be expressed as:

$$Q_{+45^\circ} = e^{j\alpha} R(+45^\circ) \begin{bmatrix} 1 & 0 \\ 0 & e^{j\pi/2} \end{bmatrix} R^T(+45^\circ), \tag{5}$$

$$Q_{-45^\circ} = e^{j\alpha} R(-45^\circ) \begin{bmatrix} 1 & 0 \\ 0 & e^{j\pi/2} \end{bmatrix} R^T(-45^\circ). \tag{6}$$

The tunable BFS is a transmissive metasurface that can rotate the polarization of the X and Y axes, independently. The Jones matrix of the BFS is:

$$B = e^{j\beta} \begin{bmatrix} 1 & 0 \\ 0 & e^{j\delta} \end{bmatrix}, \tag{7}$$

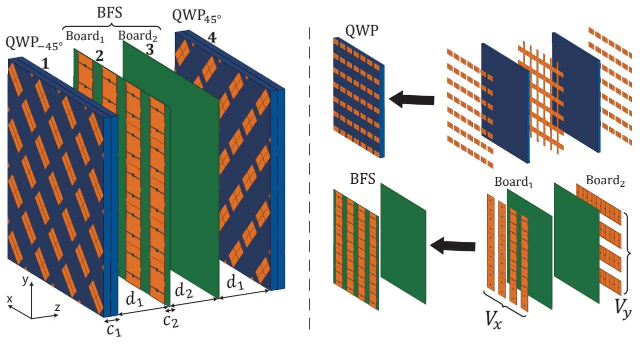
where β is the transmission phase as the signal passes through the BFS, irrespective of initial polarization orientation, while δ represents the transmission phase difference between the X and Y polarizations, which can be adjusted by manipulating the biasing voltages of the X and Y axes as shown in Figure 5. The entire Jones matrix of the polarization rotator is:

$$\begin{aligned} P &= Q_{+45^\circ} B Q_{-45^\circ} \\ &= e^{j(\alpha+(\pi/2)+\beta+(\delta/2))} \begin{bmatrix} \cos(\delta/2) & -\sin(\delta/2) \\ \sin(\delta/2) & \cos(\delta/2) \end{bmatrix}. \end{aligned} \tag{8}$$

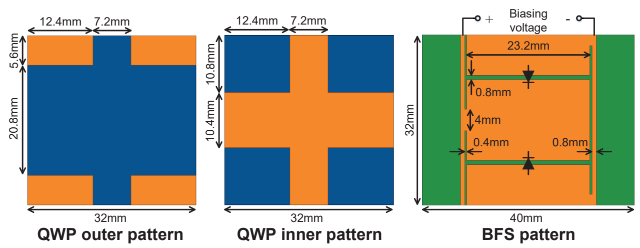
In summary, the proposed structure can rotate the polarization of a wave by $\delta/2$ rotation degrees, according to the rotation matrix presented in Equation (3).

In Figure 6 (a) we show the microstrip geometries used in our metasurface design. The metasurface consists of a tunable BFS (layers 2 and 3 in Fig. 6 (a)) placed between two QWPs (layers 1 and 4 in Fig. 6 (a)) rotated 45° with respect to the BFS. The BFS includes two birefringent boards rotated by 90° with respect to each other, each board acts as a phase shifter that supports different polarization rotations by manipulating the bias voltages (V_x and V_y) of integrated varactor diodes (black) along X and Y axes. The metallic patterns (orange) plated on the substrate boards (green and blue) act as admittance components.

We next consider the transmission efficiency (S_{21}) of X and Y axis polarized signals, as that is among the most important performance metric of the overall metasurface design. Higher



(a) Metasurface topology of LLAMA.



(b) Unit dimension of metasurface in LLAMA. The black elements in BFS represent the varactor diodes.

Figure 6: Polarization rotator structure designed for the 2.4 GHz ISM band. The distances between adjacent boards are $d_1 = 7$ mm and $d_2 = 11$ mm, the FR4 substrate thicknesses of QWP and BFS are $c_1 = 12$ mm and $c_2 = 0.6$ mm.

transmission efficiency indicates better performance. For a two-port network as shown in Figure 7, the amplitude (normalized voltage) of incoming waves (a_1 and a_2) and the outgoing waves (b_1 and b_2) are given by [35]:

$$\begin{cases} a_1 = \frac{V_1+Z_0I_1}{2\sqrt{Z_0}} \\ a_2 = \frac{V_2+Z_0I_2}{2\sqrt{Z_0}} \end{cases}, \quad \begin{cases} b_1 = \frac{V_1-Z_0I_1}{2\sqrt{Z_0}} \\ b_2 = \frac{V_2-Z_0I_2}{2\sqrt{Z_0}} \end{cases}, \tag{9}$$

where V_1 and V_2 are the normalized voltage of port 1 and port 2, I_1 and I_2 are the normalized current of port 1 and port 2, Z_0 is the matched impedance. The scattering matrix S relates the incoming waves to the outgoing waves as [35]:

$$\begin{bmatrix} b_1 \\ b_2 \end{bmatrix} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix} \times \begin{bmatrix} a_1 \\ a_2 \end{bmatrix}, \; S_{ij} = \frac{b_i}{a_j}|a_k = 0 \,\forall\, k \neq j. \tag{10}$$

S_{11} and S_{22} are reflection coefficients, S_{21} and S_{12} are transmission coefficients. Then the transmission efficiency can be calculated according to the following equation [35]:

$$eff = \begin{cases} |S_{21}^{xx}|^2 + |S_{21}^{yx}|^2 \,, & for \;\; x-polarized \;\; wave \\ |S_{21}^{xy}|^2 + |S_{21}^{yy}|^2 \,, & for \;\; y-polarized \;\; wave \end{cases}, \tag{11}$$

where S_{21}^{yx} is obtained from the x-polarized component of incoming wave a_1^x and the y-polarized component of outgoing wave b_2^y.

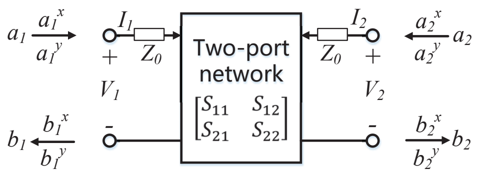


Figure 7: The scattering parameters of metasurface can be measured according to the matched impedance of the input and output ports [35].

We can potentially obtain high transmission efficiency (see Figure 8) by directly scaling the circuit geometry of an existing 10 GHz design [45] to 2.4 GHz, but a key limitation is its use of an expensive, low-loss dielectric substrate (Rogers 5880) [45]. While this material achieves high transmission efficiency, it is cost prohibitive at scale. Instead, we choose a commodity FR4 substrate and characterize the behavior of the FR4 structure using an HFSS simulation environment to analyze critical parameters in the 2.4 GHz ISM band. The key problem is that FR4 (0.02 dielectric loss tangent) causes much larger signal loss than Rogers 5880 (0.0009 dielectric loss tangent), and thus severely decreases the transmission efficiency, as shown in Figure 9.

To reduce transmission loss, we simplify the structure of the tunable phase shifter layers, and decrease the thickness of FR4 by replacing it with an air gap since the dielectric loss tangent of air is 0. By comparing Figure 10 and Figure 8, we can see that our optimized structure made of cheap FR4 can achieve comparable transmission efficiency to more complex structures and expensive materials. We use fewer (*i.e.*, two) phase shifting layers made with thinner substrate; since the supported bandwidth of a phase shifter changes approximately linearly with the transmission line length, that is, the thickness of the substrate. Suppose the thickness of substrate is λ/m, the bandwidth can be represented as below [35]:

$$\Delta f = f_0(2 - \frac{m}{\pi} arccos[\frac{\Gamma}{\sqrt{1-\Gamma^2}} \frac{2\sqrt{Z_I Z_L}}{|Z_L - Z_I|}]), \tag{12}$$

where f_0 is the design center frequency of phase shifter, Γ is the maximum tolerable reflection coefficient, Z_I and Z_L are input impedance and load impedance, respectively. Our design achieves (150 MHz of bandwidth with efficiency $>$ -5 dB), which is wider than the target ISM frequency band that has less than 100 MHz of bandwidth.

Estimating Polarization Efficiency. A voltage controlled capacitance is used to actuate the tuning of the X and Y planes — here we use an x-polarized incident wave as an example to show the polarization rotation results. The transmission efficiencies of the simulated frequencies under various voltage combinations are shown in Figure 11, which are always higher than -8 dB in the $2.4 - 2.5$ GHz ISM frequency band. The other set of measurements looks at how the polarization angle can be controlled by adjusting the lumped tuning capacitance used for the X and Y axis biasing layers. Varying

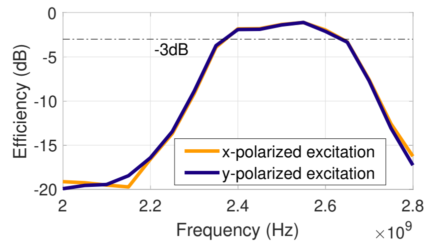

Figure 8: S_{21} efficiency of cascaded polarization rotator layers using Rogers 5880 substrate (loss tangent is 0.0009).

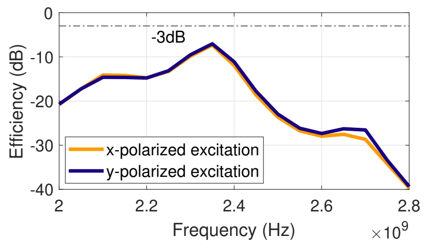

Figure 9: S_{21} efficiency of cascaded polarization rotator layers using FR4 substrate (loss tangent is 0.02).

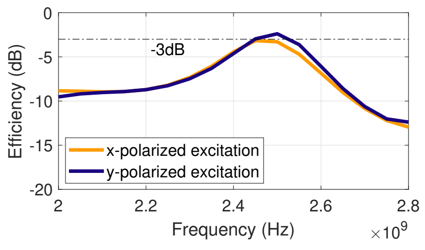

Figure 10: S_{21} efficiency of **optimized** cascaded polarization rotator layers using FR4 substrate (loss tangent is 0.02).

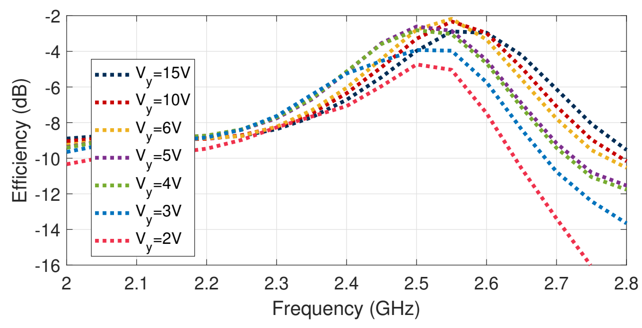

Figure 11: S_{21} efficiencies under different voltage combinations of X and Y axes. The results show polarization can be controlled by changing the biasing voltages of phase shifter.

Table 1: Simulated rotation degrees (θ_r).

θ_r (°)		$V_x(V)$						
		2	3	4	5	6	10	15
$V_y(V)$	2	11.6	26.1	36.8	41.0	44.3	48.3	48.7
	3	6.5	12.4	26.6	32.2	35.2	38.6	39.2
	4	23.0	4.9	10.9	17.3	20.8	25.0	25.6
	5	27.0	9.3	7.4	14.0	18.0	22.6	23.2
	6	41.8	25.0	7.9	2.1	4.2	10.2	10.7
	10	45.8	30.0	13.7	7.9	2.8	5.1	5.6
	15	48.2	33.1	18.2	12.9	7.3	1.9	2.0

this capacitance from 0.84 pF to 2.41 pF for both the X and Y axes resulted in a polarization rotation angle that varied between 1.9° and 48.7° (see Table 1). We have also simulated the polarization rotator structure in the 900 MHz band used for RFID and found comparable performance after additional scaling.

3.3 Metasurface Control

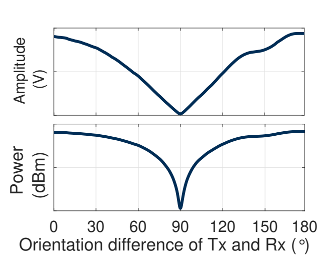
To enable polarization rotation control, we need to change the capacitance of the X and Y axis phase shifters; in our design this is accomplished by changing the bias voltage of the integrated varactor diodes (SMV1233) in the X and Y polarities, which in turn changes their capacitance and thus phase. All diodes in a given polarization are controlled using the same bias voltage; we use a programmable power supply

Algorithm 1: Biasing Voltage Sweep

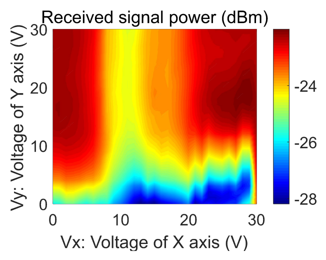
```
Input: Number of iterations: $N$; Number of voltage
  tuning steps for $X$ and $Y$ axes per iteration: $T$
Initialization: Voltage sweep range of $X$ and $Y$ axes
  in first iteration ($n = 1$): $[V^{min}_{x,1}, V^{max}_{x,1}] = [0, 30]$,
  $[V^{min}_{y,1}, V^{max}_{y,1}] = [0, 30]$
for $n = 1, ..., N$ do
    for $\tau_x = 1, ..., T$ do
        $V_{x,n,\tau_x} = V^{min}_{x,1} + (\tau_x - 1)(V^{max}_{x,n} - V^{min}_{x,n})/T$
        for $\tau_y = 1, ..., T$ do
            $V_{y,n,\tau_y} = V^{min}_{y,1} + (\tau_y - 1)(V^{max}_{y,n} - V^{min}_{y,n})/T$
        end
    end
    if Received signal power at voltage combination
      $(V_{x,n,\tau_x}, V_{y,n,\tau_y})$ is strongest then
        $V^{min}_{x,n+1} = V_{x,n,\tau_x} - (V^{max}_{x,n} - V^{min}_{x,n})/T$,
        $V^{max}_{x,n+1} = V_{x,n,\tau_x}$,
        $V^{min}_{y,n+1} = V_{y,n,\tau_y} - (V^{max}_{y,n} - V^{min}_{y,n})/T$,
        $V^{max}_{y,n+1} = V_{y,n,\tau_y}$
    end
end
Output: Optimal voltage combination:
  $(V_{x,N,\tau_x}, V_{y,N,\tau_y})$
```

for this purpose and these voltages can be as high as 30 V to account for errors induced during fabrication and assembly, hence we set $0-30$ V as the voltage sweep range of the X and Y axes. The power supply is connected to a desktop computer through a USB interface, and is controlled by a Python script that uses the Virtual Instrument Software Architecture (VISA) standard with a maximum voltage switching frequency of 50 Hz. With a voltage step of 1 V, the full scan across both X and Y axes takes $\sim$ 30 seconds, which prevents real-time applications.

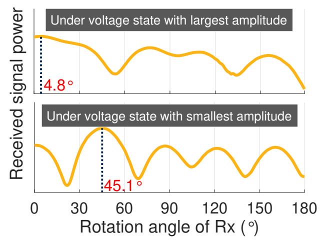
To reduce the sweep time, we start with a coarse-grained voltage sweep then increase the resolution of control as summarized in Algorithm 1. Specifically, we define N as the number of iterations, and T as the number of voltage adjust-



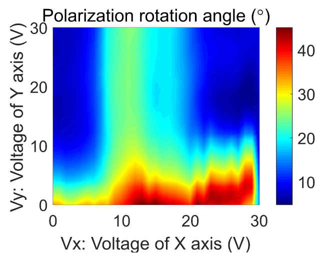
(a) Signal power as a function of Tx rotation without metasurface.



(b) Signal power over voltage combination of metasurface.



(c) Minimum and maximum polarization rotation angles computation.



(d) Estimated polarization rotation angle over voltage combination.

Figure 12: Polarization rotation degree estimation according to the received signal power. The acceptable "band" around the optimal value shown in (c) is chosen by considering multipath interference.

ments per iteration. The total time cost of N iterations is $0.02 \times N \times T^2$. We empirically set T to 5 and N to 2 , according to the switching speed and the voltage resolution of the programmable power supply. After N iterations across the X and Y axes, we can determine the optimal voltage combination to yield the strongest received signal.

Synchronization between rotator and receiver. For real-time polarization correction and communication link optimization, it is necessary to correlate the currently received sample with the bias voltage state, so that we can determine an optimal voltage combination that enables the strongest received signal power. In our prototype, for simplicity we directly connect the receive antenna to the voltage supply, which allows us to assume the voltage switch speed and receiver sampling rate have a constant relationship over time. This allows us to relate received signal samples with the voltage state of LLAMA at a given time instance. A full implementation can have the receiver explicitly send channel state information to the controller, as in previous work [18, 29].

One important aspect of the design we want to highlight is that the leaking current of our metasurface is as low as 15 nA, which means the metasurface does not need a large battery or significant power from the AC mains to keep it powered; it can maintain operation with a modestly sized capacitor.

3.4 Polarization Rotation Degree Estimation

Besides increasing SNR, we can also sense the relative orientation of the two endpoints with LLAMA. Here we present our approach for rotation angle estimation according to the received signal power reported by the endpoint receiver, no matter the transmitter-receiver distance; as distances between the transmitter and receiver become comparable to the size of the metasurface (See Figure 4), a fraction of the signal can bypass the metasurface without polarization rotation, and this results in less overall perceived rotation at the receiver. According to our benchmark experimental result plotted in Figure 12 (a), we observed that the received signal power (before the dBm conversion) can be approximated as a linear change with the orientation difference between transmitter and receiver. When we perform measurements across a full voltage sweep, we can get the maximum potential improvement to signal power. To obtain the polarization rotation angle for an unknown transmitter-receiver distance (*i.e.*, the potential power improvement over an orientation sweep is unknown), the key is determining the minimum and maximum polarization rotation angles. We take the following steps.

Step 1: Fix the receiver at the same orientation with the transmitter, by rotating the receiver to find an orientation θ_0 where the received power is largest.

Step 2: Sweep across voltage combinations V_{min} and V_{max} corresponding to min and max powers, respectively (*i.e.*, parallel and orthogonal polarizations).

Step 3: Set the voltage state to the two searched combinations, respectively. At each voltage state, rotate the receiver by 180° to find the new orientation where the power is strongest. The two new orientations of V_{min} and V_{max} can be defined as θ_{max} and θ_{min} as shown in Figure 12 (c). The differences of the receiver's initial orientation and two new orientations $|\theta_0 - \theta_{min}|$ and $|\theta_0 - \theta_{max}|$ correspond to the minimum and maximum polarization rotation angles, respectively.

The antenna that needs to be rotated is fixed on a turntable and rotated via remote control [2]. From the experimental results of the match setup shown in Figure 12 (b-d), we can see that the polarization rotation angle varies between $5° - 45°$ during the voltage sweep.

4 Implementation and Experimental Setup

Metasurface. We fabricated the metasurface with a total surface area of $48 \times 48\ cm^2$ and a thickness of 5 cm, including 180 functional units (Figure 13 (a-d)). The biasing voltages of the metasurface are provided by a programmable power supply (TektronixSeries 2230G [6]) through two DC channels, as shown in Figure 13 (a). LLAMA utilizes 720 varactor diodes (SMV1233), costing $\sim$ \$0.50 each. The total cost of LLAMA for all PCB layers is $\sim$ \$540, resulting in a total cost of $\sim$ \$900. Given economies of scale, the unit cost can be

reduced to $2 when there are more than 3000 units per PCB.

Experimental setup. For controlled experiments, we utilize one USRP N210 software-defined radio with a UBX-40 daughterboard as the ISM signal transceiver, operating at a default center frequency of 2.44 GHz. The transmitter and receiver antennas are separated by a specified distance. We experiment with both directional [9] and omni-directional antennas [3]. We configure and control the USRP using the GNU radio software development toolkit [22] run on a PC. The transmitter continuously transmits a cosine waveform over 500 KHz, while the sampling rate of the receiver is 1 MHz. We also evaluate LLAMA using low-cost Wi-Fi and Bluetooth devices (the same setup as benchmark experiments as shown in Figure 2). Additionally, we perform an experiment with a pair of GIGABYTE mini-PCs [4] with Intel 5300 wireless cards, to evaluate performance over a larger frequency range (*i.e.*, 20 MHz, including 52 OFDM subcarriers).

We perform both through-surface (*transmissive*) and surface-reflection (*reflective*) experiments as shown in Figure 13 (e). In transmissive experiments, the metasurface is placed between the transmitter and receiver. In reflective experiments, the transmitter and receiver are placed on the same side of the metasurface. In each experiment, the baseline received signal power without the metasurface is measured by averaging 30 seconds of received samples, and the maximum signal power with the metasurface is obtained after a fast sweep of voltages as detailed in § 3.3. To avoid multipath effects confounding the performance behavior of LLAMA, we cover the test area with RF absorbing material, and use directional antennas by default in USRP-based experiments.

5 Evaluation

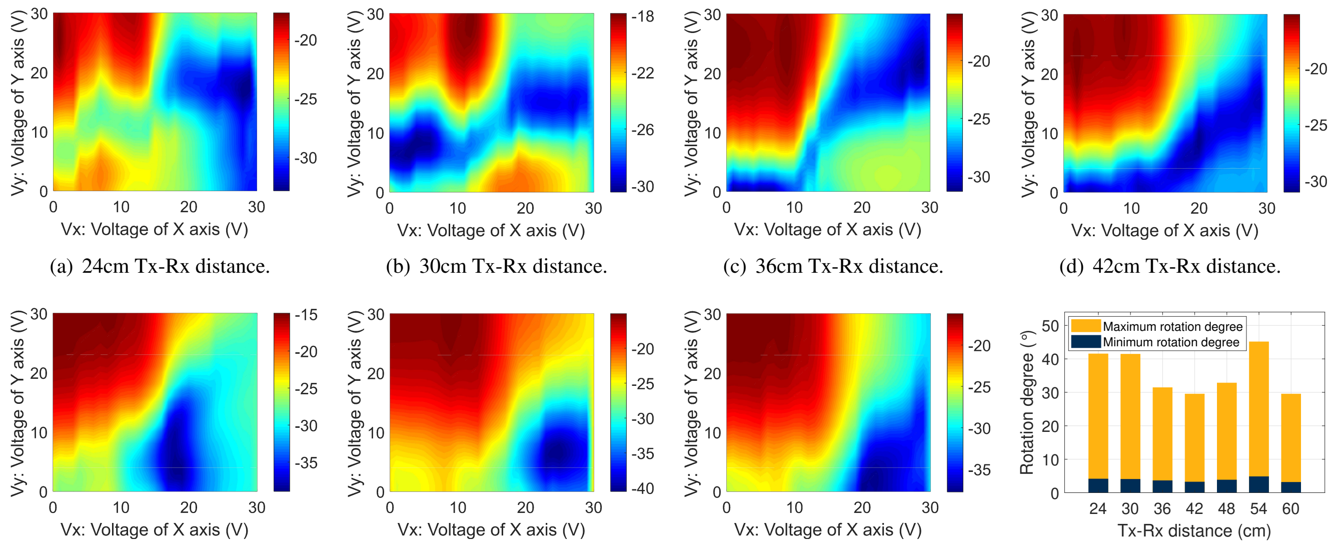
In this section, we conduct extensive experiments to evaluate the performance of LLAMA. We first answer how metasurface improves the transmissive signal power in polarization mismatch setup. Then we analyze the relationship between signal enhancement induced by the metasurface across a number of parameters including transmitted power, multipath effect, antenna directionality and operating frequency. We also evaluate LLAMA's performance for practical low-cost IoT communication links. In addition, we validate LLAMA's ability to enhance a reflected signal, and demonstrate the influence of the proposed metasurface structure for sensing.

Performance metrics. We measure signal strength at the receiver as our performance metric, since this directly characterizes the benefit of polarization rotation. An increase in the received power usually translates to a throughput improvement. While it is common to measure link throughput directly, the size limit of our current prototype makes it challenging to characterize link throughput in diverse settings.

5.1 Transmissive Operation

5.1.1 Transmissive Signal Enhancement

To verify LLAMA's ability to rotate the polarization of transmissive signals, we conduct experiments with the metasurface under different transmitter-receiver (Tx-Rx) distances (from 24 cm to 60 cm by half wavelength steps of 6 cm). The transmitter and receiver are placed orthogonally such that they are in a mismatched polarization configuration. In each experiment, we measure the received signal power across a full sweep of voltage combinations (both V_x and V_y vary from $0-30$ V). Figure 14 (a-g) show how the received signal power changes with different voltage combinations at each Tx-Rx distance and how the maximum achieved rotation angle diminishes as the distance becomes comparable to the size of the surface. The signal power changes significantly with changes in biasing voltage. We also find the mapping between these voltages as the rotation shifts gradually with respect to Tx-Rx distance. Figure 14 (h) shows the polarization rotation degree measured by the proposed method in § 3.4. We find that the metasurface can rotate the polarization over a range of $3^\circ-45^\circ$, which allows the metasurface to correct for a significant amount of mismatch. To understand the signal improvements provided by the metasurface, we also measure the signal power in mismatch configuration with no metasurface present as a baseline. By comparing the results with and without the metasurface as depicted in Figure 15, we can see that the metasurface enhances the transmissive signal power by up



(a) 24cm Tx-Rx distance. (b) 30cm Tx-Rx distance. (c) 36cm Tx-Rx distance. (d) 42cm Tx-Rx distance. (e) 48cm Tx-Rx distance. (f) 54cm Tx-Rx distance. (g) 60cm Tx-Rx distance. (h) Polarization rotation degree.

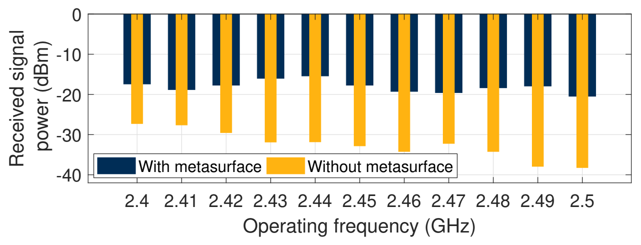

Figure 16: Power improvement VS. operating frequency in polarization mismatch setup.

to 15 dB, which extends the potential transmission distance by up to 5.6× according to the Friis equation [21].

5.1.2 Performance Benchmarks

Validating operational bandwidth. In order to evaluate LLAMA's performance over the entire ISM frequency band, we conduct experiments that vary the operating frequency from 2.4 GHz to 2.5 GHz by steps of 0.01 GHz. We measure the maximum signal power with and without the metasurface. From the results shown in Figure 16, we can see that LLAMA enables $>$ 10 dB signal enhancement across the entire ISM frequency band, when compensating for polarization mismatch (orthogonal antenna orientation). This indicates that LLAMA has potential for optimizing IoT communication links with protocols including Wi-Fi, Bluetooth and Zigbee.

Impact of incident power on performance gains. In this experiment, we sweep through transmit power settings to understand how incident power affects the performance improvement (measured in terms of channel capacity enhancement) provided by the metasurface — lower transmit powers could potentially be dominated by loss within the metasurface. The capacity is calculated according to the SNR measurement and channel bandwidth. We perform experiments with both directional [9] and omnidirectional [3] antennas on the transceiver. Figure 17 shows that the capacity initially increases slowly with transmitting power for both the directional and omnidirectional antennas.

Impact of multipath. In these experiments we seek to understand the impact of multipath propagation on LLAMA's performance. We perform experiments in an indoor lab environment without absorber material. We also measure the channel capacity by using two types of antennas at different transmit power. By comparing the results of Figure 18 with Figure 17, we find that for a directional antenna, the metasurface can still contribute similar capacity improvements to without multipath. However, the results from omni-directional antennas are different – when the transmitted power is lower than 2 mW, the metasurface will no longer enhance the passing signal, and in fact degrade the channel capacity. Directional antennas

"concentrate" the signals through the metasurface, so the incident power is higher and the metasurface can let more power through; omni-directional antennas do not send as much incident power to the metasurface, so the enhancement from polarization matching may not compensate for the loss through the surface. For that reason, the metasurface can effectively block out some weaker multipath components, and therefore the endpoint receiver will not get constructive interference from these multipath components. In that sense, it is possible the metasurface can reduce performance.

5.1.3 Experiments with Low-cost IoT Devices

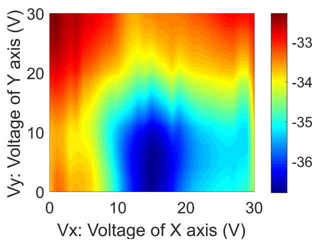
Finally, we evaluate LLAMA's performance with low-cost IoT devices. We perform tests with conventional Wi-Fi and Bluetooth links. The Wi-Fi link is between a Wi-Fi router and an Arduino with a low-cost ESP8266 module, and the Bluetooth link is between a Huawei Watch and a Raspberry Pi 3. From the signal power distributions shown in Figure 19, we find that for the Wi-Fi link, LLAMA creates around 10 dB signal power improvement in a mismatched polarization setup, which looks similar to the matched configuration depicted in Figure 2 (a). While the improvement for the Bluetooth link is lower, this is expected according to the result shown in Figure 18 (a), which indicates the amount of signal quality change that can be affected by LLAMA depends on the incident power level at the metasurface. Nevertheless, we believe LLAMA could still help Bluetooth *receivers* when the transmitter is a higher-power device, such as a mobile handset.

We next study how LLAMA performs when operating across a wider band channel. Most Wi-Fi transmissions today leverage OFDM over $20-40$ MHz. To answer this question, we leverage GIGABYTE mini-PCs equipped with conventional off-the-shelf Intel 5300 wireless cards as transceivers to conduct an experiment – the center frequency and bandwidth are 2.47 GHz and 20 MHz, respectively. Figure 20 shows the channel gain measurements with and without the metasurface in a mismatched configuration. The results show that the overall channel gain is improved, but the enhancement of individual subcarriers are different given the specific bias voltages used for the metasurface; this is consistent with the simulation results shown in Figure 11. The subcarrier channel gains with the metasurface are more consistent over frequency than without. We believe the presence of LLAMA blocks weak multipath signal components that traverse longer paths and tend to exhibit frequency-selectivity more, and the remaining components are aligned through polarization rotation.

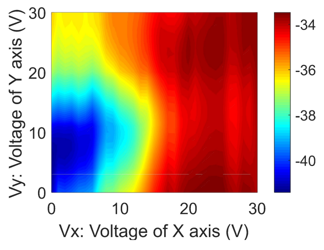
5.2 Reflective Operation

5.2.1 Reflective Signal Enhancement

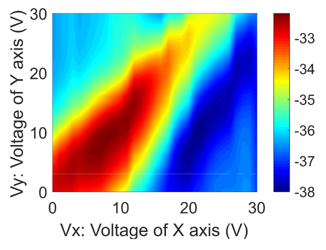
In addition to evaluating transmissive configurations, we also look at LLAMA's effect on reflected signals. We place the transmitter and receiver on the same side of the metasurface, and separate the transmitter and receiver by 70 cm. We perform experiments at different Tx-metasurface distances by moving the metasurface along the vertical line of the transceiver pair. Figure 22 shows the maximum received sig-



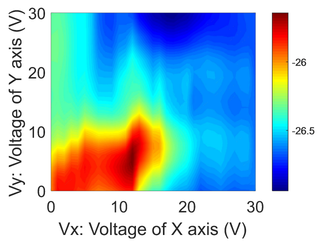
(a) 24cm Tx-Metasurface distance.



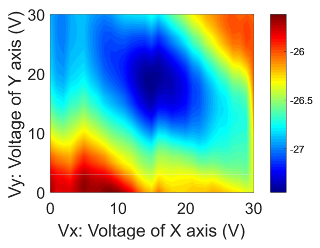
(b) 30cm Tx-Metasurface distance.



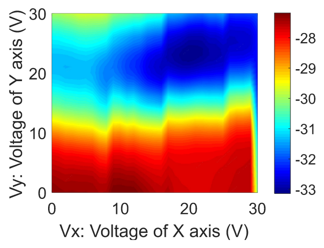
(c) 36cm Tx-Metasurface distance.



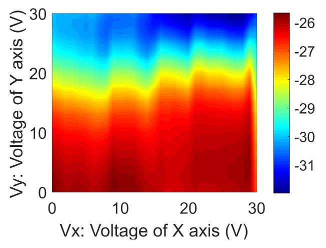
(d) 42cm Tx-Metasurface distance.



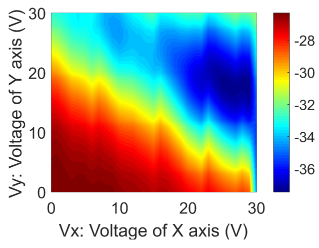
(e) 48cm Tx-Metasurface distance.



(f) 54cm Tx-Metasurface distance.



(g) 60cm Tx-Metasurface distance.



(h) 66cm Tx-Metasurface distance.

Figure 21: Experimental results in reflection scenarios. We find that LLAMA also changes the reflective signal power.

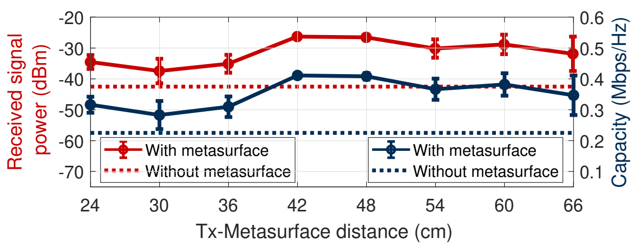


Figure 22: LLAMA provides improvements to channel capacity and power in a reflective configuration.

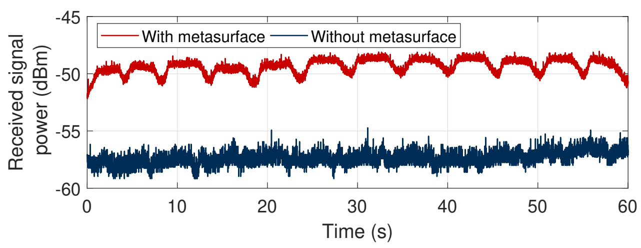

Figure 23: Human respiration sensing results with/without metasurface at low transmitting power of 5 mW.

nal power and channel capacity with the metasurface , as well as the baseline measurements without the metasurface in a mismatched configuration. These results show that LLAMA also has a positive impact on the reflection scenario—the signal power and capacity can be improved with respect to mismatch by as much as 17 dB and 180 kbps/Hz, respectively. However, the signal power difference over voltage combinations (see Figure 21) is much smaller than that in the transmission scenario. We believe this is because the rotation will be cancelled after reflection.

5.2.2 Employing LLAMA for Sensing

Based on the reflective configuration, we conjecture that LLAMA can be utilized to enhance sensing. To validate this, we consider human respiration detection as a case study to test LLAMA's potential. In this experiment, the metasurface is placed 2 m away from the center of the transceiver pair, the human subject is located on the side between the transmitter and the metasurface. First, we remove the metasurface and reduce the transmitting power to where the human subject's respiration can no longer be detected from the received signal. Then we introduce the metasurface at the predetermined location, and measure the received signal strength. The detection results with and without the metasurface are plotted in Figure 23. It is clear that the metasurface can enhance the reflected signal and allow the target's respiration rate to be detectable under a low transmit power configuration (5 mW). We believe that LLAMA can also be extended to other low SNR sensing applications [23, 50].

6 Discussion and Future Work

Scaling to a dense IoT deployment. This work marks the first step towards mitigating polarization issues for individual communication links with a LLAMA prototype. Next, we plan to scale up the size of the metasurface for a larger deployment and explore more challenging multi-link scenarios. When there are multiple IoT devices in different polarization orientations, tuning the signal polarization can lead to a new form of polarization reuse or access control and improve the network throughput of a dense IoT deployment.

Adapting to device mobility. The current search time for optimal voltage is limited by the switching speed of the commodity power supply we used, hence there is still a latency issue in mobility scenarios. In the future, we will look at methods that can speed this up once the relative antenna orientations are determined and then track the changes.

7 Related Work

Broadly speaking, our work is related to work in three areas:
Endpoint optimizations. Most efforts for improving communication quality focuses on controlling the endpoints themselves. For instance, Multiple Input, Multiple Output (MIMO) links leverage multiple antennas to exploit spatial diversity at a sub-link level, while Multi-User MIMO exploits spatial diversity at an inter-link level [24, 25]. Massive MIMO introduces many more antennas at an access point than both radio chains and users, so that the AP may search for a set of antennas that forms a well-conditioned MIMO channel to those users [34, 40, 47]. However, these approaches are fundamentally limited if the cause of performance loss is antenna polarization mismatch between endpoints. At the endpoints, the only directly relevant mitigation strategies are to use either circularly polarized antennas or multiple linearly polarized antennas. Once the antennas are fixed, not much can be done about polarization match at the endpoints. Using an antenna array like massive MIMO can enhance the received signal power, but without directly addressing the polarization issue.

In contrast, an approach that changes the radio environment itself (e.g., deploying low-cost reflectors) offers the possibilities to increase the number of degrees of freedom.
Environment-based optimizations. Previous work on radio environment optimizations fall into two categories: phase-based and amplitude-based. Initial attempts of phase based approaches such as leveraging static mirrors [52] or programmable phased-array reflectors [7, 8, 42] are in the ability of generating constructive propagation paths. These methods focus on millimeter wave links on high frequency bands (*i.e.*, 10 GHz and above). More generally, several proposals argue for dynamically reconfiguring the radio environments [11, 12, 30, 37, 43, 44, 48]. Specifically, recent prototypes manipulate the signal propagation behavior in the 2.4 GHz band, by using a large array of inexpensive antennas [18, 29, 43] or conductive surfaces [16] as phase shifting elements. These systems align phase elements according to a channel decomposition. Amplitude-based designs, such as RFocus [10], sidestep the difficulty in measuring phase. Based on the signal amplitude measurements from the receiver, RFocus configures the signal to either pass through or reflect from the surface element by setting the “on” or “off” state of each element, so that the transmitted signal is focused at the intended receiver.

Orthogonal to prior work that aligns multiple paths to achieve beamforming effects or improve spatial multiplexing efficiency, LLAMA optimizes low-cost IoT communication links by specifically overcoming the pervasive issue of polarization mismatch that affects both single and multi-path communication.
Metamaterials. Metamaterials are an earlier, more general form of metasurfaces that are constructed in 3D rather than 2D. These are artificially constructed with special properties. Recent work in the applied physics community has developed metamaterials that can directly alter existing signals in the environment itself, such as creating materials with a negative refraction index [27] and engineering complex beam patterns [33]. Other work has verified the feasibility of leveraging metamaterials to change the signal polarization [26, 45, 46, 49, 51]. With a biasing network, different voltages are provided to diodes integrated on the metasurface for rotating the polarization of a transmitted wave. While these designs have shown great promise in controlled experiments that quantify performance in a higher frequency band (*i.e.*, > 5 GHz), they were constructed using expensive, low loss substrate materials such as Rogers or F4B. Furthermore, they have not been integrated into an end-to-end system that optimizes signal paths in real time.

In contrast, we present an end-to-end system incorporating the structure of a metasurface design for the 2.4 GHz ISM band using cheaper, but higher loss FR4 material, and specifically control the structure’s polarization rotation to optimize the communication link between a pair of devices.

8 Conclusion

This paper highlights the under-appreciated issue of polarization mismatch for low-cost IoT devices that are physically limited to employing a single low-quality antenna. We present LLAMA, a system designed to mitigate the polarization mismatch without hardware modifications to the endpoints. LLAMA is capable of manipulating the polarization state of the signal arriving at the receiver with a tunable metasurface structure made with cheap material. It can optimize the communication quality in real time, and enhance the performance of sensing applications.

Bootstrapping Battery-free Wireless Networks: Efficient Neighbor Discovery and Synchronization in the Face of Intermittency

Kai Geissdoerfer
TU Dresden

Marco Zimmerling
TU Dresden

Abstract

Due to their favorable size, cost, and sustainability, battery-free devices are preferable in various applications. However, battery-free devices operate only intermittently since ambient energy sources, such as light and radio-frequency signals, are often too weak to continuously power the devices. This paper addresses the unsolved problem of efficient device-to-device communication in the face of intermittency. We present Find, the first neighbor discovery protocol for battery-free wireless networks that uses randomized waiting to minimize discovery latency. We also introduce Flync, a new hardware/software solution that synchronizes indoor light harvesting nodes to powerline-induced brightness variations of widely used lamps, which we exploit to further speed up neighbor discovery. Experiments with an open-source prototype built from off-the-shelf hardware components show that our techniques reduce the discovery latency by 4.3× (median) and 34.4× (99th percentile) compared with a baseline approach without waiting.

1 Introduction

Despite technological advances, the maintenance costs and environmental impact of batteries remain a major threat to the vision of a truly ubiquitous Internet of Things [3, 11]. *Battery-free devices* that store energy harvested from light, vibrations, radio-frequency (RF) signals, and other ambient sources in a capacitor are one of the most viable alternatives today [45]. Capacitors store electrical energy in an electrical field rather than in the form of chemical energy, and thus have negligible aging effects and are sustainable [1, 6]. Moreover, their favorable size, weight, and cost points enable new applications where batteries would be inconvenient or infeasible [30].

Challenge. The power that can be harvested from ambient energy sources can vary significantly across time and space [15], and is often too weak to directly power a battery-free node, such as a smart sensor [32]. Thus, as illustrated in Fig. 1 and further discussed in detail in Sec. 7, a battery-free device first needs to buffer sufficient energy in its capacitor before it can operate for a short period of time; then the device turns off

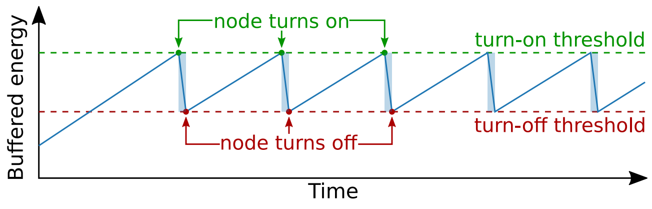

Figure 1: Because ambient power is often weak, a battery-free node must buffer energy before it can wake up and operate for a short time period. This is known as intermittent operation.

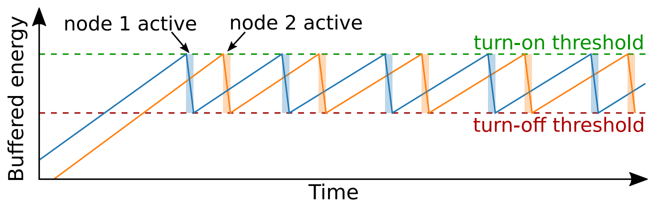
until the capacitor is sufficiently charged again. As a result, battery-free devices operate *intermittently*.

Intermittency is in stark contrast to conventional duty cycling. While duty cycling is intentionally introduced to save energy and thus predictable, intermittency is mainly dictated by uncontrollable environmental factors and thus impacts the device operation in unpredictable ways. The resulting challenges in terms of, for example, reliable time keeping [12, 18] or ensuring application progress and data consistency [8, 34] have been widely studied in the recent literature.

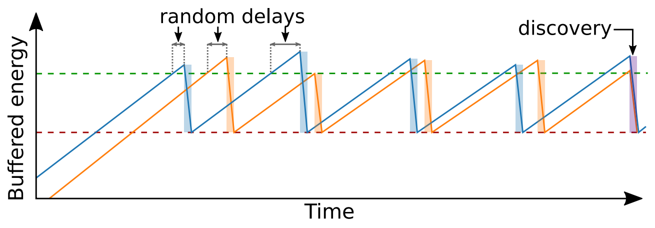
The impact of intermittency on wireless networking has instead received little attention. Just like in conventional battery-supported networks, direct communication between battery-free devices is desirable, for example, to increase the availability of the system [36], to enable novel applications [20, 32], and to reduce infrastructure costs [35]. However, to communicate with one another, sender and receiver must be active simultaneously for at least the airtime of one complete packet. This is challenging in battery-free networks for three reasons:

1. Battery-free nodes can only become active when they have accumulated sufficient energy in their capacitors.
2. They may only be active for a short period, which renders excessive sampling of the wireless channel infeasible.
3. Their duty cycles are often low and may change unpredictably due to varying availability of ambient energy.

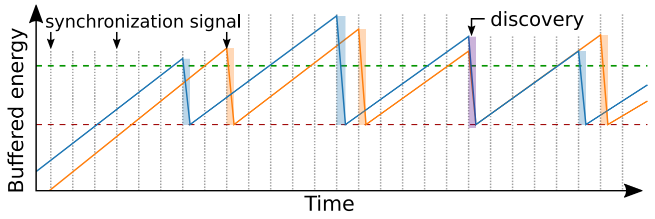
For example, our prototype battery-free node needs to charge its capacitor for hundreds of milliseconds to sustain 1 ms of activity when harvesting from indoor light. Because the short



(a) Battery-free nodes may need a long time to discover each other due to low duty cycles and the interleaving of short activity phases.



(b) Using Find, nodes randomly delay their wake-ups to avoid interleaving, thereby discovering each other faster and more efficiently.



(c) Using Find + Flync, nodes implicitly align their wake-ups to an external synchronization signal, further accelerating discovery.

Figure 2: Illustration of the battery-free neighbor discovery challenge in (a) and of our proposed mechanisms to address it in (b) and (c).

activity phases of different nodes are generally interleaved, as shown in Fig. 2a, it takes a long time until nodes encounter each other. And this is not a one-time endeavor: While nodes may attempt to synchronize their activity phases at the first encounter, they lose track of time during extended periods without energy [12, 18], which forces them to re-synchronize.

This challenge is fundamental and pertains to battery-free networks regardless of the type of wireless communication: While backscatter communication can lower the energy costs compared to active radio communication, sender and receiver still need to have sufficient energy at the same time. Prior work on backscatter has primarily focused on pushing the envelope of communication range and throughput, avoiding intermittency by evaluating the designs under high ambient energy availability [20, 32] or by powering the devices via USB or batteries to not disturb the measurements [35]. To our knowledge, direct radio communication between real battery-free devices has not been explored so far, as the overhead due to intermittency is considered too demanding [36].

Contribution. We set out to bootstrap battery-free wireless networks by presenting two mechanisms that enable battery-free nodes to discover each other quickly and efficiently.

The first mechanism, Find, is a neighbor discovery protocol. As illustrated in Fig. 2b, the key idea behind Find is to address the interleaving problem by introducing random delays after the devices have sufficiently charged their capacitors before becoming active. We develop analytical models to determine an optimized delay distribution that minimizes discovery latency. At runtime, each Find node dynamically adapts the delay distribution to changes in its energy availability.

The second mechanism, Flync, is a hardware/software solution that further speeds up the discovery process. Flync phase-synchronizes solar energy harvesting devices to powerline-induced flicker of state-of-the-art lamps; the proposed circuit draws only 5 µW of power. As shown in Fig. 2c, using Find together with Flync, nodes can implicitly align their activity phases to this external synchronization signal, dramatically increasing their chances to be active at the same time.

We prototype our mechanisms on a custom-designed ultra low-power battery-free node. It is based on a state-of-the-art microcontroller (MCU) with a 2.4 GHz Bluetooth Low Energy (BLE) radio, and buffers energy harvested via three small solar panels in a tiny 47 µF ceramic capacitor.

We use 6 of our prototype battery-free nodes to conduct extensive experiments and a contact-tracing case study. We summarize our key findings as follows:

- Find provides shorter discovery latencies than greedy and naïve random node activations. Find + Flync improves on greedy by 4.3× in terms of the median latency (141 s vs. 604 s); the 99th percentile improvement is 34.4×.
- Our hardware prototype works with 14 out of 19 fluorescent, halogen, and light emitting diode (LED) lamps we tested, demonstrating that Flync is broadly applicable in indoor environments. Flync provides a stable clock signal when nodes are deployed across different rooms, carried around, or exposed to temporary shadowing.
- We conduct a contact-tracing case study in an open-air pub with Find and in an office kitchen using Find + Flync. The median time between consecutive encounters of the same two nodes is 1.5 s and 7.5 s in the outdoor and indoor environment, respectively. This shows the potential of our battery-free designs for real-world applications.

Overall, this paper makes the following contributions:

- Find, the first neighbor discovery protocol for battery-free networks. Find is agnostic to the energy harvesting modality and the type of wireless communication.
- Flync, the first solution extracting a stable clock from solar harvesting current, whose amplitude changes due to powerline-induced flicker of state-of-the-art lamps. While we use Flync in tandem with Find to speed up discovery in indoor scenarios, Flync is useful for other purposes and also applicable to battery-supported nodes.
- A novel battery-free node design including an implementation of an efficient intermittent runtime.
- Empirical evidence that the proposed techniques work well under a diverse set of real-world conditions.

2 Battery-free Neighbor Discovery

This section presents the design of Find, the first neighbor discovery protocol for battery-free wireless networks. Find empowers battery-free nodes to quickly discover each other's presence despite intermittent operation and varying ambient energy availability. It is agnostic as to how the nodes harvest energy (from solar, vibrations, RF, etc.) and as to whether they communicate using backscatter or radio communication.

The design of Find is based on the observation that the only way battery-free nodes can reliably avoid interleaving is to not wake up and become active immediately after reaching the minimum energy level required to do so. We refer to this as the greedy approach. Instead, Find delays each wake-up for a random time. A crucial question is how to choose this random delay to ensure fast and energy-efficient discovery.

To answer this question, we devise a model that captures the impact of key parameters, such as the charging time needed to reach the minimum energy level and the random delay, on the discovery latency (Sec. 2.1). Using this model, we then determine an optimized delay distribution that minimizes the discovery latency (Sec. 2.2). Finally, we describe how these considerations materialize in the practical design of the Find protocol and its runtime operation (Sec. 2.3).

2.1 Modeling Discovery Latency

Suppose that a node needs to charge for c slots until it reaches the minimum energy level required to be active for one slot. Let k_0 denote the first slot in which a node reaches the minimum energy level. Using Find, a node waits for a random delay x in units of slots before it wakes up and becomes active. We model x as a discrete random variable X with probability mass function (pmf) $p_X(x)$. During an active slot, a node fully depletes its energy storage. The probability that a node becomes active for the first time in slot k is given by

$$p_{wk,0}(k) = p_X(k - k_0) \tag{1}$$

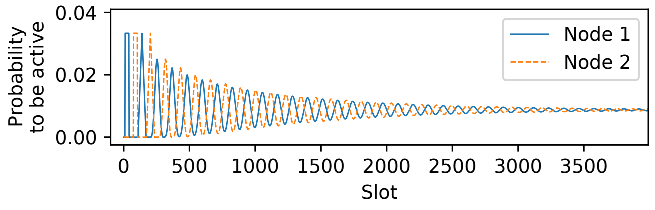
Afterward, a node needs to recharge for c slots before it can become active again. The time of the second wake-up is the sum of the time of the first wake-up, the charging time, and the second random delay. The same reasoning applies recursively to all future wake-up times. Because the random delay is independently chosen across all wake-ups, we can use a recursive convolution to determine the probability that a node wakes up for the n-th time in the k-th slot

$$p_{wk,n}(k) = (p_{wk,n-1} * p_X)(k - c) \tag{2}$$

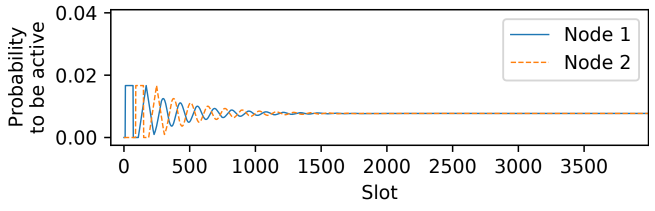
By summing over $n \to \infty$ we obtain the probability that a node is active in slot k

$$p_a(k) = \sum_{n=0}^{\infty} p_{wk,n}(k) \tag{3}$$

To model discovery latency, we consider a fully connected network of N nodes (i.e., a clique of size N). Using a suitable



(a) Random delay drawn from $X \sim U[0,30]$.



(b) Random delay drawn from $X \sim U[0,60]$.

Figure 3: Probability of being active in a slot for two nodes with identical charging times but an initial offset in their wake-ups. The more wide-spread the random delay, the faster nodes break up their interleaved wake-up pattern at the cost of a lower average duty cycle.

sequence of message exchanges in active slots (see Sec. 2.3), one of the $M = N(N-1)/2$ bi-directional links $i \leftrightarrow j$ is discovered if nodes i and j are active in the same slot while all other nodes in the network are inactive. Otherwise, a collision occurs and no link is discovered, a typical assumption in neighbor discovery protocols [24]. The probability that link $i \leftrightarrow j$ is discovered within k slots is the complement of the probability that the link is not discovered in slots $0, \ldots, k$:

$$c_{i \leftrightarrow j}(k) = 1 - \prod_{\kappa=0}^{k} \left(1 - p_{a,i}(\kappa) \cdot p_{a,j}(\kappa) \cdot \prod_{l \neq i,j} (1 - p_{a,l}(\kappa)) \right) \tag{4}$$

$c_{i \leftrightarrow j}(k)$ can be regarded as the cumulative distribution function (cdf) of the discrete random variable describing the slot in which link $i \leftrightarrow j$ is discovered. With $p_{i \leftrightarrow j}(k)$ denoting the corresponding pmf, we compute the expected fraction of links discovered up to slot k by averaging $p_{i \leftrightarrow j}(k)$ over all M links

$$d(k) = \frac{1}{M} \sum_{i \leftrightarrow j} p_{i \leftrightarrow j}(k) \tag{5}$$

If the nodes' charging times are finite, $d(k)$ is a valid cdf, and we define the discovery latency as

$$T_{nd} = \sum_{k=0}^{\infty} (1 - d(k)) \tag{6}$$

2.2 Optimized Delay Distribution

With the above model we are able to get a better understanding of how nodes should delay their wake-ups to help discovery.

Example. Suppose two nodes i and j with the same charging time of $c = 100$ slots, but different slots k_0 in which they reach

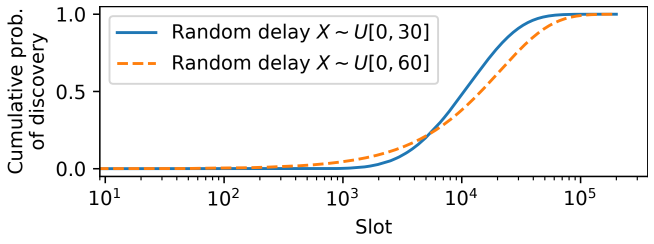


Figure 4: Cumulative distribution function of the slot in which two nodes discover each other, for the two delay distributions in Fig. 3. A more wide-spread delay performs better initially, but leads to lower performance in the long run due to a lower average duty cycle.

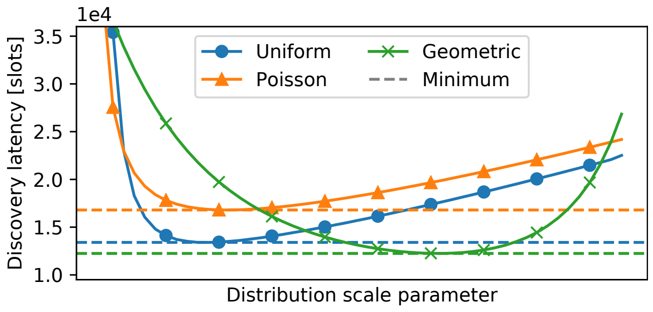

Figure 5: Discovery latency against scale parameter for three different probability distributions. The geometric distribution performs best as it yields delays with high randomness and low mean.

the minimum energy level for the first time (i.e., initial offset). Using (3) we plot in Fig. 3a for both nodes the probability of being active in a slot when they pick random delays from the discrete uniform distribution $X \sim U[0,30]$. We see that in the first thousand slots there is hardly any overlap in the activity of the nodes: Due to the initial offset, node i is likely active when node j is powered off, and vice versa. The probability of being active smears out over time and converges to an average duty cycle of $1/(c+\mathrm{E}[X]) \approx 0.0087$. Fig. 3b plots the same when the two nodes pick random delays from $X \sim U[0,60]$. Compared to Fig. 3a we find that the probability of being active smears out sooner as nodes tend to choose more wide-spread delays. However, as nodes also tend to pick longer delays, they have a lower average duty cycle of 0.0077.

Fig. 4 directly compares the two delay distributions by plotting the cdf of the slot in which nodes i and j discover each other according to (4). We observe that the more wide-spread delay induced by the second distribution $X \sim U[0,60]$ initially provides a higher probability of discovery. In the long run, however, the higher average duty cycle of the first distribution $X \sim U[0,30]$ leads to a higher probability of discovery.

Choosing a distribution. The above example suggests that a non-negative delay distribution with *high randomness and low mean* is preferable. Entropy is a commonly used measure of randomness. Maximizing the entropy of a general non-negative distribution with a given mean yields the exponential distribution [38]. Thus, in Find, we draw random delays from the geometric distribution, the discrete analogue of the exponential distribution, with scale parameter $1/r$ and pmf $(1-r)^k r$ for $k \in \{0,1,2,\dots\}$.

To confirm our reasoning, we compare the geometric distribution against other well-known distributions, namely the discrete uniform distribution and the Poisson distribution. We sweep the scale parameter of the three distributions and compute the discovery latency using (6) for the two-node case, where nodes i and j have equal charging times (25, 100, 500, or 1000 slots). We find that the geometric distribution achieves the lowest discovery latency across all charging times. Fig. 5 shows the resulting curves for a charging time of 100 slots. The differences in the minimum discovery latencies are relatively small. One reason for this is that, according to the central limit theorem, the probability that a node wakes up for the n-th time in slot k converges to a normal distribution for large n, irrespective of the underlying delay distribution.

Determining optimized distribution parameters. Having chosen a suitable delay distribution, we now turn to the problem of determining the scale parameter that minimizes the discovery latency. To formally state the optimization problem, we consider the worst case in terms of discovery latency: all N nodes have the same charging time c, and their initial wake-up times $k_{0,i}$ are all interleaved as in Fig. 3, that is,

$$k_{0,i} = i \cdot \frac{c + 2\,\mathrm{E}[X]}{N} \tag{7}$$

where i is the node index and $\mathrm{E}[X]$ is the expected delay. For specific N and c, we minimize the discovery latency given by (6) and the initial offsets given by (7)

$$\min_r T_{nd}(N,c) \tag{8}$$

Numerical evaluation suggests that $T_{nd}(N,c)$ is convex (see Fig. 5) and hence straightforward to optimize. We use Brent's method [9] to approximate the scale parameter $1/r^*$ that minimizes the discovery latency. The next section explains how we adapt the scale parameter at runtime on a real node.

2.3 Practical Protocol Design

The above analysis makes a number of simplifying assumptions that do not hold in practice. For example, the charging times are generally different across nodes and vary over time. A node typically only knows its own charging time c and is unaware of the total number N of nodes in the network.

Nevertheless, prior work has shown that neighboring nodes have similar energy availability because they harvest energy from the same ambient source(s) [4, 15]. Thus, *in the absence of any prior information*, a reasonable approach for a node is to assume that its neighbors harvest the same amount of energy and thus have the same charging time c like itself.

Moreover, we found that knowledge of the number of nodes N is often not required: optimizing for the case of a two-node

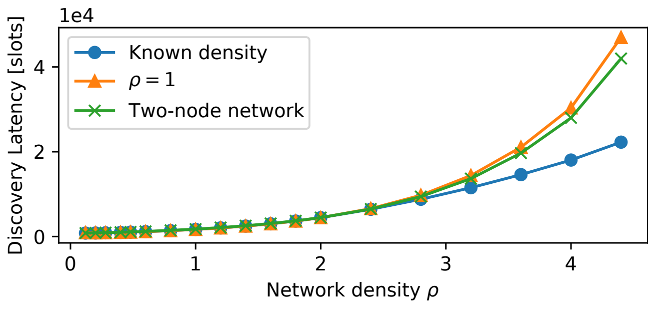

Figure 6: Discovery latency against network density ρ when optimizing for the known density, for a fixed density of ρ = 1, and for a two-node network. For ρ ≤ 2.5, all approaches perform similarly.

network yields competitive performance across a wide range of network densities. In other words, in practice it is often sufficient for a node to assume that it is has only one neighbor (although over time it may discover that it has many more). To understand why, we plot in Fig. 6 the discovery latency for a charging time of 25 slots when optimizing for (*i*) the known network density $\rho = N/c$, (*ii*) a fixed network density of $\rho = 1$, and (*iii*) a two-node network. We can see that for a network density of $\rho \leq 2.5$ the three approaches achieve almost the same performance. For realistic charging times, the network density rarely exceeds this threshold. For example, based on the charging times and beacon length in our real-world case study (see Sec. 6), a network density of $\rho = 2$ would require a network of around 4000 fully connected nodes.

Runtime operation. Prior to each wake-up, a Find node samples a geometric distribution to determine the random delay. A node dynamically adapts the scale parameter of the distribution to changes in its charging time, under the assumption that it has one neighbor with the same charging time, as explained above. To achieve an efficient runtime operation, we store a look-up table of optimized scale parameters in non-volatile memory and use inverse transform sampling to convert samples from a uniform pseudo-random number generator to the optimized, geometric distribution.

Frame structure. Taking inspiration from existing neighbor discovery protocols for battery-powered sensor nodes [5, 13], we adopt the frame structure shown in Fig. 7. During each active slot, a node first transmits a beacon, then listens for potential beacons from neighboring nodes, and finally transmits another beacon at the end of the slot. The second beacon ensures that nodes can discover bi-directional links in one common active slot. Specifically, if the slot offset $\mathcal{T}$ between two nodes (see Fig. 7) is uniformly distributed between $-T_{slot}/2$ and $T_{slot}/2$, where T_{slot} is the slot length, the probability that two nodes successfully discover each other's presence is

$$p = 1 - \frac{2 \cdot (T_{ta} + T_{tx})}{2 \cdot (T_{ta} + T_{tx}) + T_{rx}} \quad (9)$$

Here, as depicted in Fig. 7, T_{tx}, T_{rx}, and T_{ta} denote the times

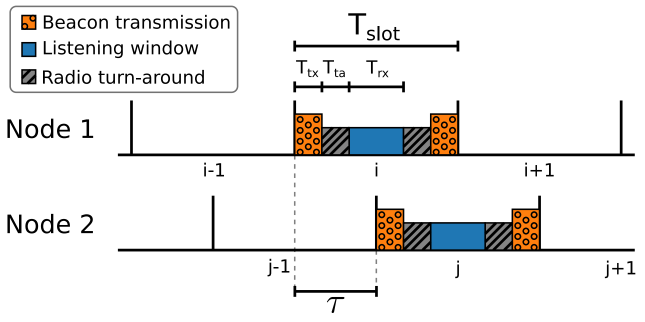

Figure 7: Find's frame structure specifying the sequence of beacon transmissions and the intermediate listening window during an active slot. Using our prototype implementation, nodes can successfully discover each other if the slot offset $\mathcal{T}$ is between 88 µs and 848 µs.

needed to transmit a beacon, to listen for potential beacons, and to switch from receive to transmit mode (or vice versa). In order to maximize the success probability according to (9), Find keeps the beacon transmission time T_{tx} as short as possible to maximize the listening window T_{rx}.

3 Further Accelerating Neighbor Discovery

Find provides fast and energy-efficient neighbor discovery in battery-free networks. Nevertheless, if the ambient energy availability is low, discovery may still take a long time due to the low duty cycles. For example, according to our model, under dim indoor light conditions it takes on average 8 min until two of our prototype battery-free nodes (see Sec. 4) discover each other. Similar observations are to be expected when nodes harvest from weak RF signals or miniature vibrations [7]. The discovery latencies in those challenging energy environments can be prohibitively long for many applications.

This section introduces an approach that facilitates, according to our model, a 10× speed-up in the above-mentioned scenario, allowing two nodes to discover each other in 45 s on average instead of 8 min at an additional cost of only 5 µW. The underlying idea is that neighboring nodes harvest energy from the same ambient source(s) and may therefore have access to a common energy signal that can be used as a time reference. In combination with Find, nodes can exploit this common time reference to align their wake-ups, thereby increasing the chances that nodes are active in the same slot.

To assess the potential of this idea, we focus in this work on harvesting energy from indoor light. While this is a popular method for powering battery-free nodes due to the ubiquity of interior lamps, the energy density of indoor light is significantly lower than that of sunlight. As such, it represents both a challenging environment for battery-free neighbor discovery and a highly relevant setting for real applications. In the following, we provide answers to three key questions:

1. What common energy signal can nodes use? (Sec. 3.1)
2. How to efficiently extract a time reference? (Sec. 3.2)
3. How to exploit this for faster discovery? (Sec. 3.3)

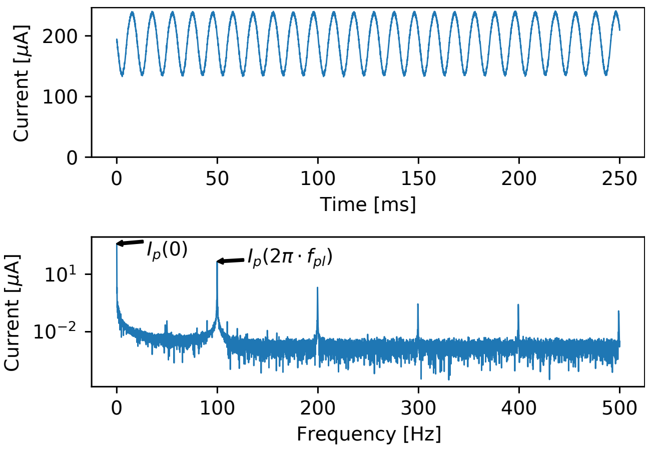

Figure 8: Time and frequency domain of solar panel current when harvesting energy from light emitted by a UP-PL30120-45W LED panel. The current varies with double the powerline frequency.

3.1 Powerline Flicker in Solar Current

When harvesting energy from indoor light, we observed that the solar panel current varies with double the powerline frequency (50 or 60 Hz depending on the region). As an example, Fig. 8 shows the solar panel current when harvesting energy from an LED panel light found in a typical office space.

Practically all indoor lamps are connected to mains power, which induces phase-synchronized brightness variations (*powerline flicker*) of the lamps through different effects. Despite their relatively high inertia, the alternating current through the filament of incandescent and halogen lamps causes temperature and, as a result, brightness variations. A similar effect occurs in gas-discharge lamps like the ubiquitous fluorescent lamps, where the alternating current through the gas modulates the brightness. Due to the exponential relation between forward voltage and brightness, voltage-controlled LEDs are also sensitive to residual ripple of the rectified supply voltage. Because the power available from a solar panel is proportional to the brightness of the incident light, it also varies with double the powerline frequency, as visible in Fig. 8.

To assess the potential of using powerline flicker as a common energy signal, we characterize the magnitude of powerline frequency induced fluctuations of the solar panel current for a wide variety of lamps. To compare lamps across diverse average brightness levels, we define the *flicker index FI* as the ratio of the amplitude of the powerline frequency component and the DC component of the solar panel current i_p

$$FI = \frac{I_p(2\pi \cdot f_{pl})}{I_p(0)} \tag{10}$$

where $I_p(\omega) = \mathcal{F}\{i_p(t)\}$ is the Fourier transform of the solar panel current and f_{pl} is the powerline frequency.

We attach an IXYS SM141K06L solar panel to a Shepherd node [15] and record 15 s of solar panel current at a sampling

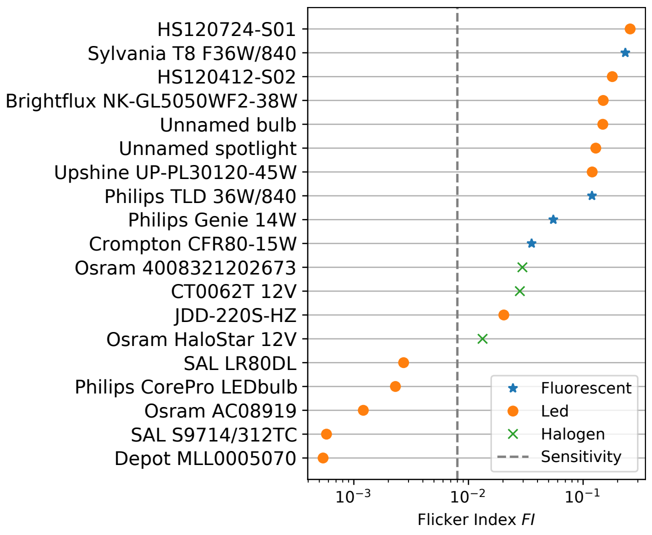

Figure 9: Flicker index for 19 tested lamps. The gray line marks the sensitivity of our Flync prototype. The proposed circuit works with all fluorescent and halogen lamps and the majority of LED lamps.

frequency of 100 kHz from each of the 19 lamps in Fig. 9. For each trace we compute the flicker index using (10). The results in Fig. 9 show that all lamps we tested exhibit varying levels of powerline flicker. We observe that all fluorescent and halogen lamps have a relatively large flicker index. The results for the tested LED lamps are more ambiguous. We suspect that highly integrated, bulb-shaped LED lamps tend to have high-quality current-controlled drivers with little flicker, whereas commercial panel-style LED lamps often rely on voltage-controlled drivers with significant levels of flicker.

We conclude that most types of lamps exhibit significant powerline flicker, which makes this an attractive common energy signal. Next, we present our design of Flync, a hardware/software solution that extracts a frequency- and phase-synchronized clock signal from this common energy signal on distributed battery-free nodes. The dashed line in Fig. 9 is the measured sensitivity (see Sec. 5.2) of our Flync prototype, showing that the proposed design works with all fluorescent and halogen lamps and the majority of tested LED lamps.

3.2 Extracting a Clock from Solar Current

To be viable, Flync needs to provide a stable clock signal while keeping the required energy costs as low as possible.

Hardware. We propose the circuit shown in Fig. 10, which converts the modulated current signal from the solar panel into a digital clock signal that can be connected to a general purpose input/output (GPIO) pin of a MCU. The current through shunt resistor R_S causes a voltage drop that is filtered with a narrow-band bandpass filter to extract and amplify the powerline frequency component. We tune the band-pass filter to a gain of 36 dB at a center frequency of exactly double the powerline frequency, taking into account the limited gain-

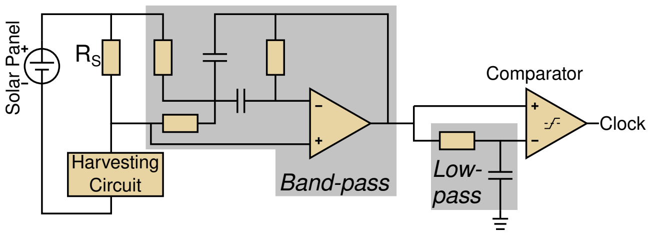

Figure 10: Flync circuit to extract a clock signal from the powerline-induced solar panel current variations (see Fig. 8 for an example).

bandwidth product of the low-power operational amplifier. The resulting signal is connected to a comparator directly and through a low-pass filter to convert it into a digital signal.

The TI TLV521 operational amplifier used in the band-pass filter has a typical current draw of 350 nA, and the TLV7031 comparator has a typical current draw of 315 nA. Including the losses over the 300 Ω shunt resistor, the Flync circuit draws a total of around 5 µW under typical harvesting conditions. This is orders of magnitude lower than the power draw of related approaches, using a light sensor and an analog-to-digital converter (ADC) (5.394 mW [31]) or an antenna to extract the signal from powerline radiation (300 µW [42]).

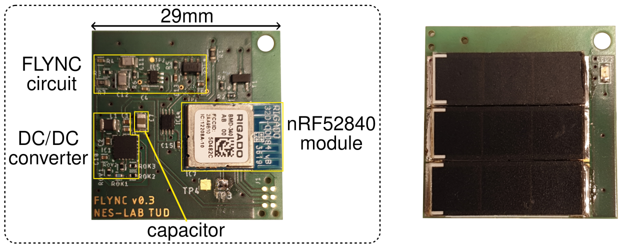
Software. To achieve a stable clock signal, we use a phase-locked loop (PLL) in combination with a proportional integral derivative (PID) controller to synchronize the MCU's real-time clock (RTC) to the powerline frequency signal extracted with our proposed circuit. In Sec. 4.2, we describe our software implementation of Flync in more detail.

3.3 Exploiting the Clock for Faster Discovery

Using Flync, neighboring battery-free nodes have access to a common clock. Nodes can use the phase information of this clock to implicitly agree on times at which they potentially become active. For the powerline flicker, this could be the rising edges of the solar panel current (see Fig. 8).

When using Find without Flync, we set the slot length to the duration of a node's active period. When using Find with Flync, we increase the slot length to $1/(2 \cdot f_{pl})$ and let nodes only become active at the beginning of a slot. This increases the probability that nodes become active in the same slot. For example, consider two nodes that randomly and uniformly wake up once within a 1 s time window. Using a slot length of 1 ms, the probability that both nodes wake up in the same slot is 1/1000. With a slot length of 10 ms, this probability is 10× higher, which speeds up the neighbor discovery process.

Flync exploits the well-behaved, widely available powerline flicker as sychronization source, but the concept applies to any phase-synchronized signal available on different nodes. Because the benefit in terms of a shorter discovery latency stems from increasing the effective slot length, the signal's period must be longer than the duration of a node's active period. The lower the frequency, the longer the slot length



(a) Front (b) Back

Figure 11: Prototype battery-free node based on the nRF52840 MCU. Solar panels on the back charge a tiny capacitor that powers the node.

and the greater the potential benefit. If the period is longer than the charging time of a node, it can be divided down to avoid nodes wasting energy while waiting for the next slot.

4 Prototype Implementation

This section describes the hardware and software components of our prototype implementation.

4.1 Hardware

We design a low-power battery-free node that integrates the circuit from Fig. 10. The node is based on a Nordic Semiconductor nRF52840 MCU, which features a 64 MHz ARM Cortex-M4F and a 2.4 GHz radio with support for Bluetooth 5.2 and IEEE 802.15.4. The node harvests energy using three 23 mm × 8 mm IXYS KXOB25-05X3F solar panels. A TI BQ25505 DC-DC boost converter steps up the voltage of the solar panels and charges a 2 mm × 1.25 mm × 1.25 mm 47 µF multilayer ceramic capacitor (MLCC). However, due to DC bias, the capacitor has only an effective capacitance of around 17 µF at 3.3 V. The BQ25505 implements a maximum power point tracking (MPPT) mechanism that aims to operate the solar panels close to their optimal voltage of around 80 % of the panels' open-circuit voltage. The MPPT circuit obtains a new reference voltage every 16 s by disabling the charger for 256 ms and sampling the panels' open-circuit voltage. Once the capacitor voltage reaches a hardware-programmable threshold of 3.3 V, the BQ25505 sets one of its pins high. This pin is connected to a TI TS5A23166 analog switch that connects the MCU to the capacitor-buffered supply voltage.

The two-layer printed circuit board (PCB) shown in Fig. 11 measures 29 mm × 29 mm. The total cost of all components is \$13.89, including \$8.11 for the relatively expensive, highly integrated nRF52840 module. Comparing our design to recently proposed battery-free platforms with similar capabilities in Table 1, we see that our prototype is indeed one of the first truly battery-free nodes in the sense that the energy storage is negligible in terms of cost, size, and environmental impact: The ceramic capacitor does not contain problematic materials, costs \$0.024, and takes up only 0.3 % of the PCB area.

Platform	Year	Capacitor	Communication
Pible [14]	2018	220 mF super-cap	BLE

This work	2021	47 µF MLCC	BLE PHY

Table 1: Our battery-free prototype node has a sustainable ceramic capacitor that is significantly smaller and cheaper than the energy storage of other recently proposed battery-free platforms.

4.2 Software

Next, we describe our implementation of an efficient runtime for battery-free nodes. We also detail the PLL implementation of Flync and key configuration parameters of Find.

Efficient runtime. Many existing battery-free runtimes discharge the capacitor until the voltage drops below the minimum and the MCU is powered off [12, 17]. To avoid the high energy costs of frequent hardware resets, we implement a different approach that we call *soft intermittency*. During charging, the MCU enters the lowest possible sleep mode, periodically waking up to sample the capacitor voltage with the built-in ADC. In this mode, we measure a total average power draw of 15 µW, including the power for the Flync circuitry and software processing. When the capacitor voltage reaches a software-defined turn-on threshold, the node arms the power-fail comparator, a dedicated peripheral that raises an interrupt when the capacitor voltage drops below a software-defined turn-off threshold. Then the node executes protocol and application code until it is notified by the power-fail comparator upon which it immediately transitions to deep sleep, drastically reducing its power draw until it has again buffered enough energy. While this soft intermittency approach cannot prevent hard resets when there is no energy input for several hundreds of milliseconds, it greatly increases the average efficiency without using additional comparators and switches.

Flync PLL. The comparator at the output of the circuit in Fig. 10 has a relatively small hysteresis, occasionally causing flickering at signal transitions. Furthermore, while MPPT obtains a new reference value, the harvesting current approaches zero, causing the clock signal to pause for hundreds of milliseconds. To provide a stable clock signal despite these disturbances, we implement a PLL that synchronizes the MCU's RTC to the signal extracted with the Flync circuit. We configure the GPIO peripheral to generate an interrupt on a rising edge at the GPIO pin connected to the output of the comparator of the circuit. After a reset, we wait for the first GPIO interrupt. Upon this interrupt, we set up an RTC interrupt to reset the RTC counter after the nominal powerline frequency interval. Ideally, all following GPIO interrupts should coincide with that RTC interrupt. Thus, the counter value at the time of the GPIO interrupt can be interpreted as phase deviation between the external clock signal and the local timer.

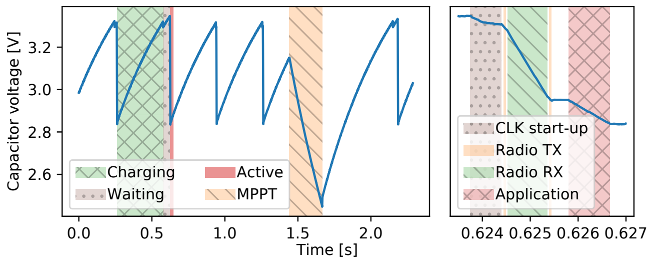

Figure 12: Example trace from a prototype node running Find.

We implement a control loop to continuously adjust the timer period in order to minimize the phase deviation. In this way, we obtain a highly stable interrupt that is phase-synchronized with the variations of the solar panel current and works even during the MPPT sampling or other disruptions.

Find settings. Each beacon in Find's frame structure shown in Fig. 7 consists of 2 B preamble, 3 B base address, 6 B payload, and 1 B cyclic redundancy check (CRC). When using the 2 Mbit BLE mode of the radio, this corresponds to a beacon transmission time of $T_{tx} = 48\,\mu s$. With 17 µF of capacitance, the time required to start the high-frequency oscillator, and a turn-around time of $T_{ta} = 40\,\mu s$, we can afford a maximum listening window of $T_{rx} = 800\,\mu s$. As a result, two nodes can successfully detect each other if they wake up with an offset $\mathcal{T}$ between 88 µs and 848 µs (see Fig. 7).

4.3 Example Real-world Trace

Fig. 12 shows capacitor voltage and activities over time while one of our prototype nodes runs Find. We see that the node charges its capacitor until reaching the turn-on threshold of 3.3 V. It wakes up and samples a random delay from Find's optimized distribution. The necessary computations cause a noticeable drop in the capacitor voltage when transitioning from charging to waiting. After the random delay, the node becomes active and quickly drains its capacitor below the turn-off threshold of 2.8 V. The overview on the left side of Fig. 12 also shows how the capacitor discharges during MPPT at around 1.5 s. The detailed view on the right side shows the individual stages while the node is active. We see that the node first starts the high-frequency clock required to run the radio. Then it sends the first beacon and starts to listen for potential beacons from other nodes. After listening for 800 µs, the node sends the trailing beacon. The remaining energy in the capacitor is assigned to the application that can run until the capacitor voltage hits the turn-off threshold.

5 Evaluation

We manufacture six prototype battery-free nodes to evaluate Find and Flync. We first look at their effectiveness in terms of discovery latency, followed by a detailed characterization of Flync's robustness and performance. Sec. 6 reports on the results of a contact tracing case study based on our techniques.

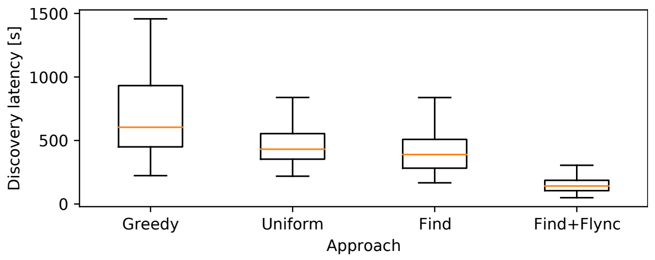

Figure 13: Discovery latency of four different approaches in a network of 6 battery-free nodes. Our techniques outperform the comparison approaches by up to 4.3× (median) and 34.4× (99th percentile).

5.1 Neighbor Discovery Performance

To fairly compare the neighbor discovery performance of our techniques against baseline approaches, we conduct experiments under controlled conditions. Sec. 6 reports on results when using Find and Flync in uncontrolled environments.

Setup. All experiments are conducted in a darkened room with a controllable light source. We place six prototype nodes next to each other on a flat surface. The nodes are programmed to output the ID of any discovered node over universal asynchronous receiver transmitter (UART), while a logic analyzer logs the output of every node. For each run, we let nodes wake up with a random initial delay, and consider the measured time until all 15 bi-directional links are discovered as the discovery latency. We compare Find and Find + Flync with a *greedy* approach, where nodes become active as soon as their capacitor voltage reaches the turn-on threshold, and a *uniform* approach, where nodes randomly delay their wake-ups by a uniformly distributed time. Overall, the measurement campaign took more than 4 days, in which we performed between 48 and 128 runs for each of the four approaches.

Results. Fig. 13 shows the measured discovery latency for each approach, including the median, the 25th and 75th percentiles, and the 1.5× of the interquartile range. Clearly, the greedy approach performs worst. This is mainly because of interleaved activity phases of the nodes, as visible from the trace in Fig. 14. If we zoom in on the first three and the last three wake-ups in the trace, we notice that nodes repeatedly wake up with the same pattern that prevents discovery despite different charging times and MPPT intervals. In Fig. 15, instead, we see that when nodes use Find to randomly delay each wake-up, they are more likely to be active at the same time. For instance, at about 4.5 s, the nodes wake up with an offset of less than 848 µs and are therefore able to successfully exchange beacons as shown in the detailed plot on the right side of Fig. 15. This explains the significant reduction in median discovery latency from 604 s with greedy to 390 s with Find, as visible in Fig. 13. We also see that Find's optimized delay distribution performs slightly better than the uniform approach (median of 431 s), which matches the magnitude of improvement predicted by our model (see Fig. 5).

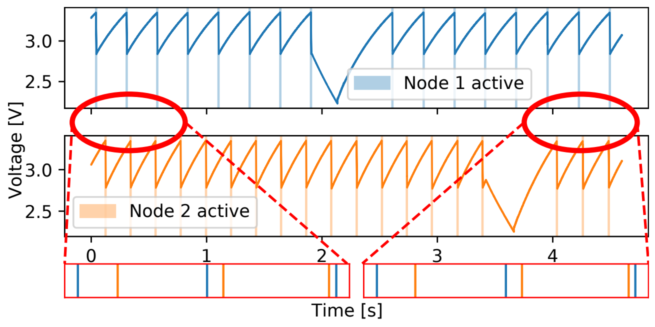

Figure 14: Interleaved activity phases of two nodes when using the *greedy* approach. The zoomed in plots on the bottom show that, despite the disturbances caused by MPPT, the two nodes repeatedly wake up with the same pattern, preventing successful discovery.

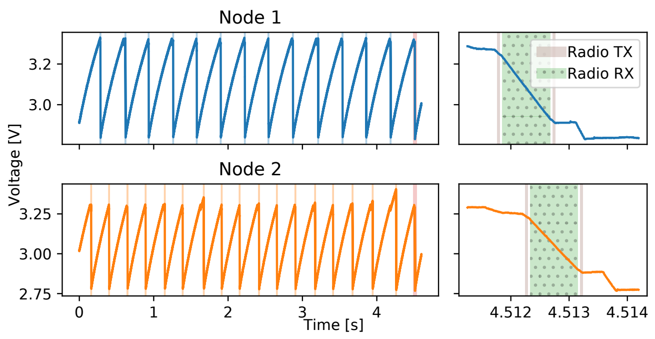

Figure 15: Using Find, nodes prevent *interleaving* by delaying each wake-up by a small random time, enabling quick discovery.

Find + Flync achieves the lowest median discovery latency of 142 s, which corresponds to an overall improvement of 4.3× (median) and 34.4× (99th percentile) compared with greedy.

5.2 Flync Sensitivity

To extract a clock signal, the Flync circuit requires a minimum magnitude of the powerline frequency component in the solar panel current. We empirically determine the corresponding minimum flicker index for our hardware prototype.

Method. The magnitude of the powerline frequency component is proportional to the DC component and decreases with smaller panel size and increasing distance from the light source. We define the worst-case minimum flicker index as the flicker index sufficient to extract a clock signal even at the lowest possible harvesting current. The latter is defined by the minimum power requirements of our prototype when running Find, the panel voltage, and the corresponding efficiency of the DC-DC converter. Our solar panels have a typical panel voltage of 1 V at the maximum power point. At this voltage, our DC-DC converter has an efficiency of 80 %. Thus, the minimum harvesting current to cover the power requirements of our prototype of about 37.5 µW is 50 µA.

We use a Keithley 2600B sourcemeter to generate a current signal with a DC offset of 50 µA while sweeping the ampli-

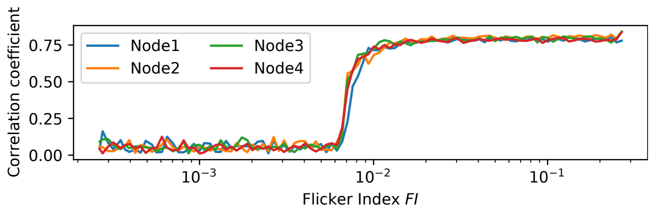

Figure 16: For a flicker index ≥0.008 Flync provides a stable clock.

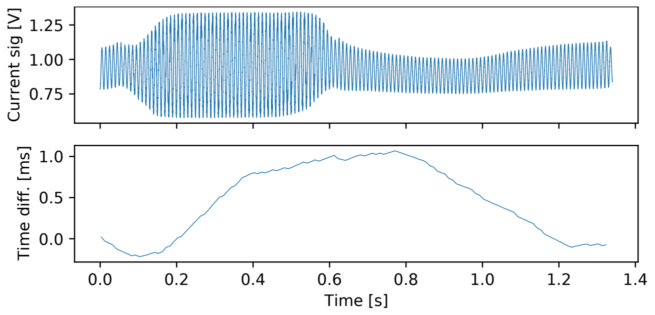

Figure 17: Current signal and time difference between two nodes while one node changes its distance and angle to the light source.

tude of the 100 Hz AC component. The current is fed to the input of our prototype that is usually connected to the solar panel. By limiting the voltage at the output of the sourcemeter to 1.25 V, the MPPT circuit regulates the input to around 1 V. For every setting of the AC amplitude, we record 5 s of clock signal with a mixed-signal oscilloscope. To quantify the quality of the clock signal, we compute the correlation coefficient between the signal and a phase-aligned 100 Hz reference. We repeat these measurements for four of our prototype nodes.

Results. The results in Fig. 16 show that there is a distinct threshold at around $FI = 0.008$ beyond which all nodes begin to output a clean clock signal. Comparing this with Fig. 9, we conclude that, with the exception of 5 LED lamps, our prototype works with the vast majority of the lamps we tested.

5.3 Flync Robustness

We now assess the robustness of Flync when a node changes its position and orientation relative to the light source, when the solar panels of a node are temporarily covered, and when electrical loads are temporarily connected to the same power strip. To this end, we experiment with two nodes powered by a desk lamp and connect them to an oscilloscope. We quantify robustness by measuring the time difference between clock edges on the two nodes. As a benchmark, we note that our implementation can tolerate a time difference of up to 848 µs.

Mobility. We keep one node static and attach the other one to the wrist of a person. The person waves, changing distance and angle between the node's solar panels and the light source.

Fig. 17 shows a period where the node moves closer and farther away from the lamp. The changes in the amplitude of the current signal affect the time difference between the nodes.

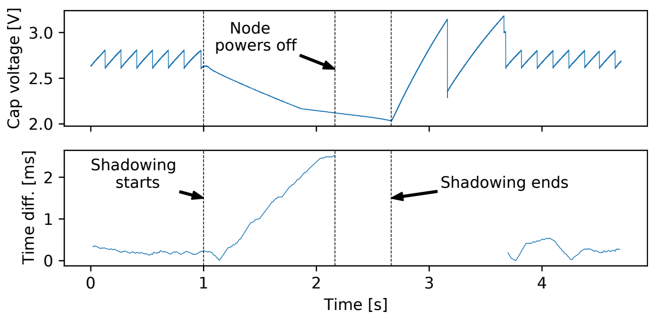

Figure 18: Capacitor voltage and time difference between two prototype nodes while temporarily covering the solar panel of one node.

The comparator that thresholds the sine wave uses a low-pass filter that reacts slowly to changes in the average amplitude. As a result, the clock signal deteriorates temporarily, causing an increased time difference of up to 1 ms. However, after a short while, the time difference recovers to previous levels.

Shadowing. To investigate the impact of shadowing, we put both nodes on a table and temporarily cover one of them by slowly moving a hand between the lamp and the node.

Fig. 18 shows that the time difference increases after covering the panel as the PLL loses its reference signal. However, without significant energy input, the node does not reach the turn-on threshold, which renders communication infeasible anyhow. As soon as the panel is uncovered, the node quickly charges up again and, after less than a second, the clock returns with a small time difference.

Electrical loads. We repeatedly switch on and off a drilling machine and a vacuum cleaner connected to the same power strip as the lamp. We do not observe any noticeable effect of the loads on the time difference between the two nodes.

5.4 Flync Jitter

In a final set of experiments, we look at the time difference between the clock signals of different nodes when these are: (*i*) powered by a single light source, (*ii*) placed in different rooms, and (*iii*) powered by different types of light sources.

Testbed. For these experiments, we built a distributed testbed of observer nodes. The observer nodes are accurately time-synchronized to within 479 ns, and record the clock signals of the attached prototype nodes with a resolution of 62.5 ns.

Single light source. We place six of our prototype nodes in the same room with a single halogen lamp. The experiments are conducted during the day, and the nodes receive a mixture of natural sunlight and artificial light from the lamp. Using our testbed, we record the clock edges of all six nodes for 1 h.

Fig. 19 shows the pairwise time difference between nodes. Because the phase offset resulting from propagation delays of light is negligible, the jitter must be introduced on each node. For example, a slight difference in the offset voltage of the comparator can lead to a significant mean difference of the

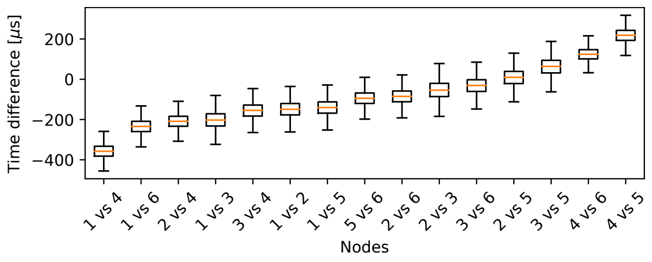

Figure 19: Pairwise time difference between clock edges on different prototype nodes when these are powered by a single light source.

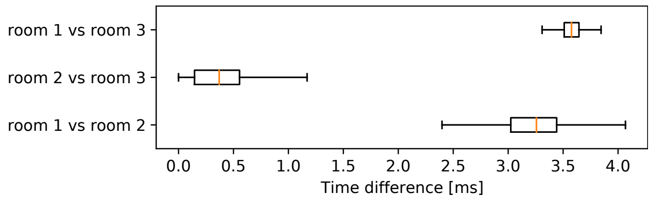

Figure 20: Pairwise time difference between clock edges on prototype nodes placed in different rooms with the same type of lamp.

resulting clock signal. Nevertheless, with 95 % of the more than five million recorded pairs below 244 µs, the jitter is well below the 848 µs tolerated by our Find implementation.

Different rooms. We conduct experiments in three rooms of an office building equipped with fluorescent tubes. The rooms are located on a long hallway with a distance of around 15 m between the middle room and the other two. We place two nodes in each room, and record with our testbed for 4 h while the nodes receive light from the tubes as well as sunlight.

Fig. 20 shows that there is a small offset between rooms 2 and 3 with 95 % of the recorded values being smaller than 700 µs. The offsets between rooms 1 and 2 and rooms 1 and 3 are centered around 3.3 ms. While residential homes are often connected to a single phase, larger apartment blocks or commercial buildings are typically fed by three-phase power. Apparently, the lights in room 1 are connected to a different phase than the lights in rooms 2 and 3, leading to a 60° phase and 3.3 ms time shift between the light intensity variations. Thus, when nodes need to discover neighbors across rooms with lights potentially connected to different power phases, they must be able to become active not only at the edge of their own Flync clock signal, but also with a 60° phase shift.

Different types of light sources. We plug an LED, a fluorescent, and two halogen lamps into the same power strip. We place one node under each lamp so that it only receives light from this lamp, and record for 30 min with our testbed.

Fig. 21 reveals large offsets between the clocks of nodes powered by different types of lamps. These offsets are due to varying phase shifts between the powerline voltage and the brightness variations of the lamp. For example, although the current through an incandescent lamp is in phase with the supply voltage, the filament may take some time to heat

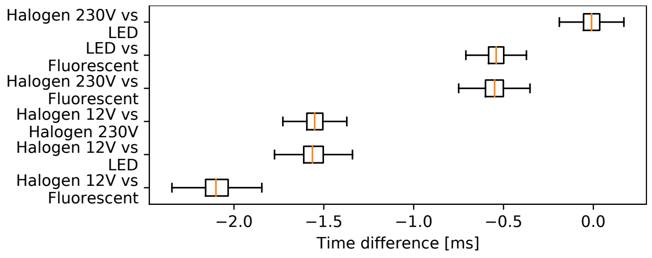

Figure 21: Pairwise time difference between clock edges on different prototype nodes when these are powered by different types of lamps.

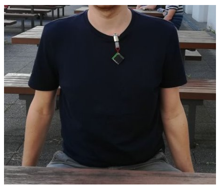
up and cool down, leading to the observed phase shift. Other types of lamps contain inductors or capacitive elements, a switching power supply, or an electronic ballast that cause different phase shifts. This shows that Flync does not work out of the box when different nodes are powered by different types of lamps. The static phase shifts would need to be measured during deployment or learned at runtime. On the other hand, Flync may not work reliably when individual nodes receive a mixture of light from different types of lamps. The results from the previous experiments (see Figs. 19 and 20) show that Flync works well when nodes receive a mixture of natural sunlight and artificial light from the same type of lamp.

6 Case Study: Contact Tracing

Automatic contact tracing is important to contain the spread of infectious diseases (e.g., SARS-CoV2) in a scalable manner. It allows to quickly identify contacts of an infected person and to quarantine potentially infected individuals before they become contagious. To assess the potential of our proposed designs for real-world battery-free applications, we conduct a contact tracing case study with our prototype nodes.

Setup. We attach six nodes to the shirts of human participants, as shown in Fig. 22a. The nodes run the Find protocol, logging the timestamp and ID of each discovered node to non-volatile memory. As we are only interested in relatively close contacts that would allow a virus to transmit from one person to another, we set the transmission power of the beacons to −16 dBm. We run experiments indoors and outdoors, as detailed below. After each run, we dump the content of the non-volatile memory of each node to a computer for analysis.



(a) Node on shirt.

(b) Setup of experiment in an open-air pub.

Figure 22: Battery-free contact tracing.

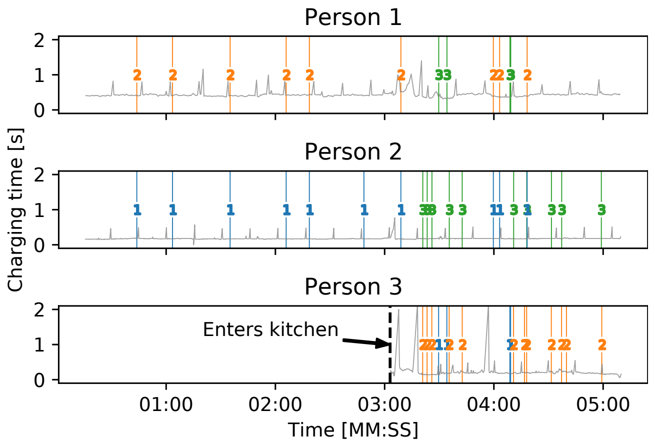


Figure 23: Charging times and rendezvous in coffee kitchen experiment. Vertical markers show rendezvous with the respective person.

Indoor experiment: coffee kitchen. Two persons sit at a table in a small coffee kitchen, roughly 1.5 m apart from each other. After 3 min a third person enters the kitchen and prepares a coffee for 2 min. The kitchen is equipped with fluorescent lamps, and we use Flync together with Find.

Fig. 23 plots the charging times and recorded rendezvous of the three nodes over time. We see a total of 49 received beacons. All contacts are logged successfully with low latency, despite the relatively long charging times of hundreds of milliseconds. Specifically, the first contact between persons 1 and 2 is detected after 43.9 s. When person 3 enters the kitchen, it takes 26.6 s and 17.9 s until the contacts with persons 1 and 2 are detected, respectively. Overall, the median time between rendezvous of the same two nodes is 7.5 s.

Outdoor experiment: open-air pub. Three pairs of persons sit at opposite sides of three tables (see Fig. 22b). Two tables are next to each other; the third table is at a distance of around 4.5 m. We perform the experiments in the morning of a slightly overcast day at an open-air pub without direct sunlight. Receiving only natural sunlight, the nodes do not make use of Flync. We conduct three consecutive 15 min runs.

We measure a total of 4426 received beacons. All contacts between persons on the same table are successfully recorded. More importantly, contacts between persons on different tables in close vicinity are also reliably detected. Due to the low transmit power, we do not see any rendezvous between the first two tables and the third remote table, which is expected and in fact desirable because we only want to trace contacts that are associated with an actual risk of virus transmission. Fig. 24 shows the histogram of the time between consecutive rendezvous between the same two nodes. As expected, the time between rendezvous is approximately exponentially distributed, and the mean is estimated between 2.61 s and 2.78 s with 95 % confidence. This means, under the given conditions, we are able to detect contacts with a resolution of around 2.67 s, allowing for fine-grained contact tracing.

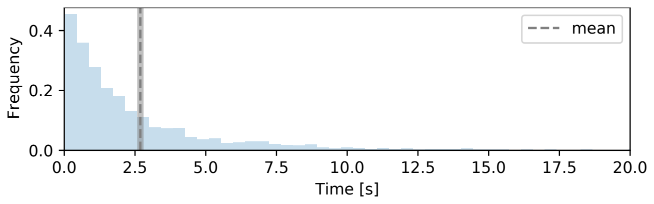

Figure 24: Histogram of the time difference between rendezvous of the same two nodes in the open-air pub experiment.

Summary. The results from our contact tracing case study show that Find and Flync are also effective under uncontrolled real-world conditions. Outdoors, energy availability is high and therefore Find alone enables fast rendezvous and fine-grained contact tracing. Indoors, Flync can compensate for the significantly lower energy density of interior light, providing decent performance even under these challenging conditions.

7 Discussion

We have presented two novel techniques that enable for the first time efficient device-to-device communication in the face of intermittency. By introducing random delays, Find breaks interleaved activity patterns of battery-free devices to discover each other faster and more efficiently. By tapping into the powerline-induced flicker of state-of-the-art lamps, Flync phase-synchronizes devices that harvest energy from indoor light. While we have exploited Flync to further speed up discovery in battery-free networks, Flync is useful for other purposes and also applicable to battery-supported devices.

Recent work tackles the intermittency problem on individual battery-free devices in terms of, for example, computing and time keeping [8,12,18,34]. We instead focus on communication between battery-free devices that operate intermittently. Like prior work, our techniques are relevant if intermittency makes traditional approaches inefficient or unreliable. To understand the scope of our work, we discuss intermittency and relevant impact factors below. Afterward, we discuss the influence of built-in randomness on our proposed techniques.

7.1 When Does Intermittency Occur?

A battery-free device goes through periods with low power requirements (e.g., system-off and sleep modes) and high power requirements (e.g., sensing, processing, and communication). Since the instantaneous power available from a harvester is often insufficient to support a battery-free device during periods with high power requirements, some form of energy storage is needed that buffers energy when the device is inactive to support a high-power workload for a short period of time.

The minimum size of the energy storage is determined by the demands of the largest atomic operation that must not be interrupted. For example, to transmit or receive a packet, the buffered energy needs to be sufficient to power the radio for at least the airtime of one complete packet; other examples of atomic operations include reading out a sensor or executing a checkpoint [21]. In our proposed Find protocol, the largest atomic operation is the frame sequence depicted in Fig. 7.

If a device with an active power draw higher than the harvesting power is equipped with an energy storage that does not support executing multiple iterations of the largest atomic operation from a single full charge, it is forced to go through periods of inactivity—the device is said to operate intermittently. Intermittency is in stark contrast to duty cycling, which is intentionally used on devices with primary or rechargeable batteries, yet the devices can become active at any point in time subject only to an upper bound on the average duty cycle. By contrast, intermittency prevents a device from becoming active at any point in time, and when a device enters and exits the inactivity phases is only partially controllable, at best.

7.2 What Factors Impact Intermittency?

Three key dimensions influence the extent of the intermittency problem: energy input, energy storage, and workload.

Energy input. An ambient energy source may exhibit intermittent behavior, including periods where it emits no energy. Clearly, a battery-free device can only harvest energy when the ambient source emits energy. In this case, provisioning a device with a harvester that provides the power required to continuously operate the device in high-power mode prevents the intermittency problem. This, however, would come with major drawbacks in terms of size, weight, and costs. For example, a battery-free device may draw only 10 µW on average but 10 mW when active, thus requiring to over-provision the harvester by a factor of 1000. While such over-provisioning is in theory always possible, it is severely limited in practice by the constraints imposed by the application requirements.

Energy storage. If permitted by the application requirements, an energy storage larger than the minimum required to execute the largest atomic operation may be used. For example, using a high-capacity rechargeable battery can prevent intermittency. Such batteries have a high energy density, but their minimum physical dimensions are typically orders of magnitude larger than those of capacitors. Batteries are also more expensive and subject to aging, losing capacity over time and eventually malfunctioning with excessive heat and leakage of potentially toxic chemicals. By contrast, capacitors have low energy density, but are extremely cheap, readily available in sizes well below 0.1 mm^3, have negligible aging effects, and do not contain problematic materials (e.g., toxic chemicals). Thus, despite advances in battery technology, alternative systems to store energy are being explored [3] and capacitors are widely regarded as a more sustainable option [11, 45].

When a device is inactive, it accumulates charge until the capacitor voltage reaches a turn-on threshold. The amount of energy that can be stored depends on the turn-on threshold, which is limited by the breakdown voltage of the capacitor and the device's maximum operating voltage. When a device is active, it discharges the capacitor until the voltage reaches a turn-off threshold, which is dictated by the device's minimum operating voltage. Thus, for the same capacitor, a device with a lower minimum operating voltage or a higher maximum operating voltage can increase the effective amount of buffered energy that can be used. This allows to either use a smaller capacitor or execute longer from a single full charge, potentially alleviating the intermittency problem.

Workload. While lower-power hardware can reduce the average power draw in sleep mode and thus the charging time, it does not generally avoid intermittency. This would require pushing also the active power below the harvesting power.

Reducing the transmission power of the radio can extend the time a device can operate from a single full charge. While this may alleviate the intermittency problem, it also reduces the communication range, which may render device-to-device communication infeasible or require multi-hop networking.

Similarly, using backscatter communication instead of active radio communication may bring the active power draw of a device below the harvesting power and thereby enable continuous operation. However, backscatter requires the presence of an external carrier and may pose limitations in terms of communication range and data rate. In particular, existing practical implementations of tag-to-tag backscatter receivers do not yet reach the point where the end-to-end power draw is negligible (i.e., below sleep power of around 1 µW) [35, 39], thus leaving a significant region in the design space of battery-free backscatter devices where intermittency occurs.

7.3 Impact of Built-in Spatial Randomness

Find tackles interleaving by letting nodes randomly and independently delay their wake-ups. This approach is particularly effective in scenarios with little built-in spatial randomness, that is, when the harvested energy exhibits limited variability *between* nodes, regardless of a potentially high temporal variability in harvested energy. We believe this holds for a broad class of battery-free application scenarios, because nodes in a confined space often harvest energy from the same ambient source(s). On the other hand, a high built-in spatial randomness may alleviate the interleaving problem. Although our case study experiments exhibit built-in spatial and temporal randomness, it remains an open question how built-in spatial randomness may influence the choice of Find's delay distribution and scale parameter as well as its overall effectiveness.

8 Related Work

Battery-free device-to-device communication. Prior work on battery-free wireless device-to-device communication is mainly theoretical [25, 51], studying the capacity limits for different energy scheduling, transmission, and decoding policies. Understanding energy issues on the receiver side [2] and the impact of intermittency have been open problems. On the other hand, practical work on tag-to-tag backscatter communication has primarily focused on physical-layer issues and considers intermittency an orthogonal problem [20, 32, 35].

Work	Type	Sensing Signal	Power
Syntonistor [42]	frequency	EM radiation	300 µW
Flight [31]	frequency	light sensor	5394 µW
Flync	freq.+phase	solar current	5 µW

Table 2: Compared with prior work using powerline frequency for synchronization, Flync provides frequency and phase synchronization from the solar panel current at significantly lower power draw.

Rendezvous and neighbor discovery protocols. Blind rendezvous is the process of establishing a communication link between nodes in a distributed system without any prior information [16]. Neighbor discovery protocols for wireless networks target a sub-class of the blind rendezvous problem with the goal of optimizing the trade-off between discovery latency and energy consumption. Deterministic protocols let nodes wake up according to a schedule based on (co-)prime numbers [13, 23], a quorum [19, 27, 28], or by systematically traversing slots [5, 50]. This way, they can provide guaranteed bounds on discovery latency [24]. Probabilistic protocols are stateless, robust to varying conditions, and offer low average discovery latency [10]. For example, the influential birthday protocol [37] and follow-up work [48, 49] analyze optimal transmit probabilities to maximize the fraction of links discovered in a given time. However, none of the existing neighbor discovery protocols are applicable to battery-free networks because they require nodes to be able to wake up at arbitrary points in time, not taking into account intermittency.

Powerline-based clock synchronization. We are not the first to exploit the powerline frequency signal for synchronization. The Syntonistor extracts a stable clock signal from electromagnetic (EM) powerline radiation using a large coil [42]. It draws 300 µW of power, 60× more than Flync. Flight samples a light sensor to synchronize a node's oscillator to the powerline-induced brightness variations of fluorescent lamps [31]. Using Flight, synchronization takes 100 ms at a power draw of 5394 µW, 1000× more than Flync. As summarized in Table 2, both approaches only synchronize the frequency of local clocks, eliminating the need to periodically compensate for clock drift, but do not exploit phase information. They also use dedicated high-power sensors, whereas Flync uses a low-power circuit to extract the signal from the current of the solar panel.

Energy harvesters as sensors. Previous work has explored the use of the harvesting current or voltage as a sensing signal for indoor positioning [41], gait recognition [33], gesture recognition [47], activity classification [44], and transport-mode detection [43]. To the best of our knowledge, we are the first to exploit context information from harvested energy for synchronization. Furthermore, Flync is the first design that extracts the sensing signal from current variations of a solar panel that is simultaneously used to power the system.

Visible light communication. Flync exploits the powerline-induced brightness variations as an intrinsic property of ubiquitous lamps. When modifying existing lighting infrastructure, it is possible to encode arbitrary data into the brightness variations. This opportunity has been used for downlink communication [40], indoor positioning [26], and battery-free duplex visible light communication [29]. By modulating light with a well-defined synchronization signal, the efficiency and applicability of Flync could be further improved. Also, our approach to harvest energy while simultaneously demodulating encoded signals from the same panel may reduce the size and power of existing visible light communication receivers.

9 Conclusions

Leaving batteries behind allows for building cheap, tiny, and maintenance-free devices that can be embedded into smart textiles, intelligent surfaces, or even the human body. In this paper, we have addressed the problem of enabling efficient battery-free device-to-device communication. Experiments with a prototype platform and implementation show that our proposed techniques empower battery-free devices to quickly and efficiently discover each other despite their unpredictable intermittent operation. By bootstrapping battery-free wireless networks, we believe that our work provides a stepping stone for future research toward full system and communication stacks for this emerging kind of networked system.

Availability

Artifacts are available to the public under a permissive MIT license at `https://find.nes-lab.org/`. These include a Python implementation of the Find model from Sec. 2, which can be used to reproduce the analytical results in Figs. 3 to 6, as well as the hardware design files and the firmware of our prototype implementation from Sec. 4, which we used for the experiments and case study described in Secs. 5 and 6.

Acknowledgments

Thanks to Brano Kusy, Carlos Pérez-Penichet, and Carsten Herrmann for their feedback that helped improve this paper, to Friedrich Schmidt for his help with the hardware design, to James Broadhead for the preliminary experiments, and to all participants of the contact tracing case study. Thanks also to the anonymous reviewers, and to our shepherd, Shyam Gollakota. This work was supported by the Emmy Noether project NextIoT (DFG grant ZI 1635/2-1) and cfaed.

Abstract

Hidden screen-camera communication emerges as a key enabler for the next generation videos that allow side information, such as TV commercials, augmented contents, and even the video itself, to be delivered to machines during normal watching. To guarantee imperceptibility to human eyes, existing solutions have to sacrifice data rate and reliability enormously. This paper presents AIRCODE, a hidden screen-camera communication system built upon invisible visual and inaudible audio dual channel. While ensuring great unobtrusiveness, AIRCODE achieves robust communication at a remarkably high rate of >1Mbps, for the first time, enabling imperceptible transmission of not only texts but also videos. AIRCODE makes two key technical contributions. First, AIRCODE takes the complementary advantages of video and audio channels by exploiting the reliable yet low-rate inaudible audio link as the control channel while the unreliable but high-rate visual link as the data channel. Second, AIRCODE incorporates visual odometry to accurately identify and track the captured screen, regardless of dynamic video contents and surrounding interference. Experiments on commercial monitors and smartphones demonstrate that AIRCODE significantly outperforms the state-of-the-art system, yielding a remarkable data rate of 1069 Kbps while with BER of 5%.

1 Introduction

Over the past few decades, video has risen into popularity across the globe. Billions of video are produced, captured, shared, and viewed every day and everywhere. Rather than merely watching them, audience often desires to acquire extra information related to the video content, especially with their carry-on devices, e.g., smart phone and smart glasses. For example, an advertisement can deliver a second video introducing detailed usage and function of the advertised product to its potential users. Instead of letting the viewers record a blurry video with unintended surrounding contents and color distortion, a video can provide a low quality version of itself for direct sharing. An AR video can compute and send the augmented contents to a viewer's device for direct rendering without draining its limited computing and power resources. To make these applications a reality, convenient and friendly communication approach, better with high data rates and reliability, is needed.

One intuitive solution is to integrate screens with Wi-Fi or Bluetooth, like nowadays smart TV, and convey side information through the wireless channel. However, such combination has several drawbacks. First, wireless connection requires explicit setup. A viewer wearing smart glasses may see multiple screens during his daily life and be bothered to search their Wi-Fi from many available networks. Second, wireless device and screen are not well synchronized. For example, a screen playing an AR video should deliver the augmented contents synchronized at the frame level, e.g., 16.7 ms with a frame rate of 60 Hz, which cannot be always achieved by Wi-Fi due to occasionally large latency and jitter [29]. Last but not least, the broadcasting behavior of wireless devices causes information spamming or leakage to unwanted people. For example, in TV commercial, only the viewers of the advertisement need the side information about the product. In video sharing, an eavesdropper must not access the low quality video due to copyright protection.

Alternatively, as cameras are indispensable to smart devices, it is more convenient, impromptu and secure to embed extra information into video and deliver them through the screen-camera channel without impacting viewers' watching experience. Thanks to the high refresh rates ($\geq$ 120 Hz) of modern screens, pioneer works [24, 36, 41] hide data in high frame rate videos to cheat human eyes that have much lower perception rates (40-50 Hz) [31]. However, they emphasize on human perception but sacrifice data rates (e.g., 551 Kbps with a bit error rate (BER) of 8% [41]), hardly reliable for real data communication of potential applications. Improving reliable data rates on hidden screen-camera channel, however, is non-trivial. Unlike conventional communication channels [8, 17, 22, 27], enhancing the signal does not help for the screen-camera channel because it immediately sets up

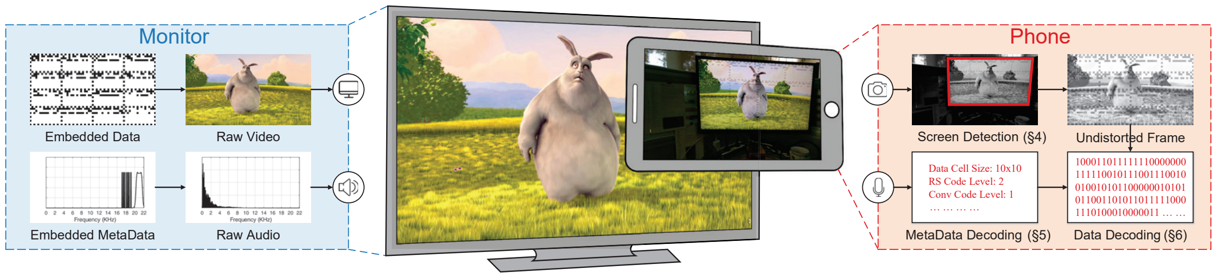

Figure 1: System overview of AIRCODE. The monitor displays a video with embedded data in raw video frames, and metadata (control information) in raw audio signals. The phone records the video, then detects screen in camera images to equalize distorted video frames, decodes metadata from audio signals, and finally decodes data embedded in video.

a conflict with unobtrusiveness to human eyes. We refer the reader to Section 2 for the more detailed analysis of the unique characteristics of the screen-camera channel. Essentially, we are facing the dilemma of foregoing three contradicting goals.

In this study, we first investigate the state-of-the-art works from distinct perspectives and discuss the root causes of unreliability. On this basis, we present AIRCODE, an imperceptible screen-camera communication system that supports high-throughput and reliable data transmission on top of regular video viewing, as demonstrated in Figure 1. The working scenario of AIRCODE is non-sophisticated: When a watcher intends to acquire information on the side channel, she simply shoots a video of the screen playing the encoded video using her smartphone, which automatically receives and decodes the embedded bits, at a rate of as high as 1069 Kbps, almost 2$\times$ higher than the state-of-the-art ChromaCode [41], underpinning various applications like video-in-video sharing. AIRCODE boosts data throughput while reducing BER by an invisible visual and inaudible audio dual-channel in three distinct ways:

(1) Precise screen tracking: Precise screen detection and tracking is critical to equalization of video frames, the key process for successful decoding of visual codes. According to our measurements, errors of a few pixels may significantly affect packet reception (§2). Precise screen detection, however, is non-trivial due to various factors, such as video contents, surrounding background, hand motions, etc. In AIRCODE, we exploit the idea of visual odometry [21] for this purpose. Specifically, AIRCODE constructs a 3-D map of a screen of interest and tracks the screen by estimating the phone pose with projections of map points and then projecting the screen with the pose estimated.

(2) Reliable audio channel: While the video channel shares the same frequency band with the ambient illuminance [41], the near-ultrasound audio channel is resistant to ambient low-frequency noises [38] and more reliable. Thus, AIRCODE allocates the inaudible speaker-microphone link as the control channel for the critical metadata of visual codes (e.g., code layout, coding scheme, etc.). To seamlessly comply with the video channel, the audio channel should fulfill two conditions, i.e., short packet duration that matches the high frame rate of the video channel, and low packet error rate (PER) that is required by the overall communication. To achieve this, AIRCODE carefully designs acoustic packets to overcome problems of reverberation and frequency spectral leakage caused by short packet duration and achieves high reliability with nearly zero PER.

(3) High-rate visual channel: AIRCODE leverages the screen-camera link as the high-rate data channel. Data bits are transmitted via imagery codes imperceptibly embedded in the primary carrier video. To minimize flickers, we adaptively choose the required lightness changes according to the spatial texture of the primary video content and perform lightness alteration as introduced in [36, 41]. The high data rate is then achieved by 1) embedding full-frame visual codes with a carefully designed frame structure; 2) effective error correction with an adaptive concatenated coding scheme.

We implement AIRCODE using commodity computer monitors and smartphones. We conduct real-world experiments and extensive evaluations on key metrics including BER, throughput, goodput and screen-tracking accuracy. Besides, various system parameters, such as distance, angle, signal strength, background interference, and frame size, are tested. Videos with various texture, luminance, quality and audios with different types of sound are used for evaluation. The imperceptibility is tested with a user study. Experimental results demonstrate that AIRCODE achieves a remarkable data rate of 1069 Kbps with an average BER of 5%, which significantly outperforms existing approaches.

The core contributions of this paper are:

- We present AIRCODE, a hidden screen-camera communication system that achieves >1Mbps throughput for the first time, allowing not only text but also image and video transmission.
- To the best of our knowledge, we are the first to exploit an invisible visual and inaudible audio channel, which jointly enables fully imperceptible, high-rate, and reliable communication by their complementary advantages.
- We propose an algorithm using visual odometry that precisely tracks screen locations even with dynamic video content, complex ambient contexts, and camera motions caused by unconsciously hand motion and shake.

2 Motivation

Hidden screen-camera communication is possible with the natural difference between the human vision system and camera system: Human eyes cannot resolve flickers, or luminance fluctuations, at frequencies higher than 100Hz, but instead only perceive the average lightness, due to the low-pass flicker-fusion property of human vision system [31]. Thus, if we inversely modify the lightness of a pair of subsequent video frames, which are termed as complementary frames, and play them at high frame rate, e.g., 120 frames per second (fps) that is supported by modern commercial monitors and TVs, human eyes will not perceive the change of lightness. Instead, they will only observe the original video content, which is the average of complementary frames. In contrast, commodity cameras with a high capturing rate can acquire the differences and decode the data if certain information is modulated on top of the change of lightness. Pioneer work has exploited this phenomenon for hidden screen-camera communication by embedding data bits unobtrusively in primary carrier videos. The visual channel of AIRCODE is also built upon this idea. The hidden screen-camera channel is reported error-prone due to some unique intrinsic errors [24, 36, 41], such as projection distortions, blurring, Moiré patterns, rolling shutter effects, and frequent changes of camera pose caused by hand motion and shake, etc.

2.1 Challenges and Measurements

Previous proposals mainly aim at minimizing flickers for good unobtrusiveness, yet sacrifice data rates and robustness. The best result to date reported is from ChromaCode, with the data rate of up to 551 Kbps and BER of 8%, which is far from sufficiency for many applications such as the above-mentioned video-in-video sharing. What's even worse, such performance is obtained with limitations including visible border markers [36] and stable cameras [24, 41].

To reveal the root causes of these limitations, we consider the state-of-the-art works, ChromaCode, and evaluates how its reliability suffers when (1) the detected screen deviates from the ground-truth, and (2) the received metadata (e.g. visual code layout, coding scheme, etc.) has bit errors. Experiments are conducted in a cubicle space and with different types of videos, as listed in Table 1. During experiments, the phone is placed static with several fixed poses, so that the ground-truth of the screen can be manually marked. Besides, the metadata is known prior as well. To evaluate the impact of screen detection, we gradually shift the input of the screen location by a small number of pixels and calculate BER accordingly. To evaluate the impact of metadata decoding, we manually add random error bits in the channel code of metadata.

(1) Impact of screen detection. Figure 2a shows that the BER of the screen-camera link remains around 2% when the location error of the screen is less than 4 pixels (in a 720p video), which is about the half-length of the smallest data cell in ChromaCode, but explodes when the location error exceeds 4 pixels. It fails when the location error reaches 15 pixels. It means that highly accurate screen detection is necessary for the screen-camera link. Recent phones incorporates image stabilization [20, 32] to reduce blurring caused by camera motion. However, these techniques can only remove small handshakes and thus require the user to uncomfortably hold the phone at a fixed position during the recording. Figure 3 further illustrates failure cases of screen detection with two representative approaches, the rule-based approach used in ChromaCode, and Mask R-CNN [10], a learning-based approach. The rule-based approach tries to find a quadrilateral whose outer bound consists of edges in the image and has consistent similar lightness, which may be misled by video contents and the surrounding environment. While Mask R-CNN can accurately recognize objects in images after sufficient training, it fails to meet the stringent requirement on accurate segmentation with errors of only several pixels for screen-camera communication. Besides, both approaches lack pertinent mechanisms to deal with continuous tracking of the screen in a video.

(2) Impact of metadata decoding. Figure 2b shows that the screen-camera link becomes lost when the number of error bits in metadata exceeds 4, which is consistent with that ChromaCode encodes 5-bit metadata with 15-bit code and corrects at most 3-bit errors. Through all experiments, 24.6% frames have BERs over 8%, among which 29.3% are due to failure in decoding metadata. The drawback of existing sole screen-camera communication schemes is that while metadata is more important than data and requires robust communication with lower BER, it is conveyed in the same erroneous visual channel as data. To achieve reliable communication with the screen-camera link, a more robust channel is needed for transmission of metadata.

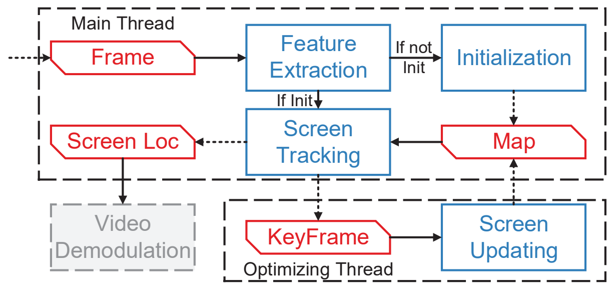

Figure 4: Logic flow of screen detection.

3 System Overview

Motivated by the measurements above, we design AIRCODE to address the two significant drawbacks, namely erroneous screen tracking and vulnerable transmission of metadata and deliver an imperceptible, high-rate, and reliable screen-camera communication system.

Figure 1 shows the system overview of AIRCODE. At the sender side, AIRCODE embeds data (visual codes) into raw video frames and embeds metadata of visual codes into raw audio signals. During playing the video, users run AIRCODE on their phones and shoot the monitor. At the receiver side, upon receiving camera images and acoustic signals, AIRCODE simultaneously tracks the screen in images with visual odometry to equalize distorted frames (§ 4) and decodes metadata embedded in acoustic signals (§ 5). Afterward, both undistorted frames and metadata are used to decode data conveyed in video frames (§ 6).

4 Screen Detection

Detecting screen is the key process for successful decoding of visual code, due to unknown perspective distortion of the screen in images. However, various video content and background environments may interfere in screen detection, leading to failure of decoding, as discussed in § 2. Existing works embed specific position codes at the edges and corners of video for screen detection, which wastes communication resources and affects the watching experience of audiences. In contrast to existing solutions that try hard to reduce the interference caused by complex background environment, AIRCODE exploits it as visual clues for odometry [21] to track the screen in frames.

Visual odometry alternately tracks the poses of image frames and maintains a global map of 3-D points seen by multiple image frames. Generally, visual odometry consists of three main steps. (1) Initialization. Visual odometry matches feature pixels of two image frames and estimates their relaive pose. The global map is then initialized with the 3-D map points of the matched feature pixels. (2) Tracking. Upon receiving a new frame, visual odometry matches its feature pixels with 3-D points in the global map, estimates the pose of the frame, and updates 3-D map points of the matched feature pixels in the global map. (3) Optimization. Visual odometry periodically buffers some frames, termed as keyframes, to refine the global map and avoid drifting error. When a new keyframe arrives, visual odometry jointly optimizes poses of all buffered keyframes that share common feature pixels with the new keyframe and all 3-D points seen by these keyframes in the global map.

To enable screen detection, AIRCODE modifies the main steps of visual odometry to further keep 4 screen points in the global map. Each screen point corresponds to one corner point of the rectangular screen. Thus, the screen can be uniquely identified and represented by its four corner points. Figure 4 shows the logic flow of screen detection of AIRCODE. In addition to visual odometry, during initialization, AIRCODE estimates the initial 3-D locations of the screen points. During the tracking process, AIRCODE projects the screen points in the frame with the frame pose for decoding. In the optimization process, AIRCODE updates the screen points with the refined poses of keyframes and the projections of the screen points on these keyframes to avoid drifting error.

4.1 Feature Extraction

Feature pixels are representative pixels invariant to translation, scaling and rotation of an image and can be used for robustly tracking successive image frames and mapping 3-D points corresponding to these feature pixels. AIRCODE uses ORB [28] which is fast to compute and match, and remains invariant across different viewpoints, yielding sufficient efficiency and accuracy for visual odometry.

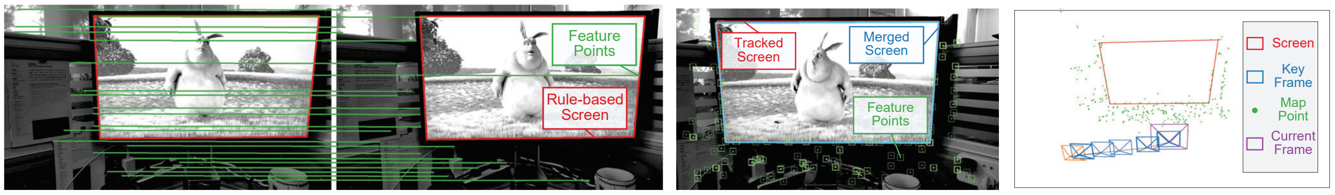
In practice, the video content may change with time, and feature pixels within the screen are not consistent across successive frames. To avoid the negative impact of mismatching these feature pixels, AIRCODE first obtains a coarse estimation of the screen frame, and filter out all feature pixels within it. The initial screen frame is calculated by the rule-based algorithm during initialization (as in § 2) or inherited from the last frame during the tracking process. Figure 5a shows examples of feature extraction, where the screen frame is highlighted and feature pixels within it are removed.

4.2 Initialization

The initialization process computes the relative pose between two frames and triangulates an initial set of 3-D map points for tracking and 4 screen corner points for communication. Lacking the knowledge of screen points, AIRCODE uses the rule-based algorithm to detect the screen and decode frames during initialization. As a successful decoding indicates accurate screen detection, AIRCODE selects two decoded frames with their detected projections of the screen for initialization.

Figure 5a illustrates an example of initialization with two matched frames. Denote the two selected frames as F_0 and F_1, any matched feature pixels as $\mathbf{p}_0$ and $\mathbf{p}_1$, and any matched projection pixels of screen corner points as $\mathbf{s}_0$ and $\mathbf{s}_1$, AIRCODE uses epipolar geometry and computes the fundamental matrix $\mathbf{F}_{10}$ that connects any pair matched pixels [9]:

$$\mathbf{p}_0^T \mathbf{F}_{10} \mathbf{p}_1 = 0, \quad \mathbf{s}_0^T \mathbf{F}_{10} \mathbf{s}_1 = 0. \tag{1}$$



(a) (b) (c)

Figure 5: Key steps of screen detection: (a) Out-of-screen feature extraction and matching for initialization, (b) frame tracking with matched feature pixels and screen tracking with frame pose, and (c) global map and key frames for screen updating.

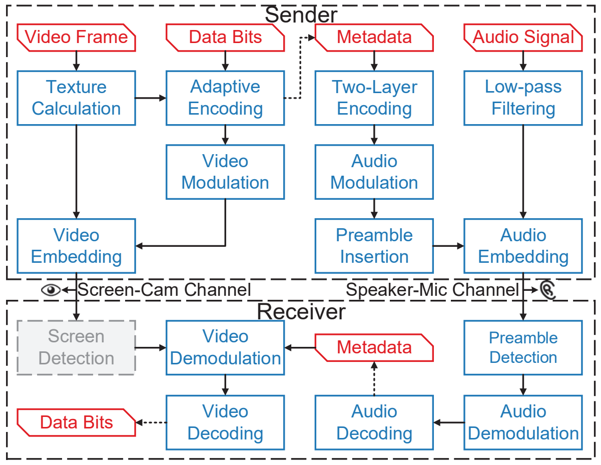


Figure 6: Logic flow of dual-channel communication.

F_{10} can be solved by integrating eight pairs of matched pixels [18]. Since the successful decoding strongly indicates that screen points are accurately located in the two frames, AIRCODE selects the projection pixels of four screen points (i.e., $\mathbf{s}$) as four pairs of the matched pixels, and four pairs of matched feature pixels (i.e., $\mathbf{p}$) as the rest.

To recover the camera pose, the fundamental matrix $\mathbf{F}_{10}$ is converted to the essential matrix $\mathbf{E}_{10}$ using the intrinsic matrix $\mathbf{K}$ of the camera:

$$\mathbf{E}_{10} \equiv \mathbf{t}_{10}^{\wedge}\mathbf{R}_{10} = \mathbf{K}^T\mathbf{F}_{10}\mathbf{K}, \tag{2}$$

where $\mathbf{t}_{10}$ and $\mathbf{R}_{10}$ the are relative translation vector and rotation matrix respectively, and the operator $(\cdot)^{\wedge}$ is to calculate the skew-symmetric matrix from a vector. The four possible poses (i.e., $\mathbf{t}_{10}$ and $\mathbf{R}_{10}$) are derived from the essential matrix $\mathbf{E}_{10}$ via singular value decomposition [9]. With each ambiguous candidate, AIRCODE triangulates 3-D points corresponding to all matched feature pixels and projection pixels of four screen points. A valid 3-D point with high confidence should be in front of the camera and have a significant parallax between the two frames. Thus, AIRCODE selects the candidate with most such points as the true pose. Finally, AIRCODE initializes the 3-D global map and the screen with all valid 3-D points of the true pose. The two frames used in initialization are set as initial keyframes.

4.3 Screen Tracking

After initialization, AIRCODE continuously tracks poses of new frames and projects the screen accordingly for decoding. As visual odometry, AIRCODE optimizes the pose of the current frame by minimizing the location error between the projections of map points and their matched feature pixels in the frame. Specifically, suppose that the pose matrix of the i-th frame is $\mathbf{T}_i = [\mathbf{R}_i \mid \mathbf{t}_i]$, where $\mathbf{R}_i$ and $\mathbf{t}_i$ are the corresponding rotation matrix and translation vector, and N matches $\langle \mathbf{P}_j, \mathbf{p}_{i,j} \rangle$ are detected, where $\mathbf{P}_j$ is the j-th map point and $\mathbf{p}_{i,j}$ is the matched feature pixel in the i-th frame, the pose $\mathbf{T}_i$ can be optimized via bundle adjustment [35]:

$$\mathbf{T}_{i,opt} = \arg\min_{\mathbf{T}_i} \sum_{j=1}^{N} \|\mathbf{p}_{i,j} - \pi(\mathbf{T}_i, \mathbf{P}_j)\|^2, \tag{3}$$

where $\pi(\cdot)$ projects the 3-D map points onto the image frame given its pose [9]:

$$\pi(\mathbf{T}_i, \mathbf{P}_j) = [\frac{(\mathbf{K}(\mathbf{R}_i\mathbf{P}_j + \mathbf{t}_i))_0}{(\mathbf{K}(\mathbf{R}_i\mathbf{P}_j + \mathbf{t}_i))_2}, \frac{(\mathbf{K}(\mathbf{R}_i\mathbf{P}_j + \mathbf{t}_i))_1}{(\mathbf{K}(\mathbf{R}_i\mathbf{P}_j + \mathbf{t}_i))_2}]^T. \tag{4}$$

With the estimation of the pose, AIRCODE projects screen points onto the current frame:

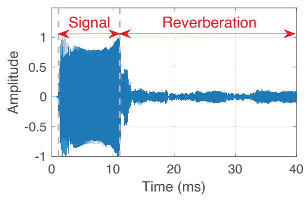
$$\mathbf{s}_{i,j} = \pi(\mathbf{T_i}, \mathbf{S}_j), \tag{5}$$

where $\mathbf{S}_j$ is the j-th screen point ($j = 1,2,3,4$). To further minimize projection error, AIRCODE searches outstanding Shi-Tomasi corners [34] within neighborhoods of these projections as the final estimation.

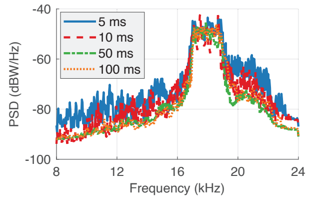
AIRCODE may fail to decode due to small but intolerant deviations of screen tracking. In contrast, despite frequent failures, the rule-based algorithm can accurately detect edges and corners in the frame and yield more accurate estimation if the screen is successfully detected. Thus, when decoding fails, AIRCODE further executes the rule-based algorithm to obtain a second estimation of the screen, denoted as $\mathbf{s}'_{i,j}$. Then, it merges the corner points of the two screens as:

$$\mathbf{s}''_{i,j} = \begin{cases} \mathbf{s}'_{i,j} & \|\mathbf{s}_{i,j} - \mathbf{s}'_{i,j}\| \geq \delta_h \\ \mathbf{s}_{i,j} & \|\mathbf{s}_{i,j} - \mathbf{s}'_{i,j}\| \leq \delta_l \end{cases}, \tag{6}$$

As screen tracking yields consistently small errors, an upper threshold, δ_h, is used to reject totally wrong estimation from the rule-based algorithm. Meanwhile, a lower threshold, δ_l, is used to accept more accurate estimation from the rule-based algorithm. When $\delta_l < \|\mathbf{s}_{i,j} - \mathbf{s}'_{i,j}\| < \delta_h$, AIRCODE has no extra information to determine which estimation is better. Thus, it forks two screen candidates, whose j-th points are assigned as $\mathbf{s}_{i,j}$ and $\mathbf{s}'_{i,j}$ respectively. Finally, AIRCODE tries all screen candidates until the frame is successfully decoded. Note that in the worst case where the screen tracking fails, e.g., due to lack of visual features around the screen, AIRCODE



(a) Reverberation



(b) Spectral Leakage

Figure 7: Main problems of short packet duration. (a) enlarged impact of reverberation, and (b) aggravated spectral leakage.

degenerates to the rule-based algorithm and still maintains a moderate decoding rate. Figure 5b illustrates the process of screen tracking, where all matched feature pixels in the frame and both the tracked screen and the merged screen are highlighted.

To avoid drifting error during tracking, AIRCODE periodically selects frames and passes them to the optimizing thread. Specifically, it creates new keyframes only when one of the following conditions are satisfied:

1. More than 0.5 fps frames have passed after the creation of the last keyframe, and the current frame tracks less than 90% points than the last keyframe.
2. The current frame fails to be decoded with the tracking screen but can be decoded with the merged screen.

Condition (1) avoids computing cost with redundant frames, while condition (2) ensures timely updating of the screen.

4.4 Screen Updating

The optimizing thread periodically refines map points and screen points to avoid drifting error. Figure 5c shows the structure of global map and keyframes. Upon receiving a new keyframe, AIRCODE first deletes obsolete map points that are seen by fewer than 3 keyframes and add new points from matches between the current keyframe and previous keyframes, as that in visual odometry. Next, AIRCODE collects all map points seen by the current keyframe and all keyframes that see any of these map points for optimization. Specifically, suppose M key frames together with the current keyframe are selected, the pose of the i-th keyframe is $\mathbf{T}_i$, and N_i matches $\langle \mathbf{P}_{i_j}, \mathbf{p}_{i,j} \rangle$ are detected in the i-th keyframe. The pose $\mathbf{T}_i$ and map points $\mathbf{P}_k$ are optimized via bundle adjustment:

$$\{\mathbf{T}_{i,opt}\}_{i=0}^{M}, \{\mathbf{P}_{\mathbf{k},\mathbf{opt}}\}_{k=1}^{K} = \underset{\{\mathbf{T}_i\}_{i=0}^{M}, \{\mathbf{P}_k\}_{k=1}^{K}}{\arg\min} \sum_{i=1}^{M} \sum_{j=1}^{N_i} \|\mathbf{p}_{i,j} - \pi(\mathbf{T}_i, \mathbf{P}_{i_j})\|^2. \tag{7}$$

Then, AIRCODE optimizes screen points via multi-view triangulation with the refined poses of keyframes. Specifically, denote the projection of the j-th screen point $\mathbf{S}_j$ on the i-th key frame as $\mathbf{s}_{i,j}$, the 3-D location of the j-th screen point is calculated by minimizing the following projection error:

$$\mathbf{S}_{j,opt} = \underset{\mathbf{S}_j}{\arg\min} \sum_{i=1}^{M} \|\mathbf{T}_i \bar{\mathbf{S}}_j - (\hat{\mathbf{s}}_{i,j}^T \mathbf{T}_i \bar{\mathbf{S}}_j)\hat{\mathbf{s}}_{i,j}\|^2, \tag{8}$$

where $\hat{\mathbf{s}}_{i,j} = \frac{\mathbf{K}^{-1}\bar{\mathbf{s}}_{i,j}}{\|\mathbf{K}^{-1}\bar{\mathbf{s}}_{i,j}\|}$ is the direction vector of the projection $\mathbf{s}_{i,j}$, and $\bar{\mathbf{S}}_j$ and $\bar{\mathbf{s}}_{i,j}$ are the homogeneous representation of $\mathbf{S}_j$ and $\mathbf{s}_{i,j}$, respectively. The term $(\hat{\mathbf{s}}_{i,j}^T \mathbf{T}_i \bar{\mathbf{S}}_j)\hat{\mathbf{s}}_{i,j}$ calculates the projection coordinate of $\mathbf{S}_j$ along the direction $\hat{\mathbf{s}}_{i,j}$. Intuitively, when $\mathbf{S}_j$ is accurately localized, $\mathbf{T}_i\bar{\mathbf{S}}_j$ has the same direction as $\hat{\mathbf{s}}_{i,j}$ and the error term becomes 0. The optimal solution $\mathbf{S}_{j,opt}$ is the eigenvector corresponding to the minimal eigenvalue of the matrix $\sum_{i=1}^{M}(\mathbf{T}_i - \hat{\mathbf{s}}_{i,j}\hat{\mathbf{s}}_{i,j}^T\mathbf{T}_i)^T(\mathbf{T}_i - \hat{\mathbf{s}}_{i,j}\hat{\mathbf{s}}_{i,j}^T\mathbf{T}_i)$, and can be calculated directly in closed form.

Finally, after optimization, AIRCODE discards redundant keyframes whose map points have been seen in at least other three keyframes, as in [33], to maintain a reasonable number of keyframes for fast optimization, and avoid large estimation uncertainty caused by co-located key frames [19].

5 Audio Control Channel

Despite orders of magnitude smaller throughput, the speaker-microphone link is more reliable than the screen-camera link due to little interference in the near ultrasound band. Thus, AIRCODE exploits the speaker-microphone link to send critical metadata of visual codes, e.g., coding layout, coding scheme, etc. By doing so, not only is metadata robustly delivered, but also more video coding area is saved to convey more data. Figure 6 shows the logic flow of the audio communication part. At the sender side, metadata is encoded with a two-layer encoding scheme, which includes Golay coding and Manchester coding, and then modulated on frequency subcarriers. A chirp signal is prepended as a preamble for timing alignment. The raw audio signal is low-pass filtered and then embedded with the control signal. At the receiver side, the signal is first high-pass filtered to remove raw audio signal and background noises, then aligned with a chirp template, and finally demodulated and decoded to yield metadata.

5.1 Design Challenges

Frame-level Packet Duration. To convey metadata for the video channel, whose data frame (a pair of complementary video frames) rate is 60 fps, the audio packets should be sent within tens of milliseconds. However, most existing solutions send packets at the second level, which is sufficiently reliable but cannot be agilely adjusted according to the video channel. For example, Dolphin [38] adopts long OFDM packets, which is 3.56 s long. Chirp packets, whose duration is 1.463 s, are used in [12]. To match the need for the high packet rate, a shorter packet should be designed.

However, reducing packet duration will cause two problems, reverberation in the time domain and spectral leakage in the frequency domain. First, the impact of reverberation is enlarged. Due to the multi-path effect, the microphone not only hears the direct signal but also delayed reverberating signals reflected by surrounding environments. Figure 7a shows an example of a 10 ms chirp signal received and its reverberations.

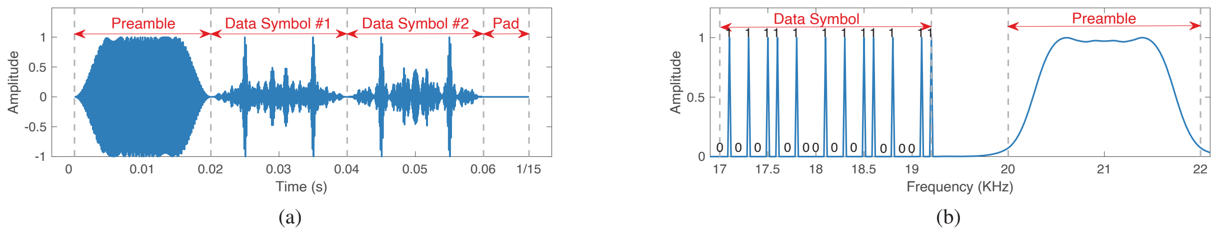


Figure 8: Audio packet design. (a) The 66.7 ms packet consists of one 20 ms preamble, two 20 ms data symbols and one silence pad. (b) The preamble and data symbol are separately located within 2 ranges of 20 – 22 kHz and 17 – 19.2 kHz, the data symbol consists of 23 subcarriers spaced at 100 Hz apart.

The dominant echo, spans the first 3 ms of the reverberation period, making it impossible to modulating bits at the sub-millisecond level in the time domain. Second, the spectral leakage aggravates as the length of bit duration decreases. Figure 7b depicts the spectrum of chirp signals modulated with on-off keying with different bit duration. Though with a duration of 5 ms, the leakage significantly increases, leading to the perception of the audience.

Low Packet Error Rate. AIRCODE assigns the audio link as the control channel. Thus, it must be reliable with a low packet error rate (PER). As audio channel suffers from multipath effect and frequency selectivity of speakers and microphones, pilot symbols are usually used to account for different channel responses of subcarriers and decide demodulation thresholds accordingly [38]. However, the threshold-based method requests that all bits '1' across all symbols are modulated with the same amplitude, leading to waste of energy and low SNR, when some symbols contain only a few bits '1'.

5.2 Audio Packet Design

Figure 8a shows the audio packet format in both time and frequency domain. To cope with the video channel, we set the packet duration as $\frac{1}{15}$ s, corresponding to 4 data frames, during which video configuration is unlikely to change.

To solve the challenge of short packet duration, AIRCODE modulates bits in the frequency domain and sets data symbol length as 20 ms, which is about 4 times longer than the major echo and has low spectral leakage. To further avoid the impact of reverberation, AIRCODE separates the preamble and the data into different frequency bands. Specifically, as shown in Figure 8b, the chirp preamble is within 20 – 22 kHz, and the data symbol is within 17 – 19.2 kHz. Both of which are inaudible to most human ears [42]. To further reduce spectral leakage, AIRCODE applies a tapered-cosine window on the preamble and each data symbol.

To solve the challenge of low packet error rate, AIRCODE adopts the two-layer coding scheme. Specifically, each packet contains 12 control bits. The 12 control bits are first encoded into 23 bits codeword via Golay code [23], which can correct any 3-bit error. Then, to fully exploit signal power allocated to the control signal, AIRCODE further adopts Manchester coding, which encodes bits '1' as '10' and bits '0' as '01'. During modulation, AIRCODE assigns 22 Manchester bits of the first 11 bits and the first Manchester bit of the 23rd bit of the Golay codeword to the 23 subcarriers of the first data symbol, and the rest 23 Manchester bits to the second data symbol. Figure 8b shows an example of the spectrum of one data symbol, where the subcarrier spacing is 100 Hz. Since each pair of Manchester bits are assigned to either adjacent subcarriers or data symbols, they experience similar channel responses caused by multipath effect and frequency selectivity of audio devices. Thus, the receiver can demodulate the data symbol by directly comparing amplitudes of pairs of Manchester bits without thresholds, and the sender can distribute all allocated signal power evenly to bits '1' in each data symbol, to increase average SNR and reduce overall PER.

6 Video Data Channel

The screen-camera link supports high throughput communication with imagery codes invisible to human eyes. The basic principle is to exploit the low-pass flicker fusion property of human eyes. Specifically, screen-camera communication generates high-rate complementary frames by inversely modifying the lightness of a pair of adjacent raw video frames. When videos are played at high frame rate, e.g., 120 FPS, human eyes can only observe raw video frames, which are the average of complementary frames, and cannot perceive the embedded data frames. In contrast, cameras with a high capturing rate can still acquire and decode data frames. AIRCODE takes the idea of hidden screen-camera communication, but focus on lower BER as well as higher data rate, by incorporating robust speaker-microphone link as the control channel, and accurate screen detection based on visual odometry.

Figure 6 shows the video communication part of AIRCODE. At the sender side, data bits are firstly encoded with a concatenated coding scheme, including Reed-Solomon (RS) coding as source code and Convolutional coding as channel code. The coding scheme is adaptively selected according to the texture complexity of the raw video, to achieve high throughput in plain frames, as well as low BER in textured frames. The encoded bits are modulated as data frames and embedded into pairs of complementary raw video frames. At the receiver side, AIRCODE inputs camera images into the screen detection process to obtain successive locations of the screen in frames. Meanwhile, the associated audio signal is pro-

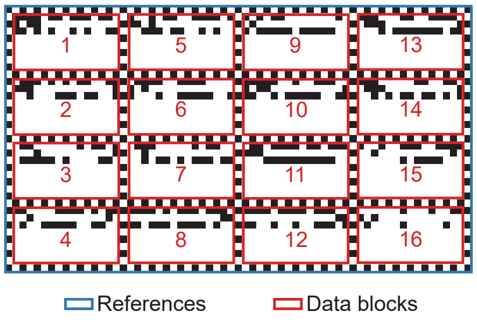

Figure 9: Data frame design. The frame consists of 16 data blocks, surrounded by black-and-white lines as references.

cessed to get corresponding metadata. Then, camera images are equalized with screen location information, and data is finally demodulated and decoded with metadata.

6.1 Data Frame Design

Figure 9 shows AIRCODE's data frame. AIRCODE follows the basic design of ChromaCode, but removes the code preamble blocks in ChromaCode that redundantly encode metadata of data frames, thanks to the use of the audio channel. AIRCODE divides the *whole* image frame into 16 data blocks with equal size. Similar to ChromaCode, each data block contains several data cells and is surrounded with alternate black and white cells as references. The encoded bits are interleaved and filled into data blocks. Specifically, the i-th bit is assigned to the $\lfloor \frac{i}{16} \rfloor$-th cell in the $(i \mod 16)$-th block.

The metadata of a data frame, including the levels of RS coding and Convolutional coding for encoding, and the data cell size for modulation, are transmitted as control packets over the reliable acoustic channel. Each control packet of metadata contains 12 data bits, with 2 bits for the RS coding level, 1 bit for the Convolutional coding level, 6 bits for the data cell size, and the rest 3 bits for parity bits for these three parameters. To save audio channel capacity, four successive data frames (embedded in eight video frames) share the same set of parameters in one control packet, as the video content is unlikely to drastically change during such a short period.

To avoid floating time offsets between the audio control channel and the video data channel, AIRCODE periodically (e.g., 5 s) sends video frames with the highest coding level and audio packets. These video frames and audio packets contain the synchronization information. At the receiver, each control audio packet will be aligned with 4 video data frames according to the latest synchronizing frame.

6.2 Adaptive Error Correction

In practice, textures of carrier video can considerably impact data transmission. In particular, the BER of the screen-camera link is lower in plain frames consisting of pixels in similar colors but significantly higher in textured frames. Therefore, to ensure robust data transmission, an error correction scheme with high correction ability should be used for textured frames. In contrast, a scheme with high efficiency yet potentially low correction ability will be preferred in plain frames to achieve high throughput.

This observation leads to the adaptive error correction scheme of AIRCODE, which adjusts the screen-camera channel parameters in metadata, i.e., RS coding level, Convolutional coding level, and data cell size, according to the dynamic texture complexity of the carrier video. In detail, AIRCODE supports 40 levels of data cell size, 2 levels of Convolutional coding and 4 levels of RS coding, which result in 320 levels of error correction. Given a video, a subset of error correction levels are selected and linearized by setting the data cell size as the most significant factor and the RS coding as the least significant factor. The video is segmented where a segment can be as short as 8 frames (i.e., $\frac{1}{15}$ s), corresponding to 1 audio packet. For each video segment, AIRCODE quantizes the texture complexity by calculating the average contrast of pixels against their neighboring 9×9 pixels, and maps the texture complexity to the error correction level.

7 Evaluation

7.1 Experimental Methodology

Experiment Setting and implementation. We use an AOC AGON AG271QX monitor as the sender of encoded videos and audios. It supports 120Hz refresh rate along with 1920×1080 resolution and has two audio speakers on its back. One Nexus 6P smartphone without hardware modification is used as the receiver. videos and audios are played by a DELL XPS 8900-R17N8 desktop, which equips a GeForce RTX 2070 GPU, and MPV player with VDPAU acceleration. AIRCODE uses FFmpeg to extract and compress video frames and audio tracks. OpenCV is used for the implementation of the rule-based screen detection algorithm and the screen tracking algorithm. AIRCODE exploits MediaCodeC interface for efficient hardware video coding and Boost library for implement of audio coding.

Video & Audio Selection. Table 1 shows the selected videos and their audios. For the video with pure gray images, an empty audio track is used as its origin audio. The bars indicate the levels of texture complexity, luminance and quality of the selected video contents, which cover a variety of combination. The more portion of a bar is filled with colors, the higher level of the metric is achieved by the corresponding video. E.g., the video Dynasties (D) has complex texture, low luminance and high quality. The corresponding audio contents include different types, e.g., human speaking, animal sound, an object moving and dropping, and background music, indicated by the icons. In practice, the quality of a streaming video frequently switches. However, frames between two adjacent switches still have the same quality. As AIRCODE encodes data at the frame level, frequent switching of streaming videos has a minor impact on AIRCODE.
Evaluation Metrics. For screen-camera communication, we compare AIRCODE with ChromaCode and InFrame++ [36]

Table 1: Origin primary video & audio clips used in the experiments and their characteristics

Quality
Audio

in terms of throughput, goodput and data BER. Throughput is the amount of all received bits. Goodput is the effective throughput of correctly decoded data bits. And BER is the number of error bits divided by total received data amount. ChromaCode uses the rule-based screen detection algorithm, and InFrame++ uses visible markers and alignment patterns at screen corners and borders. Since the speaker-microphone link serves as control channel and does not convey much data, we only evaluate its reliability in terms of BER and PER.

User Study. We invite 12 participants, including students and staffs on campus, to score the watching experience of encoded videos and audios. The ages of these participants range from 20 to 30. Nine participants are male, while the rest 3 are female. In total 40 videos together with their audios are prepared and tested. Videos and audios with or without data are randomly shuffled and played. Participants, not knowing their orders, are asked to give scores on the quality of them. Denote the scores for encoded videos and audios as *S_enc* and that for raw videos and audios as *S_raw*, the final scores for encoded videos and audios are normalized as $\frac{S\_enc}{S\_raw}$. In some cases, the normalized score is larger than 1, meaning that participants cannot statistically differentiate encoded videos and audios from their original counterparts. Moreover, to check whether young children can perceive the embedded code, we intentionally invite one 5-year-old child to watch the testing videos and audios and give feedback. Considering that children at such a young age may not have enough comprehension ability as adults to understand the meaning of the experiment, we neutrally ask him whether he can see or hear anything peculiar in videos or audios. All experiments are approved by our IRB, and do not raise any ethical issues.

7.2 Overall Performance

Performance of the communication processes. We first report the overall performance of AIRCODE in terms of throughput, goodput, and BER of the video channel, and BER and PER of the audio channel.

Figure 10a-10c show the performance of screen-camera communication in AIRCODE with different video contents. Two state-of-the-art approaches, ChromaCode and InFrame++ are evaluated for comparison. As shown in Figure 10a, AIRCODE achieves 1 Mbps throughput for all 5 videos, attributed to robust transmission of metadata through speaker-microphone channel. In contrast, though encoded with the whole screen, ChromaCode has lower throughput, especially with the videos 'D' and 'Z'. InFrame++ has the lowest throughput, due to its inefficiently CDMA-like coding scheme. Figure 10b shows that except the video 'D', the average BER achieved by AIRCODE is about 5%, which is statistically lower than its counterparts, owing to the accurate screen detection process. Figure 10c further compares the goodput of AIRCODE and ChromaCode. Due to the additive effect of accurate screen detection and robust metadata transmission, AIRCODE outperforms ChromaCode throughout all testing videos. Another key observation from Figure 10b and 10c is that the system performance is highly impacted by video content, where the video with more plain frames (i.e., 'G') tends to have lower BER and higher goodput. AIRCODE takes adaptive error correction, which further increases the reliability of AIRCODE with different video contents.

Figure 10d shows the BER and PER of the speaker-microphone link, whose reliable communication is of great importance for the overall system. Across all types of audio contents, the BER of the audio control channel consistently remains below 1%. With the help of Golay code, over 99.9% audio control packets can be successfully decoded, providing robust metadata for the screen-camera link.

Performance of the screen tracking process. The screen detection rate and tracking error of AIRCODE are evaluated and compared with the rule-based algorithm of ChromaCode. Since labeling ground-truth of all video frames is labor-intensive, we indirectly calculate screen detection rate as the ratio $\frac{r_{method}}{r_{base}}$, where r_{method} is the frame decoding rate of the method, and r_{base} is the frame decoding rate when the camera is fixed at some sampling locations. To calculate screen tracking error, we randomly sample frames with 0.5s intervals from all videos and mark the ground-truth screen in them for comparison.

On average, AIRCODE takes 0.79 s to initialize. Figure 11a shows that AIRCODE consistently detects the screen in over 97% frames across different types of videos. In contrast, the rule-based algorithm suffers from confusing video contents, and ChromaCode can detect the screen in over 90% frames in videos 'B', 'G' and 'J', but only about 70% frames in videos 'D' and 'Z'. Figure 11b further shows the tracking error of the two methods in terms of image pixels. AIRCODE achieves

(b) Audio

Figure 12: Impact of monitor-phone distance.

Table 2: Benefits of individual module.

		Throughput (kbps)	BER (%)	Goodput (kbps)
Screen Detection	**Tracking**	1086.4	6%	139.5
	Rule	1073.8	8.3%	77.3
Control Channel	**Audio**	1084.3	4.4%	149.1
	Video	893.7	4.6%	144.3
Error Correction	**Adaptive**	1086.3	5%	159.4
	Fixed	1086.4	4.4%	149.4

consistently small tracking error for all videos, while the performance of ChromaCode is highly related to video content. Specifically, all tracking errors of AIRCODE are within 9 pixels. In contrast, 12.8% tracking errors of ChromaCode exceed 9 pixels, and the maximal error is even beyond 60 pixels. This validates the effectiveness of screen tracking.

Benefits of individual module. We further evaluate the individual performance improvement from the screen detection, control channel and error correction of AIRCODE. When one module is evaluated, the other modules are disabled (error correction) or assumed to be perfect (screen detection and control channel). Table 2 shows the average system performance. First, the screen tracking method of AIRCODE has lower BER and significantly higher goodput than the rule-based method of ChromaCode, thanks to its consistently accurate screen tracking. Second, comparing with sending metadata via video, using the audio channel improves throughput and goodput. On one hand, it saves the area where metadata has to be duplicated for reliable detection in video frames. On the other hand, the audio channel is more robust and overcomes the occasion when even the duplicated metadata in video frames cannot be correctly decoded. Third, by considering the texture complexity of videos, although the adaptive error correction of AIRCODE has a slightly higher BER than error correction with fixed coding level, it achieves overall 10 kbps more goodput, as more data bits are adaptively encoded.

7.3 Parameter Study

Distance. Figure 12 shows the impact of distance between the monitor and the phone. For the video part, the data cell size is fixed to 10×10. As shown in Figure 12a, the goodput of AIRCODE abruptly decreases when the distance becomes longer than 90 cm. One main reason is that small data cells become hard to recognize when the distance increases. It suggests that larger data cells should be used at longer distances, however, with the sacrifice of the throughput. The other reason for performance deterioration is that the focal length of the receiving camera will automatically change more frequently with larger distances, leading to more blurry video records.

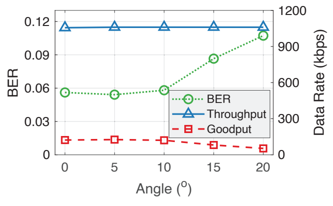
For audio part, as shown in Figure 12b, while the BER gradually increases with the distance, due to decay of receiving signal strength, all errors can be corrected and the PER remains 0 when the phone is within 150 cm from the monitor, which fulfills the requirement of the video data channel.

Angle. We evaluate the impact of relative angles between the phone and the monitor, as shown in Figure 13. For video, Figure 13a shows that the goodput decreases while the BER increases with a large angle. The main reason is that the projection distortion becomes severer as the camera deviates from the front of the monitor, and in this case, video frames cannot be easily decoded even with accurate screen estimation.

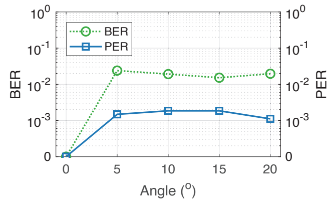
The same trend also appears in the speaker-microphone link, where the BER increases with the angle between the monitor and the phone, as shown in Figure 13b. It is mainly due to the high directivity of the monitor loudspeaker. Even though, AIRCODE still achieves ultra-low PER of about 1‰.

Signal strength. For the video part, the signal strength is represented as the quantity of lightness modification of data frames on raw video frames. As shown in Figure 14a, the BER gradually decreases as the amplitude of lightness modification increases, since data cells can be more easily recognized from the raw video content, and thus correctly decoded.

For the audio part, the signal strength is represented as the

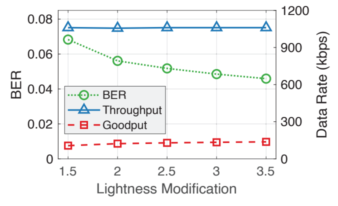


(a) Video

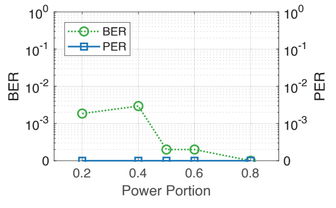


(b) Audio

Figure 13: Impact of monitor-phone angle.



(a) Video



(b) Audio

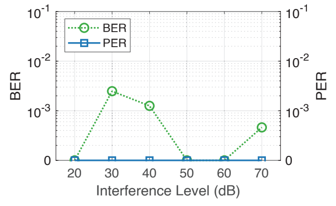
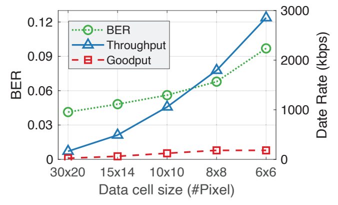
(a) Video

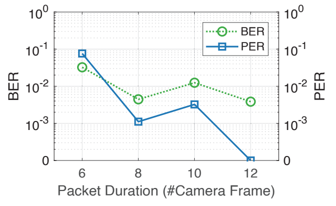


(b) Audio

Figure 15: Impact of surrounding interference.



(a) Video



(b) Audio

Figure 16: Impact of frame size.

portion of power allocated to the embedded signal. As shown in Figure 14b, the BER declines as the signal strength of the embedded signal increases, while the PER remains 0 even when only 20% power is allocated.

Background interference. We further evaluate the robustness under interferences from the environment. For the video part, the major source of interference is ambient luminance. Typical indoor ambient luminance ranging from 0 to 800 lux is evaluated. Specifically, the ambient luminance less than 600 lux is generated by an unshielded lamp suspended over the screen-camera link, while that between 600 and 800 lux is generated by natural sunlight during the daytime. A photometer is placed adjacent to the camera to measure the ambient luminance. As shown in Figure 15a, while strong ambient luminance reduces the contrast between complementary frames, the system performance only slightly degrades. It is concluded that ambient luminance has little impact on data transmission.

For the audio part, the major source of interference is environmental noises. For evaluation, we set AIRCODE to work normally at 1 m away from the monitor, and let a loudspeaker be 3 m away from the phone and play various types of audios as background interferences. The volume of the loudspeaker is adjusted to create interferences varying from 20 dB (0% volume) to 70 dB (100% volume) at the speaker. Figure 15b shows that the variance of BER is small and the PER remains 0 no matter how loud the loudspeaker plays interferences, demonstrating the robustness of the audio channel.

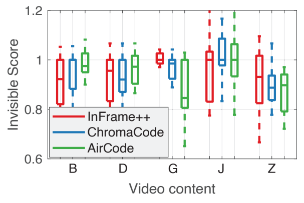
Frame size. For the video part, the frame size refers to data cell size. Figure 16a shows the data rate and BER with different data cell sizes. By gradually reducing data cell size, the throughput boosts from 163 Kbps to 2855 Kbps. AIRCODE achieves a high goodput of 182 Kbps with 8×8 data cell but saturates when data cells are further scaled down to 6×6, due to a higher chance of recognition failure and more bit errors. In practice, given the requirement of the BER and communication distance of an application, AIRCODE can trade-off the throughput by selecting appropriate data cell sizes.

For the audio part, the frame size refers to packet duration. As shown in Figure 16b, both BER and PER decrease with longer packets, as longer data symbols are less affected by reverberation and have finer frequency resolution for demodulation. By observing that the decline of BER is not obvious when the packet duration exceeds the length of 8 video frames (i.e., $\frac{1}{15}$ s), AIRCODE adopts $\frac{1}{15}$ s as the default packet duration for the audio control channel.

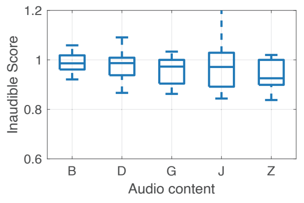
7.4 Perception Test

Video & audio content. Figure 17 shows the variation of code insensibility with different video and audio content. It is observed that all normalized scores for videos are higher than 0.6 and those for audios are higher than 0.8 for AIRCODE, indicating relatively high insensibility of the system. Among the results, some normalized scores are equal or even higher than 1, meaning that the quality of the encoded videos and audios is sufficiently high that participants cannot distinguish encoded videos and audios from original ones. For different video contents, higher scores are given to videos 'B', 'D' and 'J', which have more textured frames. It means that larger lightness modification can be applied to textured frames to ensure low BER without much impacting raw videos.

Biases of audiences. Scores given by 12 participants demonstrate different biases of their perception, as shown in Figure 18. For example, the participant 2 gives the statistically highest scores for encoded videos. From the interview after the experiment, he admits that it is difficult for him to recognize embedded data hidden in videos, meaning that the encoded videos have almost the same quality as the raw videos for him. In contrast, the participant 10 gives the lowest scores for encoded videos of all three approaches, meaning that he is relatively sensitive to unnatural alternation in videos. Among all 12 participants, only 2 (i.e., 6 and 7) of them give the highest average score to InFrame++. Yet, considering the scoring fluctuations of participants, there are no significant

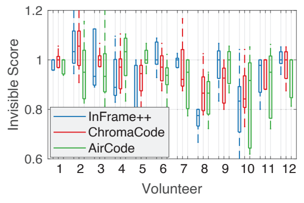


(a) Video

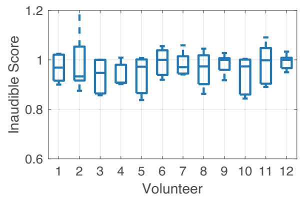


(b) Audio

Figure 17: Content diversity.



(a) Video



(b) Audio

Figure 18: Audience Diversity.

quality differences among the three approaches.

Besides 12 adults, one 5-year-old child also participates in the test. We first show him training videos with perceptible visual codes and acoustic noises. Then, the testing videos and audios are played intermittently and the child answers whether there are such codes or noises. To avoid biased hints to the child, we only give the instruction at the beginning and remain silence during playing of all testing videos. The result is that both encoded videos and audios do not discomfort the child, and he cannot observe or hear any interferences that do not belong to the origin videos and audios, demonstrating high insensibility of AIRCODE even for children.

8 Related Work

Hidden screen-camera communication. Hidden communication with the screen-camera link conveys information without interfering watching experience of audience [11, 15, 24, 30, 36, 37]. Along this direction, pioneer works, InFrame [37] and InFrame++ [36], propose and implement the basic idea, which is to switch barcodes with complementary lightness and leverage the flicker fusion property of human eyes. However, InFrame++ uses visible markers at corners of video frames for block localization, which explicitly interferes audience and consumes precious screen spaces. Extensive efforts are further made to improve the audience's experience. TextureCode [24] adaptively embeds data only in textured regions, which however is limited in throughput. PixNet [26] designs 2D OFDM symbols that can correct perspective distortions. However, they are not guaranteed to be invisible after embedded into video frames and the frequency property of OFDM symbols is destructed by changing video contents. ChromaCode [41] improves code invisibility by modifying lightness in uniform color space and achieves full imperception. However, pursuing code invisibility increases the difficulty of detecting code frames. In comparison, ensuring code invisibility, AIRCODE adopts visual odometry for accurate screen detection and achieves lower BER and higher goodput.

Speaker-microphone communication. Communication with off-the-shelf speaker-microphone links has been studied in [12, 14, 16, 22, 25, 38, 40]. Dhwani [22] adopts OFDM with PSK modulation and realizes acoustic near field communication. However, it works in the audible 6 – 7 kHz band, which interferes hearing experience of the audience and cannot be embedded in normal audio. Chirp signal is widely used in hidden acoustic communication in [12, 14, 16], for its fine correlation property. However, data rates achieved with chirp-based communication are less than 100 bps. Dolphin [38] proposes dual-mode unobtrusive communication, which still only achieves average data rates of up to 500 bps, even with the usage of a much wider frequency band from 8 kHz to 20 kHz. Noting the limitation of throughput and the advantage of the reliability of speaker-microphone communication with off-the-shelf devices, AIRCODE designs reliable and agile acoustic communication as the control channel of screen-camera link with high frame rate, boosting the overall throughput of the whole communication system. The acoustic channel will congest when multiple screens supporting AIRCODE coexist. In such a case, the screens should sense the audio channel before accessing it. Besides, audio packets should be modified to identify their belongings to the screens. We leave the support of multiple screens as future work.

Visual Odometry. Monocular visual odometry has the goal of estimating camera trajectory and reconstructing the environment with monocular commercial cameras [1–7, 13, 21, 39]. Pioneer works, e.g., MonoSLAM [2], applies filtering-based approach. Later, optimization-based methods [13] gradually substitutes the filtering-based ones for their tracking accuracy and efficiency. ORB-SLAM [21] is the representative work that uses ORB features in tracking and mapping. AIRCODE exploits the idea of visual odometry to accurately detect screens in images, enabling robust and practical screen-camera communication.

9 Conclusion

In this paper, we present the design and implementation of AIRCODE, the first hidden screen-camera communication system that achieves considerably high data rates of >1Mbps. AIRCODE is also the first system of its kind that exploits an invisible video and inaudible audio dual channel. With the high data rates being supported, AIRCODE opens up new opportunities and underpins various applications yet to be imagined for hidden screen-camera communication.

Abstract

We design and implement LRP, a device-based, standard-compliant solution to latency reduction in mobile networks. LRP takes a data-driven approach. It works with a variety of latency-sensitive mobile applications without requiring root privilege, and ensures the latency is no worse than the legacy LTE design. Using traces from operational networks, we identify all elements in LTE uplink latency and quantify them. LRP designates small dummy messages, which precede uplink data transmissions, thus eliminating latency elements due to power-saving, scheduling, etc. It imposes proper timing control among dummy messages and data packets to handle various conflicts. The evaluation shows that, LRP reduces the median LTE uplink latency by a factor up to 7.4× (from 42ms to 5ms) for four tested apps over five mobile carriers.

1 Introduction

Low latency is critical to the proper functioning of various delay-sensitive mobile applications, such as mobile VR/AR, mobile gaming, mobile sensing, mobile machine learning, and emerging robot/drone-based image/speech recognition [22, 29, 36, 40]. These applications typically run on 4G LTE and 5G mobile networks, which offer ubiquitous access and seamless service. In this work, we study how to reduce network latency over LTE networks for such applications in the connected state. This complements the work that reduces the connection setup latency [33].

Many emergent latency-sensitive mobile apps differentiate themselves for their heavier *uplink* data transfer (e.g., user motion control, sensory data, and live camera streaming) from the device to the infrastructure. Our experiments further reveal that, uplink latency contributes to a large portion of overall latency in tested apps over operational LTE (§3.1). Reducing the uplink latency is thus as important as reducing the downlink latency. While the downlink transfer has been extensively optimized, the uplink data transfer is less studied.

Reducing the uplink LTE latency turns out to be more challenging than the downlink latency. The uplink data transfer in LTE is more complex, since it involves the interaction between the device and the network. It adopts the feedback-based device power-saving, base station-controlled scheduling for data transfer, on-demand radio resource allocation, retransmissions, etc. This results in more network latency sources with complex interactions. Traditional infrastructure-based solutions fall short to optimize them due to the lack of knowledge on device-side application usage patterns.

We design and implement LRP, a device-based, software-only LTE latency reduction solution that is readily usable for *every* commodity smartphone device. A salient feature of LRP is that it does not require root/system privilege, firmware modification or hardware change. It is thus applicable to every off-the-shelf commodity device, including Android and iOS. LRP explores the application-driven network latency reduction at the device, which complements those existing infrastructure-centric solutions that are good at downlink latency reduction. LRP focuses on reducing LTE uplink network latency, which is the bottleneck based on our empirical analysis.

The overall design of LRP takes the data-driven approach. Through analysis of operational LTE traces, we identify all elements in LTE uplink latency, and quantify them via two popular applications (§3.2). Based on the gained insights, LRP designates small dummy messages, which precede those uplink data packet transfers. It thus eliminates the latency elements due to power-saving and scheduling (§5). To make this conceptually simple idea work, LRP infers critical LTE parameters at the application layer, and performs proper timing control among dummy messages and data packet streams. To reduce the overall latency, LRP further resolves the conflict that arises among dummy messages, and avoids the conflict between data packets and dummy messages. All these solution components work at the application layer without root privilege, thus available for every off-the-shelf commodity mobile device. While LRP is mainly designed in 4G LTE, it can be readily generalized to benefit the emergent 5G (§5.5).

We implement LRP on commodity Android phones (§6). Our experiments confirm LRP's effectiveness (§7). LRP reduces the median LTE uplink latency by up to 7.4× (from

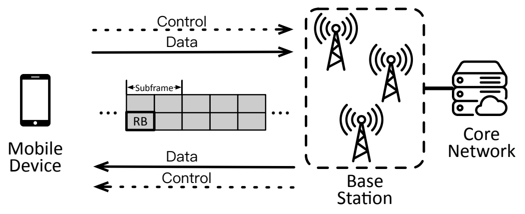

Figure 1: Network data transmission over LTE.

42ms to 5ms) for four tested applications over five mobile carriers. In any case, LRP ensures that the network latency for data transfer is no worse than the legacy LTE design. The incurred energy and data volume overhead is negligible.

2 Latency-Sensitive Mobile Apps over LTE

The mobile networks, such as 4G LTE and 5G, offer the only large-scale infrastructure that ensures universal coverage and "anytime, anywhere" access. Its infrastructure consists of radio base stations (BSes) and the core network (see Figure 1). A mobile device transfers its data with a local BS ("cell"), which covers a geographic area. The BS further relays the data to the Internet via the LTE core. A mobile device has uplink (device→BS) and downlink (BS→device) transmissions. In 4G LTE, data transfer uses scheduling-based mechanisms, where a BS schedules radio resources for each device in the cell for its uplink and downlink data transfer.

We next exemplify some representative latency-sensitive applications over the mobile networks.

Mobile VR A mobile virtual reality (VR) app typically involves 3D scenes and associated graphical engines [10, 15, 29, 31]. Standalone VR headsets such as Google Daydream [17] render 3D scenes locally. However, due to limited computation resources and high power consumption on mobile devices, high-quality VR applications typically need the edge/cloud servers to offload the rendering task [44]. In this client-server scheme, the mobile headsets or pads provide sensory/control data, while the server renders the 3D scene in the form of graphical frames. The server coordinates multiple devices, renders the VR graphical frames based on the device's input, and constructs the appropriate 3D scene for each given device.

• *Showcase VR prototype:* Following the above paradigm, we have built an example VR game with Unity 3D engine [42] on Android phones to study LTE latency. It has three modules: the controller at the device, the camera controller at the server, and the streaming component. The Android controller app acquires the device rotation data from the gyroscope sensor to control the in-game camera rotation. The GPS location is fed into the VR game so that the virtual character moves with the player's location updates. Upon receiving the player's sensory data, the camera controller at the server processes them and makes corresponding position and rotation movements for the virtual camera. We implement the streaming module with open-sourced libraries Unity Render Streaming [46] and WebRTC for Unity [18]. With the streaming module, the camera view is rendered and streamed back in 60FPS to the player with WebRTC. Players open the camera stream with the Web browser on the phone to get the real-time camera view.

Mobile sensing Smartphones today are equipped with multiple sensors: accelerometer, gyroscope, camera, to name a few. Many mobile sensing apps collect sensory data and upload them at runtime to the cloud for processing. For example, a localization app sends the GPS data to the cloud for realtime navigation. All such sensing apps are latency sensitive.

Mobile gaming In multi-player mobile games, the device acts as a controller that collects user motion, while the remote server processes the game logic. The server further provides proper synchronization and coordination among players. Moreover, pure cloud-based gaming (with rendering being processed in the cloud) is also trendy [29]. It is a new gaming paradigm being pushed by companies [40].

Cloud/edge-assisted machine learning Mobile apps with machine learning features (e.g., image/object recognition or speech understanding [14, 22]) also pose latency requirements. Network latency becomes a bottleneck for smart assistants, such as Alexa [7] and Siri [45]. Users may tolerate at most 200ms response time, while deep learning based local transcriptions take only 10ms [13].

Networking usage patterns by these mobile apps All the above representative mobile apps involve *frequent and regular uplink* data transfer. The mobile VR, sensing, and gaming [49, 50] applications collect data from device sensors and upload them to the server for subsequent actions. These sensors typically produce small data *periodically*. The user can only configure the sampling periodicity through the API provided by the mobile OS [21]. The machine learning based apps also have predictable traffic. They typically perform local computations with predictable latency before an uplink data transfer. For example, face recognition apps process a video frame locally using a fixed-sized neural network (NN). A user can gauge the delay based on the NN size. Emerging robotic or drone-based applications perform local tasks for a certain duration (e.g., scanning the surrounding environment for a few seconds [6]) before uploading the result. Such apps also exhibit uplink traffic that can be accurately predicted.

3 Demystifying LTE Latency in Mobile Apps

In this section, we empirically analyze where the application-perceived LTE latency stems from. We address two issues:

• *How large can LTE uplink latency be over operational 4G networks?* We use measurements to quantify it in §3.1.

• *Why is the uplink latency prohibitively high over LTE?* We break down this latency into multiple elements. We quantify their impact, identify root causes, and share insights in §3.2.

App	Latency	AT&T	T-Mobile	Verizon	Sprint
PUBG	UL Net	10.7	9.9	10.0	17.7
	DL Net	5.0	5.0	5.0	5.0
	UL/Total	68.2%	66.4%	66.7%	78.0%
VR	UL Net	N/A [1]	18.4	23.8	N/A
	DL Net	N/A	8.5	10.6	N/A
	UL/Total	N/A	68.4%	69.2%	N/A

Table 1: LTE latency (ms) for two mobile apps.

3.1 Measuring LTE Latency

We quantify the uplink latency over operational LTE networks via measurements and trace analysis.

Methodology We analyze the traces from our showcase VR game and another popular mobile application PUBG Mobile [40]. Our VR application uploads user motion packets (∼60Bytes) and receives 60FPS, 5Mbps downlink video stream. The downlink data packets are sent from the deployed server to the device over LTE. PUBG is a mobile game with frequent uplink data (∼40ms interval) and downlink responses. Both uplink and downlink packets are small (<100Bytes). The latency due to server processing is less than 1ms. The mobile devices (a Pixel 2 and a Pixel XL) run the apps. We collect both app logs and LTE signaling traces via MobileInsight [32]. We carry out our experiments over four US mobile carriers from 12/2019 to 09/2020. The tests cover static, low-mobility (∼1m/s), and high-mobility (∼30mph) cases, with varying signal strength (-120∼-80dBm).

Results We first measure the LTE uplink latency. We monitor the device buffer and compute the latency for each data packet. This information is available in the MobileInsight message "LTE MAC UL Buffer Status Internal". Despite small packet size, the uplink latency turns out to be non-negligible, as shown in Table 1. For all four carriers, the uplink latency (UL NET) ranges from 9.9-17.7ms for PUBG and 18.4-23.8ms for VR. These latency values might not meet the requirements of a number of latency-sensitive apps [5].

Who is the latency bottleneck? We further discover that, instead of downlink, the uplink latency poses as a major component in overall latency. We compute the downlink latency from logs of "MAC DL Transport Block" in MobileInsight. The results (DL NET) are in Table 1. We see that, uplink latency accounts for 66.4-78.0% in PUBG and 68.4-69.2% in VR. Surprisingly, even for the downlink-heavy VR app, uplink latency still contributes to a large portion of the overall latency. Recent techniques (e.g., MIMO and carrier aggregation) and 5G further reduce the DL latency with faster PHY designs. In contrast, as we will see later, the scheduling design employed for the uplink will likely be retained in 5G. As a result, we will focus on the uplink latency in this paper.

[1]VR cannot run on AT&T and Sprint, since their firewalls block the traffic.

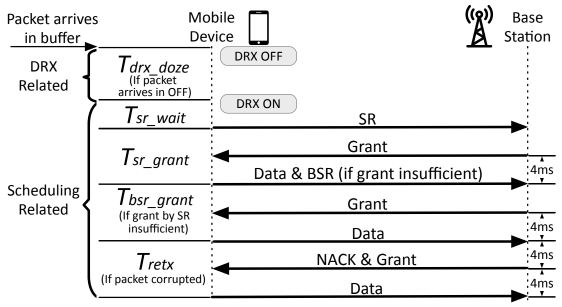

Figure 2: LTE uplink procedure & latency elements.

Latency (ms)	AT&T	T-Mobile	Verizon	Sprint
T_{drx_doze}	29.7	31.9	28.3	29.2
T_{sr_wait}	4.4	4.4	4.6	9.0
T_{sr_grant}	8.2	8.5	8.0	10.1
T_{bsr_grant}	0.03	0.00	0.03	0.16
T_{retx}	0.17	0.14	0.32	0.72

Table 2: Measured latency elements for VR application. T_{drx_doze} is the average value when present.

3.2 Why Long Latency: Breakdown Analysis

We next analyze the root causes for long network latency in 4G LTE. We identify various latency elements for the LTE uplink latency by analyzing the 3GPP standards [1, 2].

We breakdown the uplink latency as shown in Figure 2. The average number of each latency element is shown in Table 2. We can observe that, the major uplink latency bottlenecks are T_{drx_doze}, T_{sr_grant}, and T_{sr_wait}, while T_{bsr_grant} and T_{retx} are one magnitude smaller compared to other elements. We will see how each latency element acts and why it poses or does not pose as the latency bottleneck to our applications.

3.2.1 DRX Doze Latency.

Power-Saving Mode through DRX The power-saving mechanism DRX (Discontinuous Reception) in LTE may also affect latency. In a nutshell, DRX is a technique for a device to save power over LTE (see Figure 3). Instead of continuously waking up for potential downlink delivery from the BS, the device might sleep in the absence of data transfer, thus reducing its energy consumption. In DRX, a device has three states: Long DRX Cycle, Short DRX Cycle, and Continuous Reception (CRX) [2]. In CRX, the device wakes up during the ON period to monitor downlink channels. In long/short DRX, the device only wakes up for a short period of time (set by the onDuration Timer) at the start of each DRX cycle. It dozes off during the OFF period for the remaining time.

The DRX state transition is shown in Figure 3. In the Long/Short cycle state, if any downlink data is received during the ON period, the device enters the CRX state and starts the drx-InactivityTimer. Upon sending an uplink data, the device initiates an SR request. It then switches to the CRX state as well. If the device receives downlink data or initiates another SR request, the timer restarts. The short DRX state

Parameters		AT&T	T-Mobile	Verizon	Sprint
T_{sr_grant}	8ms	96.6%	96.5%	98.8%	0
	10ms	0	0.2%	0.1%	98.1%
	others	3.4%	3.3%	1.2%	1.9%
$T_{sr\_periodicity}$	10ms	94.0%	98.1%	92.3%	11.9%
	20ms	6.0%	1.9%	0	48.9%
	40ms	0	0	7.7%	39.%
$T_{inactivity\_timer}$	200ms	100.0%	99.5%	99.6%	84.5%
	others	0	0.5%	0.4%	15.5%

Table 3: Critical LTE parameters for uplink latency.

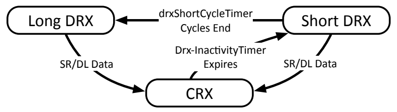

Figure 3: State transition for LTE DRX power-saving.

is entered once the drx-InactivityTimer expires. In this state, the device enters long DRX after the number of drxShortCycleTimer short cycles. All such involved timer parameters are negotiated between the device and the BS during connection setup through RRC.

How downlink DRX incurs long uplink latency DRX is designated for power saving over *downlink* transmissions. It should not block any uplink transfer. In fact, the 3GPP specification [2] stipulates that, upon the uplink sending an SR, downlink DRX should enter the CRX state as if receiving a downlink data packet. However, we found that this is not the case in practice. A new data packet refuses to invoke an SR if the device is in the doze mode. Instead, it continues to doze for a while (the time is denoted as T_{drx_doze}). It then waits for an SR slot to initiate the SR, while migrating the device to the CRX state. Table 2 shows that, T_{drx_doze} is 28.3-31.9ms on average in the four carriers. The maximum latency is 59ms with the 90th percentile being 42ms.

Note that the DRX doze latency is different from the known downlink packet delay due to waiting for DRX ON state. 3GPP [1, 2] does not mandate to prepare for SR at the DRX state. Although this latency element is not standardized, it is common for vendors as they use DRX doze to save energy. The DRX-induced doze timer is hinted in Qualcomm patents [52], where the device defers its SR during DRX OFF for energy savings. We also indirectly validate this behavior in a ZTE Z820 with Mediatek Chipset. For packets with an interval of 1 second, the measured average RTT is 35ms longer than that of packets with a small interval.

Insight: A packet keeps the device at the CRX state for $T_{inactivity\_timer}$. The idea is to reduce the DRX doze latency by sending a dummy message in advance. This way, the device is kept in the ON period before data arrival. The data packet can thus be sent without deferring until the doze period ends.

3.2.2 Scheduling Latency.

Uplink/downlink scheduling in LTE: In LTE, the uplink and downlink data transfers take different approaches:

• *Uplink data transfer over LTE* As shown in Figure 1, the uplink data transmission is through PUSCH (Physical Uplink Shared Channel). All data transmissions are regulated by the BS, which allocates resource blocks (RBs) for the actual transfer. An RB is the smallest unit allocated for a device.

In the scheduling-based LTE design, uplink data *cannot* be immediately sent out before the device is granted resource. This is done via the *request and grant* mechanism. Specifically, the device sends an SR (Scheduling Request) through PUCCH (Physical Uplink Control Channel). SR is a signaling message notifying new data arrival at the mobile device. Moreover, an SR signal cannot be sent at any time instantly. It can only be sent during certain subframes (called SR occasions). The periodicity of SR occasions is notified by the BS during connection setup. Upon receiving an SR, the BS returns an uplink Grant (i.e., *grant*) to the device. A grant specifies what RBs and modulation the device could use *4ms later*. The number of RBs in response to an SR depends on the BS configuration, since SR is just a message stating "device has data to send" without specifying the amount.

• *Downlink data transfer over LTE* LTE still uses the scheduling-based operations for its downlink. However, BS directly allocates RBs for each device upon data arrival, since BS knows what data to transmit to which device.

How scheduling incurs long latency The device also suffers from its uplink scheduling latency. It must wait for an SR occasion before receiving a grant from the BS to upload its data packet. The latency element, denoted as T_{sr_wait}, is thus affected by the periodicity of an SR occasion $T_{sr\_periodicity}$. The device then waits for a grant, which the device could use 4ms later. The latency from sending the SR to sending the data packet is denoted as T_{sr_grant}. The two elements of scheduling are shown in Figure 2. We measure them in Table 2. The SR waiting latency T_{sr_wait} is 4.4ms for AT&T, 4.4ms for T-Mobile, 4.6ms for Verizon, and 9.0ms for Sprint. Sprint has the largest T_{sr_wait} because it has the longest SR cycle. T_{sr_grant} is 8.2ms, 8.5ms, 8.0ms, and 10.1ms for the four carriers. The accumulative latency is denoted as $T_{scheduling} = T_{sr\_wait} + T_{sr\_grant}$.

Insight: This scheduling latency can be reduced. If a grant is pending at the device, a new arriving data packet can use it for transfer. Therefore, we may use a dummy message to request for a grant in advance, so that the data packet can use this grant for actual transfer without delay.

3.2.3 Other Latency Elements.

Buffer status report (BSR) SR is an indicator that informs the BS of new pending data, without specifying *how much*. When the packet that triggers SR is large, the initial grant might be insufficient. The device then sends a BSR (Buffer Status Report) together with the data packets in the scheduled RBs. Unlike SR, a BSR includes the info on how much data still remains in the device buffer. Upon receiving

the BSR, the BS will process it and respond with sufficient grants for the buffered uplink data.

We note BSR's impact on uplink latency is negligible for most applications in §2. The latency between a BSR and the time to use the grant (denoted as T_{bsr_grant}) is illustrated in Figure 2. Conceptually, it is the request processing time + 4ms, similarly to T_{sr_grant} ($\approx 10ms$). However, it equals to 0 when the initial grant is sufficient. The measurement results are in Table 2. The BSR latency is less than 1ms on average for four US carriers. This is because a base station usually provides a large grant (>100B) sufficient for our apps in response to SR,

Retransmission in LTE An uplink data packet might be corrupted during transfer. Upon receiving a corrupted packet, the BS notifies the device by sending a NACK and a grant. The device uses the grant to retransmit the corrupted data. Similar to BSR latency, the retransmission has limited impact on the uplink latency for apps in §2. The ReTx latency for uplink data packet is fixed at 8ms if needed [1] and 0 otherwise. We denote this latency as T_{retx} and the procedure is shown in Figure 2. Among all data packets, 2.1% in AT&T, 1.7% in T-Mobile, 4.0% in Verizon, and 9.1% in Sprint perceive ReTx latency. Less than 1ms latency is incurred on average, shown in Table 2. Unlike downlink with up to 10% retransmissions [48], uplink packets are small and less prone to corruption.

4 LRP Overview

We devise LRP, an in-device software solution to latency reduction for mobile apps. Figure 4 shows LRP's components. It runs as a user-space daemon at the device, **without** requiring system/root privilege, firmware modification, or hardware support. It is applicable to both Android and iOS. LRP masks the LTE latency elements in §3.2 for applications by *proactively* requesting the needed radio resources and high-speed transfer mode, while still retaining low energy and data consumption overhead. As an application-layer solution, LRP cannot directly control the low-level LTE mechanisms (that require root privilege or firmware access). Instead, it indirectly regulates the LTE uplink transfer with well-crafted *dummy packets*. LRP complements solutions designed to reduce other non-network latency elements [19, 51, 54]. While conceptually simple, LRP must address three challenges:

• **Accurate timing control for each latency element (§5.1–5.2):** Initializing the dummy packets at the right time is crucial to both reducing latency and minimizing energy consumption, signaling overhead, and radio resource usage (thus billing). The proper timing depends on the traffic pattern *and* the unique characteristics of each latency element. To this end, LRP customizes the timing control for critical latency elements, including the DRX doze and scheduling (§3.2).

• **Conflict handling for overall latency reduction (§5.3):** Simply reducing each latency element does not suffice to reduce the overall latency. Due to the complex interactions between LTE latency elements, reducing one latency element may increase other latency elements. Moreover, the dummy packets may compete radio resources with the legitimate data, incurring additional data latency. To this end, LRP devises resolution and avoidance schemes for both types of conflicts.

• **Rootless inference of critical LTE parameters (§5.4):** To be readily usable by *every* device, we design LRP as a user-space software daemon *without* requiring system/root privilege. The challenge is that, LRP's latency reduction requires the fine-grained knowledge of low-level LTE parameters inside the hardware modem chipset. Existing solutions to directly access them (e.g., MobileInsight [32] and QXDM [41]) require root privilege or external hardware support. According to [28], only 7.5% of global mobile devices are rooted. We propose a novel approach to infer these parameters without any system privilege or firmware/hardware modification.

5 The LRP Design

We next elaborate on LRP's design. We first propose component designs to reduce each latency element (§5.1–§5.2), and resolve potential conflicts among them (§5.3). To realize the components without root privilege, we propose a novel inference method at the application layer (§5.4). We analyze LRP and extend the discussion to irregular traffic and 5G (§5.5).

5.1 Energy-Efficient DRX Doze Elimination

To reduce the DRX doze latency in §3.2.1, LRP should ensure the device is in ON period when a data packet arrives at the device buffer. As an application layer solution, LRP cannot directly switch the device to the CRX state (that needs firmware modification). Instead, it sends a dummy packet (*rouser*) *before* the data packet's arrival.

Despite being straightforward at the first glance, a *rouser* is only effective if being sent at the right time. An imprudent *rouser* can either incur unacceptable energy waste or cannot help reduce latency. Therefore, timing control is crucial to balancing latency and energy cost. We first discuss some naive solutions with limitations, and then present our design.

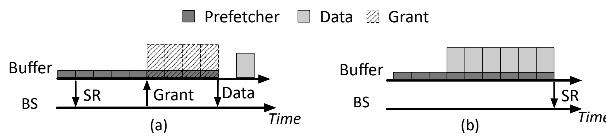

Figure 6: Impact of *prefetcher* Timing.

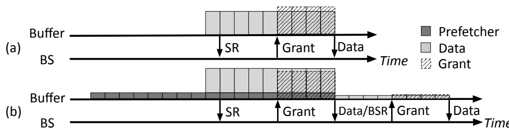

Figure 7: Corner case: a *prefetcher* increases latency.

Naive timing control One naive solution is to keep DRX at CRX state at all times by frequently sending *rouser*s. As shown in Figure 5(a), this can be achieved by sending a *rouser* every $T_{inactivity\_timer}$. Unfortunately, this results in unacceptable energy waste, as the device never enters the doze mode.

A better choice is to send a *rouser* with the time in advance, denoted as t_r, being set to $t_r = T_{inactivity\_timer}$ (Figure 5(b)). On one hand, as the packet keeps the ON period for $T_{inactivity\_timer}$ after dozing, $t_r = T_{inactivity\_timer}$ ensures that the data packet enters the buffer during the ON period. On the other hand, this saves power compared to the first naive choice, since the extra ON period is capped at $T_{inactivity\_timer}$ for each packet at most. However, extra energy consumption is still incurred. Since $T_{inactivity\_timer}$ (∼200ms) is typically much larger than T_{drx_doze} (∼30ms) in reality, the ON period between wakeup from the doze mode and the data packet is unnecessary.

`LRP`'s approach `LRP` prioritizes latency over marginal energy waste with proper timing control. Instead of frequent *rouser*s in naive solutions, `LRP` only sends a *rouser* for the time T_{drx_doze} in advance. We thus keep updating the maximum T_{drx_doze}, denoted as $T_{drx\_doze\_max}$. The timing to send the *rouser* is $t_r = T_{drx\_doze\_max}$. If the device enters the ON period during doze, i.e. $t_r > T_{drx\_doze}$, the *rouser* finishes dozing before the data packet arrives, thus eliminating the doze latency for the data packet. It is also likely that T_{drx_doze} for a *rouser* exceeds t_r. In this case, the packet enters the buffer and endures the dozing latency together with the *rouser*. Although the doze latency is not eliminated, the *rouser* reduces it by t_r.

5.2 Resource-Efficient Proactive Scheduling

`LRP` next seeks to mask the round trips of the scheduling in §3.2.2 for the mobile app. The idea is to send a scheduling request (SR) *before* the arrival of the data, so that the data does not need to wait for the radio grants. As an application-layer solution, `LRP` cannot directly trigger the SR early (which requires modifying the firmware). Instead, it requests a grant from the BS in advance by sending a dummy message, named *prefetcher*. This is feasible since the grant is not tied with the packet that requests it. Moreover, since the BS responds to each SR regardless of the pending data size, a small dummy message can receive a grant that allows for much-larger-size transmission than itself, thus sufficing to accommodate the followup data packet transfer in a single transmission.

Similar to the DRX doze elimination in §5.1, an effective *prefetcher* also needs accurate timing control. As shown in Figure 6, imprudent timing can offset the latency reduction, and/or waste radio resources. We next discuss both naive solutions in Figure 6, and then show `LRP`'s approach.

Naive timing control A too early *prefetcher* might result in both resource waste and prolonged latency as shown in Figure 6(a). The *prefetcher* is sent too early so that the timing to use the returned grant is already passed when the data packet arrives. The resource is thus wasted, while the data packet misses the opportunity to reduce its scheduling latency.

Similarly, a late *prefetcher* could also miss the opportunity to reduce the scheduling latency for the data packet, as shown in Figure 6(b). If the *prefetcher* is sent too late after a potential SR that could reduce latency, the data packet might have to wait for scheduling latency as if no *prefetcher* is issued. In the worst case for both early and late *prefetcher*, it may result in missed latency savings up to $T_{sr\_periodicity} + T_{sr\_grant}$.

`LRP`'s approach `LRP` aims at reducing the scheduling latency at marginal radio resource cost. Let a *prefetcher* be sent t_p before the data packet. The parameter t_p must meet two requirements. First, we should ensure $t_p \geq T_{sr\_grant}$. Note that, an SR can only request a grant to be used at T_{sr_grant} after the SR. Therefore, $t_p \geq T_{sr\_grant}$ guarantees that the SR is sent only if it helps to reduce the scheduling latency for the data packet. Second, we must ensure $t_p \leq T_{sr\_grant}$. This is to let the requested grant be used to transmit the data packet. No resource waste or premature SR is incurred.

Consequently, our timing design is to set the time advance as $t_p = T_{sr\_grant}$, which meets both requirements. Note that T_{sr_grant} is typically constant for a BS, being the accumulative latency of SR processing latency + 4ms, where 4ms is a standardized parameter in [1]. In our experiment, more than 96.5% of T_{sr_grant} is identical under a BS regardless of the carrier. If T_{sr_grant} changes after handover to a new BS, we update T_{sr_grant} immediately. Even if T_{sr_grant} may vary, our solution is no worse than the current practice.

Impact of the data packet size A *prefetcher* helps reduce scheduling latency if the data packet size ≤ grant - *prefetcher* size, which is common in reality as >99% of initial grants in our experiments exceed 100B in all operators, while the uplink sensory data is smaller than half of that. Therefore, a *prefetcher* initiates an SR, and gets a returned grant that suffices for the data packet to be sent with the *prefetcher*.

However, a corner case arises when the grant in response to SR is enough for the data packet, but not for a *prefetcher* + the data packet. As shown in Figure 7(b), the device could only send the *prefetcher* and a portion of the data packet. A BSR further requests a grant for the remaining data. The data packet thus suffers extra BSR latency compared to the case without *prefetcher* (Figure 7(a)). In the worst-case scenario, this latency increases by T_{sr_grant} (∼8ms). We discuss the

probability of this case in Appendix B. However, even in this corner case, the worst case happens only when the data and the *prefetcher* arrive in the same SR period, with probability T_{sr_grant}/T_{sr_wait}. For other conditions in the corner case, the latency is the same as vanilla LTE.

5.3 Handling the Conflicts for Low Latency

LRP further resolves several conflicts for overall latency reduction. Figure 8 illustrates the workflow of LRP. Let $T_{interval}$ be the time interval between the last and the next expected packet. LRP thus reduces various latency elements. It handles improper interplay between latency elements, and between dummy and data packets.

5.3.1 Conflict Resolution Between Latency Elements

LRP issues two types of dummy packets for latency reduction: *rouser*s for DRX-induced doze latency, and *prefetcher*s for scheduling latency. Figure 9(a) illustrates their conflicts. A *rouser* itself is a dummy message that needs to be sent before a *prefetcher*. Once turning the device to DRX ON, it asks for the grant, which could carry both *rouser* and *prefetcher*. Therefore, the *prefetcher* is sent by the grant requested by the *rouser*. The grant-induced scheduling latency is not reduced at all. The latency penalty can be as large as $T_{sr\_periodicity} + T_{sr\_grant}$ compared to no-conflict case in Figure 9(b).

To resolve this conflict, we refine the timing control to ensure both dummy packets' effectiveness. Specifically, we should make sure a *rouser* is sent when a *prefetcher* hits the device buffer, so that the *prefetcher* can take effect and reduce the scheduling latency. A *rouser* takes at most $T_{sr\_periodicity} + T_{sr\_grant}$ to be sent out as a dummy message and a *prefetcher* needs to be sent T_{sr_grant} before the data packet. Therefore, we adapt the timer from $t_p = T_{drx\_doze\_max}$ to $T_{drx\_doze\_max} + T_{sr\_periodicity} + 2T_{sr\_grant}$ to ensure a *rouser* is sent before a *prefetcher*. The *rouser* thus endures $T_{drx\_doze\_max}$ that guarantees the doze is completed and then sent out.

5.3.2 Conflict Avoidance Between Dummy and Data

The next conflict arises between LRP's dummy packets and the last legitimate data packet. If a *rouser* conflicts with the last packet, this does not pose an issue: the *rouser* can still help the device to remain in the ON period for $T_{inactivity\_timer}$. We thus only discuss where a *prefetcher* intervenes with the last packet. We show how LRP adapts this for latency reduction.

There are two instances when a *prefetcher* arrives in the buffer *before* the last data packet being completely sent out, shown in Figure 10. In case (a), the *prefetcher* does not provide any latency reduction. The grant for the last packet has enough room to carry the *prefetcher*, which will be sent together. There is no *prefetcher*-requesting grant for the next data packet. In case (b), a *prefetcher* may increase the latency. The grant for the last data packet cannot accommodate the piggy-backed transmission of the *prefetcher*. A BSR request is thus triggered by the device to request for more grants. Since BSR specifies the size for the dummy message *prefetcher*, the returned grant does not suffice to transmit the data packet. This subsequently invokes another round of BSR-grant operations. The data packet might suffer from extra BSR latency.

To avoid the conflicts, LRP adjusts the timing of a *prefetcher*. It leaves enough time for the last packet to complete its transmission before the *prefetcher*. Recall that the theoretical maximum uplink latency that the last packet would experience after optimization is T_{sr_grant}. The dummy *prefetcher* is then sent at least T_{sr_grant} after the application sent its last packet. Specifically, if the time gap (between the last packet arrival and the next packet arrival) is larger than $2T_{sr\_grant}$, we send a *prefetcher* T_{sr_grant} before the next packet. This is the timing we designed in §5.2; it will not break the above condition. Otherwise, we send a *prefetcher* T_{sr_grant} after the last packet. This choice will reduce less latency compared to the timing in §5.2 without conflicts. However, we avoid the cases of Figure 10, where a conflict negatively affects the latency.

5.4 Rootless Inference of Critical Parameters

As shown in §5.1–5.3, LRP relies on knowing certain LTE parameters for latency reduction. Obtaining such parameters through the root privilege can definitely work. However, such an approach limits the applicability of LRP. To let LRP work with *every* commodity device, we seek to infer these parameters at the application layer. Note that existing tools typically require system privilege (e.g., MobileInsight [32]) or additional hardware (e.g., QXDM [41]).

To infer these critical LTE timers, LRP exploits packet pairs for probing. Figure 11 shows the general procedure. LRP sends two adjacent probing requests and records their interval t_1. Upon receiving the responses to both packets, LRP compares the responses' intervals t_2 with t_1, and estimates the corresponding timers. This approach is based on the premise that, the difference between t_1 and t_2 mainly arises from the different uplink LTE latency experienced by two packets. This premise largely holds in practice, because latency fluctuations from the base station are much larger than those in the core network or servers[2]. Compared with the conventional packet-pair technique, LRP customizes probing packets with the LTE

[2]We have validated this premise in operational LTE. We send a pair of DNS requests at $t_1 = 0$. A UL grant suffices to send both requests; they arrive at the BS simultaneously. t_2 is solely affected by the core network and DL. The results show that $t_2 < 1ms$ for >99% responses.

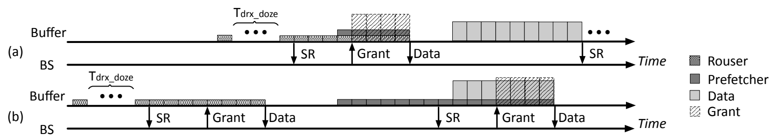

Figure 9: Improper timing control causes conflicts between components.

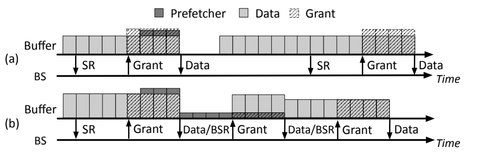

Figure 10: Conflicts: dummy msgs & data.

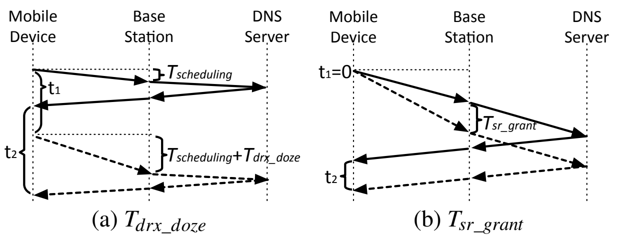

Figure 11: Inferring parameters at application layer.

domain knowledge for accurate inference.

Inferring DRX-related parameters To reduce DRX doze latency, LRP should know $T_{drx\_doze\_max}$ (§5.1). Recall that the DRX doze latency is only present when the packet interval is large. The idea is to let t_1 be large enough so that the first response packet cannot keep the second request in DRX ON. The second packet in the pair experiences UL DRX doze latency, while the first does not as we immediately start next pair after one is done. We can thus use the interval difference $t_2 - t_1$ to infer DRX doze latency. Consider that two requests can also be different in terms of scheduling latency, we repeat the pair for 10 times and take the interval difference average. Figure 11(a) illustrates this procedure.

One caveat is that we need to know how large t_1 is so that the second request suffers from DRX doze latency. We increase the interval t_1 gradually until a certain spike appears in measured RTT for the second request, caused by DRX doze latency ($\approx$30ms as shown in §3). The time interval between the first response and the second request that triggers such spike infers $T_{inactivity\_timer}$. We can thus infer $T_{drx\_doze} = t_2 - t_1$. We take the max in multiple rounds as $T_{drx\_doze\_max}$.

Inferring scheduling-related parameters LRP needs T_{sr_grant} to reduce the scheduling latency (§5.2). Figure 11(b) shows how LRP infers it. We let t_1 as 0 by sending both requests together. As we just showed, the grant is sufficient for a single request packet. We increase the size of the second request so that the grant will not be sufficient for both request packets. According to the scheme, the first request experiences only scheduling latency while the second experiences the same scheduling latency plus T_{bsr_grant}, which equals to T_{sr_grant} under a same BS. We thus can derive LRP optimization parameter T_{sr_grant} from the measured t_2 as $T_{sr\_grant} = t_2$.

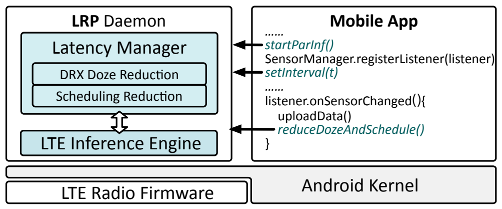
5.5 Miscellaneous Issues

Energy Analysis LRP incurs extra energy overhead from four sources. First, transmitting a *rouser* incurs a longer ON period. The time to send a *rouser* can be as long as $T_{sr\_periodicity} + T_{sr\_grant}$. It incurs $T_{sr\_periodicity}/2 + T_{sr\_grant}$ on average. Second, T_{drx_doze} is not predictable so we select $T_{drx\_doze\_max}$ to prioritize latency over energy. The extra ON period is $\delta = T_{drx\_doze\_max} - T_{drx\_doze}$ for each *rouser*. If the packet arrives during DRX OFF, $T_{drx\_doze\_max}$ equals to T_{drx_doze} and $\delta = 0$. Otherwise, $T_{drx\_doze} = 0$ and $\delta = T_{drx\_doze\_max}$. The expectation of δ is thus $p_{on} \cdot T_{drx\_doze\_max}$, where p_{on} is the probability of a packet arriving during DRX ON period. If we ignore background traffic and assume the packet arrives in the buffer at a random time, p_{on} = onDurationTimer / DRX cycle. Third, an early *rouser* (due to inaccurate estimation) also causes a longer ON period. Denote ε as the estimation error. When the *rouser* arrives during DRX OFF, the extra ON period is ε. Otherwise, ε incurs no extra ON period. Finally, sending extra small messages incurs extra energy waste.

Impact on the spectrum efficiency For every data packet, we define its spectrum efficiency $SE = \frac{\text{sizeof (data packet)}}{\text{sizeof (Total UL resource granted)}}$. When a data packet suffers from doze latency and LRP sends a *rouser*, it reduces *SE* by half: the *rouser* and the *prefetcher* initiate two grants, while the legacy LTE only requests for one. The extra grant occupies $\approx$2 RB in commercial networks. LRP trades-off *SE* for low latency. When LRP sends a *prefetcher* only, two scenarios arise. In the normal case, the grant from SR can carry both the data packet and a *prefetcher*. Therefore, LRP requests no extra grant and *SE* is the same as the legacy LTE. In the corner case discussed in §5.2, the BS allocates at most sizeof (*prefetcher*) extra grant. One extra RB is thus wasted, since a single RB is sufficient to carry a *prefetcher*. *SE* is reduced by $\frac{\text{sizeof}(\textit{prefetcher})}{\text{sizeof}(\textit{prefetcher} + \text{grant from SR})}$. This value multiplying the probability of the corner case (see Appendix B) yields the expectation of *SE* reduction.

Impact of background traffic LRP still reduces latency in the presence of background traffic. No matter whether the background packet is sent before a *rouser* or between a *rouser* and a data packet, the *rouser* will keep the data packet at the DRX ON state, thus eliminating the DRX doze latency. On scheduling latency, if the background traffic is sent after the data packet, it does not affect the *prefetcher*. If the background traffic is in between, the *prefetcher* reduces its latency, which indirectly reduces latency for the real data packet. It still does not increase the latency compared to legacy LTE without LRP. When the background traffic is sent before a *prefetcher*, it will be sent out through BSR before the data packet in the worst case, equivalent to no optimization.

What if the uplink traffic is not strictly regular? While mobile sensors produce regular data packets, the actual uplink



```
......
startParInf()
SensorManager.registerListener(listener)
setInterval(t)
......
listener.onSensorChanged(){
    uploadData()
    reduceDozeAndSchedule()
}
```

Figure 12: Implementation of **LRP** in Android.

data packets might not be strictly periodic. This can be caused by mobile OS overhead, prediction inaccuracy, or sensor periodicity variance. LRP still guarantees no worse latency than legacy LTE, and saves LTE latency in most scenarios. We show the following Theorem 5.1 and prove it in Appendix C.

Theorem 5.1. For the data packet that should have arrived at $T_{interval}$ but actually arrives at T, LRP does not incur extra latency compared with the legacy 4G LTE.

LRP for non-regular traffic For those ML/AI apps of §2 with irregular but predictable uplink traffic, LRP works equally well. For others with irregular yet unpredictable uplink traffic, we do not recommend LRP for such apps. If users intend to use our APIs, latency reduction cannot be ensured.

Applicability to 5G In principle, LRP is applicable to 5G, which has three usage cases. Enhanced Mobile Broadband (eMBB) extends the current 4G technology. Massive Machine Type Communication (mMTC) is for cellular IoT devices. Its design is based on LTE-M and NB-IoT [8]. The scheduling mechanisms of both modes largely remain unchanged [3, 4]. LRP is still applicable. Ultra Reliable Low Latency Communications (URLLC) targets low-latency communication. The potential grant-free scheduling might partially achieve LRP's latency reduction, but LRP's DRX doze latency reduction will still help the URLLC applications.

Network impact LRP incurs little overhead on the network side. The overhead stems from processing extra signaling, which is marginal compared with normal operations. This is because the BS monitors the control and data channels continuously, regardless of whether it receives an SR.

Impact on other users If the devices under a BS all use LRP, they will still benefit from LRP. The core idea of LRP is to schedule a device's allocated resources in advance if its data arrival can be predicted. The procedure does not sacrifice other users' access in general. Moreover, if certain device does not adopt LRP, its latency may be slightly prolonged. This arises when the BS assigns the last available resource to an LRP user who advances its scheduling, while this resource could have been available to the non-LRP user. However, the impact is minimal, as the BS will serve the user the next subframe (in 1ms) and the throughput is not affected.

6 Implementation

We implement LRP as a standalone user-space daemon with Android NDK. A similar implementation is also feasible for iOS. Figure 12 shows its key components, including a latency manager for latency reduction with conflict resolution in §5.1–5.3, an inference engine that offers key parameters for LRP based on the solutions in §5.4, and a set of APIs for latency-sensitive applications. To use LRP, a latency-sensitive mobile app requests LRP service using its APIs as detailed below. At runtime, LRP first detects if the device connects to a new base station by checking the change of serving cell ID. Upon cell changes, LRP starts to infer the key LTE parameters for this new cell. Once the key parameters are obtained, LRP initiates its latency manager to reduce DRX doze latency in §5.1 and scheduling latency in §5.2, and resolves the conflicts in §5.3.

APIs LRP provides easy-to-use application-layer APIs for mobile application developers. Figure 12 showcases these APIs with a mobile VR application. The app first calls startParInf() so that LRP daemon starts and infers the LTE parameters relevant to latency reduction components. The daemon detects possible parameter changes (say, upon handover) and re-runs the inference procedure whenever necessary. As our VR application uploads periodic sensory data packets, it calls setInterval(t) to inform LRP such periodicity. Whenever a data packet is sent, the application calls reduceDozeAndSchedule() for LRP to reduce latency for the next packet.

Latency manager It realizes the latency reduction in §5.1–5.2 and conflict resolution in §5.3. A practical issue to realize them is to optimize the dummy packet's construction and delivery for low cost. Both *prefetcher* and *rouser* messages in LRP should be as small as possible so that extra data overhead is minimized. In addition, a smaller *prefetcher* will decrease the likelihood of the corner case discussed in §5.2. The smallest packet we could generate in the Android device without root is an ICMP ping packet with IP header only via system command. Our implementation issues only one small ICMP packet to the local gateway in LTE that serves the users.

LTE inference engine It infers the key LTE parameters for LRP's latency reduction based on the approaches in §5.4. We use DNS requests/responses as probing packets, which have low deployment cost (by using LTE's readily-available DNS servers) and higher accuracy (compared to other probing packets delivered with low priority such as ICMP). For DNS servers, LTE assigns its own in-network DNS server when the device attaches to it, which provides fast and stable service. We use such DNS servers for our experiment.

Moreover, we note that simply running the inference in §5.4 may be inaccurate in practice, since it is sensitive to the noises from background traffic, vendor-specific base station behaviors, and server load. To this end, we optimize our implementation to mitigate these noises and improve the inference accuracy. Specifically, we add a few filters to get rid of the noises. For instance, when measuring the scheduling-related parameters, we know that T_{rtt} should be greater than 4ms in reality, therefore, if the packet response pair is received within 4ms, we ignore this round of experiment.

7 Evaluation

We assess how LRP improves the overall latencies and QoEs for emergent mobile applications, evaluate the effectiveness of solution components in LRP, and quantify LRP's overhead.

Experimental setup We run LRP on Google Pixel, Pixel 2, Pixel XL, and Pixel 5. We quantify the latency reduction in both US and China over AT&T, Verizon, T-Mobile, Sprint, and China Mobile. The evaluation covers 375 unique cells. We repeat the tests in static, walking (∼1m/s), and driving (∼30mph) scenarios. We do experiments mostly in metropolitan areas while driving tests cover rural areas as well. The radio signal strength varies from -120 to -80dBm, covering good (>-90dBm), fair ([-105, -90dBm]), and bad (<-105dBm) conditions. To quantify LRP's latency reduction, we use MobileInsight [32] to extract the ground truth of fine-grained per-packet latency breakdown from the chipset.

To gauge LRP's impact on the network side, we build a USRP-based testbed. A server with Intel i7-9700k CPU and 32G RAM runs srsLTE [20] for the functions of core network and BS processing. A USRP B210 connects to the server and provides wireless access for the devices. We plug sysmoUSIM [47] into the test phones, and register them.

7.1 Overall Benefits for the Applications

We showcase LRP's latency reduction and QoE improvements with four representative emergent mobile applications:

◦ *Mobile VR.* We use the showcase VR game as described in §2. We measure the latency of the sensor data and control data, and use it to gauge how our design reacts to VR games.

◦ *Localization.* We write an Android app that uploads the periodic GPS location status to the cloud via the Android API [21]. We encode each location update in 22 bytes and send it to the cloud every second.

◦ *Object recognition.* We prototype an object recognition app using MobileNetV2 [43], a phone-based deep learning model. The app processes camera frames and uploads the recognition result to the cloud. The typical inference time is 250ms.

◦ *Gaming.* We evaluate its latency by replaying the traces from PUBG Mobile [40], one of the most popular multi-player online mobile games. Since PUBG traffic is not strictly regular, we use it to demonstrate the effectiveness of LRP as discussed in §5.5. We use the traffic emulator to send data packets based on the trace.

Overall LTE latency reduction Table 4 and Figure 13 show LRP's latency reduction for these apps in static settings with fair-good signal strength; other scenarios have similar results as detailed in §7.2. On average, LRP achieves 4-5ms (0.5-0.8×) latency reduction in mobile VR, 8-37ms (1.2-7.4×) reduction in localization, 8-29ms (1.0-5.6×) reduction in object detection, and 1-6ms (0.3-0.7×) reduction in gaming for all 5 LTE carriers. Our breakdown analysis further shows these apps suffer from different latency bottlenecks. For the localization and object detection, the majority of data packets suffer from both DRX doze and scheduling latency. For the VR and gaming with more frequent packets, the scheduling latency is the major latency bottleneck. LRP can reduce both bottleneck latencies and thus benefit all these applications.

QoE improvement To showcase the impact of LRP on the mobile VR, we conduct a user study with 10 participants to evaluate the subjective experiences of using VR with/without LRP. Figure 14 shows the average Mean Opinion Score (MOS) on three aspects: graphical visual quality, responsiveness, and overall experience. Participants rate 1 (Bad) to 5 (Excellent) on these three aspects of the VR game with constant head position changes. The results show that LRP can improve the visual quality by 8% (3.1→4.0), responsiveness by 63% (2.4→3.9), and overall experience by 46% (2.4→3.5).

5G latency reduction We evaluate how LRP reduces 5G latency under AT&T 5G network. Since we do not have access to its fine-grained data-plane traces, we measure RTT at the application layer. LRP reduces RTT by 4.6ms for Gaming, 20.5ms for Localization, and 19.8ms for Object Detection. The results are similar to the latency reduction in AT&T 4G.

7.2 Micro-Benchmarks

We next assess LRP's solution components under various signal strengths and user mobility patterns.

DRX-induced latency reduction (§5.1) As shown in §5.1, LRP helps reduce the DRX doze latency if the inter-packet interval larger than $T_{inactivity\_timer}$ (otherwise the DRX doze latency is always 0 with/without LRP). Figure 15 shows LRP's

Table 5: Scheduling latency (ms) in five mobile carriers. η=(Legacy-`LRP`)/`LRP`.

DRX latency reduction under various signal strengths and mobility patterns. We run this test under the most popular setting of $T_{inactivity\_timer}$ = 200ms (Table 3) when the inter-packet interval is $1.5 \cdot T_{inactivity\_timer}$. We also test other intervals and get similar results. In all scenarios, `LRP` reduces the DRX doze latency to 0 for all LTE carriers. This results in 21–41ms mean latency reduction and 40–57ms 95% latency reduction.

Scheduling latency reduction (§5.2) We next quantify the reduction in uplink scheduling latency. The latency reduction ratio, η, is defined as that of the reduced latency and the `LRP` latency. Table 5 shows the results in different carriers, signal strengths, and mobility patterns. In all these scenarios, `LRP` reduces the median scheduling latency by 0.3-2.5×, and reduces the 95th latency by up to 1.7×.

Conflict handling for latency reduction (§5.3) We confirm the effectiveness of `LRP`'s conflict resolution/avoidance. We adapt `LRP`'s APIs to enable/disable the conflict handling in §5.3. Table 6 compares the overall latency with/without `LRP`'s conflict handling. We first illustrate `LRP` can resolve *rouser* and *prefetcher* conflict. We use Localization as its traffic pattern satisfies the condition (long interval) for potential conflict. Compared with no conflict resolution, `LRP` reduces extra 8.82-60.0% latency in all operators. We next evaluate how `LRP` handles data and dummy packets conflicts. The heavy traffic in the Gaming application potentially causes such conflict. We run the Gaming application with `LRP` and the APIs without conflict avoidance. Compared with no conflict avoidance, `LRP` reduces up to 20% extra latency.

Accuracy of critical parameter inference (§5.4) We finally check how accurate our LTE parameter inference is.

Conflicts		AT&T	Ver.	T-M.	Spr.	C. M.

Infer $T_{drx\_doze\_max}$	3.0%	1.3%	3.0%	1.3%	2.5%

Table 7: Error rate of `LRP` parameter inference.

For each cell, we first collect ground truth by analyzing the physical/link/RRC-layer signaling messages from MobileInsight. We then use `LRP` component to infer the parameters and compare them with the ground truth. We calculate the average error rate in terms of inference. The results are shown in Table 7. As we can see, the inference error rate is at most 3.2% for both parameters in all 5 operators. `LRP` inference is accurate as argued in §5.4 and §6.

7.3 Overhead

Overhead of dummy messages The dummy messages may incur additional data usage and thus billing. Table 8 shows that `LRP` incurs no more than 0.6KB data per second under all carriers. The data overhead depends on the frequency of calling LRP APIs. For heavy traffic applications (VR, Gaming), the extra overhead is 0.33KB/s while the number for the other two apps is 0.05KB/s. The overhead is acceptable in typical data plans and the extra data is only incurred when `LRP` APIs are called. As explained in §6, `LRP` has minimized the use of dummy for efficient latency reduction.

	AT&T	Verizon	T-Mobile	Sprint	C. Mobile
Extra Data (KB/s)	0.20	0.15	0.41	0.23	0.60
Extra Sig. Msg	3.8%	3.7%	4.3%	3.3%	1.1%
Energy Overhead	1.7%	4.2%	5.8%	2.1%	4.7%

Table 8: Overhead of `LRP`.

Extra signaling message The dummy messages incur extra signaling between the device and the BS. We measure this overhead as shown in Table 8. LRP incurs up to 4.3% messages, which are marginal compared with the total volume of signaling messages. Reducing latency for apps with DRX doze generates more messages. LRP incurs on average 1.6 extra signaling messages per second for Location and Object Detection. While the other two apps with LRP generate 0.8 extra message every second on average.

Energy consumption While LRP exploits the DRX for lower latency, it still respects the LTE's energy saving with accurate timing control and incurs marginal energy cost. We first compare the percentage of the extra ON period with and without LRP. We track the CDRX events with MobileInsight. As shown in Table 8, for all carriers, at most 5.8% of extra ON period is invoked. Furthermore, we fully charge the device and run Object Detection (with DRX doze) and VR (no DRX doze) applications for one hour, and compare the energy consumption with or without LRP. With LRP, two applications incur 2.5% (16.12% to 16.52% of total battery) and 1.0% (37.04% to 37.40% of total battery) extra battery consumption, respectively. This overhead is marginal, as we adjust the timing of *rouser*s to reduce unnecessary energy waste.

Network impact We measure the network impact of LRP in our SDR testbed. Even in the absence of data transfer, the server spends 0.055ms on average to process the collected signal in every subframe (1ms). In contrast, processing LRP's extra signaling costs 0.002ms, about 3.6% extra overhead.

Impact on other users We next examine whether LRP affects those non-LRP users. We test a two-device scenario, with both running the Gaming app. Device A never uses LRP, whereas device B turns on/off LRP in the test. When B does not run LRP, A's average uplink network latency is 15.79ms, and the 95th percentile is 24.0ms. When B activates LRP, A's average latency becomes 15.84ms and the 95th percentile is 24.0ms. Both numbers are not visibly affected. Therefore, the latency of non-LRP device is not affected, regardless of whether the other runs LRP or not.

8 Related Work

Many cross-layer techniques have been designed to improve user experience and application performance in mobile networks (see [19] for a survey). They use lower-layer information to improve video streaming [54], to optimize Web access [12, 26, 34, 35, 51], to name a few. Most such solutions seek to boost the application-perceived throughput. Other recent proposals detect whether LTE is the bottleneck for applications [9], estimate the radio link speed [11], or examine how LTE configurations affect applications [25]. In contrast, we focus on devising LTE latency-oriented reduction solutions.

Early efforts are also made to reduce the LTE network latency. They analyze the latency for Web access over LTE [39, 53], devise application-specific solutions to LTE scheduling latency with modified modem firmware [48], measure the impact of DRX upon LTE from the energy perspective [23], and adjust the RRC parameters to reduce data-plane latency with infrastructure update [38]. Recent work [9, 30] also makes device-based throughput prediction for performance improvement. Our work differs from them since we work on the latency elements that cannot be eliminated with higher throughput. Authors from [16, 33] target reducing one-time connection setup latency, while LRP reduces latency elements for every data packet in the connected state. Other recent efforts seek to refine the 4G/5G network infrastructure [24, 37]. In contrast, we propose an effective solution without root privilege, device firmware change, or infrastructure upgrade.

9 Conclusion

Reducing latency is critical to many delay-sensitive applications, such as mobile AR/VR, mobile gaming, sensing, machine learning, and robot/drone-based image/speech recognition. In mobile networks like 4G LTE, reducing uplink latency is more challenging than its downlink counterpart, since it involves multiple latency elements stemming from power-saving, scheduling, on-demand resource allocation, etc.

We have designed and implemented LRP, a device-based solution to LTE latency reduction without any infrastructure changes. LRP does not require root privilege at the device and works with mobile apps directly. It ensures the network latency is no worse than the legacy 4G LTE, and is applicable to the upcoming 5G. By design, LRP uses small dummy messages with proper timing control and conflict handling, in order to eliminate unnecessary latency components from scheduling and power-saving operations. Our experiments have confirmed its effectiveness with a variety of mobile apps.

In the broader context, reducing latency poses a more challenging problem than improving throughput for the networked system community. In the mobile network domain, various tricks have been invented for boosting throughput (e.g., massive MIMO, more sophisticated modulation, mmWave, etc.). This is not the case for latency. Both its fundamental theory and effective practice are lacking. Moreover, exploring pure device-based solution, which does not require root privilege and has direct access to user application-level information, offers a nice complement to the infrastructure-centric design, which typically takes years to be deployed.

Acknowledgments We greatly appreciate our shepherd Dr. Lin Zhong and the anonymous reviewers for their constructive feedbacks and advices to help improve the quality of this work. We also thank Mr. Kaiyuan Chen and other members at UCLA WiNG for their early effort and feedback. This work is supported in part by NSF CNS-1910150 and CNS-2008026.

APPENDIX

A Notations

Notation	Explanation
T_{drx_doze}	The DRX Doze latency for an uplink packet between it enters buffer during DRX OFF and DRX enters ON state
$T_{drx\_doze\_max}$	The maximum doze latency T_{drx_doze} measured under a cell
T_{sr_wait}	The latency of waiting for an uplink scheduling request (SR)
T_{sr_grant}	The time difference between an SR and sending data using the requested grant
T_{bsr_grant}	The time between the first segment of a packet being sent and the last segment being sent through grants via BSR
T_{retx}	The latency of uplink packet retransmission
$T_{scheduling}$	$T_{scheduling} = T_{sr\_wait} + T_{sr\_grant}$
$T_{inactivity\_timer}$	A new data transmission will restart this timer and keep the device in DRX ON state until this timer expires
$T_{sr\_periodicity}$	The periodicity of subframes where a device can initiate an SR
$T_{interval}$	The time interval between the last and the next expected packet

Table 9: Notation table.

B Discussion on the Corner Case

The corner case happens when the grant from an SR is sufficient for the data packet, but insufficient for the data packet and its *prefetcher*. In this section, we discuss the size of the grant from an SR and the probability of this corner case.

Since the size of a data packet and a *prefetcher* is fixed, the occurrence of the corner case depends on the grant from an SR. The BS assigns a grant for the SR according to 3GPP standard [1]. However, it has the freedom to determine the size of the grant. It can assign certain RBs to the user. The number of the RBs is denoted as N_{PRB}. The RB amount is not sufficient to determine the grant size, which is also affected by the modulation index, denoted as I_{MCS}. A BS sends a grant with I_{MCS}, which is affected by channel condition, device power, etc. N_{PRB} can be selected from a subset of discrete values from {1, ...,110}, depending on the channel bandwidth. I_{MCS} can be selected from a subset of discrete values {0, ..., 63}, depending on the modulation capability of the device. Multiple I_{MCS} can map to the same modulation scheme. The UL data that can be sent using this grant is a function of both N_{PRB} and I_{MCS}. This discrete function, denoted as $F(N_{PRB}, I_{MCS})$, is shown in a 110x44 table in 3GPP 36.213 [1].

$F()$ is monotonically increasing with either N_{PRB} or I_{MCS}. Suppose the selection of N_{PRB} and I_{MCS} are independent. Let the probability of the BS selecting $P(N_{PRB} = j) = p_j$, where $j \in \{1, ..., 110\}$ and $\sum p_j = 1$. Similarly, let $P(I_{MCS} = i) = q_i$, where $i \in \{0, ..., 63\}$ and $\sum q_i = 1$. Let the size of the data packet be a and the size of a *prefetcher* be a'. $(j,i) \in X_1$ if $a \leq F(j,i) < a + a'$. Otherwise, $(j,i) \in X_2$ Therefore, $p_{corner} = \sum_{(j,i)\in X_1} p_j \cdot q_i$.

From the operational traces, a BS tends to assign $N_{PRB} = 2$ or 3 in response to an SR. When $N_{PRB} = 2$, any $I_{MCS} \geq 3$ can guarantee $F(N_{PRB}, I_{MCS}) > 100$. When $N_{PRB} = 3$, any $I_{MCS} \geq 2$ can guarantee $F(N_{PRB}, I_{MCS}) > 100$. In our experiments, >99% of initial grants exceed 100B in all operators. This is sufficient for a small uplink sensory data packet and a small *prefetcher* message.

C Proof for Theorem 5.1

Proof. LRP operates based on the value of $T_{interval}$. When $T_{interval} \geq T_{inactivity\_timer}$, LRP sends a *rouser* to eliminate DRX doze latency. When the next packet arrives later than expected ($T > T_{interval}$), LRP is still very likely to reduce DRX doze latency as the *rouser* sent T_{drx_doze} before the next packet will keep the device in ON state for $T_{inactivity\_timer}$. Therefore, as long as $T \leq T_{interval} - T_{drx\_doze} + T_{inactivity\_timer}$, LRP still reduces DRX doze latency. If $T > T_{interval} - T_{drx\_doze} + T_{inactivity\_timer}$, the device might have already turned to DRX OFF when the next packet arrives. In this situation, the DRX doze latency still exists but LRP does not add extra latency source. Similarly, when the next packet arrives early ($T < T_{interval}$), LRP still reduces doze latency when the *rouser* precedes the data packet, namely $T \geq T_{interval} - T_{drx\_doze}$. LRP cannot eliminate the entire DRX doze latency as the optimal solution, but can still reduce doze latency to $T - (T_{interval} - T_{drx\_doze})$. Otherwise, LRP does not send any *rouser* and the latency is the same compared to no LRP. In summary, if the next packet actually arrives in T where $T_{interval} - T_{drx\_doze} \leq T \leq T_{interval} - T_{drx\_doze} + T_{inactivity\_timer}$, LRP still eliminates or reduces the DRX doze latency. The margin allowed for error (T_{drx_doze} and $T_{inactivity\_timer} - T_{drx\_doze}$) can be 30-80ms in reality depending on common LTE parameters. Otherwise, LRP does not increase the latency.

When $T_{interval} < T_{inactivity\_timer}$, LRP sends a *prefetcher* only (T_{sr_grant} before the next packet) to reduce scheduling latency. If data arrives later, the *prefetcher* is still possible to save its latency if its requested grant can be used by the next packet, which is $T < T_{interval} + T_{sr\_wait}$. Similarly, if data arrives earlier, the *prefetcher* reduces scheduling latency if it is sent before the real data packet, i.e., $T > T_{interval} - T_{sr\_grant}$. When the next scheduled packet arrives in $T_{interval}$ where $T_{interval} - T_{sr\_grant} < T < T_{interval} + T_{sr\_wait}$, LRP still reduces the LTE uplink scheduling latency. This margin allowed for error (T_{sr_grant} and T_{sr_wait}) is usually 8-20ms in reality depending on LTE parameters. Otherwise, the scheduling latency is not reduced but LRP does not incur extra latency. □

BMC: Accelerating Memcached using Safe In-kernel Caching and Pre-stack Processing

Abstract

In-memory key-value stores are critical components that help scale large internet services by providing low-latency access to popular data. Memcached, one of the most popular key-value stores, suffers from performance limitations inherent to the Linux networking stack and fails to achieve high performance when using high-speed network interfaces. While the Linux network stack can be bypassed using DPDK based solutions, such approaches require a complete redesign of the software stack and induce high CPU utilization even when client load is low.

To overcome these limitations, we present BMC, an in-kernel cache for Memcached that serves requests before the execution of the standard network stack. Requests to the BMC cache are treated as part of the NIC interrupts, which allows performance to scale with the number of cores serving the NIC queues. To ensure safety, BMC is implemented using eBPF. Despite the safety constraints of eBPF, we show that it is possible to implement a complex cache service. Because BMC runs on commodity hardware and requires modification of neither the Linux kernel nor the Memcached application, it can be widely deployed on existing systems. BMC optimizes the processing time of Facebook-like small-size requests. On this target workload, our evaluations show that BMC improves throughput by up to 18x compared to the vanilla Memcached application and up to 6x compared to an optimized version of Memcached that uses the SO_REUSEPORT socket flag. In addition, our results also show that BMC has negligible overhead and does not deteriorate throughput when treating non-target workloads.

1 Introduction

Memcached [24] is a high-performance in-memory key-value store used as a caching-service solution by cloud providers [1] and large-scale web services [5, 40]. Memcached allows such services to reduce web request latency and alleviate the load on backend databases by using main memory to store and serve popular data over the network.

Memcached, however, is prone to bottlenecks introduced by the underlying operating system's network stack, including Linux's [16, 36], since the main goal of general purpose operating systems is to provide applications with flexible abstractions and interfaces. To achieve high throughput and low latency, user applications can give up using the standard kernel interfaces by using kernel-bypass technologies such as DPDK [6] which allow an application to program network hardware and perform packet I/O from userspace. The application that has control of the network hardware is then responsible for implementing a network stack that fits its specific needs [14, 28]. However, kernel-bypass comes with drawbacks. First, it eliminates security policies enforced by the kernel, such as memory isolation or firewalling. Specific hardware extensions, i.e. an IOMMU and SR-IOV [15, 20], or software-based isolation are then required to maintain standard security levels. Second, kernel-bypass relies on dedicating CPU cores to poll incoming packets, trading off CPU resources for low latency. This prevents the cores from being shared with other applications even when the client load is low. Third, kernel-bypass requires an extensive re-engineering of the existing application in order to achieve high performance with a dedicated network stack.

In this paper, we propose BPF Memcached Cache (BMC) to address the kernel bottlenecks impacting Memcached. BMC focuses on accelerating the processing of small GET requests over UDP to achieve high throughput as previous work from Facebook [13] has shown that these requests make up a significant portion of Memcached traffic. Contrary to hardware-specific accelerators, BMC runs on standard hardware and thus can be deployed on infrastructure with heterogeneous hardware. BMC relies on a *pre-stack processing* approach that consists in intercepting requests directly from the network driver, before they are delivered to the standard network stack, and processing them using an in-kernel cache. This provides the ability to serve requests with low latency and to fall back to the Memcached application when a request cannot be treated by BMC. BMC can leverage modern network card features such as multi-queues to process multiple requests in parallel (see Figure 1). In addition, BMC uses a separate lock for each cache entry to introduce minimal overhead and allow performance to scale with the number of cores.

Running BMC at the kernel level raises safety issues as a bug in its implementation could put the entire system at risk. To address this issue, BMC is implemented using eBPF. The Berkeley Packet Filter (BPF) [37], and its extended version, eBPF, is a bytecode and a safe runtime environment offered by the Linux kernel to provide userspace an approach to inject code inside the kernel. The Linux kernel includes a static analyzer to check that the injected code is safe before it can be executed, which limits the expressiveness of the injected code. We show how to circumvent this limitation by partitioning complex functionality into small eBPF programs and by bounding the data that BMC processes. Using eBPF also allows BMC to be run without requiring any modification to the Linux kernel or to the Memcached application, making it easy to deploy on existing systems. The eBPF bytecode of BMC is compiled from 513 lines of C code and is JIT compiled by the Linux kernel. This results in BMC introducing very little overhead into the OS network stack.

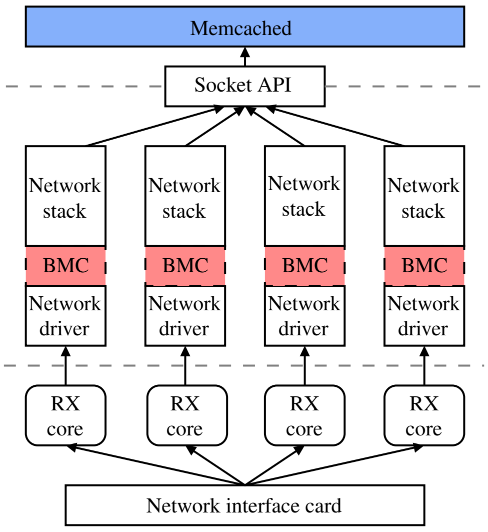

Figure 1: General architecture

The main results of this paper include:

- The identification of the bottlenecks of Memcached when processing requests over UDP. We propose MemcachedSR, a modified version of Memcached that uses the SO_REUSEPORT socket option to scale with the number of threads, improving throughput by 3x compared to the vanilla Memcached.
- The evaluation of BMC under our target workload consisting of small requests. In this setting, BMC improves the throughput by up to 6x with respect to MemcachedSR and by up to 18x with respect to vanilla Memcached.
- The evaluation of BMC under a non-target workload that consists of large requests not processed by BMC. In this setting, BMC has negligible overhead and does not deteriorate throughput with respect to MemcachedSR.
- The comparison of BMC with a dummy cache that shows that BMC's design is well suited for high throughput performance as it does not introduce unnecessary complexity.
- The comparison of Memcached running with BMC against a Memcached implementation based on Seastar, a networking stack for DPDK [6]. Our results show that Memcached with BMC achieves similar throughput to Seastar but uses 3x less CPU resources.

The rest of this paper is organized as follows. Section 2 provides background on Memcached and the OS network stack bottlenecks it suffers from. Section 3 describes BMC and its design. Section 4 discusses implementation details. Section 5 presents the experimental results. Section 6 discusses the generalization of BMC and its memory allocation challenges. Section 7 presents related work. Finally, Section 8 concludes the paper.

2 Background and motivation

This section describes the limitations of Memcached that motivate our work, and describes the eBPF runtime used to implement BMC.

2.1 Memcached

Memcached [10] is a mature in-memory key-value store traditionally used as a cache by web applications in a datacenter environment to speed up request processing and reduce the load on back-end databases. Because of its popularity, a lot of work has been put into optimizing it [35, 44].

A Memcached server operates on *items*, which are objects used to store a key and its associated value and metadata. Clients send requests to a Memcached server using a basic command-based protocol, of which GET and SET are the most important commands. A GET *key* command retrieves the value associated with the specified key if it is stored by Memcached and a SET *key value* command stores the specified key-value pair. A GET command can also be used as a multiget request when a client needs to retrieve multiple values at once. Requests can be sent using either the TCP or the UDP transport protocol.

The data management of Memcached has been well optimized and relies on slab allocation, a LRU algorithm and a hash table to allocate, remove and retrieve items stored in memory. Previous studies [16, 30] have shown that Memcached performance and scalability are heavily impaired by OS network stack bottlenecks, especially when receiving a large number of small requests. Since Facebook's production workloads show a 30:1 distribution between GET and SET commands, Nishtala et al. [40] proposed using UDP instead of TCP for GET commands to avoid the cost of TCP processing.

To gain additional insight into the performance of a Memcached server using UDP to receive GET requests, we profiled the CPU consumption while trying to achieve maximum throughput (the experimental setup is described in Section 5). As shown in Figure 2, more than 50% of Memcached's runtime is spent executing system calls. Moreover, the CPU usage of both sys_recvfrom and sys_sendmsg increases as more threads are allocated to Memcached. When eight threads are used by Memcached, the total CPU usage of these three system calls reaches 80%.

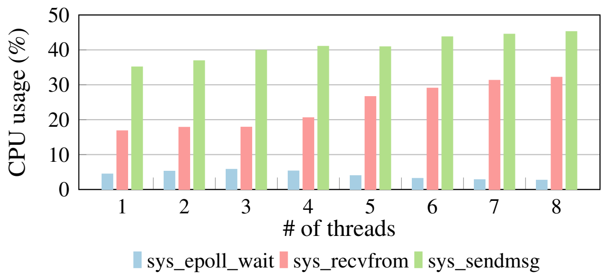

Figure 2: CPU usage of the three most used system calls by Memcached

Figure 3 shows the throughput of the vanilla Memcached application when varying the number of threads (and cores). The results show that vanilla Memcached does not scale and that its performance even deteriorates when more than four threads are used. Table 1 shows the top ten most time consuming functions measured by the *perf* tool while running Memcached with eight threads, all of them are kernel functions. The *native_queued_spin_lock_slowpath* and *__udp_enqueue_schedule_skb* functions account for a total of 28.63% of the processing time of our machine under test and are used to push packets to the UDP socket queue. The kernel's socket queues are data structures shared between the Memcached threads and the kernel threads responsible for the execution of the network stack, and therefore require lock protection. In the case of Memcached, a single UDP socket is used and its queue is shared between the cores receiving packets from the NIC and the cores running the application, leading to lock contention. This lock contention is then responsible for the decrease in Memcached throughput.

To allow Memcached to scale with the number of threads, we have modified the version 1.5.19 of Memcached to use the SO_REUSEPORT socket option. The SO_REUSEPORT option allows multiple UDP sockets to bind to the same port. We refer to this modified Memcached as *MemcachedSR* in the rest of the paper. We use this option to allocate a UDP socket per Memcached thread and bind each socket to the same port. Received packets are then equitably distributed between each socket queue by the Linux kernel which reduces lock contention. As shown in Figure 3, MemcachedSR scales with the number of threads and achieves a throughput that is up to 3 times higher than the vanilla version of Memcached.

Despite the scalability of MemcachedSR, there is still room for improvement as Memcached requests still have to go through the whole network stack before they can be processed by the application.

Function	% CPU utilization
native_queued_spin_lock_slowpath	17.68%
__udp_enqueue_schedule_skb	10.95%
clear_page_erms	5.04%
udp4_lib_lookup2	3.23%
_raw_spin_lock	3.04%
fib_table_lookup	2.90%
napi_gro_receive	2.27%
nfp_net_rx	1.97%
i40e_napi_poll	1.32%
udp_queue_rcv_one_skb	1.14%

Table 1: Top ten most CPU-consuming functions on a Memcached server under network load

2.2 eBPF

The Berkeley Packet Filter (BPF) [37] is an in-kernel interpreter originally designed to run packet filters from userspace using a reduced instruction set. BPF has evolved into the extended BPF (eBPF), which introduces a new bytecode and just-in-time compilation for improved performance. An eBPF program can be loaded from userspace by the Linux kernel and triggered by a specific kernel event. The eBPF program is then run whenever the event is triggered.

eBPF programs can maintain and access persistent memory thanks to kernel data structures called *BPF maps*. Maps are designed to store arbitrary data structures whose size must be specified by the user application at creation time. They can be used for communicating between different eBPF programs or between eBPF programs and user applications. Furthermore, eBPF programs can call a restricted set of kernel functions, called helpers, allowing eBPF programs to interact with the system and access specific kernel data (e.g. map data, time since boot up). *Tail calls* allow an eBPF program to call another eBPF program in a continuation-like manner. The eBPF bytecode backend is supported by the Clang/LLVM compiler toolchain, which allows using the C language to write eBPF programs in a high-level language.

Because running user-space code inside the kernel can impact the system's security and stability, the Linux kernel calls the in-kernel eBPF verifier every time it loads an eBPF program to check if the program can be safely attached and executed. The goal of the verifier is to guarantee that the program meets two properties: safety, i.e., the program neither accesses unauthorized memory, nor leaks kernel information, nor executes arbitrary code, and liveness, i.e., the execution of the program will always terminate.

To analyze an eBPF program, the verifier creates an abstract state of the eBPF virtual machine [9]. The verifier updates its current state for each instruction in the eBPF program, checking for possible out-of-bounds memory accesses or jumps. All conditional branches are analyzed to explore all possible execution paths of the program. A particular path is valid if the verifier reaches a *bpf exit* instruction and the verifier's state contains a valid return value or if the verifier reaches a state that is equivalent to one that is known to be valid. The verifier then backtracks to an unexplored branch state and continues this process until all paths are checked.

Because this verification process must be guaranteed to terminate, a complexity limit is enforced by the kernel and an eBPF program is rejected whenever the number of explored instructions reaches this limit. Thus, the verifier incurs false positives, i.e. it can reject eBPF programs that are safe. In Linux 5.3, the kernel version used to implement BMC, this limit is set to 1 million instructions. Other parameters, such as the number of successive branch states, are also used to limit path explosion and the amount of memory used by the verifier. Since Linux 5.3, the verifier supports bounded loops in eBPF programs by analyzing the state of every iteration of a loop. Hence, the verifier must be able to check every loop iteration before hitting the previously-mentioned instruction complexity limit. This limits the number of loop iterations as well as the complexity of the instructions in the loop body. Moving data of variable lengths between legitimate memory locations requires a bounded loop and conditional instructions to provide memory bounds checking, which in turn increase the complexity of an eBPF program. Finally, eBPF does not support dynamic memory allocation, instead eBPF programs have to rely on eBPF maps (array, hashmap) to hold a fixed number of specific data structures.

Because of all these limitations, eBPF is currently mostly used to monitor a running kernel or to process low-layer protocols of network packets (i.e. L2-L4). Processing application protocols is more challenging but is required to allow the implementation of more complex network functions [38].

3 Design

In this section, we present the design of BMC, a safe in-kernel accelerator for Memcached. BMC allows the acceleration of a Memcached server by caching recently accessed Memcached data in the kernel and by relying on a *pre-stack processing* principle to serve Memcached requests as soon as possible after they have been received by the network driver. This approach allows BMC to scale to multicore architectures by leveraging modern NIC's multi-queue support to run BMC on each individual core for each received packet. The execution of BMC is transparent to Memcached, and Memcached does not need any modification to benefit from BMC. In the rest of this section, we first present the pre-stack processing approach. We then describe the BMC cache and how its coherence is insured.

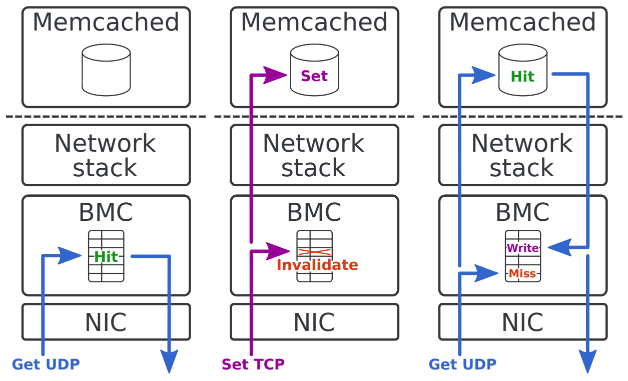
3.1 Pre-stack processing

BMC intercepts network packets at the network-driver level to process Memcached requests as soon as possible after they have been received by the NIC. BMC filters all network packets received by the network driver based on their destination port to only process Memcached network traffic. It focuses on processing GET requests using the UDP protocol and SET requests using the TCP protocol. Figure 4 illustrates how pre-stack processing allows BMC to leverage its in-kernel cache to accelerate the processing of Memcached requests.

When processing a GET request (4a), BMC checks its in-kernel cache and sends back the corresponding reply if it finds the requested data. In that case, the network packet containing the request is never processed by the standard network stack, nor the application, freeing CPU time.

SET requests are processed by BMC to invalidate the corresponding cache entries and are then delivered to the application (4b). After a cache entry has been invalidated, a subsequent GET request targeting the same data will not be served by BMC but rather by the Memcached application. BMC always lets SET requests go through the standard network stack for two reasons. First, it enables reusing the OS TCP protocol implementation, including sending acknowledgments and retransmitting segments. Second, it ensures SET requests are always processed by the Memcached application and that the application's data stays up-to-date. We choose not to update the in-kernel cache using the SET requests intercepted by BMC because TCP's congestion control might reject new segments after its execution. Moreover, updating the in-kernel cache with SET requests requires that both BMC and Memcached process SET requests in the same order to keep the BMC cache consistent, which is difficult to guarantee without a overly costly synchronization mechanism.

When a miss occurs in the BMC cache, the GET request is passed to the network stack. Then, if a hit occurs in Memcached, BMC intercepts the outgoing GET reply to update its cache (4c).



(a) Lookup (b) Invalidation (c) Update

Figure 4: BMC cache operations

Pre-stack processing offers the ability to run BMC on multiple cores concurrently. BMC can benefit from modern NIC features such as multi-queue and RSS to distribute processing among multiple CPU cores. The set of cores used to run BMC can also be fine-tuned in order to share a precise memory level (CPU caches, NUMA node, etc.). The performance of BMC can efficiently scale by configuring NICs to use multiple RX queues and mapping them to different cores. Pre-stack processing also enables running specialized code without having to modify existing software. Contrary to kernel-bypass, this approach does not require a whole NIC to be given to a userspace process and other applications can share the network hardware through the kernel network stack as usual.

3.2 BMC cache

The BMC cache is designed as a hash table indexed by Memcached keys. It is a direct-mapped cache, meaning that each bucket in the hash table can only store one entry at a time. BMC uses the 32-bit *FNV-1a* [21] hash function to calculate the hash value. Because this is a rolling hash function that operates on a single byte at a time, it allows BMC to compute the hash value of a key while parsing the Memcached request. The hash value is reduced to an index into the cache table by using the modulo operator. Each cache entry contains a valid bit, a hash value, a spin lock, the actual stored data, and the size of the data. This cache design offers constant-time complexity for lookup, insertion, and removal operations. To validate a cache hit, BMC checks that the valid bit of a cache entry is set and that the stored key is the same as that of the processed request.

The BMC cache is shared by all cores and does not require a global locking scheme since its data structure is immutable. However, each cache entry is protected from concurrent access using a spin lock.

4 Implementation

This section explains how BMC deals with the eBPF limitations to meet the required safety guarantees.

4.1 Bounding data

The verification of a loop contained in a single program may hit the maximum number of eBPF instructions the verifier can analyze. Loop complexity depends on the number of iterations and the complexity of the body. To make the verification of loops possible, BMC bounds the data it can process. It first limits the length of Memcached keys and values. BMC uses a loop to copy keys and values from a network packet to its cache, and vice-versa. For every memory copy, BMC must guarantee that it neither overflows the packet bounds nor overflows the cache memory bounds using fixed data bounds. Bounds checking then increases the loop complexity. To ensure the complexity of a single eBPF program does not exceed the maximum number of instructions the verifier can analyze, we empirically set the maximum key length BMC can process to 250 bytes and the maximum value length to 1000 bytes. Requests containing keys or values that exceed these limits are transmitted to the Memcached application. We also limit to 1500 the number of individual bytes BMC can read from a packet's payload in order to parse the Memcached data, bounding the complexity of this process. According to Facebook's workload analysis [13], about 95% of the observed values were less than 1000 bytes. Moreover, the Memcached protocol sets the maximum length of keys to 250 bytes. Hence, bounding the BMC data size does not have a big practical impact.

4.2 Splitting complex functions

In order to avoid reaching the limits of the eBPF verifier, BMC's functional logic is separated into multiple small eBPF programs, as each eBPF program is checked for safety independently. Each program then relies on *tail calls* to jump to the next program and continue packet processing without interruption. Linux limits the maximum number of successive tail calls to 33, preventing infinite recursion. However BMC uses at most three successive tail calls.

BMC is implemented using seven eBPF programs that are written in C code and are compiled to eBPF bytecode using Clang/LLVM version 9 and the default eBPF instruction set. The processing logic of BMC is split into two chains: one chain is used to process incoming Memcached requests and the other is used to process outgoing replies. Figure 5 illustrates how BMC's eBPF programs are divided. BMC's eBPF programs consist of a total of 513 lines of C code.

4.2.1 Incoming chain

The incoming chain is composed of five eBPF programs. It is attached to the XDP [27] driver hook and is executed

Program name	# of eBPF instructions	# of analyzed instructions	analysis time (µs)	# of CPU instructions
rx_filter	87	31 503	11 130	152
hash_keys	142	787 898	290 588	218
prepare_packet	178	181	47	212
write_reply	330	398 044	132 952	414
invalidate_cache	163	518 321	246 788	224
tx_filter	61	72	43	104
update_cache	125	345 332	95 615	188

Table 2: Complexity of BMC's programs. Column 2 represents the number of eBPF bytecode instructions of the program compiled from C code. Columns 3 and 4 respectively show the number of eBPF bytecode instructions processed by the Linux verifier and the time spent for this analysis. Column 5 shows the number of CPU instructions after JIT compilation.

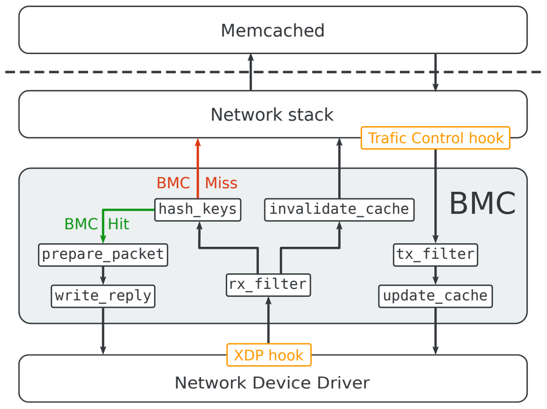


Figure 5: Division of BMC into seven eBPF programs

whenever a new packet is processed by the network driver. This hook is the earliest point in the network stack at which an eBPF program can be attached and allows BMC to use pre-stack processing to save the most CPU cycles by responding to Memcached requests as soon as possible.

rx_filter. The goal of this first eBPF program is to filter packets corresponding to the Memcached traffic using two rules. The first rule matches UDP packets whose destination port corresponds to Memcached's and whose payload contains a GET request. The second rule matches TCP traffic whose destination port also corresponds to Memcached's. The incoming chain branches based on which rule matches. If neither rule matches, the packet is processed by the network stack as usual.

hash_keys. This program computes hashes for every Memcached GET key contained in the packet. It then checks the corresponding cache entries for any cache hit or hash collision and saves the key hashes that have been hit in a per-cpu array used to store context data for the execution of the chain.

prepare_packet. This eBPF program increases the size of the received packet and modifies its protocol headers to prepare the response packet, swapping the source and destination Ethernet addresses, IP addresses and UDP ports. It then calls the last eBPF program of this branch of the chain. The maximum number of bytes BMC can add to the packet is limited by the network driver implementation. In our current implementation of BMC, this value is set to 128 bytes based on the different network drivers BMC attaches to, and it can be increased to a higher value to match other network driver implementations.

write_reply. This eBPF program retrieves a key hash saved in the per-cpu array to copy the corresponding cache entry to the packet's payload. If the table contains multiple key hashes, this eBPF program can call itself to copy as many items as possible in the response packet. Finally, this branch of the incoming chain ends by sending the packet back to the network.

invalidate_cache. The second branch of the incoming chain handles Memcached TCP traffic and contains a single eBPF program. This program looks for a SET request in the packet's payload and computes the key hash when it finds one to invalidate the corresponding cache entry. Packets processed by this branch of the incoming chain are always transmitted to the network stack so that Memcached can receive SET requests and update its own data accordingly.

4.2.2 Outgoing chain

The outgoing chain is composed of two eBPF programs to process Memcached responses. It is attached to the Traffic Control (TC) egress hook and is executed before a packet is sent to the network.

tx_filter. The first eBPF program of this chain serves as a packet filter and applies a single rule on outgoing packets. The rule matches UDP packets whose source port corresponds to Memcached's. In this case the second eBPF program of the chain is called, otherwise the packet is sent to the network as usual.

update_cache. The second eBPF program checks if the packet's payload contains a Memcached GET response. If positive, its key is used to index the BMC cache and the response data is copied in the corresponding cache entry. The network stack then carries on its execution and the Memcached response is sent back to the network.

Table 2 provides complexity metrics for each eBPF program. For the most complex ones, the number of eBPF instructions the Linux verifier has to analyze to ensure their safety is a thousand times higher than their actual number of instructions. The table also shows that it is necessary to divide BMC's logic into multiple eBPF programs to avoid reaching the limit of 1,000,000 instructions that can be analyzed by the Linux verifier.

5 Evaluation

In this section, we evaluate the performance of MemcachedSR running with BMC. We aim to evaluate the throughput gain offered by BMC and how performance scales with the number of cores when processing a target workload that consists of small UDP requests. We also evaluate MemcachedSR with BMC on a non-target workload to study the overhead and impact of BMC on throughput when it intercepts Memcached requests but does not cache them. We show that the increase in throughput can be obtained without allocating additional memory, and that the cache memory can be partitioned between the Memcached application and BMC. We compare BMC with a dummy cache implementation and show that its design is efficient for high performance. Finally, we compare MemcachedSR running with BMC to Seastar, an optimized networking stack based on DPDK. We study their performance using our target workload and a workload that uses both TCP and UDP requests. We also measure their CPU resource consumption for an equivalent client load and show that BMC allows saving CPU resources.

5.1 Methodology

Platform. Our testbed consists of three machines: one acting as the Memcached server under test, and two as the clients. The server machine is equipped with a dual socket motherboard and two 8-core CPUs (Intel Xeon E5-2650 v2 @ 2.60 GHz) with HyperThreading disabled, 48 GB of total memory and two NICs (one Intel XL710 2x40GbE and one Netronome Agilio CX 2x40GbE). The other two machines are used as clients to send traffic and are equipped with the same Intel Xeon CPU and an Intel XL710 2x40GbE NIC. One client is connected back to back to the server using its two network ports while the other client is connected using a single port. In total, the server machine uses three network ports to receive traffic from the clients. In all experiments, the server machine runs Linux 5.3.0.

Target workload and Method. Our target workload is the following: the client applications generate skewed workloads based on established Memcached traffic patterns [13]. Clients use a non-uniform key popularity that follows a Zipf distribution of skewness 0.99, which is the same used in Yahoo Cloud Serving Benchmark (YCSB) [19]. MemC3 [23] is an in-memory key-value store that brings carefully designed algorithms and data structures to Memcached to improve both its memory efficiency and scalability for read-mostly workloads. Similarly to the evaluations performed in the MemC3 paper, our workload consist of a population of 100 million distinct 16-byte keys and 32-byte values. By default, we allocate 10 GB of memory for the Memcached cache and 2.5 GB for the BMC cache. With this amount of memory, the Memcached cache can hold about 89 million items while the BMC cache can hold 6.3 million. Hence, some items can be missing from both the BMC and the Memcached cache. The memory allocated to both Memcached and BMC is not only used for keys and values but also stores metadata. For each cache entry in BMC, 17 bytes are used as metadata. Before each experiment, the clients populate Memcached's cache by sending a SET request for every key in the population. Note that this does not populate BMC's cache as it is only updated when the application replies to GET requests.

The client applications send requests at the rate of 12 million requests per second (Req/s) in an open-loop manner in order to achieve the highest possible throughput and highlight bottlenecks. A total of 340 clients are simulated to efficiently distribute requests among multiple cores on the server by leveraging the NICs' multi-queue and RSS features. We further refer to these cores as *RX cores*. We limit our evaluations to a maximum of 8 RX cores on a single CPU to enforce NUMA locality with the NICs.

Table 3 summarizes this target workload as well as other default evaluation settings that are used in the following experiments unless otherwise specified.

Key distribution	Zipf (0.99)
Key size	16 bytes
Value size	32 bytes
Key population	100 million
BMC to Memcached cache size ratio	25%
Number of Memcached application threads	8
Number of RX cores	8

Table 3: MemC3-like evaluation settings

5.2 Throughput

Target workload. We evaluate the throughput of Memcached under three configurations: vanilla Memcached alone, MemcachedSR alone and MemcachedSR with BMC. We also evaluate how these three configurations scale with the number of cores. We allocate the same CPU resources for all three configurations. For all configurations, we vary the number of threads the application uses to process requests simultaneously and dedicate cores to the application by pinning its threads. For MemcachedSR with BMC, we also vary the number of queues configured on each of the server's NICs and use the same cores to handle interrupts. This allows BMC to be executed by each core serving interrupts in parallel. For the vanilla Memcached application alone and MemcachedSR alone, 8 cores are used to execute the network stack.

Figure 6 shows the throughput achieved by these three configurations. As mentioned in Section 2.1, the vanilla Memcached application does not scale due to the socket lock contention; at best it achieves 393K requests per second using 4 cores. MemcachedSR offers better scalability and achieves 1.2M requests per second when using 8 cores. For MemcachedSR with BMC, the overall system throughput is split between requests answered using the BMC cache and requests handled by the application. When running on a single core, MemcachedSR with BMC achieves 1M requests per second, which is 6x the throughput of both vanilla Memcached and MemcachedSR. When BMC runs on 8 cores, the server achieves a throughput of 7.2M requests per second, 6.3 million being processed by BMC, the rest being processed by Memcached. This is 18x better performance with respect to vanilla Memcached and 6x with respect to MemcachedSR.

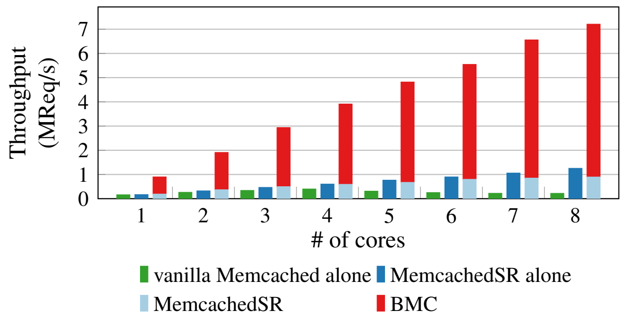

Figure 6: Throughput of BMC

Worst-case workload. We now change our workload to use 8KB Memcached values instead of 32 bytes. This is BMC's worst-case workload since the Memcached requests are still analyzed by BMC but the values are too large to be stored in its cache, thus the Memcached application is always used to serve the requests. To study the impact of the additional processing of BMC, we compare the throughput of the MemcachedSR application alone and that of the MemcachedSR application running with BMC. Figure 7 shows that BMC's additional processing has negligible overhead and does not significantly deteriorate the application throughput.

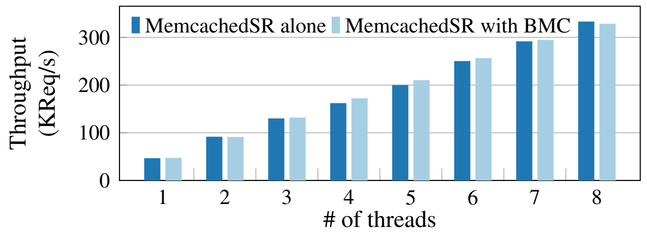

Figure 7: Throughput under a worst-case workload

We now modify the workload so that part of it are requests that BMC targets while the rest is for 8KB values. We then and evaluate how varying the ratio of the target requests affects throughput. As shown in Figure 8, BMC improves throughput by 4x compared to MemcachedSR alone when the workload consists of 25% of targeted requests even though it does not speed up the majority of requests received. This shows that BMC is valuable even when the workload contains few target requests and that BMC further improves throughput as the ratio of target requests increases.

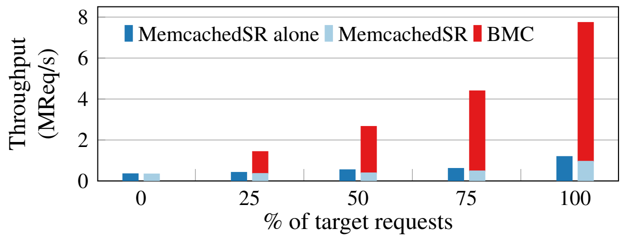

Figure 8: MemcachedSR vs. MemcachedSR with BMC throughput for varying request size distributions.

5.3 Cache size

We then evaluate the impact of BMC's cache size on throughput. In this experiment, we use a total of 10 GB of memory and split it between the Memcached cache and the BMC cache, varying the distribution from 0.1% of memory allocated to BMC to a maximum of 40%. The latter corresponds to a size of 4 GB for the BMC cache, which is the maximum size accepted by the Linux kernel for the allocation of a single eBPF map [7]. The results are shown in Figure 9 where the total system throughput is broken down into hits in the BMC cache, and hits and misses in the application cache. For all distribution schemes tested, there is an increase in performance compared to running MemcachedSR alone. The best throughput is achieved when BMC uses 25% of the total memory. In this case, the BMC cache size is well-suited to store the hottest items of the Zipf distribution. Throughput decreases from 25% to 40% because the Memcached cache hit rate shrinks from 89% to 43% as its cache gets smaller. This causes the BMC cache hit rate to diminish as well because only responses from Memcached cache hits allow entries of the BMC cache to be updated. When only 0.1% (10 MB) of the memory is used by the BMC cache, throughput is multiplied by 2.3 compared to the best throughput achieved by MemcachedSR alone, showing that BMC offers good performance even with minimal memory resources.

5.4 BMC processing latency

We now evaluate the overhead induced by a BMC cache miss, which characterizes the worst-case scenario since BMC processes a request and executes additional code that does not lead to any performance benefit. To characterize this overhead,

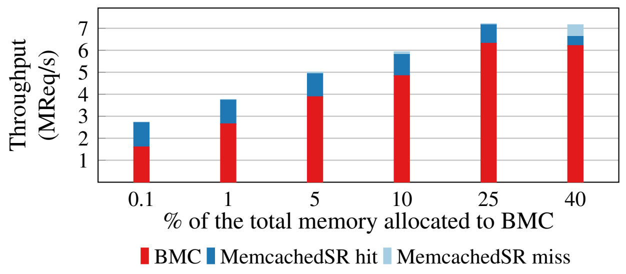

Figure 9: System throughput under various memory partition schemes

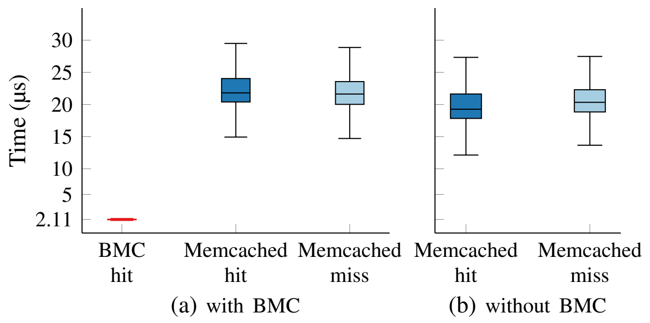

Figure 10: Time to receive, process and reply to a request.

we use *kprobes* to measure the total time required to receive, process and reply to a Memcached request. The *nfp_net_rx* and *nfp_net_tx* driver functions are respectively instrumented to record the time at which a request is received and the corresponding reply is sent back to the network. In this experiment, a single client machine is used to send requests to the server and a single Memcached key is used to ensure that a cache result is always either a hit or a miss. After sending a request, the client always waits for the server's reply to make sure the server does not process more than one request at a time.

Figure 10 shows the time distribution of 100,000 measurements for cache hits and misses separately. Figure 10a shows the distributions of MemcachedSR running with BMC as well as BMC hits. For Memcached hits, the valid bit of BMC's cache entries is never set to ensure BMC lookups result in a cache miss and that the request is always processed by the Memcached application. However, the BMC cache is still updated to measure additional data copies. The median of the distribution of BMC cache hits is 2.1 µs and that of Memcached cache hits and misses are respectively 21.8 and 21.6 µs. Hence, a BMC cache hit can reduce by 90% the time required to process a single request. Running the same experiment on MemcachedSR without BMC (Figure 10b) shows that the processing time of both Memcached hits and misses is lower by about 1 µs. This shows that BMC has a negligible processing overhead compared to the total time required for the execution of the Linux network stack and the Memcached application. Moreover, this additional processing time is entirely recovered by a single BMC cache hit.

Next we study the impact of the processing time of the kernel cache on its throughput. To do so we have implemented a dummy cache that always replies the same response and whose processing time can be parameterized using a empty loop. This dummy cache is implemented using a single eBPF program and is attached to the XDP network-driver hook just like BMC. Figure 11 shows the throughput of the dummy cache while varying its processing time and compares it with the actual BMC cache perfoming cache hits. This experiment demonstrates that the cache throughput is highly dependent on its processing time: increasing the processing time from 100 ns to 2000 ns decreases throughput by a factor of 4.5. The average time to perform a cache hit in BMC is fairly close to the time of the dummy cache with no additional processing time; this shows that choosing simple and fast algorithms for BMC's cache design introduces little processing overhead and contributes to its high throughput performance. Implementing overly complex algorithms may lead to a sharp drop in performance. Hence, adding new features to BMC, such as an eviction algorithm, must be well thought out to result in an improved hit rate that compensates for the additional processing time.

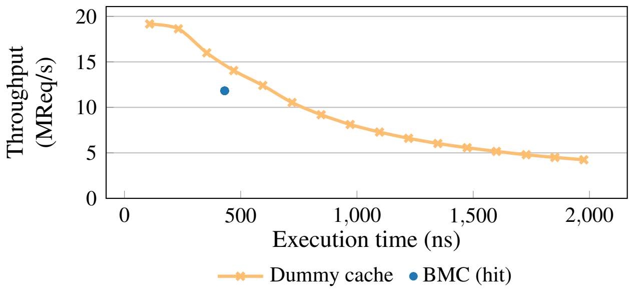

Figure 11: Execution time impact on throughput.

5.5 Impact on concurrent network applications.

As BMC intercepts every network packet before the OS network stack, its execution may have a performance impact on other networking applications running on the same host. To study this impact, we use *iperf* to transfer 10GB of data over TCP from one client machine to the server machine while serving Memcached requests, and measure the time required to complete this transfer. This experiment is conducted for MemcachedSR alone and MemcachedSR with BMC, while varying clients' request throughput. Figure 12 shows the results. When there is no load, the baseline transfer time is 4.43 seconds. When the Memcached load rises, the time required to complete the data transfers increases since the cores are busy processing incoming Memcached traffic in addition to the *iperf* traffic, which leads to an increase in TCP retransmission rate and UDP packet drops. When using BMC, the transfer time is lowered when the server is under load as CPU resources are saved when BMC processes Memcached requests in place of the application. For a Memcached load of 5000K Req/s, BMC allows *iperf* to complete its transfer 83% faster compared to the configuration in which Memcached processes the requests alone and the OS network stack is always executed.

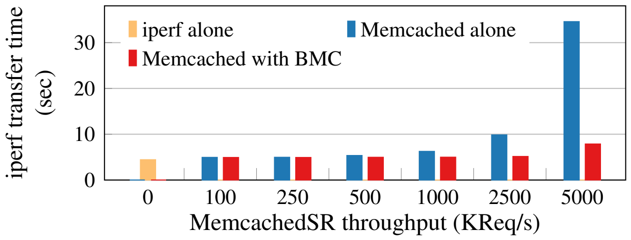

Figure 12: Time required to transfer 10GB of data using *iperf* under client load.

5.6 Kernel-bypass comparison

We now compare MemcachedSR with BMC against the Memcached implementation from Seastar [4] 20.05, a framework for building event-driven applications that comes with its own network stack built on top of DPDK.

Target workload. In this experiment, we evaluate the throughput of Seastar and compare the results with MemcachedSR running with BMC. We perform the experiment using a single client to generate our target UDP workload as Seastar does not support multiple network interfaces. This single client alone generates 4.5 million requests per second. Figure 13 shows the throughput of Seastar and MemcachedSR with BMC when varying the number of cores. BMC is able to process the workload generated by a single client machine using 4 cores. Using the same number of cores, Seastar achieves 443K requests per second. Seastar's throughput increases to 946K requests per second when using 8 cores. We are not sure why Seastar's throughput drops when using 2 cores; our investigations revealed that this only happens when Seastar receives UDP packets and that Seastar performs best when it processes Memcached requests over TCP.

Workload mixing UDP and TCP requests. As our preliminary investigation shows that Seastar performs best on TCP, we change our workload to send half of the Memcached requests with TCP while the other half keeps using UDP. This workload coincides with a Memcached deployment for which the protocol used by clients cannot be anticipated. Figure 14 shows that the throughput of both configurations scales with the number of cores. Seastar's high-performance TCP stack enables its Memcached implementation to process 2.3 million requests per second when using 8 cores. Accelerating the processing of UDP requests allows MemcachedSR with BMC

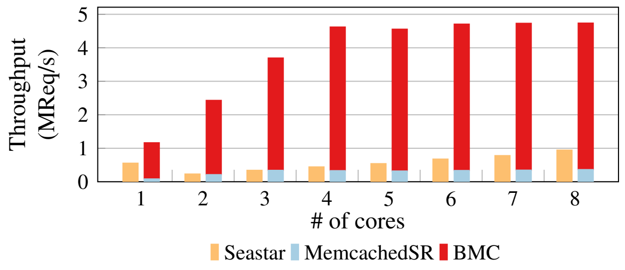

Figure 13: Seastar vs. BMC throughput

to achieve similar throughput when using 3 cores. Increasing the number of cores does not increase the throughput of MemcachedSR with BMC as the client TCP workload generation becomes the bottleneck.

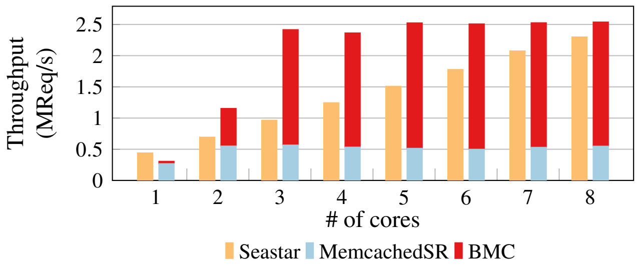

Figure 14: Seastar vs. BMC throughput when mixing TCP and UDP requests

CPU usage. We then measure the CPU usage of both MemcachedSR with BMC and Seastar for different client loads. In both configurations we use a total of 8 CPU cores to process the workload. For MemcachedSR with BMC, we use 6 RX cores and pin the Memcached threads to the two remaining cores. This configuration offers the best performance and allows us to measure the CPU usage of the Memcached application and the network stack (including BMC) separately. The CPU usage is measured on each core for 10 seconds using the *mpstat* tool. Figure 15 shows the average CPU core usage per core type (Seastar, MemcachedSR and BMC). The results show that Seastar always uses 100% of its CPU resources, even when throughput is low. This is because DPDK uses poll mode drivers to reduce the interrupt processing overhead when packets are received by the NIC. The CPU usage of MemcachedSR with BMC scales with the load thanks to the interrupt-based model of the native Linux drivers BMC builds upon. As shown in Figure 14, Seastar can process 2.3 million requests per second when using 8 cores, Figure 15 shows that MemcachedSR with BMC consumes 33% of the CPU (91% of the two Memcached cores and 13% of the six RX cores) to achieve similar throughput. Therefore, using Memcached with BMC saves CPU resources that can be used by other tasks running on the same system when the workload is low.

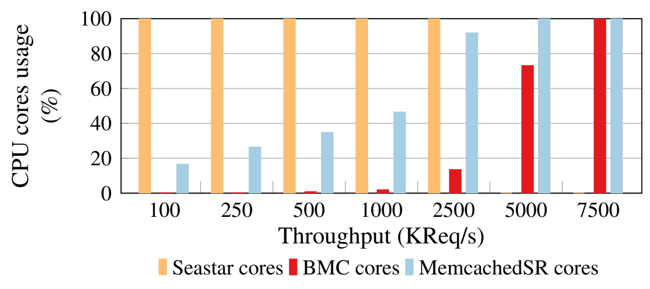

Figure 15: CPU usage of BMC compared to Seastar

6 Discussion

Although the BMC cache is fairly generic and can store any datatype, most of BMC is specialized to filtering and processing Memcached requests. Applying in-kernel caching to another key-value store like Redis [11] would then require specific eBPF programs to process Redis's RESP protocol. Because Redis requests are only transmitted over TCP, adapting BMC to Redis requires the support of the TCP protocol. This can be done by either sending acknowledgements from an eBPF program or reusing the existing TCP kernel implementation by intercepting packets past the TCP stack. As Redis is more focused on functionality and Memcached on performance, an in-kernel cache for Redis will require more eBPF programs to implement the minimal subset of Redis commands required to ensure cache coherence with the application. Just like BMC, some of the functionalities can be left to the application to focus on accelerating the most frequent request types. Redis usually performs worse than Memcached when processing a large volume of requests because it is single-threaded, hence we expect the throughput speed-up to be even higher than for Memcached.

Although static memory allocation enables the verification of BMC's eBPF programs, it also wastes memory. BMC suffers from internal fragmentation because each cache entry is statically bounded by the maximum data size it can store and inserting data smaller than this bound wastes kernel memory. The simplest approach to reduce memory fragmentation would be to fine-tune the bound of the cache entries to minimize the amount of fragmented memory. A more flexible approach would be to reuse fragmented memory to cache additional data. Each cache entry would then be able to store multiple data, making BMC a set-associative cache for which the number of slots varies according to the size of the stored data to reduce memory fragmentation. The fact that BMC is a non-exclusive cache also leads to memory loss since some data is duplicated between the BMC cache and Memcached. This duplication occurs for the majority of data that is not frequently accessed. On the other hand, frequently accessed data are eventually discarded from the application by Memcached's LRU algorithm because the BMC cache is used instead. Ideally, BMC should be able to directly access the application's cache memory to avoid any duplication, however, this requires browsing Memcached data structures which could create security vulnerabilities.

The XDP driver hook leveraged by BMC requires support in the NIC driver. With no XDP driver support, BMC can still be used with the generic Linux kernel hook but its performance will not be as high. However, this is not a critical concern as most of the drivers for high-speed network interfaces support XDP.

7 Related Work

This section discusses the most relevant related work in the field of optimization of the network stack and Memcached.

Programmable hardware switches. Recent advances in programmable hardware switches with languages like P4 [41] have raised significant interest on offloading network processing operations into the network. NetCache [29] implements an in-network key-value cache on Barefoot Tofino switches [12]. NetCache uses switch lookup tables to store, update and retrieve values. To access the key-value store, clients have to use a specific API to translate client requests into NetCache queries. Switch KV [32] and FlairKV [43] leverage programmable ASICs to implement a caching solution also acting as a load balancer. Switch KV uses an efficient routing algorithm to forward client queries to the right server. The OpenFlow protocol is used to install routes to cached objects and invalidate routes to recently modified ones. FlairKV accelerates GET queries by intercepting every SET query and the corresponding reply to detect unmodified objects. While these approaches leverage ASIC optimizations to offer high throughput and low latency, they consume switch memory, TCAM and SRAM, which is an expensive resource primary reserved for packet forwarding. Thus, using lookup table resources to store key-value data exposes the entire network to bottlenecks and failures.

FPGA and NIC offloading. Examples of key-value store applications offloaded to FPGA include TSSP [34] which implements part of the Memcached logic, i.e., the processing of GET requests over UDP, on a Xilinx Zynq SoC FPGA. A more complete FPGA Memcached implementation [17] supports processing of SET and GET requests over both TCP and UDP protocols. Similar work [18] deployed and evaluated an FPGA Memcached application within the public Amazon infrastructure. These approaches achieve high throughput with up to 13.2 million RPS with 10GbE link but they are constrained by the FPGA programming model, which requires replacing the Memcached protocol by more FPGA-compatible algorithms. KV-Direct [31] leverages Remote Direct Memory Access (RDMA) technology on NICs to update data directly on the host memory via PCIs. With this approach, KV-Direct alleviates CPU bottlenecks at the expense of PCI resources. NICA [22] introduces a new hardware-software co-designed framework to run application-level accelerators on FPGA NICs. NICA enables accelerating Memcached by serving GETs directly from hardware using a DRAM-resident cache and achieves similar performance to BMC since it still requires host processing to handle cache misses. NICached [42] proposes to use Finite State Machines as an abstract programming model to implement key-value store applications on programmable NICs. With this abstraction, NICached can be implemented with different languages and platforms: FPGA, eBPF, P4 and NPU-based NICs. NICached is the closest work to BMC but it targets NICs and does not propose an implementation of this model.

Compared to hardware approaches, BMC offers competitive performance, does not make use of expensive hardware resources such as SRAM and does not require hardware investment and software re-engineering.

Kernel-bypass. A kernel-bypass version of Memcached has been built on top of StackMap [46], an optimized network stack that achieves low latency and high throughput by dedicating hardware NICs to userspace applications. Using StackMap improves vanilla Memcached throughput by 2x in the most favorable scenario. MICA [33] employs a full kernel-bypass approach to process all key-value store queries in user space. MICA avoids synchronization by partitioning hash-maps among cores. MICA relies on a specific protocol that requires client information to map queries to specific cores and is not compatible with Memcached. To the best of our knowledge, MICA is the fastest software key value store application with a throughput of 77 million RPS on a dual-socket server with Intel Xeon E5-2680 processors. MICA is built with the DPDK library making MICA inherit most of DPDK's constraints: dedicated CPU cores to pull incoming packets, reliance on the hardware for isolation and requiring entirely re-engineering existing applications.

Compared to MICA, BMC achieves lower throughput but keeps the standard networking stack, does not implement any modification of clients and saves CPU resources.

Memcached optimizations Prior works [35, 44] have proposed to change the locking scheme of a former Memcached version to remove bottlenecks that impacted performance when running a large number of threads. To scale Memcached network I/O, MegaPipe [26] replaces socket I/O by a new channel-based API. Hippos [45] uses the Netfilter hook with a kernel module to serve Memcached requests from the Linux kernel, but does not ensure the safety of its kernel module and requires modifications to Memcached's source code to update its kernel cache.

eBPF verification. Gershuni et al. [25] have proposed a new verifier based on abstract interpretation in order to scale the verification of eBPF programs with loops. The authors showed that they could verify programs with small bounded loops and eliminate some false positives, however, their implementation has a time complexity about 100 times higher than the current Linux verifier, and uses from 100 to 1000 times more memory. Serval [39] introduces a general purpose and reusable approach to scale symbolic evaluation by using symbolic profiling and domain knowledge to provide symbolic optimizations. However, Serval does not consider domain specific symbolic evaluation. For example, the Linux verifier is capable of inferring register types based on the attach type of an eBPF program. Type inference then allows the Linux verifier to check the type correctness of the parameters passed to a helper function. Without this specific symbolic evaluation, Serval cannot ensure a precise analysis of eBPF programs and therefore cannot be used in place of the Linux verifier.

eBPF usage. eBPF is extensively used in industry for fast packet processing. Cilium [2] uses eBPF as a foundation to provide networking and security to Linux containers. Cloudflare uses eBPF to replace their complex infrastructure filtering rules by eBPF programs. As an example, Cloudflare's DDoS mitigation solution uses XDP in L4Drop, a module that transparently translates iptable DDoS mitigation rules into eBPF programs [8]. These eBPF programs are pushed to the edge servers located in Cloudflare's Points of Presence (PoPs) for automatic packet filtering. Facebook developed Katran [3], an XDP based L4 Load balancer. Katran consists of a C++ library and an XDP program deployed in backend servers in Facebook's infrastructure PoPs.

8 Conclusion

We present BMC, an in-kernel cache designed to improve performance of key-value store applications. BMC intercepts application queries at the lowest point of the network stack just as they come out of the NIC to offer high throughput and low latency with negligible overhead. When compared to user space alternatives, BMC shows comparable performance while saving computing resources. Moreover, BMC retains the Linux networking stack and works in concert with the user space application for serving complex operations. We believe that the BMC design can motivate the emergence of new system designs that make it possible to maintain the standard Linux networking stack while offering high performance.

BMC focuses on the optimization of Memcached because it is a performance-oriented key-value store. As a future work, we plan to apply the design of BMC to other popular key-value store applications such as Redis.

BMC is publicly available at `https://github.com/Orange-OpenSource/bmc-cache`.

Segcache: a memory-efficient and scalable in-memory key-value cache for small objects

Juncheng Yang

K. V. Rashmi
Carnegie Mellon University

Abstract

Modern web applications heavily rely on in-memory key-value caches to deliver low-latency, high-throughput services. In-memory caches store small objects of size in the range of 10s to 1000s of bytes, and use TTLs widely for data freshness and implicit delete. Current solutions have relatively large per-object metadata and cannot remove expired objects promptly without incurring a high overhead. We present Segcache, which uses a segment-structured design that stores data in fixed-size segments with three key features: (1) it groups objects with similar creation and expiration time into the segments for efficient expiration and eviction, (2) it approximates some and lifts most per-object metadata into the shared segment header and shared information slot in the hash table for object metadata reduction, and (3) it performs segment-level bulk expiration and eviction with tiny critical sections for high scalability. Evaluation using production traces shows that Segcache uses 22-60% less memory than state-of-the-art designs for a variety of workloads. Segcache simultaneously delivers high throughput, up to 40% better than Memcached on a single thread. It exhibits close-to-linear scalability, providing a close to 8× speedup over Memcached with 24 threads.

1 Introduction

In-memory caches such as Memcached [54] and Redis [13] are widely used in modern web services such as Twitter [18, 46], Facebook [21, 55], Reddit [3] to reduce service latency and improve system scalability. The economy of cache lies within supporting data retrieval more cheaply, and usually more quickly, compared to the alternatives. The usefulness of in-memory caches is judged by their efficiency, throughput, and scalability, given certain hardware resource constraints. Memory efficiency determines the amount of memory a cache needs to achieve a certain miss ratio. Throughput is typically measured in queries per second (QPS) per CPU core. Scalability reflects how well a cache can use multiple cores on a host. There have been several efforts to reduce miss ratio via better eviction algorithms [22, 26, 36, 37]. Many other works focus on improving throughput [41, 51]. However, several other aspects of in-memory caching also play import roles in memory efficiency.

Web services tend to cache small key-value objects in memory, typically in the range of 10s to 1000s of bytes [21, 46].

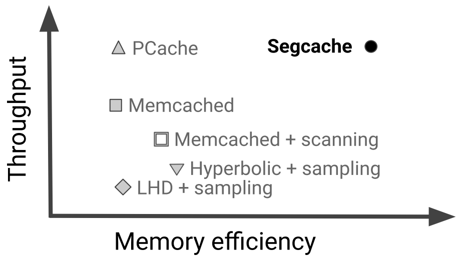

Figure 1: How Segcache compares to state-of-the-art caches

However, most popular production caching systems store a relatively large amount of metadata. For example, both Memcached and Redis impose over 50 bytes of memory overhead per object. Furthermore, research aimed at reducing miss ratio typically ends up expanding object metadata even further [22, 26, 28, 36, 60], as shown in Table 1.

Time-to-live (TTL) is widely used in caching to meet data freshness and feature requirements, or comply with regulations such as GDPR [42, 65–67]. Twitter mandates the use of TTLs in cache, with values ranging from a few minutes to a month. Existing caching systems either remove expired objects lazily or incur high overhead [70] when they attempt to expire more proactively. We summarize the techniques for removing expired objects in Table. 2 and discuss them in §2.

Most production in-memory caches use an external memory allocator such as `malloc` or a slab-based memory allocator. The former often subjects the cache to external fragmentation, and the latter to internal fragmentation [63]. In addition, slab-based allocators often suffer from the so-called slab calcification problem [18, 44], or introduce extra cache misses due to slab migration [29, 34].

One way to reduce memory fragmentation is to adopt a log-structured design. This approach has been widely used for file systems [62] and durable key-value stores [14, 31, 33, 57, 58, 63] for their simplicity, high write throughput [51, 62], low fragmentation, and excellent space efficiency [63]. There have been several in-memory caches built with log-structured design. MICA [51], a throughput-oriented system based on one giant log per thread, limits its eviction algorithm to FIFO or CLOCK, both of which are sub-optimal for many

Table 1: Comparison of research systems (all comparisons are with corresponding baselines)

System	Memory Allocator	Memory fragmentation	Improve TTL expiration	Object metadata size	Throughput	Memory efficiency improvement approach
MICA	Log	No	No	Decrease	Higher	Worse
Memshare	Log	No	No	Increase	Lower	Memory partitioning and sharing
pRedis	Malloc	External	No	Increase	Lower	Better eviction
Hyperbolic	Malloc	External	No	Increase	Lower	Better eviction
LHD	Slab	Internal	No	Increase	Lower	Better eviction
MemC3	Slab	Internal	No	Decrease	Higher	Small metadata
Segcache	Segment	No	Yes	Minimal	Higher	Holistic redesign

workloads. Memshare [37], a multi-tenant caching system, divides DRAM into small logs (called segments) and uses segments to enforce memory partitioning between tenants. However, its computation of miss ratio curve for each tenant and object migration are relatively expensive, which result in reduced throughput compared to Memcached.

As modern servers become denser with CPU cores over time, thread-scalability becomes essential in modern cache design. Several techniques have been proposed to improve scalability in key-value caches and key-value stores, such as static DRAM and data partitioning [50, 51], opportunistic concurrency control with lock-free data structures [32, 41, 52], and epoch-based design [31]. However, each technique comes with its own problems. Static partitioning uses memory inefficiently. Opportunistic concurrency control works better on read-heavy workloads, whereas some caching workloads are write-heavy [46]. An epoch-based system requires a log-structured design with a sub-optimal eviction algorithm.

Achieving high memory efficiency, high throughput, and high scalability simultaneously in caching systems is challenging. Previous works tend to trade one for the other (Fig. 1 and Table 1). In this paper, we present Segcache, a cache design that achieves all the three desired properties. Segcache is a TTL-indexed, dynamically-partitioned, segment-structured[1] cache where objects of similar TTLs are stored in a small fixed-size log called a segment. Segments are first grouped by TTL and then naturally sorted by creation time. This design makes timely removal of expired objects both simple and cheap. As a cache, Segcache performs eviction by merging a few segments into one, retaining only the most important objects, and freeing the rest. Managing the object life cycles at the segment level allows most metadata to be shared within a segment. It also allows metadata bookkeeping to be performed with a limited number of tiny critical sections. These decisions improve memory efficiency and scalability without sacrificing throughput or features.

Below are some highlights of our contributions:

- To the best of our knowledge, Segcache is the first cache design that can efficiently remove all objects immediately after expiration. This is achieved through TTL-indexed, time-sorted segment chains.

[1]Since segments are small-sized logs, Segcache can be viewed as a log-structured cache with special properties; see §6 for in-depth comparisons.

Table 2: Techniques for removing expired objects

Technique	Remove all expired?	Is removal cheap?
Deletion on access	No	Yes
Checking LRU tail	No	Yes
Transient item pool	No	Yes
Full cache scan	Yes	No
Random sampling	No	No

- We propose and demonstrate "object sharing economy", a concept that reduces per-object metadata to just 5 bytes per object, a 91% reduction compared to Memcached, without compromising on features.
- Our single pass, merge-based eviction algorithm uses an approximate and smoothed frequency counter to achieve a balance between retaining high value objects and effectively reclaiming memory.
- We demonstrate that a "macro management strategy", replacing per-request bookkeeping with batched operations on segments, improves throughput. It also delivers close-to-linear CPU scalability.
- Segcache is designed for production on top of Pelikan, and is open sourced (see §4).
- We evaluated Segcache using a wide variety of production traces, and compared results with multiple state-of-the-art designs. Segcache reduces memory footprint by 42-88% compared to Twitter's production system, and 22-58% compared to the best of state-of-the-art designs.

2 Background and Motivation

As a critical component of the real-time serving infrastructure, caches prefer to store data, especially small objects, in DRAM. DRAM is expensive and energy-hungry. However, existing systems do not use the costly DRAM space efficiently. This inefficiency mainly comes from three places. First, existing solutions are not able to quickly remove expired objects. Second, metadata overhead is considerable compared to typical object sizes. Third, internal or external memory fragmentation is common, leading to wasted space. While improvements of admission [24, 25, 39, 40, 43], prefetching [73, 74], and eviction algorithms [22, 23, 26, 30, 36, 37, 49, 68] have been the main focus of existing works on improving memory efficiency [22, 25, 26, 39], little attention has been paid to addressing expiration and metadata reduction [41, 63]. On the contrary, many systems add more per-object metadata to make smarter decisions about what objects to keep [22, 36, 39, 73].

We summarize recent advancements of in-memory caching systems in Table 1 and discuss them below.

2.1 TTL and expiration in caching

TTLs are extremely common in caching. As a result, object expiration is an integral part of all existing solutions.

2.1.1 The prevalence of TTL

TTLs are used by users of Memcached and Redis [4, 8, 10, 12], Facebook [17], Reddit [3], Netflix [6]. In Twitter's production, *all* in-memory cache workloads use TTLs between one minute and one month. A TTL is specified at write time to determine how long an object should remain accessible in the caching system. An expired object cannot be returned to the client, and a cache miss is served instead.

Cache TTLs serve three purposes. First, clients use TTLs to limit data inconsistency [4, 46]. Writing to the cache is usually best-effort, so it is not uncommon for data in cache and database to fall out of sync. Second, some services use TTLs to prompt periodic re-computation. For example, a recommendation system may only want to reuse cached results within a time window, and recompute periodically to incorporate new activities and content. Third, TTLs are used for implicit deletion. A typical scenario is rate-limiting. Rate limiters are counters associated with some identities. Services often need to cap requests from a particular identify within a predefined time window to prevent denial-of-service attacks. Services store rate limiters in distributed caches with TTLs, so that the counts can be shared among stateless services and reset periodically. Another increasingly common scenario is using TTLs to ensure data in caches comply with privacy laws [42, 67].

2.1.2 Lazy expiration

Lazy expiration means expiration only happens when an object is reaccessed. *Deletion on access* is the most straightforward approach adopted by many production caching systems. If a system uses lazy expiration only, an object that's no longer accessed can remain in memory long past expiration.

2.1.3 Proactive expiration

Proactive expiration is used to reclaim memory occupied by expired objects more quickly. Although there has been no academic research on this topic to the best of our knowledge, we identified four approaches introduced into production systems over the years, as summarized in Table. 2.

Checking LRU tail is used by Memcached. Before eviction is considered, the system checks a fixed number of objects at the tail of the LRU queue and removes expired objects. Operations on object LRU queues reduce thread scalability due to the extensive use of locking for concurrent accesses [22, 26]. Additionally, this approach is still opportunistic and therefore doesn't guarantee the timely removal of expired objects. Many production caches track billions of objects over a few LRU queues, so the time for an object to percolate through the LRU queue is very long.

Transient object pool was introduced by Facebook [55]. It makes a special case for the timely removal of objects with small TTLs. The main idea is to store such objects separately, and only allow them to be removed via expiration. However, choosing the TTL threshold is non-trivial and can have side effects [46]. Although Memcached supports it, it is disabled by default.

Full cache scan is a popular approach adopted by Memcached and CacheLib [17]. As the name indicates, this solution periodically scans all the cached objects to remove expired ones. Full cache scan is very effective if the scan is frequent, but it wastes resources on objects that are not expired, which can be the vast majority.

Random sampling is adopted by Redis. The key idea is to periodically sample a subset of objects and remove expired ones. In Redis, if the percentage of the expired objects in the sample is above a threshold, this process continues. While sampling is cheaper per run, the blind nature of sampling decides that it is both inefficient and not very effective. Users have to accept that the sampling can only keep the percentage of expired objects at a pre-configured threshold. Meanwhile, the cost can be higher than full cache scan due to random memory access. There have been some production incidents where Redis could not remove enough expired objects and caused unexpected evictions [70].

Despite the various flaws, proactive expiration is highly regarded by developers of production systems. When asked to replace LRU for a better eviction strategy in Memcached, the maintainer states that "*pulling expired items out actively is better than almost any other algorithmic improvement (on eviction) I could think of.*" [10] Meanwhile, Redis' author mentioned that "*Redis 6 expiration will no longer be based on random sampling but will take keys sorted by expiration time in a radix tree.*" [2]

In summary, efficiently and effectively removing expired objects is an urgent problem that needs to be solved in current caching systems.

2.2 Object metadata

We observe that the objects stored in in-memory caches are small [46], and the mean object sizes (key+value) of Twitter's top four production clusters are 230, 55, 294, 72 bytes, respectively. This observation aligns with the observations at Facebook [21], and Reddit [3].

Existing systems are not efficient in storing small objects because they store considerable amount of metadata per object. For example, Memcached stores *56 bytes* of metadata with each object [3], which is a significant overhead compared

[2]As of Redis v6.0.6, this change is not implemented yet.

[3]2×8 bytes LRU pointers, 8 bytes hash pointer, 4 bytes access time, 4 bytes expire time, 8 bytes object size, 8 bytes `cas` (compare-and-set, used for atomic update).

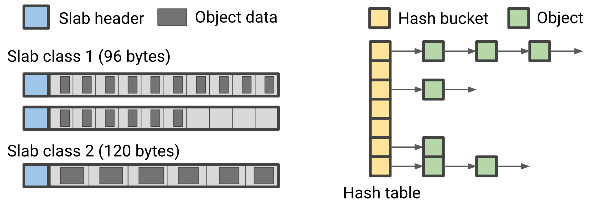

Figure 2: Slab memory allocation (left) and object-chained hash table (right) in Memcached.

to typical object size. All of the metadata fields are critical for Memcached's operations, and cannot be dropped without first removing some functionalities or features.

There have been several attempts at Twitter to cut metadata overhead. For example, Pelikan's slab-based storage removes object LRU queues and reuses one pointer for both hash chain and free object chain. As a result, it reduces object metadata to 38 bytes. However, this prevents Pelikan from applying the LRU algorithm to object eviction, and results in higher miss ratio compared to Memcached in our evaluation. Pelikan also introduced Cuckoo hashing [59] as a storage module for fixed-size objects, only storing 6 bytes (or 14 bytes with `cas`) of metadata per key.

Several academia works have also looked at reducing metadata size. RAMCloud [63] and FASTER [31] use a log-structured design to reduce object metadata. However, their designs target *key-value stores* instead of key-value caches (See discussion in §5). MemC3 [41] redesigns the hash table with Cuckoo hashing and removes LRU chain pointers. However, it does not consider some operations such as `cas` for atomic updates, does not support TTL expiration or other advanced eviction algorithms.

2.3 Memory fragmentation

Memory management is one of the fundamental design aspects of an in-memory caching system. Systems that directly use external memory allocators (e.g., *malloc*) such as Redis are vulnerable to external memory fragmentation and OOM.

To avoid this problem, other systems such as Memcached use a slab-based memory allocator, allotting a fixed-size slab at a time, which is then explicitly partitioned into smaller chunks for storing objects, as shown in Fig. 2 (left). The chunk size is decided by the `class id` of a slab and configured during startup. A slab-based memory allocator is subjected to internal memory fragmentation at the end of each chunk and at the end of each slab.

Using a slab-based allocator also introduces the slab calcification problem, a phenomenon where some slab classes cannot obtain enough memory and exhibit higher miss ratios. Slab calcification happens because slabs are assigned to classes using the first-come-first-serve method. When popularity among slab classes change over time, the newly popular slab classes cannot secure more memory because all slabs have been assigned. This has been studied in the previous works [29, 44, 46]. Memcached automatically migrates slabs between classes to solve this problem, however, it is not always effective [2, 5, 9, 15]. Re-balancing slabs may increase the miss ratio because all objects on the outgoing slab are evicted. Moreover, due to workload diversity and complexity in slab migration, it is prone to errors and sometimes causes crash in production [7, 16].

Overall, existing production systems have not yet entirely solved the memory fragmentation problem. Among the research systems, log-structured designs such as MICA [50, 51], memshare [37] and RAMCloud [63] do not have this problem. However, they cannot perform proactive expiration and are limited to using basic eviction algorithms (such as FIFO or CLOCK) with low memory efficiency.

2.4 Throughput and scalability

In addition to memory efficiency, throughput and thread-scalability are also critical for in-memory key-value caches. Memcached's scalability limitation is well documented in various industry benchmarks [11, 55]. The root cause is generally attributed to the extensive locking in the object LRU queues, free object queues, and the hash table. Several systems have been proposed to solve this problem. Some of them remove locking by using simpler eviction algorithms and sacrificing memory efficiency [41, 51]. Some introduces opportunistic concurrency control [41], which does not work well with write-heavy workloads. Some other works use random eviction algorithms to avoid concurrent reads and writes [22, 26], which do not address all the locking contention. Moreover, they reduce throughput due to the large number of random memory accesses.

3 Design principles and overview

The design of Segcache follows three principles.

Be proactive, don't be lazy. Expired objects offer no value, so Segcache eagerly removes them for memory efficiency.
Maximize metadata sharing for economy. To reduce the metadata overhead without loss of functionality, Segcache maximizes metadata sharing across objects.
Perform macro management. Segcache operates on segments to expire/evict objects in bulk with minimum locking.

At a high level, Segcache contains three components: a hash table for object lookup, an object store comprised of segments, and a TTL-indexed bucket array (Fig. 3).

3.1 TTL buckets

Indexing on TTL facilitates efficient removal of expired objects. To achieve this, Segcache first breaks the spectrum of possible TTLs into ranges. We define the time-width of a TTL range t_1 to t_2 ($t_1 < t_2$) as $t_2 - t_1$. All objects in range t_1 to t_2 are treated as having TTL t_1, which is the *approximate TTL* of this range. Rounding down guarantees an object can only be expired early, and no object will be served beyond expiration. Objects are grouped into small fix-sized groups called segments (see next section), and all the objects stored in the same segment have the same approximate TTL. Second, Segcache

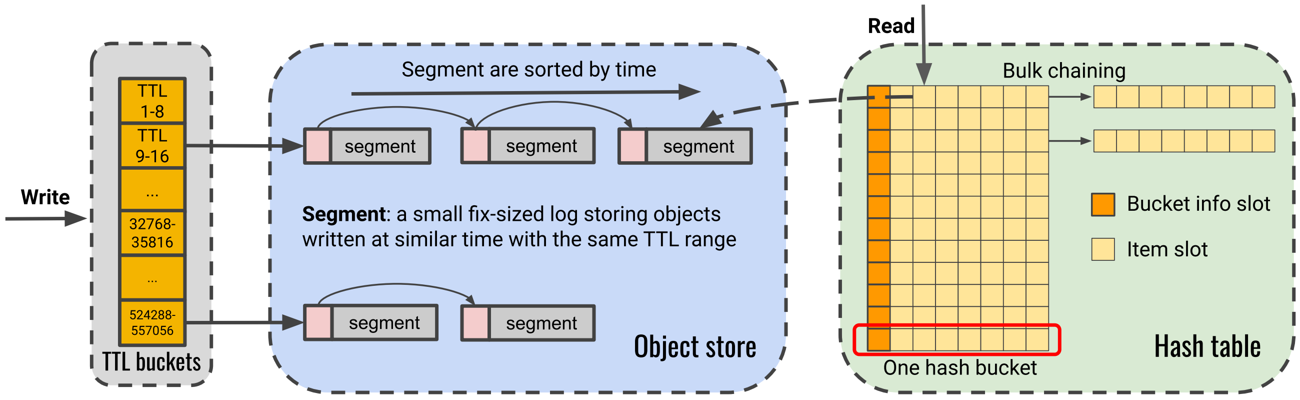

Figure 3: Overview of Segcache. A read request starts from the hash table (right), a write request starts from the TTL buckets (left).

uses an array to index segments based on *approximate TTL*. Each element in this array is called a *TTL bucket*. A segment with a particular approximate TTL value is associated with the corresponding TTL bucket. Within each bucket, segments are chained and sorted by creation time.

To support a wide TTL range from a few second to at least one month without introducing too many buckets or losing resolution on the lower end, Segcache uses 1024 TTL buckets, divided into four groups. From one group to the next, the time-width grows by a factor of 16. In other words, Segcache uses increasingly coarser buckets to efficiently cover a wide range of TTLs without losing relative precision for typical TTL buckets. The boundaries of the TTL buckets are chosen in a way that finding the TTL bucket only requires a few bit-wise operations. We show that this design allows Segcache to efficiently and effectively remove expired objects in §3.5.

3.2 Object store: segments

Segcache uses segments as the basic building blocks for storing objects. All segments are of a configurable size, default to 1 MB. Unlike slabs in Memcached, Segcache group objects stored in the same segment by approximate TTL, not by size. A segment in Segcache is similar to a small log in log-structured systems. Objects are always appended to the end of a segment, and once written, the objects cannot be updated (except for `incr`/`decr` atomic operations). However, unlike other log-structured systems [37, 51, 57, 58, 62, 63], where available DRAM is either used as one continuous log or as segments withou no relationship between each other, segments in Segcache are sorted by creation time, linked into chains, and indexed by approximate TTLs.

In Segcache, each non-empty TTL bucket stores pointers to the head and tail of a time-sorted segment chain, with the head segment being the oldest. A write in Segcache first finds the right TTL bucket for the object, and then appends to the segment at the tail of the segment chain. When the tail segment is full, a new segment is allocated. If there is no free segment available, eviction is triggered (§3.6).

3.3 Hash table

As shown in previous works [41], the object-chained hash tables (Fig. 2 (right)) limits the throughput and scalability in the existing production systems [54,71]. Segcache uses a bulk-chaining hash table similar to MICA [51] and Faster [31].

An object-chained hash table uses object chaining to resolve hash collisions. The throughput of such a design is sensitive to hash table load. Collision resolution requires walking down the hash chain, incurring multiple random DRAM accesses and string comparisons. Moreover, object chaining imposes a memory overhead of an 8-byte hash pointer per object, which is expensive compared to the small object sizes.

Instead of having just one slot per hash bucket, Segcache allocates 64 bytes of memory (one CPU cache line) as eight slots in each hash bucket (Fig. 3). The first slot stores the bucket information, the following six slots store object information. The last slot stores either object information or a pointer to the next hash bucket (when more than seven objects hash to the same bucket). This chaining of hash buckets is called bulk chaining. Bulk chaining removes the need to store hash pointers in the object metadata and improves the throughput of hash lookup by minimizing random accesses.

The bucket information slot stores an 8-bit spin lock, an 8-bit slot usage counter, a 16-bit last-access timestamp , and a 32-bit `cas` value. Each item slot stores a 24-bit segment id, a 20-bit offset in the segment, an 8-bit frequency counter (described in §3.6.3), and a 12-bit tag. The tag of a key is a hash used to reduce the number of string comparisons when hash collisions happen.

3.4 Object metadata

Segcache achieves low metadata overhead by *sharing metadata across objects*. Segcache facilitates metadata sharing at two places: the hash table bucket and the segment. Objects in the same segment share creation time, TTL, reference counter, while objects in the same hash bucket share last-access timestamp, spinlock, `cas` value, and hash pointer.

Because objects in the same segment have the same approximate TTL and are written around the same time, Segcache computes the approximate expiration time of the whole segment based on the oldest object in the segment and approximate TTL of the TTL bucket. This approximation skews the clock and incurs early expiration for objects later in the segment. As we will show in our evaluation, early expiration has negligible impact on miss ratio.

Segcache also omits object-level hash chain pointers and LRU chain pointers. Bulk chaining renders hash chain pointer unnecessary. The LRU chain pointers are not needed because because both expiration and eviction are performed at the segment level. Segcache further moves up metadata needed for concurrent accesses (reference counter) into the segment header. In addition, to support `cas`, Segcache maintains a 32-bit `cas` value per hash bucket and shares it between all objects in the hash bucket. While sharing this value may increase false data race between different objects hashed to the same hash bucket, in practice, the impact of this compromise is negligible due to two reasons. First, `cas` traffic is usually orders of magnitude lower than simple read or write, as observed in production environment [46]. Second, one `cas` value is shared only by a few keys, the chance of concurrent updates on different keys in the same hash bucket is small. In the case of a false data race, the client usually retries the request.

The final composition of object metadata in Segcache contains one 8-bit key size, one 24-bit value size, and one 8-bit flag. And Segcache stores only 5 bytes[4] of metadata with each object, which is a 91% reduction compared to Memcached.

3.5 Proactive expiration

In Segcache, all objects in one segment are written sequentially and have the same approximate TTL, which makes it feasible to remove expired objects in bulk. Proactive removal of expired objects starts with scanning the TTL buckets. Because segments linked in each TTL bucket are ordered by creation time and share the same approximate TTL, they are also ordered by expiration time. Segcache uses a background thread to scan the first segment's header in each non-empty TTL buckets. If the first segment is expired, the background thread removes all the objects in the segment, then continues down the chain until it runs into one segment that is not yet expired, at which point it will move onto the next TTL bucket.

Segcache's proactive expiration technique uses memory bandwidth efficiently. Other than reading the expired objects, each full scan only accesses *a small amount of consecutive metadata* — the TTL bucket array. This technique also ensures that memory occupied by expired objects are promptly and completely recycled, which improves memory efficiency.

As mentioned before, objects are subject to early expiration. However, objects are usually less useful near the end of their TTL. Our analysis of production traces at Twitter shows that a small TTL reduction makes negligible difference (if any) in the miss ratio.

[4]The 5-byte does not include the shared metadata, which is small per object. And it also does not include the one-byte frequency counter, which is stored as part of object pointer in the hash table.

3.6 Segment eviction

While expiration removes objects that cannot be used in the future and is preferred over eviction, cache cannot rely on expiration alone. All caching systems support eviction when necessary to make room for new objects.

Eviction decisions can affect the effectiveness of cache in terms of the miss ratio, thus have been the main focus of many previous works [22, 26, 35, 49, 56, 69]. Segcache does not update objects in-place. Instead, it appends new objects and marks the old ones as deleted. Therefore, better eviction becomes even more critical.

Unlike most existing systems performing evictions by object, Segcache performs eviction by segments. Segment eviction could evict popular objects, increasing the miss ratio. To address this problem, Segcache uses a *merge-based* eviction algorithm. The basic idea is that by combining multiple segments into one, Segcache selectively retains a relatively small portion of the objects that are more likely to be accessed again and discards the rest. This design brings out several finer design decisions. First, we need to pick the segments to be merged. Second, there needs to be an algorithm making per-object decisions while going through these segments.

3.6.1 Segment selection

The segments merged during each eviction are always from a single TTL bucket. Within this bucket, Segcache merges the first N *consecutive*, *un-expired*, and *un-merged* (in current iteration) segments (Fig. 4). The new segment created from the eviction inherits the creation time of the oldest evicted segment. This design has the following benefits. First, the created segment can be inserted in the same position as the evicted segments in the segment chain, and maintains the time-sorted segment chain property. Second, objects in the created segment still have relatively close creation/expiration time, and the merge distorts their expiration schedules minimally.

While within one TTL bucket, the segment selection is limited to consecutive ones, across TTL buckets, Segcache uses round-robin to choose TTL bucket.

3.6.2 One-pass merge and segment homogeneity

When merging N consecutive segments into one, Segcache uses a dynamic threshold for retaining objects to achieve merge in a single pass. This threshold is updated after scanning every $\frac{1}{10}$ of a segment and aims to retain $\frac{1}{N}$ bytes from each segment being evicted.

The rationale for retaining a similar number of bytes from each segment is that objects and segments created at a similar time are homogeneous with similar properties. Therefore, no segment is more important than others. Fig. 5a shows the relative standard deviation (RSD, $\frac{std}{mean}$) of the mean object size in consecutive segments and across random segments, and Fig. 5b compares the RSD of live bytes in consecutive and random segments. Both figures demonstrate that consecutive segments are more homogeneous (similar) than random segments. As a result, retaining a similar number of bytes from

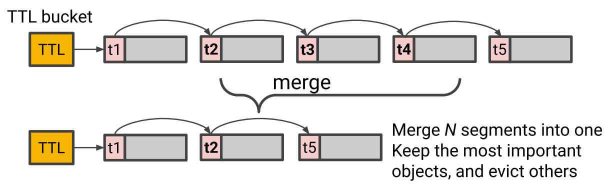

Figure 4: Merge-based segment eviction.

each is reasonable. However, we remark that the current segment selection and merge heuristics may not be the optimal solution in some cases, and deserve more exploration.

3.6.3 Selecting objects

So far, one question remains unsolved: what objects should be retained in an eviction? An eviction algorithm's effectiveness is determined by its ability to predict future access based on past information. Under the independent reference model (IRM), a popular model used for cache workloads, an object with a higher frequency is more likely to be re-accessed. Moreover, it has been shown in theory that under IRM and for fix-sized objects, the least frequently used (LFU) is k-competitive and the best policy [27, 39, 61, 64].

Similar to greedy dual size frequency [35], Segcache uses the frequency-over-size ratio to rank objects. Therefore it needs a frequency counter that is memory-efficient, computationally-cheap, and scalable. Meanwhile, it should allow Segcache to be burst-resistant and scan-resistant. Moreover, The counter needs to provide *higher accuracy for less popular* objects (opposite of the counter-min sketch). This is critical for cache eviction because the highly-popular objects are always retained (cached), and the less popular objects decide the miss ratio of a cache. Segcache uses a novel one-byte counter (stored in hash table), which we call *approximate and smoothed frequency counter* (ASFC), to track frequencies.

Approximate counter. ASFC has two stages. When frequency is smaller than 16 (last four bits of the counter), it always increases by one for every request. In the second stage, it counts frequency similar to a Morris counter [1], which increases with a probability that is the inverse of current value.

Smoothed counter. Segcache uses the last access timestamp, which is shared by objects in the same hash bucket, to rate-limit updates to the frequency counters. The frequency counter for each object is incremented at most once per second. This technique is effective in absorbing sudden request bursts.

Simple LFU is susceptible to cache pollution due to request bursts and non-constant data access patterns. While several approaches such as dynamic aging [20, 39, 61], and window-based frequency [38, 47] have been proposed to address this issue, they require additional parameters and/or extensive tuning [19]. To avoid extra parameters, Segcache resets the frequency of retained objects during evictions, which has a similar effect as window-based frequency.

The linear increase at low frequency and probabilistic increase at high frequency allow ASFC to achieve a higher accuracy for less popular objects. Meanwhile, the approximate design allows ASFC to be memory efficient, using one byte to count up to $2^8 \times 2^8$ requests. The smoothed design of ASFC allows Segcache to be burst-resistant and scalable.

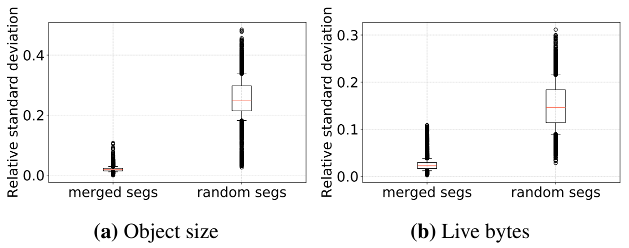

Figure 5: a) Relative standard deviation of mean object size in consecutive segments and random segments. b) Relative standard deviation of live bytes in consecutive segments and random segments.

3.7 Thread model and scalability

Segcache is designed to scale linearly with the number of threads by using a combination of techniques such as minimal critical sections, optimistic concurrency control, atomic operations, and thread-local variables. Most notably, because object life cycle management is at the segment level, only modifications to the segment chains require locking, which avoids common contention spots related to object-level bookkeeping, such as maintaining free-object queues. This macro management strategy reduces locking frequency by four orders of magnitude in our default setting compared to what would be needed in a Memcached-like system.

More specifically, no locking is needed on the read path except to increment object frequency, which is at most once every second. On the write path, because segments are append-only, inserting objects can take advantage of atomic operations. However, we observe that relying on atomic operation is insufficient to achieve near-linear scalability with more than eight threads. To solve this, each thread in Segcache maintains a local view of active segments (the last segment of each segment chain), and the active segments in each thread can be written only by that thread. Although the segments are local to each thread for writes, the objects that have been written are immediately available for reading by other threads. During eviction, locking is required when segments are being removed from the segment chain. However, the critical section of removing a segment from the chain is very tiny compared to object removal, which is *lock-free*. Moreover, evicting one segment means evicting thousands of objects, so segment eviction is infrequent compared to object writes.

4 Implementation and Evaluation

In this section, we compare the memory efficiency, throughput, and scalability of Segcache against several research and production solutions, using traces from Twitter's production. Specifically, we are interested in the following questions,

- Is Segcache more memory efficient than alternatives?

Table 3: Traces used in evaluation

Trace	Workload type	# requests	TTLs (TTL: percentage)	Write ratio	Mean object size	Production miss ratio
c	content	4.2 billion	1d: 65%, 14d: 27%, 12h: 7%	7%	230 bytes	1-5%
*u*1	user	6.5 billion	5d:1.00	1%	290 bytes	<1%
*u*2	user	4.5 billion	12h:1.00	3%	55 bytes	<1%
n	negative cache	1.6 billion	30d:1.00	2%	45 bytes	~1%
mix	content + user + negative cache + transient item	11.88 billion	30d: 14%, 14d:11%, 24h: 23%, 12h: 38%, 2min:12%	7%	243 bytes	NA

- Does Segcache provide comparable throughput to state-of-the-art solutions? Does it scale well with more cores?
- Is Segcache sensitive to design parameters? Are they easy to pick or tune?

4.1 Implementation

Segcache is implemented as a storage module in the open-sourced Pelikan project. Pelikan is a cache framework developed at Twitter. The Segcache module can both work as a library or be setup as a Memcached-like server. Our current implementation supports multiple worker threads, with a dedicated background thread performing proactive expiration. For our evaluation, eviction is performed by worker threads as-needed, but it is easy to use the same background thread to facilitate background eviction. We provide configurable options to change the number of segments to merge for eviction and segment size. The source code can be accessed at http://www.github.com/twitter/pelikan and archived at http://www.github.com/thesys-lab/segcache.

4.2 Experiment setup

4.2.1 Traces

Single tenant traces. We used week-long unsampled traces from production cache clusters at Twitter (Table. 3, the same as in previous work [46])[5]. Trace *c* comes from a cache storing tweets and their metadata, which is the largest cache cluster at Twitter. Trace *u*1 and *u*2 are both user related, but the access patterns of the two workloads are different, so different TTLs are used. Notably, they are separated into two caches in production because effective and efficient proactive expiration was not achievable prior to Segcache. Trace *n* is a negative result cache, which stores the keys that do not exist in the database, a common way of using cache to shield databases from unnecessary high loads.

Multi tenant trace. Although Twitter's production deployments are single-tenant, multi-tenant deployments are also common because of better resource utilization [21]. To evaluate the performance under multi-tenant workloads, we merged workloads from four types of caches: user, content, negative cache, and transient item cache.

4.2.2 Baselines

Memcached used in our evaluation is version 1.6.6 with segmented LRUs. It supports lazy expiration and checks LRU tail for expiration. We ran Memcached in two modes, one with cache scanning enabled (s-Memcached), which scans the entire cache periodically to remove expired objects; the other with scanning disabled (Memcached). Other expiration techniques are enabled in both modes. Our evaluation also includes pelikan_twemcache (PCache), Twitter's Memcached equivalent and successor to Twemcache [18]. Compared to Memcached, PCache has a smaller object metadata without LRU queues, and only performs slab eviction [75]. We implemented LHD [22] and Hyperbolic [26] on top of PCache since original implementations are not publicly available. These systems do not consider object expiration. To make the comparisons fairer, we add random sampling to remove expired objects in these two systems, which is also how Redis performs expiration. In the following sections, r-LHD and r-Hyperbolic refer to these enhanced versions. Note that adding random sampling to remove expired objects does not significantly impact the throughput, and we observe less than a 10% difference.

Because we do not modify the networking stack, we focus our evaluation on the storage subsystem. We performed all evaluations by close-loop trace replay on dedicated hosts in Twitter's production fleet using the traces described in §4.2.1. The hosts have dual-socket Intel Xeon Gold 6230R CPU, 384 GB DRAM with one 100 Gbps NIC.

4.2.3 Metrics

We use three metrics in our evaluation to measure the memory efficiency, throughput, and scalability of the systems.

Relative miss ratio. Miss ratio is the most common metric in evaluating memory efficiency. Because workloads have dramatically different miss ratios in production (from a few percent to less than 0.1%) and compulsory miss ratios, directly plotting miss ratio is less readable. Therefore, we use *relative miss ratio* (defined as $\frac{mr}{mr_{baseline}}$ where *mr* stands for miss ratio and the baseline is PCache) in the presentation.

Relative memory footprint. Although miss ratio is a common metric, a sometimes more useful metric is how much memory footprint can be reduced at a certain miss ratio. Therefore, in §4.3, we show this metric using PCache memory footprint as the baseline.

Throughput and scalability. Throughput is measured in million queries per second (MQPS) and used to quantify a caching system's performance. Scalability measures the throughput running on a multi-core machine with the number of hardware threads from 1 to 24 in our evaluations.

[5]The traces are available at http://www.github.com/twitter/cache-trace.

Figure 7: Relative memory footprint to achieve a certain miss ratio, lower is better.

4.3 Memory efficiency

In this section, we compare the memory efficiency of all systems. We present the relative miss ratio at two cache sizes[6] in Fig.6. (1) The "large cache" is the cache size when the miss ratio of Segcache reaches the plateau (<0.05% miss ratio reduction when the cache size increases by 5%). Miss ratios achieved at large cache sizes are similar to production miss ratios. (2) we choose the "small cache" size as 50% of the large cache size.

Compared to the best of the five alternative systems, Segcache reduces miss ratios by up to 58%. Moreover, it performs better on both the single-tenant and the multi-tenant workloads. This large improvement is the cumulative effect of having timely proactive expiration, small object metadata, no memory fragmentation, and a merge-based eviction strategy.

We observe that Memcached and PCache have comparable miss ratios in most workloads (except workload *mix* because PCache is not designed for multi-tenant workloads). While comparing Memcached and s-Memcached, we observe that adding full cache scanning capability significantly reduces the miss ratio by up to 40%, which indicates the importance of proactive expiration. However, as we show in §4.4.1, cache scanning is expensive and reduces throughput by almost half for some workloads. Moreover, we observe that workload *n* and *mix* do not benefit from full cache scanning. Workload *n* shows no benefit because it uses a single TTL of 30 days and no objects expire in the evaluation. Although workload *mix* has a mixture of short and long TTLs, it shows no benefit because the objects of different TTLs are from different workloads with different object sizes, and are stored in different slab classes with different LRU queues. As a result, checking LRU tail for expiration is effective at removing expired objects and scanning provides little benefit. Overall, we observe that proactively removing expired objects can effectively reduce miss ratio and improve memory efficiency.

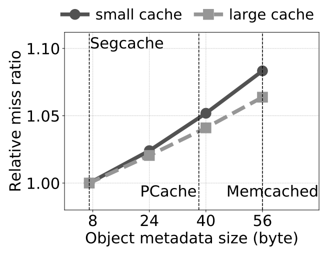
[6]We experimented with twenty cache sizes, and the two set of results presented here are representative.

State-of-the-art research caching systems, r-LHD and r-Hyperbolic use ranking to select eviction candidates and often reduce miss ratio compared to LRU. In our evaluation, r-Hyperbolic shows lower miss ratio compared to Memcached and PCache, while r-LHD is only better on workload *c*. r-LHD is designed for workloads with a mixture of scan and LRU access patterns (such as block access in storage systems), while in-memory caching workloads rarely show scan requests. This explains why it has higher miss ratios. We have also evaluated r-LHD and r-Hyperbolic without sampling for expiration (not shown), and as expected, they have higher miss ratios due to the wasted cache space from expired objects.

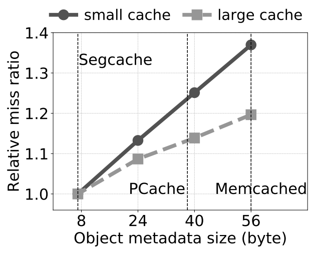
An alternative way of looking at memory efficiency is to determine the cache size required to achieve a certain miss ratio. We show the relative memory footprints of different systems in Fig. 7, using PCache as the baseline. The figures show that for both the production miss ratio and a higher miss ratio, Segcache reduces memory footprint by up to 88% compared to PCache, 60% compared to Memcached, 56% compared to s-Memcached, and 64% compared to r-Hyperbolic.

4.3.1 Ablation study

In Fig. 6, we observe that s-Memcached reduces miss ratio by up to 35% compared to Memcached, which demonstrates the importance of proactive expiration, one of the key design features of Segcache. Besides proactive expiration, another advantage of Segcache over previous systems is smaller object metadata. To understand its impact, we measure the relative miss ratio of increasing object metadata in Segcache (Fig. 8). It shows that reducing object metadata size can have a large miss raito impact for workloads with small object sizes. Workload *c* has relatively large object sizes (230 bytes), and reduc-



(a) Workload *c*



(b) Workload *n*

Figure 8: Impact of object metadata size on miss ratio. Workload *n* has smaller object sizes as compared to workload *c* and hence enjoys larger benefit from reduction from object metadata.

ing the metadata from 56 bytes to 8 bytes reduces the miss ratio by 6-8%. While workload *n* has small object sizes (45 bytes) and reducing object metadata size provides a 20-38% reduction in miss ratio. This result indicates reducing object metadata size is very important, and it is a critical component contributing to Segcache's high memory efficiency.

4.4 Throughput and scalability

4.4.1 Single-thread throughput

Besides memory efficiency, the other important metric of a cache is the throughput. Fig. 9 shows the throughput of different systems. Compared to other systems, PCache and Segcache achieve higher throughput, up to 2.5× faster than s-Memcached, up to 3× faster than r-Hyperbolic, and up to 4× faster than r-LHD. The reason is that PCache performs slab eviction only, and Segcache performs merge-based segment eviction. Both systems perform batched and sequential bookkeeping for evictions, which significantly reduces the number of random memory accesses and makes good use of the CPU cache. In addition, PCache and Segcache do not maintain an object LRU chain, which leads to less bookkeeping and also contributes to the high throughput.

Although r-LHD and r-Hyperbolic have lower miss ratios than Memcached, their throughput is also lower. The reason is that both systems use random sampling during evictions, which causes a large number of random memory accesses. One major bottleneck of a high-throughput cache is the poor CPU cache hit ratio, and optimizing CPU cache utilization has been one focus of improving the throughput [51, 52]. Although r-LHD proposes to segregate object metadata for better locality [22], it requires adding more object metadata, and hence would further decrease memory efficiency.

4.4.2 Thread scalability

We show the scalability results in Fig. 10a, where we compare Segcache with Memcached and s-Memcached. Fig. 10a shows that compared to Memcached, Segcache has a higher throughput and close-to-linear scalability. With 24 threads, Segcache achieves over 70 MQPS, a 19.9× boost compared to using a single-thread, while Memcached only achieves 9 MQPS, 3.4× of its single-thread throughput. The reason why Segcache can achieve close-to-linear scalability is the effect of multiple factors as discussed in §3.7. While there is not much throughput difference between Memcached and s-Memcached, s-Memcached is deadlocked when running with more than 8 threads.

Note that we do not present the result of PCache in this figure because it does not support multi-threading. We also do not show the result of r-LHD and r-Hyperbolic because we could not find any simple way to implement a better locking than the one in Memcached. Although r-LHD and r-Hyperbolic removes the object LRU chain and lock, the slab memory allocator still requires heavy locking.

4.5 Sensitivity

In this section, we study the effects of parameters in Segcache using workload *c* (from Twitter's largest cache cluster). The most crucial parameter in Segcache is the number of segments to merge for eviction, which balances between processing overhead and memory efficiency. Fig. 10b shows how the miss ratio is affected by the number of merged segments. Compared to retaining no objects (the bar labeled eviction), using merge-based eviction reduces the miss ratio by up to 20%, indicating the effectiveness of merge-based eviction. Moreover, it shows that the point for the minimal miss ratio is between 3 and 4. Merging two segments or more than four segments increases the miss ratio, but not significantly.

There are two reasons why merging too few segments leads to a high miss ratio. First, merging too few segments can lead to unfilled segment space. For example, when merging only two segments, 50% of the bytes are retained from each segment in one pass. If the second segment does not have enough live objects, the new segment will have space wasted. Second, the fidelity of predicting future accesses on unpopular objects is low. Merging fewer segments means retaining more objects, so it requires distinguishing unpopular objects, and the decision can be inaccurate. Meanwhile, merging fewer segments means triggering eviction more frequently, giving objects less time to accumulate hits.

On the other hand, merging too many segments increases the miss ratio as well. Because merging more segments means setting a higher bar for retained objects, some important objects can be evicted. In our evaluation, we observe three and four are, in general, good options. However, merging more or fewer segments does not adversely affect the miss ratio significantly and still provides a lower miss ratio than current production systems. Therefore, we consider this parameter a stable one that does not require tuning per workload.

Besides the number of segments to merge, another parameter in Segcache is the segment size. We use the default 1 MB in our evaluation; Fig. 10c shows the impact of different segment sizes. It demonstrates that segment size has little impact on the miss ratio, which is expected. Because the fraction of objects retained from each segment does not depend on the segment size, thus not affecting the miss ratio.

5 Discussion

5.1 Alternative proactive expiration designs

Besides the TTL bucket design in Segcache, there are other possible solutions for proactive expiration. For example, a radix tree or a hierarchical timing wheel can track object expiration time. However, neither is as memory efficient as Segcache. In fact, any design that builds an expiration index strictly at the object level requires two pointers per object, an overhead with demonstrated impact for our target workloads. The radix tree may also use an unbounded amount of memory to store the large and uncertain number of expiration timestamps. In addition, performing object-level expiration and eviction requires more random memory access and locking than bulk operations, limiting throughput and scalability.

5.2 In-memory key-value cache vs store

In the literature, we observe several instances where there is a mix-up of *volatile key-value caches* (such as Memcached) and *durable key-value stores* (such as RAMCloud and RocksDB). However, from our viewpoint, these two types of systems are significantly different in terms of their usage, requirements, and design. Indeed, one of the main contributions is to identify the opportunity to approximate object metadata and share them (time, pointers, reference counters, version/cas number) across objects. Time approximation in particular is not as tolerated in a traditional key-value store. Below we discuss the differences between caches and stores.

TTL. TTLs are far more ubiquitous in caching than in key-value store [3, 6, 12, 17, 55, 70]. We described Twitter's use of TTLs in detail in [46]. In comparison, many datasets are kept in key-value stores indefinitely.

Eviction. Eviction is unique to caching. In addition, eviction is extremely common in caching. A production cache running at 1M QPS with 10% writes, which can be new objects or on-demand fill from cache misses, will evict 100K objects every second. Re-purposing compaction and cleaning techniques in log-structured storage may not be able to keep up with the write rate needed in caching. On the other hand, caches have considerable latitude in deciding what to store, and can choose more efficient mechanisms.

Design requirements. In-memory caches are often used in front of key-value stores to absorb most read requests, or to store transient data with high write rates. Production users expect caches to deliver much higher throughput and/or much lower tail latencies. In contrast, key-value stores are often considered sources of truth. As such they prioritize durability (crash recovery) and consistency over latency and throughput.

The differences between cache and store allow us to make some design choices in Segcache that are not feasible for durable key-value stores (even if they are in-memory).

6 Related work

6.1 Memory efficiency and throughput

Approaches for improving memory efficiency fall broadly in the two categories: improving eviction algorithms and adding admission algorithms.

Eviction algorithm. A vast number of eviction algorithms have been proposed in different areas starting from the early 90s [45, 53, 56, 61, 76]. However, most of them focus on the cache replacement of databases or page cache, which are different from a distributed in-memory cache because cached contents in databases and page cache are typically fix-sized blocks with spatial locality. In recent years, several algorithms have been proposed to improve the efficiency of in-memory caching, such as LHD [22], Hyperbolic caching [26], pRedis [60], and mPart [28]. However, all of them add more object metadata and computation, which reduces usable cache size and reduces throughput, which has significant repercussions for caches with small objects.

Segcache uses a merge-based eviction strategy that retains high-frequency small-sized objects from evicted segments, which is similar to a frequency-based eviction algorithms such as LFU [20,47] and GDSF [35]. However, unlike some of these systems that require parameters tuning, Segcache uses ASFC that avoids these problems. In addition to the eviction algorithm, two major components that contribute to Segcache's low miss ratio is efficient, proactive expiration, and object metadata sharing, which are unique to Segcache.

Admission control. Adding admission control to decide which object should be inserted into the cache is a popular approach for improving efficiency. For example, Adaptsize [25], W-TinyLFU [39], flashshield [40] are designed in the recent years. Admission control is effective for CDN caches, which usually have high one-hit-wonder ratios (up to 30%) with a wide range of object sizes (100s of bytes to 10s of GB). Segcache does not employ an admission algorithm because most of the in-memory cache workloads have low one-hit-wonder ratios (<5%) and relatively small object size ranges. Moreover, adding admission control often add more metadata and extra computation, hurting efficiency and throughput.

Other approaches. There are several other approaches in improving efficiency, such as optimizing slab migration strategy in Memcached [29,44], compressing cached data [72], and prefetching data [73]. Reducing object metadata size has also been considered in previous works [41]. However, for supporting the same set of functions (including expirations, deletions, `cas`), these approaches need more than twice as much object metadata as Segcache.

Throughput and scalability. A large fraction of works on improving throughput and scalability focus on durable key-value stores [31,50,52], which are different from key-value caches as discussed in §5. Segcache is inspired by these works and further improves throughput and scalability by macro management using approximate and shared object metadata.

6.2 Log-structured designs

Segcache's segment-structured design is inspired by several existing works that employ log-structured design [31, 33, 51, 57, 58, 62, 63] in storage and caching systems. The log-structured design has been widely adopted in storage systems to reduce random access and improve throughput. For example, log-structured file system [62] and LSM-tree databases [14,48] transform random disk writes to sequential writes. Recently log-structured designs have also been adopted in in-memory key-value store [31,33,57,58,63] to improve both throughput and scalability.

For in-memory caching, MICA [51] uses DRAM as one big log to improve throughput, but it uses FIFO for eviction and does not optimize for TTL expiration. Memshare [37] also uses log-structured design and has the concept of segments. However, Memshare optimizes for multi-tenant cache by moving cache space between tenants to minimize miss ratio based on each tenant's miss ratio curve. Memshare uses a cleaning process to scan N segments, evict one segment, and keep $N-1$ segments where the goal is to enforce memory partitioning between tenants. In terms of performance, scanning N ($N = 100$ in evaluation) segments and *evicting one* incurs a high computation overhead and negatively affects the throughout. Moreover, to compute the miss ratio of different tenants, Memshare adds more metadata to the system, which reduces memory efficiency.

Systems employing a log-structured design benefit from reduced metadata size and memory fragmentation, and increased write throughput, for example, several of the existing works [14,41,63] and including Segcache. Compared to these existing works, Segcache achieves a higher memory efficiency by *approximating* and *sharing* object metadata, *proactive TTL expiration*, and using ASFC to retain fewer bytes during eviction while providing a low miss ratio (10% - 25% bytes from each segment are retained in Segcache compared to 75% in RAMCloud [63] and 99% in Memshare [37]).

In a broad view, Segcache can be described as a *dynamically-partitioned* and *approximate-TTL-indexed* log-structured cache. However, one of the key differences between Segcache and log-structured design is that Segcache is centered around the indexed and sorted segment chain. Both objects in a segment and segments in the chains are time-sorted and indexed by approximate TTLs for metadata sharing, macro management, and efficient TTL expiration.

7 Conclusion

Segcache stems out of our insights from production workloads, in particular, the observation that object expiration and metadata play an important role in improving memory efficiency. We chose a TTL-indexed segment-structured design to achieve both high throughput, high scalability and memory efficiency. Our evaluation against state-of-the-art designs from both research and production projects shows that Segcache comes out ahead on our stated goals. Its efficient use of memory bandwidth, near linear scalability, and low-touch configuration poise it favorably as a practical production caching solution suitable for contemporary and future hardware.

Acknowledgements. We thank our shepherd Ryan Stutsman and the anonymous reviewers for their valuable feedback. We also thank Rebecca Isaacs, Xi Wang and Dan Luu for providing feedback, and the Cache, IOP and HWEng teams at Twitter for their support in evaluating Segcache. Abstract

A production-level cloud storage system must be high performing and readily available. It should also meet a Service-Level Agreement (SLA). The rapid advancement in storage media has left networking lagging behind, resulting in a major performance bottleneck for new cloud storage generations. Remote Direct Memory Access (RDMA) running on lossless fabrics can potentially overcome this bottleneck. In this paper, we present our experience in introducing RDMA into the storage networks of Pangu, a cloud storage system developed by Alibaba. Since its introduction in 2009, it has proven to be crucial for Alibaba's core businesses. In addition to the performance, availability, and SLA requirements, the deployment planning of Pangu at the production scale should consider storage volume and hardware costs. We present an RDMA-enabled Pangu system that exhibits superior performance, with the availability and SLA standards matching those of traditional TCP-backed versions. RDMA-enabled Pangu has been demonstrated to successfully serve numerous online mission-critical services across four years, including several important shopping festivals.

1 Introduction

Alibaba Group [12] is a China-based multinational technology company specializing in e-commerce, e-finance, and cloud computing. Numerous companies, including Alibaba, have moved their core business systems onto clouds. As a fundamental part of information technology (IT) infrastructure, a cloud storage provides a storage service to tenants both inside and outside the cloud provider. In 2009, Alibaba introduced Pangu [18], a cloud storage system that has subsequently played a crucial role in many Alibaba core businesses. As of 2020, Pangu has been deployed in hundreds of clusters, and it has been managing hundreds of thousands of storage nodes. Furthermore, it supports the real-time access to exabyte-level data in numerous production environments.

In order to ensure comparability to local physical storage clusters, a cloud storage system must meet the following requirements:

(i) *High performance:* Small latency and high throughput provide competitive advantages across many scenarios.

(ii) *High availability:* System disruptions incur significant financial/reputation loss for both tenants and their cloud providers.

(iii) *Service-Level Agreement (SLA):* A cloud storage system must be resilient, and thus its performance should gracefully downgrade when various software/hardware failures happen.

The rapid advancement in storage media has left networking lagging behind, resulting in a major performance bottleneck for new cloud storage generations. Networking is not a problem for traditional storage systems built with Hard Disk Drives (HDDs). However, the access latency of current Non-Volatile Memory Express (NVMe) disks is at the microsecond level [50] and the total throughput of a storage node can exceed 100Gbps. In contrast, the latency of traditional network stacks (*e.g.*, TCP/IP) can reach milliseconds [13], while the bandwidth per kernel TCP thread is only tens of Gbps at most [51].

Remote Direct Memory Access (RDMA) running on lossless fabrics offers a promising solution to the network bottleneck in cloud storage. By implementing its entire protocol stack on host NICs, RDMA is able to provide both microsecond level access latency and a per-connection throughput of approximately 100Gbps with almost zero CPU consumption [23]. The application of RDMA over Commodity Ethernet (RoCE) in data centers relies on the Priority Flow Control (PFC) mechanism to provide a lossless fabric.

In this paper, we present our experience in introducing RDMA into Pangu's storage networks (*i.e.*, the network among storage nodes). Our objective is to provide an RDMA-enabled Pangu system that exhibits superior performance, with availability and SLA standards equal to that of traditional TCP-backed versions. Our experience spans 4 years and will continue with the development of RDMA. We faced a number of challenges specifically related to cloud storage, with additional problems associated with RDMA. We have developed a number of solutions to allow for RDMA to function in a production-level cloud storage, several of which are engineering-level work-arounds. However, overcoming the aforementioned RDMA issues proves to be a complicated task. Here, we expose the practical limitations of the production systems in order to facilitate innovative research and applications in this area.

In addition to the performance, availability, and SLA requirements, the deployment planning of Pangu at the production scale should consider storage volume and hardware costs. Following the *availability-first* principal, RDMA communication is enabled only inside each *podset* [13]. Such a podset contains a group of leaf switches, and all Top-of-Rack (ToR) switches connected to these leaf switches. The podsets are connected via spine switches. This setting is currently the optimal balance between application demands, performance, and availability/SLA control. Storage node configurations are carefully planned to match the disk throughput with the network bandwidth. We adopt the hybrid deployment of RDMA/TCP in Pangu to exploit TCP as the last resort for the system (§3).

The performance optimization aims to minimize latency while maximizing throughput. We leverage *software-hardware co-design* to minimize performance overhead. We build a software framework in Pangu that integrates RDMA with Pangu's private user-space storage platform designed for new storage media. By eliminating data-copy operations, the latency of a typical block service request is reduced to tens of microseconds. We observed that the memory bandwidth becomes a bottleneck when upgrading Pangu to a 100Gbps network. By exploiting the RDMA features and offloading critical computations, Pangu is able to saturate the underlying networks. Furthermore, we leverage a new thread communication mode in Pangu to reduce the performance pitfall caused by a large number of Queue Pairs (QPs, RDMA connection abstraction) per node (§4).

Previous studies have reported the risks of large-scale RDMA deployment [13]. RDMA-enabled Pangu clusters do encounter such problems, including PFC deadlocks [13], PFC pause frame storms, and head-of-line blocking [27, 44]. We determined several PFC storms to be attributed to a previously unexplored source that consequently invalidates an earlier solution [13]. In order to guarantee availability, we apply the *escape-as-fast-as-possible* design principle to handle PFC storms. We bring up a fine-grained switching mechanism between RDMA/TCP traffic in Pangu and it handles PFC storms regardless of their causes (§5).

In order to meet the SLA standards, we adopt the design principal of *exploiting storage semantics whenever useful* in Pangu. By taking advantage of its ability to control the application layer, Pangu performs the real-time checking and alarming for a large number of storage service and network

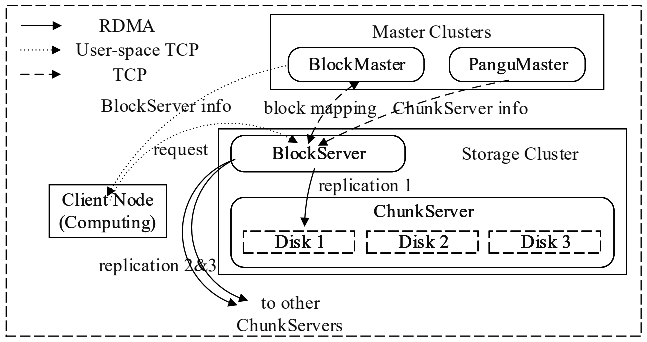

Figure 1: Pangu block storage service framework.

metrics. With the help of the dual-home topology feature, we optimize the fail-over performance of Pangu by reducing the connection recovery time. We also fix network problems by exploiting application controls, for example, blacklisting problematically connected nodes (§6).

We share our experience in adopting the RDMA-enabled Pangu system and discuss several potential research directions (§7). This system has successfully served numerous online mission-critical services under the scope of Alibaba over the past four years, including several important shopping festivals (*e.g.*, Double-11 [8]). Sharing our experience in integrating RDMA into Pangu can be helpful for other RDMA-enabled systems.

2 Background

2.1 Pangu in Alibaba Cloud

Pangu Framework. Pangu is a distributed file system developed by Alibaba Cloud. Released in 2009, it plays a major role in the core Alibaba businesses (*e.g.*, e-business and online payment, cloud computing, enhanced solid state drive backed cloud disk, elastic compute service, MapReduce-like data processing, and distributed database). In this paper, we focus on the network features of Pangu.

Pangu provides numerous storage services, including elastic block service, object storage service, store service, *etc.* We take the block service as an example to demonstrate the system framework. Fig. 1 presents the I/O workflows of Pangu. Virtual block devices contain continuous address spaces that can be randomly accessed by applications. A Pangu client in a computing node organizes data into fixed-sized (*e.g.*, 32 GB) *segments*, while the BlockServers and ChunkServers run on storage nodes. Each segment is aligned to a BlockServer for I/O processing. On the BlockServers, a segment is divided into blocks and replicated to the ChunkServers, which are in charge of the standalone back-end storage of the blocks and device management.

The BlockMasters manage metadata such as the mapping between a segment and its located BlockServer and the BlockServer's living states. The PanguMasters manage the states of the ChunkServers. These master nodes are synchronized using consistent protocols, such as Raft [36].

All data communication in Pangu is in the form of Remote Procedure Calls (RPCs). Each ChunkServer initiates the RPC clients/servers, and storage operations are performed by issuing pre-registered RPCs. An RPC client can simultaneously use different RPC channels (*i.e.*, connections via RDMA, kernel TCP, user-space TCP, or shared memory)according to the required RPCs.

Cloud Storage Requires RDMA. The principal performance metrics for storage services are read/write throughput and access latency. Low latency and high throughput prove to be advantageous for numerous application scenarios. Many customers expect similar performance of the cloud storage to that of the local physical storage. For example, the Alibaba e-commerce database requires extremely low latency in order to ensure fast responses due to the potentially large peak number of transactions per second (*e.g.*, 544,000 orders per second at peak hours [8]). Moreover, the enhanced SSD service promises 1 million IOPS, 4GB/s throughput, and 200µs latency for 4KB random writes [17].

The latency of traditional network stack (*e.g.*, TCP/IP) is generally within hundreds of microseconds [13]. The maximum achievable TCP bandwidth per kernel thread can reach tens of Gbps [51]. In contrast, the access latency of current NVMe SSDs is only at the microsecond level, while the read/write bandwidth of a single device is at the GB/s level [49]. The total throughput of each storage node (generally with 8-16 NVMe disks) can exceed 100Gbps and the incoming Storage Class Memory (SCM, *e.g.*, Intel 3D-XPoint) can even achieve nanosecond level latency [35]. Thus, networking is currently the primary performance bottleneck for cloud storage.

RDMA is an alternative networking choice for cloud storage. By implementing its entire protocol stack on host NICs, RDMA provides both microsecond level access latency and a per-connection throughput close to 100Gbps with almost no CPU consumption [23]. RDMA has successfully been integrated into numerous network-bottlenecked systems, for example, key-value stores [22, 33], distributed transactions [6, 24, 48], and graph queries [40], demonstrating an improved performance compared with non-RDMA predecessors.

2.2 Challenges

Besides performance, availability and SLA are also critical for a successful cloud storage system.

Availability. System disruptions incur significant financial/reputation loss for both tenants and their cloud providers. In 2018, Amazon S3 experienced a system disruption that lasted for 4 hours [2], affecting Amazon Elastic Compute Cloud , Amazon Elastic Block Store volumes, and AWS Lambda [3]. This disruption also had an impact on tens of thousands of websites built on the Amazon storage service, including Netflix [34], Spotify [43], Pinterest [37], and Buzzfeed [5]. Similar events have occurred with Google Cloud and Microsoft Azure [4, 9].

Service-Level Agreement. Software and hardware failures are extremely common in distributed systems. A cloud storage system should exhibit graceful performance downgrade with the occurrence of various failures. Distributed storage systems include mature node monitoring and fail-over mechanisms. A single storage node failure has a minimal impact on the service quality. In our experience, the most challenging aspect of ensuring a stable performance lies in the storage networks. Network failures generally result in a larger affected range compared to storage node failures.

In addition to its superior performance, customers of our RDMA-enabled Pangu require the same levels of availability and SLA standards to that of traditional TCP-backed versions.

2.3 State-of-the-art Work Do Not Fit

Unknown PFC Storm Sources. PFC runs under a hop-by-hop mechanism, with the possibility of PFC storms, spreading into the whole cluster. A PFC storm can seriously affect cluster availability and is the most well-known issue of RDMA. In 2016, Microsoft presented its experience in the deployment of RDMA [13], where they revealed that a bug in the receiving pipeline of an RDMA-capable NICs (RNICs) causes PFC storms. The problem was fixed by building watchdogs on the NICs and switches. However, we identified an additional type of PFC storms that originates from switches, implying the complexity of PFC storms with multifarious sources. The Microsoft solution [13] fails to solve this new problem (§5).

Practical Concerns that Limit Design Options. We are not able to simply treat RDMA as a black-box and wait for future research and technical advances to solve the current problems. Despite the large number of recent studies [10, 22, 29, 33, 40, 48], a production-level comprehensive PFC-free solution is still premature. The application of RDMA over lossy Ethernet has been explored in previous work [7, 11, 15, 26], allowing for the bypass of the PFC mechanism. However, such solutions rely on new hardware features.

The deployment of new hardware is a long process, with several months or even years of testing, followed by the subsequent introduction to business applications. For example, the process of testing Pangu with CX-4 RNICs, a joint collaboration with NIC providers, lasted for over two years. There is a tension between the fast growth of new RDMA demands and the long update cycles of new hardware. To date, these PFC-free proposals are not mature enough for large-scale business deployment, particularly for the availability and SLA standard requirements of cloud storage systems.

Furthermore, large-scale industry deployment is generally associated with multiple generations of legacy RDMA NICs. For example, we have already deployed several Mellanox NIC generations (*e.g.*, CX-4, CX-5), with the number of each reaching tens of thousands. It is operationally infeasible and costly to replace all legacy NICs in the running nodes,

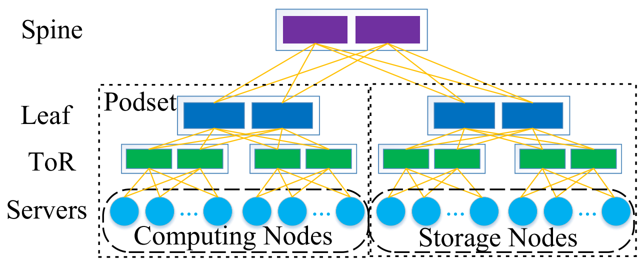

Figure 2: Topology of Pangu.

Hardware	25Gbps	100Gbps
CPU	Xeon 2.5GHz, 64 cores	Xeon 2.5GHz, 96 cores
Memory	DDR4-2400, 128GB	DDR4-2666, 128GB $\times3$
Storage	1.92TB SSD$\times$12	3.84TB SSD$\times$14
Network	CX-4 Lx Dual-port	CX-5 Dual-port
PCIe	PCIe Gen 3.0	PCIe Gen 3.0

Table 1: Example configurations of 25/100Gbps nodes.

while upgrading the firmware of tens of thousands of running servers is both time-consuming and error-prone. Thus, the need for new hardware features or firmware should be minimized.

Domain Knowledge of Distributed Storage Should be Exploited. Existing work largely ignores potential help from the application layer. Storage service metrics, rather than networking metrics, are a key concern for cloud service applications. We take into account such storage semantics in the design of Pangu when improving the engineering trade-off and the decision making process for various networking problems.

3 RDMA Deployment

3.1 Consideration in Deployment Planning

The deployment planning of storage clusters governs the network topology, RDMA communication scope, storage node configurations, *etc.* Multiple factors must be considered, including matching the storage volume with demands, controlling hardware costs, optimizing performance, and minimizing availability and SLA risks. The final outcome is a trade-off among all these factors.

For example, Microsoft deploys RDMA at the scale of an entire Clos network [13]. Thus, if not prevented, PFC storms could spread across the whole network and bring down an entire cluster. This amount of risk is unacceptable in a production-level storage system.

3.2 Deployment Choices of Pangu

The key principle employed by our RDMA deployment is *availability-first*.

Network and Node Configurations. Fig. 2 displays the Clos-based network topology of Pangu. Consistent with the common dual-home practice, we deploy Mellanox CX series dual-port RNICs to connect a host with two distinct ToR switches. In particular, two physical ports are bonded to a single IP address. Network connections (*e.g.*, QPs in RDMA) are balanced over two ports following a round-robin fashion.

Total bandwidth	TCP bandwidth ratio	TX pauses
25Gbps	40%	0
30Gbps	45%	1Kpps
32Gbps	50%	8Kpps
35Gbps	46%	15Kpps

Table 2: TX pauses in hybrid RDMA/TCP traffic.

When one port is down, the connections on this port can be migrated to another port.

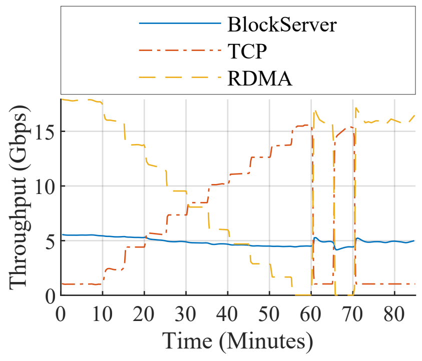
Table 1 reports typical hardware configurations for 25Gbps and 100Gbps RNIC storage nodes. The number of SSD per node is determined by the total RNIC bandwidth versus the throughput of a single SSD, allowing the I/O throughput to match the network bandwidth. Note that the SSD types in the 25Gbps and 100Gbps configurations are distinct, resulting in disproportional numbers. Computing and storage nodes are deployed in different racks within a single podset. The numbers of computing and storage nodes are then calculated according to the computational demands.

RDMA Scope. In order to minimize the failure domain, we only enable RDMA communication within each podset and among storage nodes. The communication between computing and storage nodes is performed via a private user-space TCP protocol (Fig. 1). This is attributed to the complex hardware configurations of computing nodes, which update rapidly. Thus, TCP can be effectively applied as a hardware-independent transport protocol. User-space TCP is more convenient for upgrade and management compared to kernel TCP, while kernel TCP is selected for cross-podset communication due to its generality.

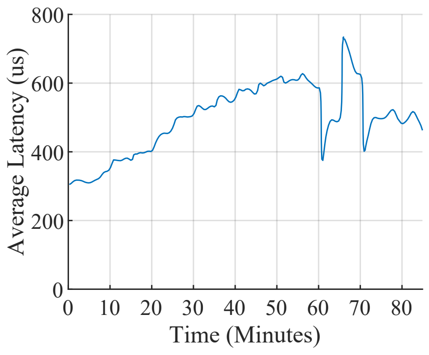
The production deployment is an additional concern for podset-level RDMA. In many datacenters, podsets are located in different buildings. For cross-building RDMA links, the base link delay is much larger, while the PFC mechanism requires much larger headroom buffer. In order to enable RDMA, the PFC/ECN thresholds located on the spine switches must be carefully adapted and tested. This is a tough task and at present, does not result in sufficient gains.

RDMA/TCP Hybrid Service. To the best of our knowledge, previous research on RDMA deployment does not explore RDMA and TCP hybrid services. We keep TCP as the last resort in Pangu following the *availability-first* principal. Despite current progress, RDMA devices are far from flawless. Thus, when either availability or SLA are threatened, switching affected links from RDMA to TCP can maintain the available bandwidth. This escape plan does not impact the unaffected RDMA links.

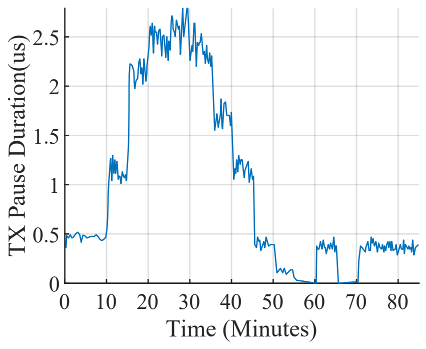
However, during the hybrid deployment process, we determined that coexistent TCP traffic provoked a large number of TX pauses (*i.e.*, PFC pause frames sent by NICs), even if RDMA/TCP traffic are isolated in two priority queues. Table 2 reports the TX pause generation rate in Pangu under different loads with approximately 50% TCP traffic. The tests are performed on Mellanox CX-4 25Gbps dual-port RNICs. Such a large number of TX pauses are detrimental to the



(a) Throughput of RDMA/TCP/BlockServer.



(b) Latency of BlockServer requests.



(c) Average TX pause duration.

Figure 3: RDMA/TCP hybrid deployment tests at different ratios (from 0% to 100% TCP).

performance and may result in PFC storms. We investigated this problem together with Mellanox and determined that the processing of TCP in the Linux kernel is highly I/O-intensive. Kernel TCP initiates too many partial writes on NICs' PCIe bus. As the PCIe bandwidth is consumed, the receiving pipeline of a NIC is slowed down. The buffer overflows and the NIC subsequently begins to transmit PFC pause frames.

In order to optimize the memory access of TCP, we make several adjustments on the data access procedure. First, disabling the Large Receive Offset (LRO) can reduce the memory bandwidth usage. This is attributed to the access of multiple cache lines when the LRO is enabled. Furthermore, enabling NUMA also improves the efficiency of memory accesses, which subsequently aids in relieving the pressure of PCIe. We also allocate a larger buffer on the RNICs for RDMA traffic to prevent TX pauses. Finally, making application data cacheline-aligned is a common optimization practice that improves memory efficiency [23].

3.3 Evaluation

We test several RDMA/TCP traffic ratios to investigate the effects of RDMA/TCP hybrid deployment. Each computing node runs FIO with 8 depths (inflight I/O requests), 8 jobs (working threads), and 16 KB block size in order to write virtual disks. Note that one write request on a BlockServer generates three data replicas. We enable all optimizations approaches detailed in §3.2 for the TCP kernel.

Fig. 3(a) depicts the BlockServer bandwidth with varying RDMA/TCP ratios. The workload starts at 10 minutes with 100% RDMA traffic. Afterwards, in every 5 minutes, the workload contains 10% more TCP traffic and 10% less RDMA traffic. At 60, 65, 70 minutes we change the TCP traffic ratio to 0%, 100%, and 0% respectively in order to explore the performance of Pangu with quick traffic switching between RDMA and TCP. The average BlockServer throughput exhibits minimal reduction as the RDMA traffic ratio decreases.

Fig. 3(b) presents the BlockServers' average request latency for the same workload as that in Fig. 3(a). The average latency under 100% RDMA traffic is approximately half of the latency under 100% TCP traffic, while the tail latency under 100% TCP is more than 10× larger compared to 100% RDMA traffic. RDMA presents great latency advantages compared to TCP. Fig. 3(c) demonstrates the average TX pause duration per second for this workload. Only a limited number of TX pauses are observed. When the TCP bandwidth ratio is around 50% at 30 minutes, the pause duration reaches a peak value.

Overall, these results demonstrate the stable performance of our RDMA/TCP hybrid mechanism.

4 Performance Optimization

4.1 Performance Hurdles

The performance optimization of Pangu aims to *minimize latency while maximizing throughput*.

RDMA-Storage Co-Design. Integrating the RDMA protocol stack with the storage backend is challenging. It must cover key performance points such as thread modeling, memory management, and data serialization. The thread model directly affects latency due to communication costs among threads. Well-designed memory management and data serialization are key to achieving zero-copy during data access. Here we present a brief introduction on the design of these components for storage purposes.

The User Space Storage Operating System (USSOS) is a unified user-space storage software platform that aims to support new storage media such as NVMe SSD and persistent memory. Its design principles (*e.g.*, memory management, shared memory mechanism, and user-space drivers) are based on well-known user-space technologies (*e.g.*, DPDK [19] and SPDK [42]). Related tests reveal that enabling USSOS in Pangu can improve CPU efficiency by more than 5× on average.

As a central part of USSOS, the User Space Storage File System (USSFS) is a high-performance local file system designed for SSDs. By running in the user space, USSFS is able to bypass the kernel to avoid user-/kernel-space-crossing overhead. USSOS divides disks into "chunks" which ChunkServer uses in its APIs (*e.g.*, create, seal, and delete).

Components	Average Utilization	Peak Utilization	Maximum Physical Capacity
Physical CPU utilization ratio	66%	70%	100%
Memory read/write throughput	28GB/s / 29GB/s	33GB/s / 32GB/s	61GB/s in total (1:1 read/write)
SSD PCIe throughput (socket 0 + socket 1)	550MB/s + 550MB/s	1000MB/s + 1000MB/s	3.938GB/s + 3.938GB/s
Network PCIe RX throughput	10GB/s	11GB/s	15.754GB/s
Network PCIe TX throughput	8GB/s	9GB/s	15.754GB/s

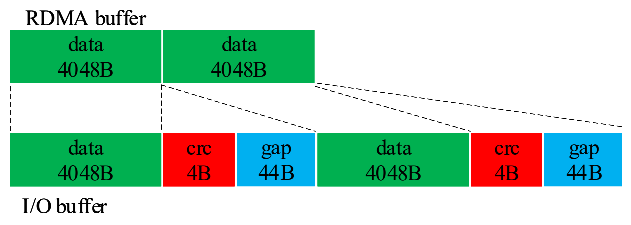

Figure 4: Potential triggering of data copying by CRC.

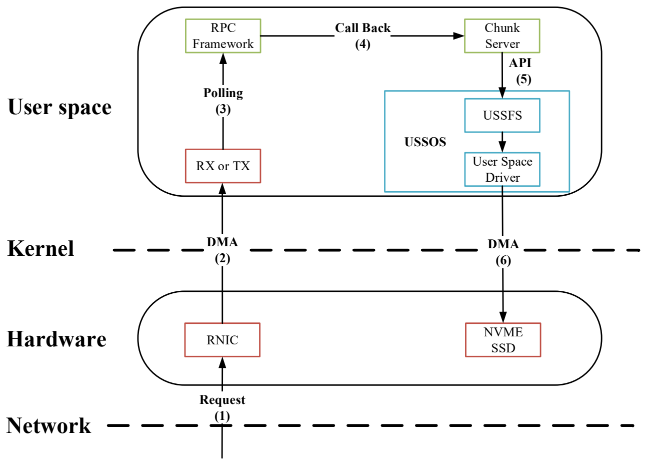

Figure 5: Integrated network/storage processing.

USSOS directly writes data and metadata to disks and uses polling to perceive completion events. For different block sizes, USSFS is able to improve IOPS by 4-10× compared to the Ext4 file system.

A run-to-completion model is considered as the optimal approach for the integration of the RDMA network stack with the storage stack. This model has previously been explored in studies discussing disaggregated storage (*e.g.*, Reflex [25], i10 [16]). However, these studies were published after the introduction of RDMA to Pangu in 2017. Reflex and i10 focus on remote direct I/O while a ChunkServer in Pangu is applied as a local storage engine for distributed storage. Google's Snap [31] leverages a separate network process to unify network functionalities and reduce the number of network connections.

Memory Bottleneck with 100Gbps networks. Deploying 100Gbps networks can achieve lower latency and higher throughput. With faster network, now the memory throughput becomes a bottleneck in our system.

In order to obtain the upper bounds of the memory access throughput, we test the memory throughput using the Intel Memory Latency Checker (MLC) tool [20]. Table 3 details the measured usage of the hardware resources. In our test, the maximal achievable memory bandwidth is 61GB/s with a 1:1 read/write ratio. However, the average memory throughput with Pangu's workload is already $29\text{GB/s}+28\text{GB/s} = 57\text{GB/s}$. This indicates the memory to be the bottleneck rather than the network.

By monitoring the memory usage in Pangu, we determined that both the verification and data copy processes require optimization. Data integrity is one of the most significant features of distributed storage. We adopt Cyclic Redundancy Check (CRC) for application-level data verification in Pangu. As shown in Fig. 4, the received data is split into chunks of 4KB, with a 4B CRC value and a 44B gap added to each chunk. This operation is a memory- and computation-intensive operation as the calculations are applied to the entire dataset. The data are also copied when they are written into the disks in order to include CRC footers. Copying is not performed in other components due to the remote-memory access semantic of RDMA.

Large Number of QPs. We used to adopt the full-mesh link mode among running threads in Pangu in order to maximize throughput and minimize latency (Fig. 6(a)). Assume that each ChunkServer has 14 threads, each BlockServer has 8 threads, and each node contains both ChunkServers and BlockServers. For the full-mesh mode in a cluster of 100 storage nodes, there could be $14 \times 8 \times 2 \times 99 = 2,2176$ QPs in each node. RNICs' performance drop dramatically for large numbers of QPs due to cache miss [21]. In particular, the number of RX pauses (*i.e.*, PFC pause frames received) is very high.

Previous studies have demonstrated the same issue [10, 23, 47]. In order to solve this problem, FaSST [24] shares QPs among threads, which subsequently lowers the CPU efficiency and performance due to the lock contention of QPs between threads. An alternative heuristic is the inclusion of a dedicated proxy thread that manages all receive and send requests [41]. However, switching to/from a dedicated proxy thread increases latency. Furthermore, it is difficult to saturate the full network bandwidth with a single thread. Moreover, the proxy solution is not transparent to the underlying RDMA libraries.

(b) Shared-link mode

Figure 6: Different link modes for send/receive RPC requests

4.2 Designs

The designs related to performance in Pangu are based on the principle of *software-hardware co-design to minimize performance overhead.*

Storage-RDMA Unified Run-to-Completion Stack. We adopt a run-to-completion thread model for both storage and network to achieve low latency. Fig. 5 demonstrates the procedure used to process requests. When a write RPC is received by a node, the RNIC posts it to the user space via DMA. The RPC framework obtains the request using polling and subsequently hands it over to a ChunkServer module for processing. The ChunkServer then informs USSFS to allocate a "chunk" resource to the request. Finally, a user-space driver interacts with NVMe SSDs to store the data. These operations are generally performed in a single server thread without thread switching. This run-to-completion model minimizes the latency. In order to reduce the blocking time caused by large jobs, large I/O requests are split into smaller requests when submitted by applications. This optimization ensures a quick response to I/O signals. An additional optimization strategy for large I/O requests involves the passing of auxiliary work (*e.g.*, formatting and CRC calculation) to non-I/O threads, where they are subsequently processed. These optimizations reduce the average latency of a typical storage request (*e.g.*, 4KB size) to less than 30μs.

The data formats are unified as I/O vectors. An I/O vector is transmitted without copying via a single RDMA verb using scatter-gather DMA (the transfer of discontinuous data through a single interruption) in network. Serialization is not necessary due to RDMA semantics.

Zero-Copy & CRC Offloading. As discussed in §4.1, in Pangu, data has to be copied once on the I/O path as each 4KB chunk is verified and attached with a CRC footer. Here, we leverage the User-Mode Memory Registration (UMR) [32] feature of RNICs to avoid such data copy. UMR can scatter RDMA data on the remote side through the definition of appropriate memory keys. Thus, data can be formatted and organized according to storage application formats. We use UMR to remap the continuous data from the sender into an I/O buffer at the receiver, which contains 4KB data, a 4B footer, and a 44B gap in each unit. Following the CRC calculation, the filled I/O buffer can be directly applied for disk writing. Besides, the CRC calculation is able to be offloaded to capable RNICs (*e.g.*, Mellanox CX-5), thus lowering CPU and memory usage. The 4KB data are posted to the RNIC and the 4B CRC checksum is then generated.

Shared Link. We adopt the shared link mode, an effective solution for reducing the number of QPs in Pangu. The shared link mode is implemented in the application layer and leaves RDMA libraries untouched. A *correspondent* thread in the destination node is assigned to each thread in the source node (Fig. 6(b)). The thread's requests to the node are sent to its correspondent thread, which subsequently dispatches requests to correct target threads.

Consider a daemon with N threads, each thread polls N request/response queues to obtain the requests/responses. Note that there is only a single producer/consumer for each request/response queue. Thus we use lock-free queues for each request/response queue to avoid contention. According to our test, this design adds approximately 0.3 μs latency.

In the shared link mode, there is resource overhead at the correspondent thread during request dispatching when the source thread sends too many requests. Pangu supports shared groups, where threads in a node can be divided into several groups. A correspondent thread only relays requests for its group members. Returning to the previous example, the number of QPs in the *All Shared* mode is now reduced to $(8+8)\times 99 = 1,584$. If the threads are divided into 2 shared groups, the number of QPs will be $(8\times 2+8\times 2)\times 99 = 3,168$.

4.3 Evaluation

Zero-Copy & CRC Offloading. We use FIO with 16 jobs and 64 I/O depth to test a virtual I/O block device on a single ChunkServer. Fig. 7(a) demonstrates the memory bandwidth usage (including read/write tasks) when UMR zero copy and CRC offloading are used. The memory bandwidth usage is reduced by more than 30%, revealing that these measures are able to relieve the pressure of memory usage. Fig. 7(b) depicts

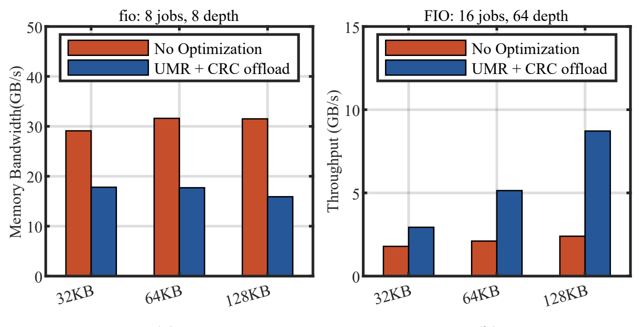

Figure 7: Performance of UMR zero copy + CRC offloading

the improvement in throughput following the optimization. The throughput of a single ChunkServer thread is improved by approximately 200% for a block size of 128KB.

Shared Link. We tested the shared link mode with several shared QP groups in a cluster of 198 computing nodes and 93 storage nodes. The background workload compromises 4KB random writes with 8 threads and 8 I/O depths. Fig. 8(a) presents the throughput in the All Shared, 2 Shared Groups, and 4 Shared Groups modes, whereby a performance trade-off can be observed. The All Shared mode exhibits slightly lower throughput but generates the lowest number of PFC pauses. Note that the reduction in bandwidth at 5 and 24 minutes in the All Shared mode is attributed to the garbage collection mechanism in Pangu. Fig. 8(b) presents the TX pause duration with 1, 2, and 4 Shared Groups, respectively. The lower the number of groups, the fewer the PFC pauses are generated due to the reduction in QP number. We use the All Shared Group mode in our scale and configuration framework.

5 Availability Guarantee

5.1 PFC Storms

A New Type of PFC Storm. The PFC storm previously discussed in [13] originates from the NICs, with a bug in the receiving pipeline acting as the root cause. Fig. 9(a) depicts the phases of this PFC storm: (1) The bug slows down the NIC receive processing, filling its buffer; (2) the NIC transmits the PFC pauses to its ToR switch in order to prevent packet drop; (3) the ToR switch pauses the transmission; (4) the ToR switch's buffer becomes full and starts to transmit the PFC pauses; and (5) the victim ports are paused and are unable to transmit.

We encountered a different type of PFC storm when operating RDMA in Pangu. The root cause is a bug in the switch hardware of a specific vendor. The bug reduces the switching rate of the lossless priority queues to a very low rate. Fig. 9 compares the two types of PFC storms. As an example, we assume that the bug occurs in a down port of a ToR switch: (1) due to the low transmitting rate, the switch's buffer becomes full; (2) the switch transmits the PFC pauses to the connected ports; and (3) the additional switches and NICs stop the transmissions. The leaf switches and NICs connected to this ToR switch receive continuous pause frames and thus the storm spreads.

State-of-the-Art Solutions. Guo *et al.* [13] built a NIC-based watchdog to continuously monitor transmitted pause frames, disabling the PFC mechanism if necessary. In addition, watchdogs were also deployed on the switches for disabling the PFC mechanism when switches receive continuous pause frames and are unable to drain the queuing packets. The switches can subsequently re-enable PFC in the absence of pause frames over a specific period of time. Thus, PFC storms can be controlled via these two watchdogs during phase (2).

However, this solution is unable to completely solve the PFC storms originating from switches. In particular, the TX pause watchdogs on the NICs will not work since the NIC only receives PFC storms from the switches. Furthermore, current switch hardware does not support the monitoring of pause frame transmissions. If a storm occurs on a ToR switch, even though the watchdogs on other switches are able to stop its spread, the ToR switch will continue to send pauses to end-hosts in the rack. The RDMA traffic via this ToR is consequently blocked.

Challenges. This new type of PFC storms invalidates Guo *et al.*'s solution, which focuses on insulating the PFC pause sources to prevent the storm from spreading. This methodology fails when the source is a ToR switch as all the hosts in the ToR are paused by the storm. Therefore, in order to achieve high availability, a general solution is required in Pangu to handle all PFC storm types, particularly those with unknown causes.

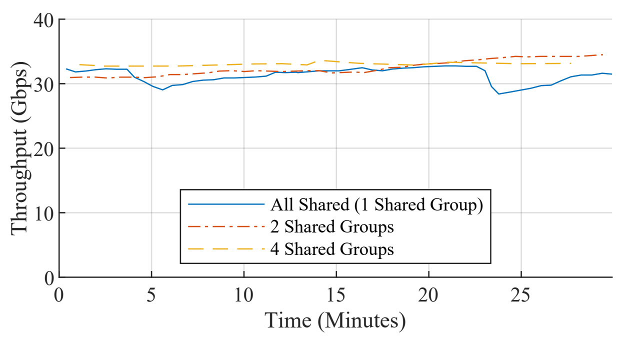
Ensuring the service quality of Pangu while simultaneously solving PFC storms is challenging. PFC storm detection must be timely and accurate to rapidly protect network traffic. In terms of availability, the overall convergence time of the PFC storm should be controlled to at most the minute level.

5.2 Design

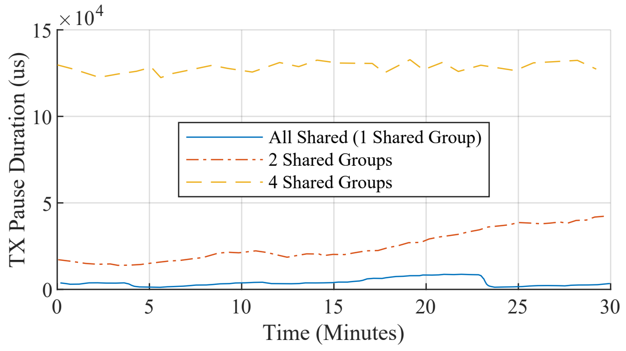
Our design principle of handling PFC storms is *escaping as fast as possible*. Despite new PFC storm solutions [11, 21, 26], we still resort to engineering-level work-arounds due to practical considerations (§2.3).

In Pangu, each NIC monitors the received PFC pause frames. For continuous pause frames, the NIC determines the presence of a PFC storm. Two work-around solutions are available for administrators in the case of a PFC storm.

Workaround 1: Shutdown. This solution, denoted as the "shutdown" solution, shuts down NIC ports affected by PFC storms for several seconds. The dual-home topology provides an emergency escape for PFC storms, whereby QPs will disconnect and connect again via another port. This method works together with the optimization to reduce the length of the QP timeout. This optimization is discussed further in §6.2. Although this solution is simple and effective, it is sub-optimal due to the loss of half of the bandwidth.

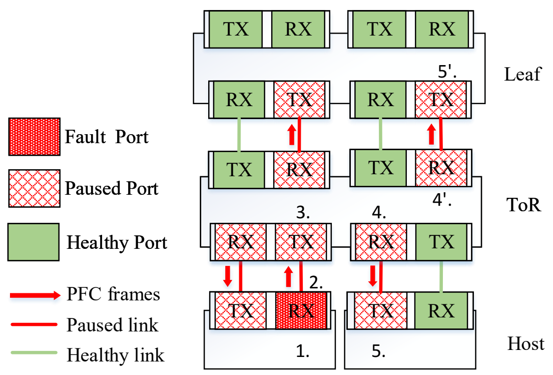


(a) Throughput in different thread groups.

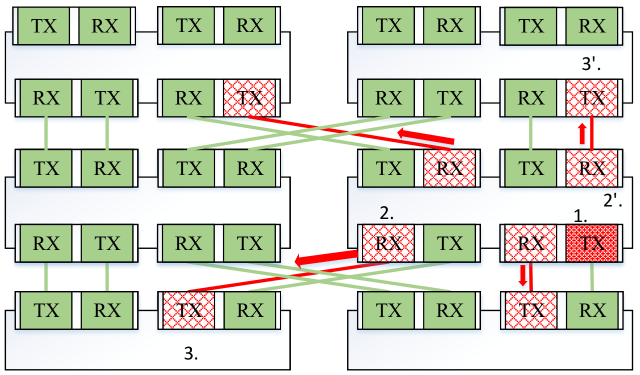


(b) Pause time in different thread groups.

Figure 8: Throughput and pause for different types of thread groups.



(a) The PFC storm originates in NICs.



(b) The PFC storm originates in switches.

Figure 9: Different types of PFC storms.

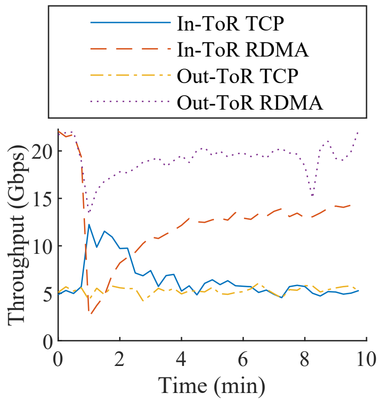
Workaround 2: RDMA/TCP Switching. In this solution, the affected RDMA links in a PFC storm are switched to TCP links. It compromises a more complex procedure compared to the shutdown solution, yet it is able to maintain the available bandwidth. We adopt a method similar to PingMesh [14] to detect the RDMA links affected in PFC storms. At each T ms, every worker thread picks a server and separately pings all its threads via the RDMA and TCP links. If the RDMA ping fails and the TCP ping succeeds for more than F times, the traffic on this RDMA link is switched to the TCP link. Once the RDMA ping has succeeded more than S times, the traffic on the switched TCP link is switched back to the RDMA link. For $T = 10$ ms and $F = 3$, bad RDMA links can be detected in approximately 10 seconds in a podset of 100 storage nodes. By switching the RDMA traffic to the TCP connections, the throughput can recover to more than 90% in less than 1 minute.

5.3 Evaluation

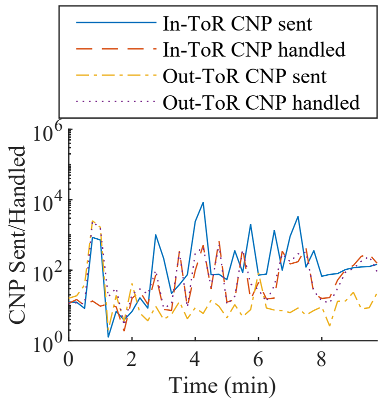
We simulate PFC storms by injecting the aforementioned bug into a switch for several cases, including the uplink/downlink ports on the ToR and Leaf switches. The RDMA/TCP switching solution exhibits strong performance for all cases. Fig. 10 displays the results for a PFC storm originating from a ToR switch downlink port. Note that the nodes inside the ToR behave differently from nodes outside the ToR. We choose two nodes (inside and outside the ToR) in order to demonstrate the difference. In such a case, the pause frames are transmitted to NICs and leaf switches directly connected to the given ToR switch.

The shutdown solution shuts down the NICs via the watchdogs in the occurrence of a fault due to excessive RX pauses. RDMA links subsequently reconnect through another NIC port, thus recovering traffic. Note that the counters of Congestion Notification Packet (CNP) and PFC frames gradually increase since the system load (at 0 minutes) is larger than the available bandwidth of a single port (25Gbps). The system then reaches a new balance in approximately 30 minutes. However, the shutdown solution has several limitations. For example, computing node requests may not respond within 1 minute (known as I/O hang sensed by applications). The downlink breakdown of a leaf or ToR switch can result in tens to hundreds of hang requests. Furthermore, the shutdown of ports is itself an aggressive action. Hundreds of ports may be shut down due to unexpected pauses. This risk may itself influence the availability of a large number of nodes.

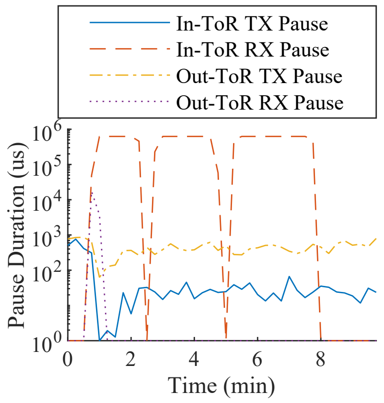
The RDMA/TCP switching solution switches the RDMA traffic that passes through the broken-down switch to TCP.



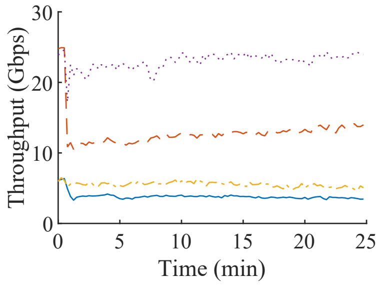
(a) Throughput of RDMA/TCP switching.



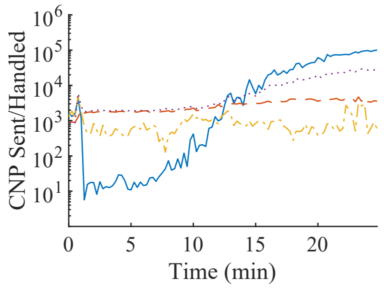
(b) CNP of RDMA/TCP switching.



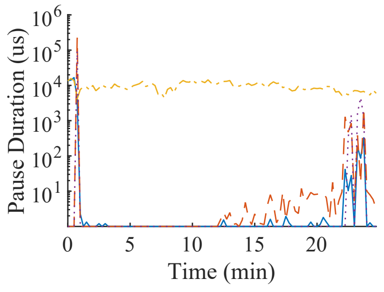
(c) PFC Pause of RDMA/TCP switching.



(d) Throughput of shutdown.



(e) CNP of shutdown.



(f) PFC Pause of shutdown.

Figure 10: Performance of two different solutions for PFC storms.

The RDMA links are then disconnected due to timeout. The QPs are separately distributed over the server's two NIC ports, thus the RDMA links may need several attempts to reconnect successfully. Note that although the pause storm in the ToR is not terminated, it will not spread further as the neighboring switch ports are transformed into the lossy mode via the RX pause watchdogs. The traffic throughput is not impacted during the migration to the TCP, and I/O hangs are not present.

6 SLA Maintenance

6.1 SLA in Pangu

It is commonly-known that network failures are hard to locate and repair. Network failure causes include mis-configuration, hardware/software bugs, and link errors. For example, the mis-configuration of the switch Access Control List (ACL) may only affect a specific flow while other flows behave normally [28, 45]. As a comparison, malfunctions occurring at storage devices or nodes can generally be easily located.

Sometimes network failures may not be explicit. Ideally, when a node breaks down, the heartbeat mechanism should ensure that the unavailability of service daemons (BlockServers and ChunkServers) on the node are informed to their masters (BlockMasters and PanguMasters). However, real situations can be more complicated, failing to be detected with just heartbeats. Connections may suffer intermittent packet loss or long latency rather than simple break downs. We also identified an interesting failure type involving a small number of links that flap between up and down states for a short period of time (*e.g.*, several seconds). This results in an extremely high tail latency for I/O requests, denoted as slow I/O (*e.g.*, over 1 second for storage clients). Hundreds of slow I/Os are observed daily for numerous reasons. Root causes of link flapping include optical ports covered with dust, loose physical interfaces, aging hardware, *etc.*

Previous Research on Network Failures. The majority of previous studies focus on determining the location of network failures (*e.g.*, Pingmesh [14] and 007 [1]). These solutions focus on the system network and can achieve the timely discovery of network errors. However, it may still take hours for engineers to manually check, fix, and replace the failed switches and links. Cloud storage calls for a methodology that integrates the storage and network function modules to ensure stable service quality in failed cases.

6.2 Design

Our SLA design principle aims to *exploit storage semantics whenever useful*. Distributed storage is designed with a redundancy mechanism and its performance is measured via the storage semantics. These semantics, such as data replicas and distributed placements, can be leveraged during a failure to improve system performance.

Network-Integrated Monitoring Service. Monitoring is a necessary component of distributed systems. A comprehensive monitoring system is key for the safe deployment of RDMA in production storage systems, as well as reliable performance.

Both configurations and counters must be monitored. NIC configurations include system environments, PFC/ECN/QoS configurations, and several link configurations. Pangu automatically checks, collects, and reports suspicious terms. Inspecting potential mis-configurations can reduce configuration and environment errors. For example, accidental reboot and software upgrades may reset the QoS, PFC, DCQCN [52] configurations and affect system performance. Monitoring can discover such cases and help fix them in advance.

Counters include storage system performance counters (*e.g.*, IOPS/latency) and network counters (*e.g.*, CNP sent/handled, TX/RX pauses, and RDMA errors on NICs). Congestion control counters that exceed thresholds can result in monitor daemons sending alarms to engineers for diagnosis and repair. Monitoring both storage and network indexes is crucial for the diagnosis of errors and for predictable performance. Storage indexes such as tail latency, slow I/O, and queuing time can directly reflect the status of a system. Moreover, monitoring system performance also help locate errors. For example, network features are unable to quickly reflect the flapping problem described in §6.1. However, this problem can be easily located by monitoring slow I/Os on the endpoints of storage applications.

Faster Timeout for Connection Failures. The basic solution to network failures is to reconnect through an alternative path. Since we use dual-home topology, each single point failure of the network can be bypassed using a different path. Thus, the timeout duration of the QPs is crucial in improving the system performance during a failure. In the NIC manual, the timeout duration of QPs is calculated as $4\mu s \times 2^{\text{timeout}} \times 2^{\text{retry\_cnt}}$, where $timeout$ and $retry\_cnt$ denote the retransmission timeout value and the retransmission retry times respectively. Initially, this value was a constant (approximately 16 seconds) configured in the hardware and cannot be changed. In a combined effort with the NIC providers, we were able to fix this bug. By using a smaller timeout value for QPs, the action time required for reconnecting during network failures was reduced by 4×.

An alternative work-around involves altering the connection path by modifying the source ports of the QPs (rather than a direct reconnection). This can accelerate the link recovery during a fail-over. However, effectively changing the QP source port requires a more recent NIC firmware (MLNX OFED 4.7 or newer) than what is currently deployed in Pangu. We leave this challenge to future work.

Blacklist. We adopt *blacklist* in Pangu to further improve the service quality in fail-over cases. BlockMasters collect information on I/O errors (including timeout) and slow I/Os from clients. If a BlockServer has a large number of slow/error I/Os from multiple clients, the masters adds it to the blacklist for a short period of time. The number of clients and slow/error I/Os that triggers the blacklist is configured according to the scale of the cluster. In order to ensure reliability, the maximum number of BlockServers in the blacklist is usually small (*e.g.*, 3 hosts). This blacklist mechanism temporarily isolates the BlockServers that provide a poor service. The system performance is not affected and engineers have sufficient time to fix the problems.

6.3 Daily Operation Scheme of Pangu

The daily operations of Pangu rely on these modules to work together. The monitoring system collects and reflects the status of Pangu. If abnormal network indicators or I/O metrics are observed, the monitoring system attempts to locate and report them to the administrators. For accidental failures such as link errors, the small QP timeout shortens the time required for failure recovery. The blacklist mechanism is able to determine and isolate nodes with poor service quality. By following these design and operator framework specifications, our RDMA-enabled Pangu system has not experienced any major faults in the last two years.

7 Experiences and Future Work

Monitoring NACK in Lossless RDMA. The operation of RDMA over a lossless fabric is difficult due to PFC risks. However, the lossless fabric increases the effectiveness of NACK events as indicators of the network error location since NACK is usually rare in a lossless fabric.

In order to detect and locate network problems, we build a subsystem based on packet loss in Pangu. In particular, Out-Of-Sequence (OOS) counters on RNICs and packet drop counters on switches are gathered. A packet loss is classified as either explicit or implicit based on whether it is recorded by switch counters. The former is easy to locate by checking the switch counters. However, determining the location of the latter is complex as RNIC counters do not distinguish between flows. By monitoring NACK in the networks, we can extract flows' five tuples and locate the root of a problem.

Building a System-Level Benchmark. To evaluate the system network performance and SLA, a representative benchmark must be constructed. Building the benchmark based on just the network metrics is simple. However, storage features such as replica completion time, slow I/O, and failure recovery should not be ignored. To measure the storage system performance and the SLA, we build a benchmark at the storage service level. The system evaluation indexes include FIO latency, IOPS, SLA with network errors, *etc.* Each upgrade in Pangu (for network and other components) is evaluated with the benchmark, allowing us to measure the overall system performance.

Congestion Control for Fail-Over Scenarios. In §3, we introduced the dual-home topology adopted in Pangu. Dual-home topology is also crucial to fail-over cases since it provides a backup path on NICs. However, we encounter a problem when deploying dual-home topology in practice.

According to our test, when one ToR switch is down, the RX pause duration can increase to 200ms per second. This is due to the transfer of the traffic from the broken ToR switch to the other switch. DCQCN handles the traffic burst poorly under this asymmetric topology. We adapt several DCQCN parameters as a temporary solution and leverage the fluid models [53] to analyze the available choices, including canceling the Fast Recovery stage and extending the rate increase duration. When removing the Fast Recovery stage in DCQCN, the pause can be eliminated yet the flow tail latency increases due to the slow recovery of the flow rate. In contrast, extending the duration of the rate-increase can result in a sharp reduction in the pause but only slightly increases the flow tail latency. In our experience, extending the rate-increase duration in DCQCN is effective for storage traffic patterns. The bandwidth drops slightly while the number of RX pauses is dramatically reduced.

This problem of DCQCN in fail-over scenarios (*e.g.*, asymmetric topology and traffic burst) indicates their important role when designing congestion control. We adopt parameter tuning to fix this problem at the price of a slight performance loss. The storage network still requires a flexible, robust and well-implemented congestion control mechanism that functions well in all scenarios. In 2019, Alibaba designed HPCC [30], a novel congestion control algorithm for the RDMA network. Adapting and integrating HPCC with the storage networks is left for future work.

Slow Processing of RDMA Read. The majority of large RPCs in Pangu are transferred via RDMA READ. We observed that when a NIC receives too much RDMA requests within a short period, it will send out many PFC frames. This is due to the slowed receiving process that results from cache misses. When a NIC is preparing for an RDMA READ, it accesses the QP context in its cache. Processing many RDMA READs consumes an excessive amount of cache resources. For slow RX rates, the NIC sends out PFC pause frames to prevent packet drops. We are currently working with the RNIC provider to solve this problem.

Lossy RDMA in Storage. Lossy RDMA is supported by Mellanox CX-5 and CX-6 RNICs. Note that CX-6 supports Selective Repeat (SR) retransmission. SR might be the ultimate step required to effectively eliminate PFC. The construction of lossy RDMA is a focal point for all RDMA-based systems. We tested lossy RDMA with Pangu over an extensive period and will deploy it for new clusters.

However, enabling the lossy feature with early generation RNICs (*e.g.*, CX-4) that have limited hardware resources and do not support SR is hard, and many production RDMA-based systems still host early generations RNICs.

NVMe-Over-Fabric. The ChunkServer data flow in Pangu is processed by CPUs. However, with NVMe-Over-Fabric, NICs can directly write the received data into NVMe SSDs. This CPU-bypass solution can save CPU costs and reduce latency. We are currently building our specialized storage protocol (and corresponding hardware) based on NVMe-over-Fabrics. A customized storage protocol for Pangu with hardware support can allow for more flexibility and control.

8 Related Work

PFC in RDMA PFC storm is the most well-known issue of RDMA. Several studies [11, 30, 52] focus on controlling network congestion to reduce the numbers of generated PFC pauses. DCQCN [52] is integrated in Mellanox RNICs. In Pangu, we tune several parameters in DCQCN to improve its performance in fail-over scenarios. However, PFC storms still occur due to hardware bugs [13]. In this paper, we present a different hardware bug that originates from switches. Existing solutions to remedy PFC storms include deadlock elimination [38] and performance optimization [46]. These solutions require switch modification. In Pangu, we combat PFC storms by switching affected links from RDMA to TCP without the need for any switch changes.

System & Network Co-Design. Recently, there have been increasing amount of work that adopts system and network co-design, including RPC systems [21, 47], distributed memory systems [39], key-value stores [22], distributed databases and transaction processing systems [6], and graph-processing systems [40]. We co-design our storage system and RDMA in Pangu. To our best knowledge, we are the first to share the experience of employing RDMA networks in large-scale distributed storage systems.

9 Conclusions

As a distributed storage system, Pangu has provided storage services to tenants both inside and outside of Alibaba for over a decade. In order to overcome the challenges of rising high-speed storage media and growing business requirements, we integrate RDMA into the storage network of Pangu, providing a common solution to different types of PFC storms. This allows for the safe deployment of RDMA. Pangu has successfully moved to a 100Gbps network by solving several new problems, such as the memory bandwidth bottleneck and QP number explosion. Furthermore, we improve the system performance of Pangu in fail-over cases.

Abstract

Object storage systems, which store data in a flat name space over multiple storage nodes, are essential components for providing data-intensive services such as video streaming or cloud backup. Their bottleneck is usually either the compute or the network bandwidth of customer-facing frontend machines, despite much more such capacity being available at backend machines and in the network core. Prism addresses this problem by combining the flexibility and security of traditional frontend proxy architectures with the performance and resilience of modern key-value stores that optimize for small I/O patterns and typically use custom, UDP-based protocols inside a datacenter. Prism uses a novel connection hand-off protocol that takes the advantages of a modern Linux kernel feature and programmable switch, and supports both unencrypted TCP and TLS, and a corresponding API for easy integration into applications. Prism can improve throughput by a factor of up to 3.4 with TLS and by up to 3.7 with TCP, when compared to a traditional frontend proxy architecture.

1 Introduction

A scale-out architecture for object storage systems is essential not only for supporting large storage capacities but also to incorporate sufficient compute and network bandwidth so the system can offer a predictable high-throughput and low-latency service to clients. Non-volatile memories (NVM) now fill the performance gap between networking and storage [28] with measured throughputs of 39.4 Gb/s and access latencies of 305 ns [34], emphasizing the importance of minimizing storage stack overheads for use with NVM [33].

A common design pattern seen in object storage systems [2, 3, 22, 35, 41, 65] uses a set of frontend machines to mediate client requests and relay them to a set of backend machines, as illustrated in the left diagram in Figure 1. The frontend often acts as a cache and/or load balancer to sharded or replicated backends. In this architecture, handling small objects incurs severe network inefficiencies, and handling large objects is limited by both network and compute resource availability because of data movement and encryption [2]. However, such systems have been widely adopted because of practical tractability when encryption and filtering are required, and because the performance characteristics of traditional disk-based backends are so poor that the CPUs and network typically are under-utilized, i.e., are not bottlenecks [67].

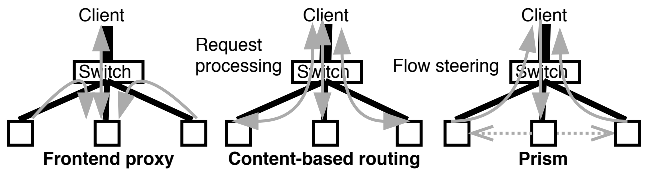

Figure 1: **Scale-out architecture variants.**

Recent approaches such as SwitchKV [45], NetCache [37] and Pegasus [44] use a content-based routing architecture, where servers interact with programmable switches, as illustrated in the central diagram in Figure 1. These approaches significantly improve throughput, latency and resilience to skew that is prevalent in realistic workloads, because the switches can redirect traffic that would otherwise be arriving at congested backend nodes.

While this overall concept is promising, these systems can only handle unencrypted single-packet-sized objects of up to 1.5 to 9 K B (with jumbogram fabrics), because the switch data path must understand the application logic. Also, clients need to use custom UDP-based protocols and implement loss recovery and congestion control functionality by themselves, which is non-trivial especially when serving clients over the Internet. Other content-routing approaches support large objects [13, 40, 71], but do not fully support TCP and hence cannot support industry-standard TLS security or popular application-level protocols (e.g., HTTP and Amazon S3).

This paper presents Prism, a framework that enables the new object storage architecture that combines the flexibility of frontend proxies with the efficiencies and resilience of content-routing approaches, as illustrated in the right diagram in Figure 1. It transparently scales out to many clients and supports arbitrarily-sized objects, TCP and TLS, allowing applications to secure industry-standard protocols such as S3 over HTTPS.

A key concept of Prism is *repeatable* TCP connection hand-off, which allows a TCP connection to be re-homed to different machines over its lifetime. This enables the frontend to examine (even encrypted) requests without requiring it to then also relay object payloads (i.e., bulk data), addressing one of the main drawbacks of traditional proxy architectures (Section 2). At the expense of a fixed per-request cost, repeatable connection hand-off smoothly distributes the I/O, compute and network bandwidth usage across the backends, avoiding bottlenecks in the data path.

The novelty and viability of Prism are based on two other recent innovations. Prism is novel because of its new TCP hand-off protocol that conforms to the TCP state serialization feature available in modern Linux, which is also under development in FreeBSD [66], and overcomes the limitation of this feature (Section 4). Prism is now viable because of the availability of scalable, fine-grained state management techniques for programmable switches, such as SilkLoad [51] and FlowBlaze [8, 58], which enable Prism to control a large number of concurrent flows with fast switch rule management.

Prism has been implemented on Linux hosts and eBPF-based software switches, and for this paper was instantiated as an S3-compatible object store in order to demonstrate much better throughput and latency when compared to a frontend proxy architecture.

This paper makes three main contributions:

- Characterization of network and CPU utilization in the current proxy-based architecture with TLS (Section 2.3).
- A robust TCP hand-off protocol for commodity programmable switches and network stack (Section 4.2).
- Improvement of resource utilization in the replicated or sharded backend architecture (Section 5).

In the remainder of this paper, Section 2 reviews how object storage systems work and characterizes their performance. Section 3 describes our high level approach and design challenges. Section 4 details the design and implementation of Prism, including its connection hand-off protocol and software stack. Section 5 evaluates Prism, and Section 6 discusses implications of our work. Section 7 describes related work. The paper concludes with Section 8.

2 Background and Problem

The primary focus of this paper is commercial object storage systems. This section describes the concepts behind such systems, then characterizes their performance.

2.1 Motivation: Object Storage Systems

Object storage systems serve huge amounts of data, both when instantiated as public cloud services, such as Amazon S3, Azure Storage, Dropbox and others, or as private installations, such as NetApp StorageGRID or Dell/EMC ECS. Cloud storage systems are also being deployed in edge clouds [4, 43], which are smaller but closer to clients, compared to hyperscalar public clouds, but can still generate a terabit of data per second [4]. Scale-out object storage systems are also used in many other scenarios. For example, OpenStack, a popular multi-tenant cloud platform, uses them as a primary data repository [65], and optionally supports bandwidth isolation and fine-grained filtering [22, 23]. IBM has deployed them to build a scale-out Docker registry that maintains Docker images and other data [3].

A common design pattern for such object storage systems uses a set of client-facing *frontend* machines that arbitrate access to a set of *backend* storage machines. The frontend typically does not persistently store any data, but may in some instantiations locally cache some objects. Clients that connect to the storage system, over the wider Internet or from within an enterprise or datacenter network, will be routed to one of the frontend machines via DNS round-robin or L4 load-balancers. The designated frontend machine then acts as a proxy for the set of storage backends. The role of the proxy includes application-level firewalling the internals of the storage system from the outside, possibly TCP and/or TLS termination, client and/or request authentication and authorization, in addition to relaying requests and responses.

Once the TCP connection is established, the network traffic consists mostly of bulk data transfer between client and the backend servers, relayed by a frontend machine. Consequently, a frontend machine spends the majority of their resources relaying traffic between clients and backends. The protocols used by clients are usually RESTful, reusing TCP connections for many individual storage transactions that can be served by the different backends. The frontends are responsible for concurrently handling many clients, which can lead to congestion at the client-facing links [2]. Modern storage devices, such as NVMe SSD and persistent memory, further stress frontend machines, because unlike slow spinning disks [6, 54] these devices do not constrain the networking throughput.

2.2 System Model and Components

In summary, the frontend machine in scale-out object storage systems:

1. terminates client TCP and/or TLS connections
2. receives requests that contain a target object identifier, e.g., a key or URL
3. redirects the request to a suitably chosen backend
4. forwards request data from the client to the backend
5. forwards response data from the backend to the client

Subsequent requests over an already-established connection can be directed to different backends. This re-homing of the connection incurs a cost that is made up of several components, which we will review here to better understand the measured end-to-end performance in Section 2.3.

Data movement: A proxy relays data between two TCP sockets issuing two system calls: `read()` on one socket and `write()` on another, each copying data to and from the kernel. The costs of these system calls increase with the number of bytes read or written. When the data is very small (a few hundreds of bytes or smaller), the fixed *per-call* costs, i.e., the context switch overhead (several tens of ns) dominates the total cost—the cost of moving the data is negligible. For large data sizes, the total cost is dominated by the *per-byte* cost of moving the data. Proposed optimizations include TCP Splice [48, 63] and `tproxy` in recent Linux kernels, which move data between two TCP sockets within the kernel by swapping socket buffer pointers, without actually copying any data. However, these approaches struggle to support encryption and other more complex application logic.

Data encryption: For confidentiality and authentication, TLS has become the standard in today's Internet and datacenters. Therefore, offloading techniques for TLS have attracted considerable attention. Some TLS libraries can take advantage of hardware acceleration for various ciphers (e.g., AES-NI CPU instructions). In-kernel TLS support was recently added to Linux and FreeBSD to use cryptographic engines available on some NICs. Nevertheless, encrypting traffic comes at significant *per-byte* processing costs, similar to the data movement costs.

Application logic: Proxies typically perform application-level processing when relaying data. For example, they look up a key or URL embedded in the request data to select a suitable backend for the target value or object, or they may scan data to filter out particular requests. Since such information is typically included in the application-level protocol headers, the costs of such application logic usually does not increase with the size of transferred object. (Although it can if this information is contained in the request payload.)

Network stack: Modern kernel TCP/IP stacks can send and receive bulk data at the rate of tens of Gb/s by utilizing NIC offload features (in particular, checksum, TCP segmentation and large receive offloads). TCP and especially TLS connection establishment is an expensive operation due to needing multiple network round-trips, and the required updates to shared resources in the kernel impair multi-core parallelism [57]. However, modern application protocols are usually already designed to maximize connection reuse to amortize these costs. Hence, this paper does not concern itself with application protocols that have high connection-open rates; various improvements that are complementary to our work have already been proposed for high-rate connection openings [46, 57] and small data transfers [24, 36].

Network topology: In rack-scale storage in large datacenters [44, 53] or edge clouds such as used for content delivery networks (CDNs) [4], operators wire servers uniformly so that they can assign the role of servers (e.g., frontend and backend) flexibly depending on the node failure or service demands, as it is very expensive to rewrite cables [73] or the physical space is at a premium in the edge clouds [4]. Each rack consists of one or more top-of-rack (ToR) switches equipped with high bandwidth uplinks. These uplinks are a Clos [16] network fabric in datacenters and Internet exchanges in CDNs, respectively. In such a deployment, individual machines cannot be "scaled up" to create additional proxying capacity.

2.3 End-to-End Performance

To characterize performance of the proxy-based systems, we imitate the aforementioned network topology using a six logical node cluster, each of which connects to a cluster switch over a 10 Gb/s link, and a client machine that is connected to the cluster switch over a 40 Gb/s link that serves as a high bandwidth uplink (see Section 5.1 for hardware details). We install `nginx`, a high-performance, popular web server, to every server cluster node; one acts as a frontend (also generally called reverse proxy) and the other five act as backends. The client node runs `wrk` HTTP benchmark tool to generate requests to retrieve objects from the server cluster.

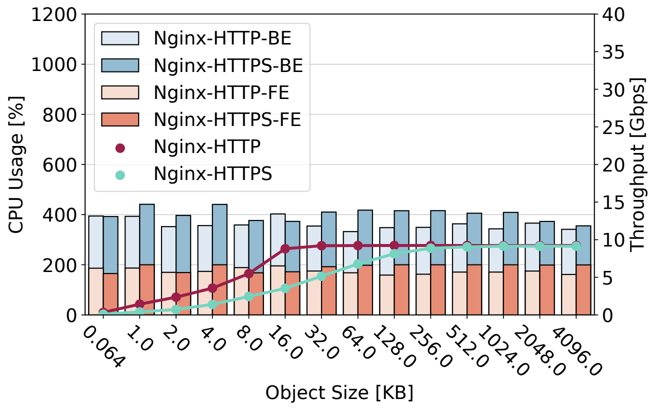

Figure 2: **Throughput and CPU usage of an `nginx` cluster.** One node acts as a proxy and the other five act as backends. Every node connects to a switch with a 10 Gb/s link. The switch connects to a client machine with a 40 Gb/s link (See Figure 8 for illustration). CPU usage can be at most 1200 % due to six dual-core servers.

Figure 2 plots throughput measured by the client and CPU utilization monitored at the servers. The requested object sizes vary, from 64 B to 4 MB. Although the real object storage systems handle a wider range of object sizes (e.g., hundreds of KB to a few MB for photos, and tens or hundreds of MB for videos, deep learning models and VM images), we select the range that characterizes the performance of the system.

With unencrypted HTTP, the frontend ("Nginx-HTTP") can serve up to 9.2 Gb/s, which is close to the 10 Gb/s line rate, taking into account protocol header and framing overheads. At the same time, the frontend CPU resources ("Nginx-HTTP-FE") are also fully utilized. When we allocate one more CPU core to the frontend (not plotted), the network bandwidth becomes the bottleneck (i.e., it results in idle CPU cycles).

When using HTTPS, the frontend ("Nginx-HTTPS") is able to serve only up to 9.1 Gb/s ("Nginx-HTTPS-FE"). Further, it requires larger objects to achieve that throughput than HTTP cases. This performance reduction is due to performing TLS cryptographic operations at the frontend that acts as a proxy, which fully utilizes its CPU resources.

These experiments confirm that either the fabric attachment bandwidth or the CPU resources of the frontend proxy become the bottleneck for this workload, depending on the hardware setup and the use of TLS. Since the Internet-facing capacity of the switch and backend CPU resources are left underutilized in these experiments, ideally the backends would circumvent the proxy and the switch would forward data directly between clients and backends. The Prism architecture enables this design.

3 Approach and Challenges

These observations confirm the need for reducing CPU usage at the frontend and increasing network utilization at the backends and switch uplink. Is it possible to exclude the frontend from the end-to-end data path for the majority of a transaction, while allowing it to perform its necessary tasks? We will show that it indeed is possible, but that doing so requires a different request-redirection approach than traditionally used. In this section we describe the high-level approach and highlight the main challenges, then describe our resulting design of Prism in Section 4.

3.1 Request-Granularity Redirection

The fundamental problem with a proxy architecture is that all traffic is mediated by the frontend; it relays all traffic between clients and backends. If the ToR switch itself could be instructed to relay data between clients and backends, that forwarding would happen at the faster core network speeds, and—more importantly—eliminate the traditional frontend participation in bulk data relaying. In other words, the frontend could focus on the control-plane aspects of relaying, and the fabric would focus on the data-plane aspects, which optimizes their relative strengths. A frontend confined to the control plane would have a great deal more network and CPU bandwidth available to support more clients per machine, and would thus reduce the overall number of frontend machines needed to support a given client population, making the service more cost effective.

Specialized examples if such a general architecture have been realized in the narrow domain of small-object key-value stores, such as SwitchKV [45], NetCache [37] and Pegasus [44]. However, these systems handle only single-packet-sized transactions and require clients to use custom, unencrypted protocols. It should be noted that for large objects, it is not trivial to implement congestion control and loss recovery that are able to cope with various Internet conditions, such as tail loss [9], incast [1] and phase effects [17].

General, commercially viable object storage systems of course need to support objects larger than a single packet. They also need to be able to secure their client communications with industry standard protocols such as TLS. One example is Amazon S3, the de facto industry standard for object storage, which runs over HTTPS, i.e., TCP and TLS. For such a protocol, *after* the frontend has processed application-level connection setup (e.g., user authentication), it is hence necessary to migrate the entire TCP and TLS connection state to one of the storage backends and have the fabric switches redirect traffic to it—based on *flow-level* information rather than application-level information.

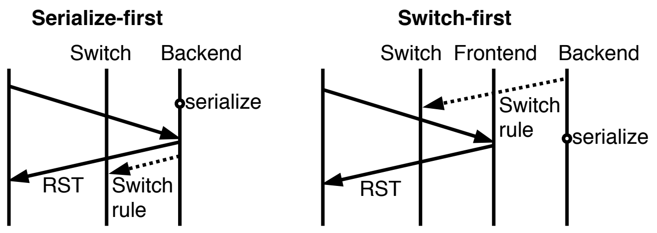

Figure 3: **Breakages with naive TCP hand-off designs.** Leaked packets trigger a connection reset (Section 3.2).

3.2 TCP Hand-Off

Basic TCP hand-off provides a starting point for the request-granularity TCP redirection of Prism. Although TCP hand-off was already explored over twenty years ago [5, 55] based on a custom TCP stack, it has not seen much real-world deployment or open source availability. However, TCP connection serialization, one of the essential features to enable TCP hand-off, was added to the Linux kernel in 2012 [12]. The identical feature is also under development in FreeBSD [66]. Therefore, designing a new TCP hand-off protocol based on this feature could ease the deployment of Prism approach.

When TCP connection state is serialized and then migrated to another machine, it is essential to carefully coordinate the updates to the necessary fabric switch rules, so that no packets "leak" to machines that do not hold the required state—such leakage would generate TCP RST (reset) messages, impacting client operation. Figure 3 depicts two example scenarios where such a connection reset occurs, because the hand-off protocol is incorrectly designed. On the left, an already-migrated connection receives a packet at the original machine, because the switch does not yet to redirect packets to the new target another server. On the right, the switch begins forwarding packets to the new target before the connection has been migrated there. These scenarios can happen with the hand-off protocol designed in the past [5]. The Prism migration protocol avoids any such problems, using the two-phase hand-off protocol described in Section 4.2.

Also, a fabric-based connection hand-off raises concerns about latency and scalability, because it requires manipulating fabric switch rules on a per-request basis (or at least every time the connection migrates). Previous studies imply that this might pose a significant hurdle: In 2014, Liu et al. [47] report that configuring a hardware switch can take hundreds of µs, meaning that for short backend transactions, the hand-off cost could significantly increase the overall request processing cost. In 2011, Yu et al. [69] show maintaining fine-grained flow state in hardware switches to be infeasible because of limited on-chip memory.

However, more recent work has addressed some of these constraints. SilkLoad [51] and FlowBlaze [8, 58] store state for millions of flows in hardware switches; the latter inserts hardware switch rules in a few µs. The Prism hand-off protocol incorporates these more recent observations.

4 Design

Based on the challenges above, the goals of Prism are to (1) design an efficient connection hand-off protocol that works for both TCP and TLS without breaking client sessions, and (2) to build a software stack that implements the protocol and provides a suitably abstract API to applications. We start with describing what an end-to-end data TCP transfer looks like, using the example of a read request that is received by a frontend and served by a backend. We then detail our connection hand-off protocol, which performs a two-phase switch configuration, and our software stack, which ensures correct kernel- and application-level operations.

4.1 Prism in Action

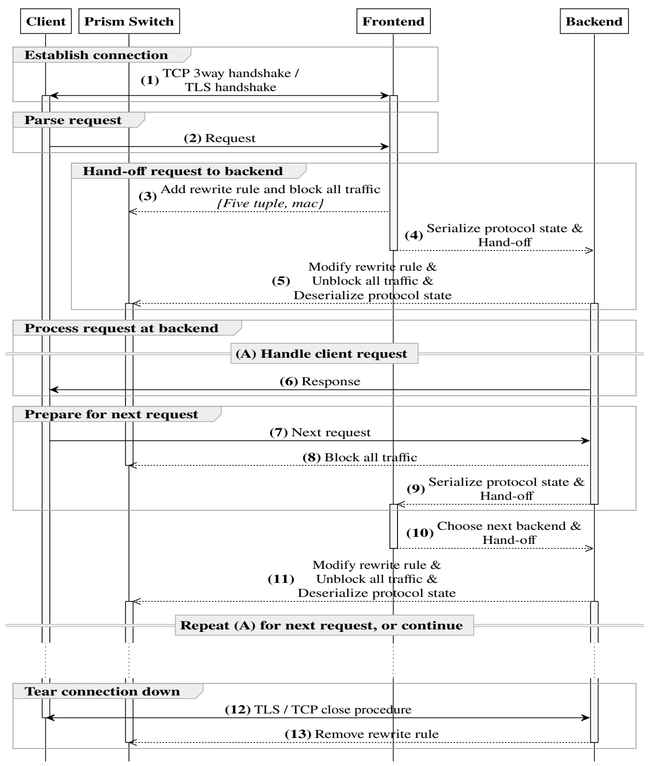
Figure 4 illustrates the Prism hand-off protocol in a packet sequence diagram. Solid arrows indicate packets sent on the TCP connection; dashed lines indicate Prism control messages between the frontend, switch and backends.

Establish connection: As illustrated in Figure 4, a client opens a TCP connection with a Prism frontend server, optionally followed by a TLS handshake.

Parse request: The client begins a transaction by sending a request, which the frontend receives and parses. When the frontend determines that it has received the entire request, it consults the metadata it maintains about the backend servers to select one to handle the request.

Hand-off request to backend: The frontend serializes the TCP connection and TLS session state. TCP state includes ports, sequence and ACK numbers and the TCP options negotiated for both directions of the connection; the TLS state includes the exchanged shared secrets. The frontend then contacts the chosen backend and passes the serialized states, the client IP address, and the client request, so that the backend can take over the connection and serve the request.

The backend instructs the Prism switch to rewrite the destination IP address of packets sent from the client to that of the chosen backend server, and to rewrite the source IP address of packets sent from that backend server to the client to that of the frontend. The switch also rewrites the destination or source MAC address, if the client resides in the same broadcast domain. The consequence of this is that any subsequent packets on this connection will be exchanged directly between the client and the backend, with the switch performing the required rewriting. Since the inserted rules only affect a single TCP connection, other connections, either



Client
Prism Switch
Frontend
Backend
Establish connection
(1) TCP 3way handshake / TLS handshake
Parse request
(2) Request
Hand-off request to backend
(3) Add rewrite rule and block all traffic {Five tuple, mac}
(4) Serialize protocol state & Hand-off
(5) Modify rewrite rule & Unblock all traffic & Deserialize protocol state
Process request at backend
(A) Handle client request
(6) Response
Prepare for next request
(7) Next request
(8) Block all traffic
(9) Serialize protocol state & Hand-off
(10) Choose next backend & Hand-off
(11) Modify rewrite rule & Unblock all traffic & Deserialize protocol state
Repeat (A) for next request, or continue
Tear connection down
(12) TLS / TCP close procedure
(13) Remove rewrite rule

Figure 4: **End-to-end Prism operation.** Solid arrows indicate TCP packets, dashed ones control messages. Step (8)–(11) indicates our two-phase hand-off protocol described in Section 4.2.

to the same frontend or other destinations, remain unaffected. We describe detailed procedures later in this section.

The backend then de-serializes the TCP and TLS state by instantiating a TCP socket based on the information in the serialized connection state and its local IP address (i.e., not frontend's). Because of the active switch rules, the client sees the traffic coming from this backend as if it was coming from the original frontend.

Process request at backend: The backend serves the client, sending back the response over the migrated connection.

Prepare for next request: After a transaction has completed, the backend may return the connection to the frontend and remove the corresponding switch rules, if it wishes subsequent requests on the same connection to be handled by the original frontend. The backend may parse the next request by itself and hand off the request to another backend.

Tear connection down: When the client or the backend itself closes the connection, the backend withdraws the corresponding switch rules.

4.2 Two-Phase Hand-Off Protocol

As shown in Figure 3, a deficient TCP hand-off protocol design breaks client connections. We therefore develop a

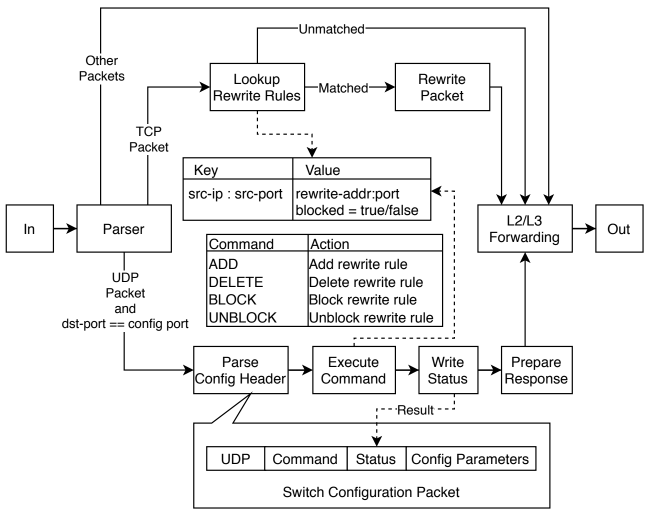


Figure 5: **Prism switch logic.** Custom UDP packets update switch rules.

new connection hand-off protocol that works with the TCP serialization feature available in Linux.

One "hack" would be to drop reset segments sent on a connection under migration with host firewall rules. However, this design requires maintaining flow steering state across the switch fabric *and* the servers, which complicates failure handling. We thus reject this design option.

Our solution instead employs a two-phase switch configuration. First, the host instructs the fabric switch to *drop* all traffic that belongs to the connection being migrated. This prevents this connection from receiving any further packets that might then lead to RSTs. It should be noted that this does not affect performance, because what may be dropped are only unusual packets, such as spurious retransmissions.

Then, a machine serializes a TCP connection and its TLS session and hands this serialized state off to another machine. The target machine then restores the TCP and TLS state. Finally, the target machine sends three commands to the switch atomically. The first one inserts a new rule that rewrites the source IP address of outgoing packets sent from the target machine. The second updates the existing switch rule to redirect any inbound packets to the target machine (instead of the original one). The third removes the drop rule. This two-phase hand-off procedure is depicted over step (8)–(11) in Figure 4.

Prism inserts or withdraws switch rules over a simple, stateless UDP control protocol that triggers in-switch rule manipulation without control-plane involvement. The switch logic that enables the two-phase connection hand-off is illustrated in Figure 5. This protocol implements a simple timeout-based retransmission mechanism, because we assume the communication over the shared links with client data traffic, which can be congested.

4.3 Stack and API

The hand-off protocol described above dictates that many individual commands and application I/O, which runs asynchronously, be executed in coordination with each other. Thus, we need a *software stack* that ensures the correct system state transitions, rather than just API extensions. This stack adds a loadable kernel module that allows applications to detect completed connection removal, an event-based execution engine that drives both the hand-off protocol and application I/O, and high-level APIs for applications to read and write data, and open, close and redirect connections. Figure 6 illustrates the Prism stack; the rest of this section details key components.

TCP state tracking. Before the withdrawal of a switch rule that rewrites the source IP address, the in-kernel connection state must have been freed *completely* to ensure the connection does not transmit any further packets. Unfortunately, this happens silently, long after an application closes a socket. Since the kernel does not notify applications of such events, we implemented a new kernel module to do so, using the Linux `eventfd` framework and socket destructor ("Conn. dtor" in Figure 6). This approach is suitable because the event loop component in the stack, described later, can monitor connection removal events together with any other events, such as new data read from the kernel and requests issued by the application. A similar method is possible also in FreeBSD.

TCP and TLS state serialization. Prism relies on the Linux `TCP_REPAIR` feature [12] to serialize TCP connection state. Based on the option parameter, `getsockopt()` serializes send and receive buffer data, sequence and ACK numbers and negotiated TCP options, which are restored using `setsockopt()` with the same option name. Prism uses the `tlse` library for TLS handshake and serialization, but for the data path, it uses the in-kernel TLS stack of recent Linux kernels, in order to benefit from future hardware offload support. We implemented a new `getsockopt()` option to retrieve the in-kernel TLS state, and upstreamed it to the mainline Linux kernel.

Switch communication. The stack is in charge of communication with the switch using the custom UDP-based packets (Section 4.2). It schedules and sends switch rule update commands to the switch when the application requests connection hand-off or restoration, and waits for the response that includes a status code.

Event loop. Because of the need to perform migration operations for application sockets, Prism discourages applications from using their sockets directly. The stack needs to coordinate and execute these operations for multiple file descriptors in parallel. Therefore, Prism augments `libuv`, a popular event-based I/O library that hides low-level system calls, like `epoll`, `kqueue`, `read` and `write`, from applications. An application associates its own callbacks with events, such as new connection establishment or network or file descriptor readiness for I/O. Prism extends `libuv` to allow applications

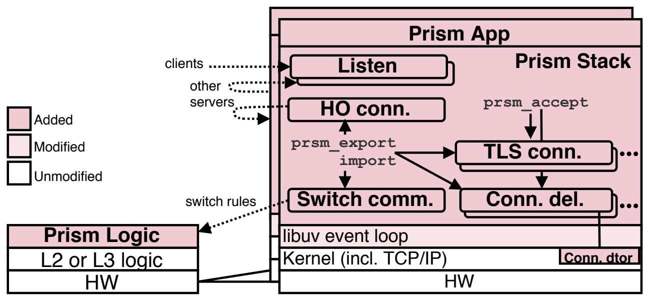

Figure 6: **Prism stack in the host (right) and switch (left).** Rounded rectangles represent file descriptors, and monospaced font corresponds to the calls used in Figure 7.

to associate their callbacks on top of TLS connections, and to coordinate the application requests and its hand-off protocol, including TCP state tracking and switch communication described above.

API. The programming model of Prism is based on `libuv` with two new methods to export or import migrating connections, and a TLS connection abstraction. Figure 7 implements the frontend and backend roles of the example object store, which statically partitions data across the servers by key, and covers the vast majority of Prism APIs. The `main()` function initiates the event loop with two TCP ports to monitor: one for client requests and the other for hand-offs from other servers. `on_accept()` runs upon establishment of a client TCP connection and initiates the TLS handshake via `uv_tls_init()`. When new client data arrives, it is decrypted and `on_read()` is executed. `who_has_val()` identifies whether the current server hosts the requested content, based on its key. The server either redirects the request to another server using `prsm_export()`, or returns the content using `uv_write()`, which schedules transmission in the event loop.

Although the use of these APIs ensures the correct hand-off state transitions, we do not prevent applications from the use of regular socket APIs. A regular application based on an `epoll` event loop would monitor three additional types of file discriptors: one for the terminated connection notification, another for switch communication and the other for connections to other servers. The application then needs to coordinate the events of these descriptors, for example, to serialize and hand-off a connection only after configuring the switch.

Switch. Many conventional frameworks, including eBPF and P4, are suitable to implement the Prism switching logic described in Figure 5. Although OpenFlow can also be used, this option incurs higher connection hand-off latency due to the access to remote control plane.

The Prism packet transformation logic can be implemented *on top of* an existing L2 switching or L3 forwarding logic without having to disrupt the existing network addressing, as shown in Figure 6. This also allows the Prism switch to be deployed alongside a non-programmable switch as a software switch, as we will show in our experiments.

```
1  on_read(client, buf) { // buf contains a decrypted request
2    const uint64_t key = get_key(buf);
3    who = who_has_val(key);
4    if (who != me)
5      prsm_export(client, who); // prsm_* are Prism methods
6    else {
7      (char *obj, int objlen) = get_objp(key);
8      req = new uv_buf_t(.base = obj, .len = objlen);
9      uv_write(req, client, on_write);
10   }
11 }
13 on_write(req) {
14   free(req->base);
15 }
17 on_accept(server) {
18   client = new uv_tls_t;
19   loop = server->loop;
20   uv_tls_init(loop, client); // uv_* are libuv
       objects/subclasses
21   prsm_accept(server, client);
22   uv_read_start(client, on_read);
23 }
25 main() {
26   uv_tls_t server, internal; // extend uv_tcp_t
27   loop = uv_default_loop();
28   uv_tls_init(loop, &server);
29   uv_tcp_bind(&server, "0.0.0.0:50000");
30   uv_tcp_bind(&internal, "0.0.0.0:60000");
31   uv_listen(&server, on_accept);
32   uv_listen(&internal, prsm_import);
33   uv_run(loop);
34 }
```

Figure 7: **Prism application pseudo code.** Prism extends `libuv`. Server returns requested object (line 9) if present, otherwise hands off request to actual custodian (line 5). The code thus serve the role of both frontend and backend.

4.4 Limitations

Concurrent requests. When a frontend or backend receives parallel requests being handled by different backends in the same TCP connection, it must serialize these requests using one of the following options. The first option is for a backend to simply block any arriving subsequent requests. If these requests need to be processed by different backends, the server hands off the connection after processing its current request. The second option is for the backend to send a TCP "zero window" advertisement to the client. This method turns out to be rather complex, because the backend must do so *before* TCP acknowledges received data, which may already have contained a subsequent request.

To maximize the performance, it is ideally the responsibility of the application-level protocol to prevent the client from issuing another request that might need to be handled by a different backend before an ongoing transaction on the same connection has completed. Traditional proxies can process parallel requests faster than Prism, if the frontend has enough attachment network bandwidth and spare CPU cycles to aggregate the responses from multiple backends; we leave this analysis as future work.

Small transfers. For a small-message transactional workload, i.e., where requests and responses fit into a few TCP packets, Prism may not be a good solution. In such cases, the overheads—switch configuration and connection hand-off—

cannot be sufficiently amortized. We analyze this trade-off in Section 5, which shows that 8 K B (i.e., 6 packets) is sufficient to amortize these overheads.

4.5 Implementation

The Prism server stack consists of 2193 Lines-of-Code (LoC): 612 LoC for TCP and TLS state serialization, 255 LoC for the switch configuration protocol, 167 LoC for active connection tracking, 130 LoC for the loadable kernel module to detect TCP connection removal and 1029 LoC for integration of these components. We modify a single line of `libuv`, and port `tlse` for our TLS abstraction.

We also implement a high performance software switch that makes up the Prism logic in Figure 5. To run the same code in hardware in the future, and to prevent the system from unexpected crash caused by software bug that affects many servers, we implement an eBPF execution environment as a switching logic module of mSwitch [29], a scalable, modular software switch that runs in the kernel. eBPF is popular these days and known that some switch vendors will support hardware offloading of eBPF processing. This software switch never becomes a bottleneck throughout the experiments in the next section.

Our source code is publicly available at `https://github.com/YutaroHayakawa/Prism-HTTP`.

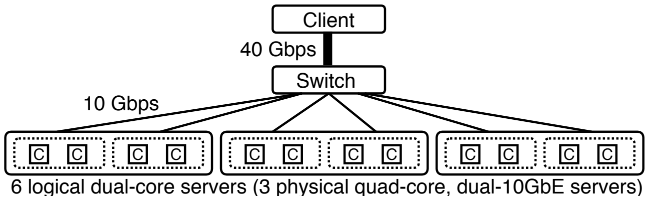
5 Evaluation

This section evaluates Prism and reports the following main results:

- Prism improves throughput by a factor of up to 3.7 (with HTTP) and 3.4 (with HTTPS), utilizing the switch uplink and backend CPU resources efficiently.
- Prism's throughput increases with the number of backends due to the very light remaining load at the frontend, in terms of both network bandwidth and CPU usage.
- Prism improves object retrieval latency by up to 74 % and 96 % in the 50th and 90th percentile, respectively.
- Prism's connection hand-off latency is 232 µs, which is a win when transferring at least 2 K B with HTTP or 16 K B with HTTPS.
- Prism can be used to build object storage systems with partitioned or replicated backends.

5.1 Experiment Setup

Hardware and OS: Figure 8 depicts the testbed setup used for the experiments. Each machine has a quad-core Xeon E-1231v3 CPU clocked at 3.4 GHz, 16 GB of RAM and a dual-port Intel X540-T2 10 Gb/s NIC, running Linux kernel 4.18. We partition it into two logical servers, dedicating one 10 Gb/s port and two CPU cores to each. The switch has a ten-core Xeon E5-2690v4 CPU clocked at 2.6 GHz, 64 GB



Client
40 Gbps
Switch
10 Gbps
C
6 logical dual-core servers (3 physical quad-core, dual-10GbE servers)

Figure 8: **Experimental topology.**

of RAM, three dual-port Intel 10 Gb/s NICs where each port connects to a logical server, and one Intel XL710 40 Gb/s NIC that connects to the client. We confirmed that this switch never becomes a bottleneck during the experiments. The client has two Xeon E5-2640v4 CPUs, 64 GB of RAM and the same 40 Gb/s NIC as the switch. Our network does not use jumbo frames. The connection hand-off traffic shares the same links with the data traffic.

Software: In the baseline experiment, all of the logical servers run a single `nginx` process. One server acts as a reverse proxy, the others as backends. In the Prism experiment, each logical server runs our custom application implemented on top of the Prism stack described in Section 4.3. Unlike the pseudo code in Figure 7, we use a static frontend setup where the same frontend always establishes incoming TCP connections and examines every request. Therefore, a backend that receives the next request always returns the connection to the frontend.

The communication protocol is always S3, either over HTTP or HTTPS (i.e., with or without TLS). The client continuously generates read or write requests using the `wrk` HTTP benchmark tool [21], instrumented to issue S3 requests (using the Lua scripting support) over 100 parallel persistent TCP connections per backend.

5.2 Link and CPU Utilization

Figure 9 plots the throughput and CPU utilization of Prism and the `nginx` baseline. Both systems redirect requests to the backends in round-robin fashion and each backend serves static, in-memory content.

For HTTP, Prism saturates the 40 Gb/s switch uplink (with the protocol headers and framing overheads) for object transfers of 256 K B and above, whereas `nginx` throughput is constrained by the 10 Gb/s attachment link capacity. Furthermore, Prism reduces the CPU utilization of the frontend by 23 to 53 % in comparison to `nginx`, which utilizes nearly the entire CPU to relay data, and uses the same amount of backend CPU resources as the Prism backends.

For HTTPS, Prism achieves a throughput of 31.4 Gb/s whereas the `nginx` baseline achieves only 9.2 Gb/s. Prism consequently leads to a much higher utilization of the backend CPUs, whereas `nginx` leaves around 75 % of backend CPU resources idle. Since the Prism frontend offloads and load-balances data encryption to the backends and avoids relaying data, its CPU usage reaches at most 70 %, which is spent on

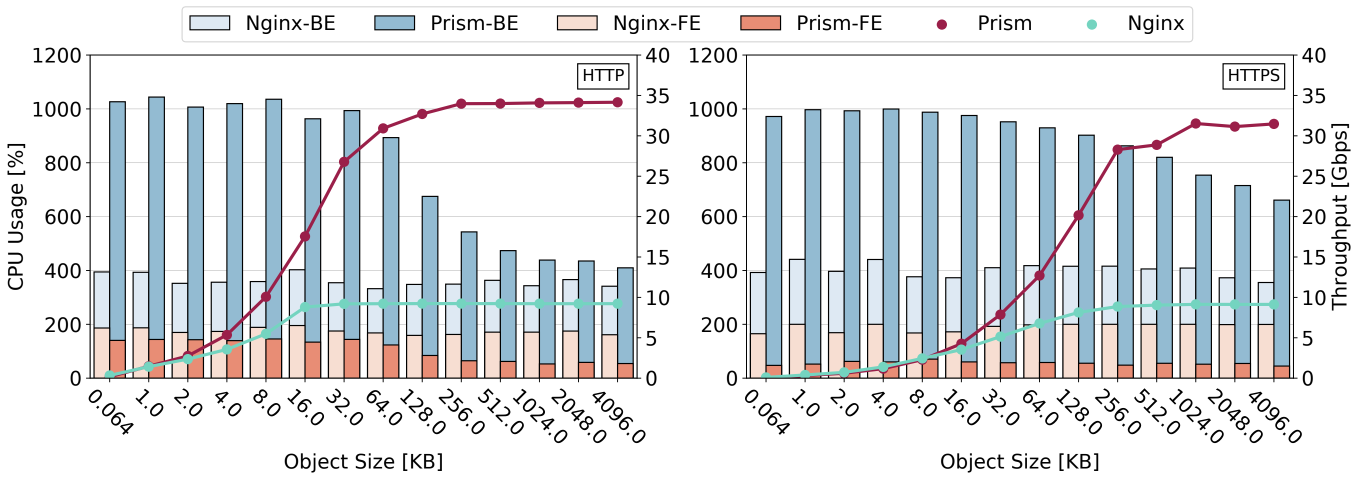


Figure 9: **Throughput and CPU usage with Prism and `nginx`.** FE and BE stand for frontend and backend, respectively. Prism utilizes backend CPU and network resources while keeping the frontend load low.

request redirection. These results imply that Prism would allow operators to provision a fewer number of frontend machines than traditional proxy architectures.

It may seem odd that overheads of the Prism frontend appear low even for 1 K B object sizes, but there is an obvious explanation. With `nginx`, all requests and responses over all 500 parallel connections are relayed by the frontend. Prism's frontend hands off connections to the backends instead of relaying requests, but it does *not* relay responses from the backends. Our results indicate that the advantage of not relying (nor encrypting) the responses at the frontend outweighs the connection hand-off costs.

Figure 10 plots the throughput and CPU utilization of Prism and baseline on a fewer number of backends for a subset of the object sizes, which are 16 , 256 and 512 K B. It confirms that throughputs of Prism have increased almost proportionally to the number of backends until they reach the limit of client processing capacity, which is lower with HTTPS (34 Gb/s and 28 Gb/s with HTTP and HTTPS, respectively) because of decryption and framing overheads.

Overall, Prism improves throughput by a factor of up to 3.7 without TLS, and 3.4 with TLS. It improves CPU utilization by factors of 2.4 and 2.6, respectively.

5.3 End-to-End Latency

Figure 11 plots the 50th and 90th percentile transaction latencies to retrieve 16, 256 or 512 K B objects (same experiments as Figure 10). These latencies decrease when adding more backends, except for the 90th percentile latencies with five backends and 256 or 512 K B objects, where the throughputs reach the maximum and queues start building up (see Figure 10). With `nginx`, those latencies do not change much with the number of backends, and are always higher than Prism, except for those 90th percentile latencies with 256 or 512 K B object sizes and five backends.

5.4 Connection Hand-Off Latency

Operation	Latency [µs]	Std. dev. [µs]
Block all traffic	22	13.1
Serialize TCP	7	1.1
Serialize TLS	5	1.1
Serialize HTTP	2	0.6
Close TCP socket	9	5.0
Hand-off (to frontend)	21	14.4
Hand-off (to backend)	21	14.4
Deserialize HTTP	3	1.5
Deserialize TLS	109	64.3
Deserialize TCP	11	1.0
Modify rewrite rule	22	9.4
Total	**232**	-

Table 1: **Connection hand-off latency breakdown.** The sequence starts from a backend returning the current connection to the frontend.

The largest concern about Prism is the connection hand-off overheads. As described in Section 4.2, the hand-off protocol takes two network round trips to the switch, in addition to the connection state transfer between frontend and backends.

Table 1 reports a breakdown of the latencies of a single connection hand-off cycle in which a backend returns a connection to a frontend, which then hands off the connection to another backend. The total is 232 µs. Each operation takes 21 to 22 µs if the network is involved, otherwise 2 to 11 µs, except for TLS deserialization that takes 109 µs and whose improvement is left as future work. The hand-off latency could be improved if the backend examined the next request after serving the current one, as in described in Figure 7, bypassing the frontend and saving 21 µs. Nevertheless, since Prism out-

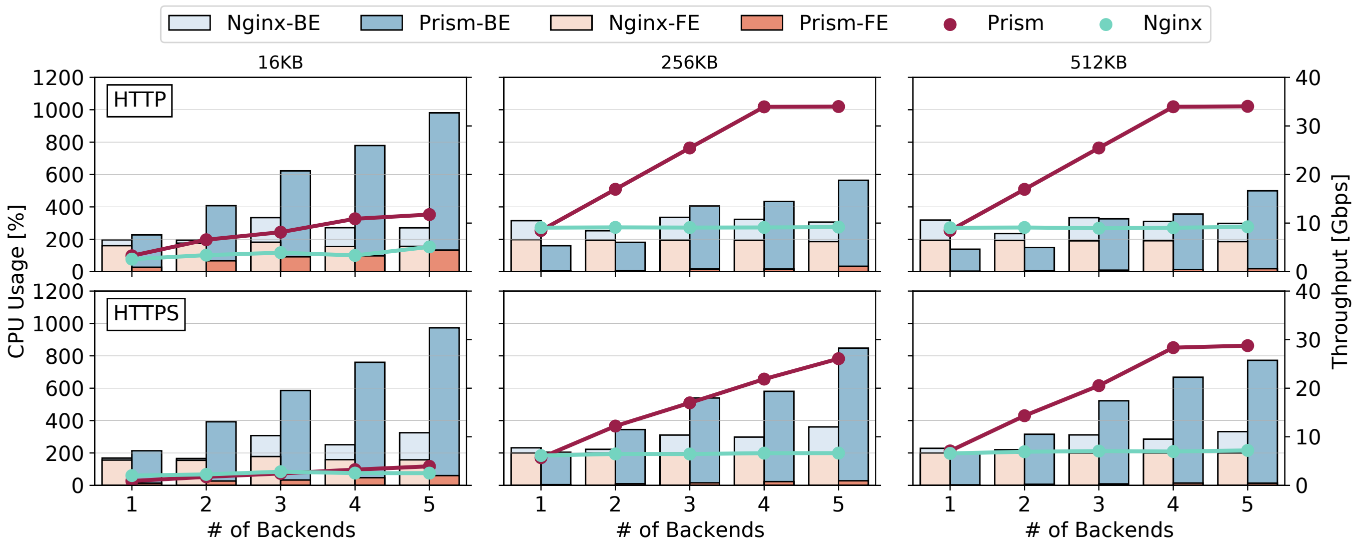

Figure 10: **Prism throughput with different numbers of backends.** The top and bottom row indicates HTTP and HTTPS, respectively. Prism linearly increases the throughput until the limit of client processing capacity.

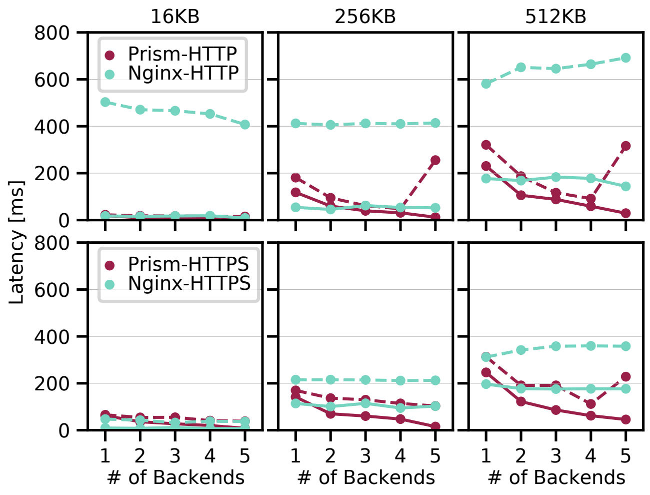

Figure 11: **Prism latency.** Solid and dashed lines indicate 50th and 90th percentile latencies, respectively.

performs the throughput of the traditional proxy architecture with 2 K B (HTTP) or 16 K B (HTTPS) of objects (Figure 9), we conclude that Prism outweighs the costs of the hand-off latency in various workloads.

5.5 Use Case

We implement two variants of an object storage system. The first *partitions* content across the backends, and the second *replicates* content at *all* backends. Thus, the partition variant writes a write request to one of the backends based on the key, but the replication variant does it to all the backends, before responding to the client. In contrast to the previous microbenchmarks in which a backend always serves the same in-memory content, these object storage variants use LevelDB where keys identify objects that are organized into a log structured merge tree. Thus, they include realistic storage stack overheads. We use a RAM disk for the storage medium, assuming faster-than-network NVM-style storage medium. The client protocol is again S3.

5.5.1 Partitioned Object Storage Backends

Figure 12 shows throughputs over two YCSB workloads, read-only and read-mostly that contains 5 % writes. We vary object sizes between 16 to 512 K B and request key skewness, which is 0.9 to 1.2 of Zipfian parameters, uniform distribution (least skewed) and requests that always ask for the same key (most "skewed").

We observe throughputs stay almost the same up to Zipfian 1.0 of skewness, and a slight, up to by 17 %, drop at Zipfian 1.2 that can be considered extremely skewed. We observe that even for an extremely skewed workload (Zipfian 1.2), throughput decays only by up to 17 % in comparison to the uniform distribution, demonstrating Prism's robustness against skewed workloads.

5.5.2 Replicated Object Storage Backends

Figure 13 shows throughputs with the same workloads but for the replicated backends, assuming fault tolerance and load balancing. We observe the same throughput regardless of skewness, as the frontend redirects requests in a round-robin fashion. Since every write is replicated to all the backends, throughput decreases with higher write rates, more so in comparison to the partitioned-backend cases. The lower overall rates compared to those cases can be attributed to larger active data that stress OS buffer caches.

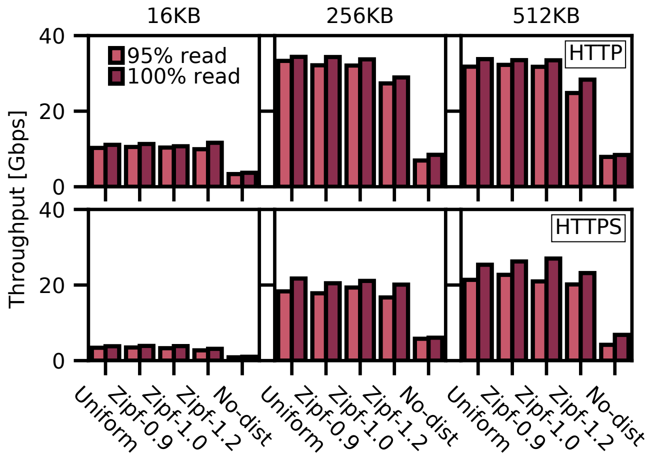

Figure 12: **Prism throughputs with partitioned backends.** Top and bottom rows plot results with HTTP and HTTPS, respectively. Prism preserves high throughputs even under skewed workloads.

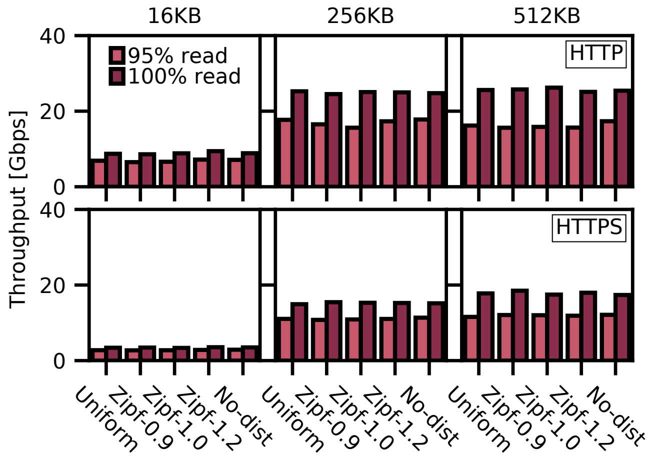

Figure 13: **Prism throughputs with replicated backends.** Throughputs are unaffected by key skewness due to evenly distributed requests.

Prism's ability to handle a partitioned key space and to balance loads across replicas indicates its feasibility for implementing sophisticated data layouts and replication algorithms, respectively.

6 Lessons Learned

Although TCP hand-off had been proposed multiple times at least since 1998, it has never been widely used. We initially attributed this to the lack of scalable flow-level programmable switches, but increasingly realized many other reasons. The mechanism to snapshot or instantiate TCP connections in any state, an essential feature, has been enabled in Linux in a rather inconvenient form, that is, packet transformations must be performed elsewhere, such as with a host firewall or at a switch. Moreover, the TCP stack needs to emit RST packets during the hand-off process to conform to the invariants that apply throughout the TCP implementation.

Alternative approaches that do not require programmable switches have been proposed by Snoeren et al. in 2000 [61, 62]. However, deploying new TCP options has been increasingly difficult over the last decade due to slow network stack evolution [30] and middlebox interferences [32].

These constraints resulted in difficulties for TCP hand-off overall, because it requires that many operations be performed atomically. This requirement prevents the use of a host firewall for source address rewriting, because otherwise manage flow state needs to be managed at both hosts and switches, requiring a complex coordination mechanism.

Building the end-system stack was also a great burden. However, since the TCP connection serialization has become available in the mainline kernel, systems like Prism can now be realized without modifications to the kernel; in fact, we still needed kernel modification, but the Linux community accepted the necessary changes, which are to implement a new API to access the in-kernel TLS state [26], to be included in the mainline kernel. We were able to implement the other kernel extension, which is the connection removal notification (Section 4.3), as a loadable kernel module. Moreover, fewer applications today call "low-level" socket APIs directly; many use higher-level networking libraries such as `libuv`, which we extend to enable the Prism stack (Section 4.3). These phenomena support the deployability of Prism.

Another problem is frequent switch rule updates. This has been problematic for older switches, because the rules must be updated via the switch control plane that runs slow CPUs. In fact, our initial prototype communicated with an RPC server running in the control plane, and it consequently suffered from high latencies of up to 828 µs, which requires 256 K B of transmitted data to amortize these hand-off costs. This led us to the use of a custom switch manipulation mechanism that updates the rules directly within the data plane. This becomes possible with newer hardware and software switches, such as P4 and eBPF, that have advanced programmability. Further, recent improvements of flow scalability in hardware switches [8, 51, 58] also supports the feasibility of this approach.

Further, Prism does not complicate layer 4 firewalls in the network or host, because Prism hosts never rely on host firewalls, nor "spoof" packet addresses, as the packet transformation happens in the switch. This means that host firewall rules can be configured based on not the address of the frontend but that of the individual host. Local firewall policies apply to the restored TCP connections, because Linux `netfilter` creates connection states when it sees any egress packets [11].

Last but not least, we believe our approach is feasible even in sharing switches, which has been a major concern in the use of programmable switches in many existing systems [50].

This is because we turn the feature of the content-based routing approaches into flow-level operations that can be easily isolated between tenants and machines; for example, the operator can limit address-modification rules inserted to the switch within the address range allocated to the tenant.

7 Related Work

Our previous short paper [27] introduced Prism's overall approach with a minimalistic proof-of-concept implementation. This paper significantly extends Prism by incorporating the ability to handle TLS-encrypted communication, a robust hand-off protocol, a much-improved software stack, a more mature implementation and an extensive evaluation.

TCP connection migration. The closest related work is a proposal by Aron et al. in 2000 [5] that proposes content-aware request distribution to the backend cluster, similar to Prism. However, their hand-off protocol can break client connections (Section 3.1) and does not support TLS (or SSL). TCP Migrate Options [61, 62] achieve TCP connection migration using TCP options instead of programmable switches, but have deployment problems (Section 6).

Proxy enhancements and L7 load balancers. TCP Splice (Section 2.2) has been improved by software [10, 59] or hardware-assisted [52, 72] approaches. Yoda [19] improves the fault tolerance of the proxy architecture. Squid [64], HAProxy [25] and Proxygen [60] are open source proxy implementations. Unlike Prism, these approaches do not eliminate the need of a frontend proxy to remain involved in bulk data relaying.

Content based routing. SwitchKV [45], Pegasus [44] and NetCache [37] as discussed in Section 3.1 eliminate frontends that mediate traffic between the client and the backend, by having programmable switches play the role of the frontend. They only support data that fits into a single packet over unencrypted custom UDP-based protocol. NICE [40] supports large data objects, but it relies on unencrypted UDP-based requests and TCP connections initiated by the server for reply. Therefore, it supports neither TLS nor industry-standard protocols such as S3. Strata [13] is a scale-out storage system with NFSv3. It breaks client connections and relies on reconnection to resume the NFS session after change of the storage backend. NetKV [70] is an application-level load balancer for memcached, but does not support TCP.

L4 load balancers. Maglev [14] and Ananta [56] are software load-balancers implemented in commodity servers. Duet [20], Rubik [18] and Faild [4] are similar, but partially leverage standard hardware switches for improved performance. Unlike Prism, none of these approaches support request-granularity redirection. L4 load balancers are used to distribute traffic between multiple frontends of the Prism or proxy architecture.

Flexible packet processing. The Prism frontend might resemble a packet forwarding system implemented as middleboxes, but it differs in that it does not forward packets but hands off established TCP connections. Our software implementation on a programmable soft-switch uses mSwitch [29] for performance and flexibility, and eBPF for protection, but it can be other flexible packet processing frameworks. Recent scalable hardware packet processing systems, such as SilkRoad [51] and FlowBlaze [8, 58], enable Prism to scale to a large number of flows and reduce the latency of switch rule updates. Some vendors are implementing eBPF hardware offloading [39], which accelerates our switch logic (Figure 5).

Caching, sharding and replication algorithms. Many object placement algorithms for storage systems have been proposed [7, 15, 40, 44]. Prism is a framework to implement object storage systems with these algorithms without worrying about communication with clients. In Section 5, we experimentally demonstrated that Prism can be used to implement replicated backends for load balancing and sharded ones for capacity scaling. More sophisticated algorithms, such as selective replication [44], will further improve the storage utilization and performance.

High performance host storage stack with TCP/IP. This class of work, such as Diskmap [49], ReFlex [42] and i10 [33] for NVMe, and Decibel [53] and PASTE [31] for persistent memory, could enhance Prism's backends, and benefit from Prism, because they encrypt or push data at higher rates than traditional host storage stack.

8 Conclusion

As faster storage devices push data to CPUs and networks at higher rates, it is important to scale-out these resources. We built Prism, which combines the performance and resilience of content-based routing approaches with the generality and flexibility of a conventional proxy architecture. We demonstrated that Prism can be used to build object storage systems for the industry-standard S3 protocol over TCP and TLS, and to implement partitioned and replicated backends for capacity scaling and load balancing. Prism is based on a connection hand-off technique that has been proposed in the past, but we redesigned it to address practical problems with the previous systems, taking into account modern technology and requirements across the network switches and today's OS kernels.

Future work will develop object storage systems with advanced data layout or load balancing algorithms, and further reduce the overheads of the TCP/TLS connection migration. Modern low-latency networking techniques based on efficient stacks [68] or RPC designs [38] are a perfect fit in this space.

Abstract

Middleboxes are becoming indispensable in modern networks. However, programming the network stack of middleboxes to support emerging transport protocols and flexible stack hierarchy is still a daunting task. To this end, we propose Rubik, a language that greatly facilitates the task of middlebox stack programming. Different from existing hand-written approaches, Rubik offers various high-level constructs for relieving the operators from dealing with massive native code, so that they can focus on specifying their processing intents. We show that using Rubik one can program the middlebox stack with minor effort, *e.g.*, 250 lines of code for a complete TCP/IP stack, which is a reduction of 2 orders of magnitude compared to the hand-written versions. To maintain a high performance, we conduct extensive optimizations at the middle- and back-end of the compiler. Experiments show that the stacks generated by Rubik outperform the mature hand-written stacks by at least 30% in throughput.

1 Introduction

Middleboxes are pervasively deployed in modern networks. In the middlebox, a low-level *network stack* (*e.g.*, TCP/IP) is responsible for parsing raw packets, and a set of high-level hooks (*e.g.*, HTTP dissector) process the parsed data for various purposes. There is a constant need for programming the network stack of middleboxes in order to accommodate different networks (*e.g.*, IEEE 802.11 [9] in WLAN), support new protocols (*e.g.*, QUIC [50]), realize customized functions (*e.g.*, P4 INT [5]), and capture new events (*e.g.*, the IP fragmentation [11]), *etc*.

By programming a middlebox stack, an operator Alice is mainly concerned with the following tasks. (1) *Writing new parsers.* It is common that a network needs to support a new protocol. Then, Alice needs to write a new parser to parse such traffic. (2) *Customizing stack hierarchy.* Another common need is to change the protocol layering, say to support encapsulation methods like IP-in-IP [1]. Then, Alice needs to re-organize the parsers. (3) *Adding new functions.* Finally, new functions may be requested from the network stack to meet diverse needs. For example, Alice may need to know when IP fragmentation happens, and modify an existing network stack to capture this event. In the following, we will show the difficulty of the above programming tasks.

The difficulty of writing new parsers. Currently, protocol parsers are written in low-level native code to ensure the high efficiency, which leads to a large number of lines of code (LOC) even for a single protocol, *e.g.*, ∼7K C LOC for TCP protocol parser in mOS [14]. Someone may argue that the TCP/IP is the de facto narrow waist for middlebox processing, so a general-purpose TCP/IP substrate is sufficient for extended programmability. However, many networks have their own customized transport layers (*e.g.*, QUIC [50]), and in those cases, Alice still needs to manually write new parsers.

The difficulty of building stack hierarchy. The data structures in current middlebox stacks are monolithic and closely coupled with standard stacks, making it difficult to reuse the existing protocol parsers for upgrading the stacks. For example, `libnids` [11] can parse Ethernet, IP, UDP and TCP protocols, but due to its TCP-specific data structure, it can hardly support the IP-in-IP stack, *i.e.*, ETH→IP→GRE→IP→TCP, although there is only one thin GRE parser need to be added. As a result, we have to modify 1022 LOC of `libnids` in our preliminary work to support the IP-in-IP stack, where most effort (815 LOC) is devoted to stack refactoring.

The difficulty of adding new functions. Since the network stack is closely coupled, adding a new function often needs a deep understanding of a huge code base. For example, if one wants to capture a low-level IP fragmentation event that is not supported in Zeek [24], she has to first read all the native code related to the IP protocol and the event callback module, which involves ∼2K LOC. Another scenario would be the feature pruning: *e.g.*, for writing a stateful firewall without the need to buffer the TCP segments, the operator has to go through considerable code to ensure the code deletion in a full-functional TCP stack will not produce other side effects.

Table 1: Existing approaches to program middlebox stack and their support of the three programming tasks.

Approaches	Protocol Parser	Stack Hierarchy	Stack Functions
Packet Parser (*e.g.*, P4 [18], VPP [23])	◐	◐	○
TCP-Specific Stacks (*e.g.*, mOS [44])	○	○	◐
NFV Frameworks (*e.g.*, NetBricks [58])	◐	●	◐

● : *Can be fully programmed with high-level abstractions, i.e., minor LOC*
◐ : *Partially supported or can be programmed with moderate LOC*
○ : *Not supported or can only be programmed with large amount of LOC*

Apart from the mature and fixed TCP stack libraries like mOS and `libnids`, many attempts have been made to fulfill the above three tasks in order to make the middlebox stack programmable. However, none of them can fully facilitate those onerous tasks, as shown in Table 1: the packet parsers like P4 [18] cannot efficiently buffer the packets; the NFV frameworks like NetBricks [58] and ClickNF [37] often rely on TCP-specific modules that are pre-implemented with many native LOC. We discuss these related work in detail in §2.2.

In fact, there exists a dilemma between the abstraction level and code performance when enabling programmability on the performance-demanding middlebox stack. On the one hand, many exceptions like out-of-order packets can arise in L2-L4, so higher-level abstractions are desired to relieve the developers from handling those corner cases. On the other hand, optimizing a stack at wire speed also relies on tuning underlying processing details, which becomes much more challenging if those details are transparent to the developers. As a result, previous works tend to trade off the programmability for the performance, offering limited programmability over specific stacks, *e.g.*, TCP (see §2.3).

In this paper, we propose Rubik, a domain-specific language (DSL) for addressing the above dilemma, which can *fully* program the middlebox stack while assuring *wire-speed* processing capability. For facilitating the stack writing, Rubik offers a set of handy abstractions at the language level, *e.g.*, packet sequence and virtual ordered packets, which handle the exceptions in an elegant fashion. Using these declarative abstractions, operators can compose a more robust middlebox stack with much fewer lines of code, and retain the possibility of flexible extension for future customization needs. For maintaining high performance, Rubik translates its program into an intermediate representation (IR), and uses domain-specific knowledge to automatically optimize its control flow, *i.e.*, eliminating the redundant operations. The optimized IR is then translated into native C code as the performant runtime.

In sum, we make the following contributions in this paper.

- We propose Rubik, a Python-based DSL to program the network stack with minor coding effort, *e.g.*, 250 LOC for a complete TCP/IP stack (§3 and §4).
- We design and implement a compiler for Rubik, where a set of domain-specific optimizations are applied at the IR layer, so that all stacks written in Rubik can benefit from those common wisdom, without caring about how to integrate them into the large code base (§5).
- We prototype Rubik, and build various real cases on it, including 12 reusable protocol parsers, 5 network stacks, and 2 open-source middleboxes (§6). Experiments show that Rubik is at least 30% faster than state of the art (§7).

2 Motivation and Challenges

In this section, we demonstrate that programming middlebox stack is a necessity in modern networks (§2.1), while no existing tool can really enable such programmability (§2.2). We pose the challenges of designing a DSL for middlebox stack, and summarize how our approach addresses them (§2.3).

2.1 Programming Middlebox Stack Matters

As presented in §1, programming a middlebox stack requires huge human effort. However, some argue that it might not be a problem: most middleboxes work with standard TCP/IP protocols, thus a well-written TCP/IP stack should be sufficient. In contrast, we believe there are plenty of scenarios where a deeply customized middlebox stack is desired.

First, the middlebox stacks need to be customized for serving diverse networks with different protocols [13,32,34,42,43, 63,70]. Apart from the existing ones, we note that the emerging programmable data plane may cause an upsurge of new protocols, each of which requires an upgrade of the middlebox stack, or its traffic cannot traverse the network [16, 55].

Second, even for a fixed stack, the operators may still manipulate the packets in arbitrary ways, and the implementation of middlebox stacks varies to satisfy those user-specified strategies. For example, if a TCP packet is lost in the mirrored traffic [22], `libnids` will view this as a broken flow and directly drop it for higher performance [11], while mOS will keep the flow and offer an interface to access the fragmented sequence for maximumly collecting the data [44].

Third, middleboxes are constantly evolving for providing value-added functions, *e.g.*, adding a new layer [12, 35], measuring performance [20], inspecting encrypted data [40,49,67] and migrating/accelerating NFV [38, 47, 57, 68, 72]. These extensions heavily rely on a highly customized stack.

The above facts prove that programming middlebox stack is a necessity in modern networks, which however demands massive human effort. In practice, such overhead has begun to hinder the birth of new protocols: the middlebox vendors tend to be negative to support new protocols, as the huge code modification can cost large human labor and introduce bugs or security vulnerabilities. For example, some middlebox vendors suggest blocking the standard port of QUIC (UDP 443) to force it falling back to TCP, so that their products can analyze such connections [10]. This heavily impacts the user experience [4, 19], and will finally result in the ossification of underlying networks [60].

2.2 Related Work

Plenty of attempts have been made to facilitate the middlebox development, as shown in Table 1. In the following, we show why they are not sufficient to program the middlebox stack.

Programmable packet parsers like P4 [18] and VPP [23] can dissect arbitrary-defined protocols in an amiable way. However, since they target at implementing a switch/router, they cannot efficiently buffer and/or reassemble the packets.

There are also DSLs, *e.g.*, Binpac [59], Ultrapac [52], FlowSifter [56] and COPY [51], that can automatically generate L7 protocol parsers. The parsers they generate focus on the L7 protocols like HTTP, hence can only work on the already reassembled segments. In other words, they can facilitate the development of high-level functions of a middlebox, *e.g.*, HTTP proxy, deep packet inspection, but have to cooperate with a low-level stack, instead of serving as one.

TCP stack libraries include those for end-host stacks and those for middlebox stacks. The end-host stack libraries, *e.g.*, mTCP [45], Modnet [61], Seastar [27], F-Stack [25], only maintain the unidirectional protocol state for a certain end host, while middlebox stacks must track the bidirectional behaviors of both sides. As a result, the middlebox developers cannot build their applications on end-host stack libraries.

On the other hand, the major feature a middlebox stack library provides is the bidirectional TCP flow management. Previously, such libraries are closely embedded in IDS frameworks like Snort [21] and Zeek [24], therefore cannot be reused when developing new applications. `libnids` [11] decouples the TCP middlebox stack from the high-level functions, making the stack reusable. Recent works like mOS [44] and Microboxes [53] implement a more comprehensive TCP stack with fast packet I/O, and more importantly, provide the flexible user-defined event (UDE) programming schemes, *e.g.*, dynamic UDE registration, parallel UDE execution. Besides, they provide limited programmability over TCP stack, *e.g.*, unidirectional buffer management. However, all above approaches are hard-coded, hence cannot support non-TCP stacks without massive native code understanding and writing.

NFV frameworks offer a packaged programming solution from L2 to L7. However, none of them provide complete middlebox stack programmability. MiddleClick [30] and ClickNF [37] can manipulate the stack hierarchy using Click model [48], but they rely on pre-implemented elements, *e.g.*, ClickNF implements the TCP-related elements with 156 source files (12K LOC in C++) [7]. NetBricks [58] supports the customization of the header parser, the scheduled events, *etc*, which is sufficient for programming a connectionless protocol. However, the abstractions for programming a connection-oriented protocol, *e.g.*, transmission window, connection handshake, are still TCP-specific. OpenBox [33] and Metron [46] abstract and optimize a set of L2-L7 elements for middlebox applications. However, the flow management element still has to be pre-implemented using native code.

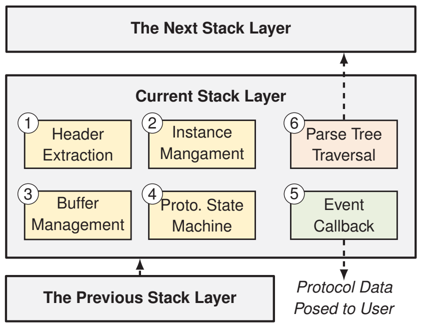

Figure 1: The three key modules in a middlebox stack layer: protocol parser (yellow boxes), event callback (green box), and parse tree traversal (red box).

2.3 Challenges and Our Approach

A DSL that fully captures the L2-L4 abstractions can be a cure to above problems. In the next, we revisit the high-level pipeline of middlebox stack, and pose the challenges of designing and implementing a DSL corresponding to it.

Middlebox stacks follow a layer-based processing pipeline, which is largely the same with the end-host stacks, as shown in Figure 1. Specifically, each stack layer starts by *parsing the protocol* (①–④), which extracts the header, manages the instance, buffers the segments, updates the protocol state machine (PSM), *etc*. Next, the *event callback* module (⑤) will raise the events with the protocol data fed to the users, *e.g.*, the reassembled or retransmitted data. Finally, the *parse tree* (⑥) will decide the next protocol to be parsed. However, even the above pipeline is seemingly natural and generalized, designing and implementing a DSL corresponding to it can still be a challenging task. The reason is two-fold.

First, working at L2-L4, the middlebox stacks run more complex logic than it appears in the pipeline. For example, the out-of-order packets can mess around the PSM, *e.g.*, an early-arrived FIN packet may mislead the stack to tear down the TCP connection. Each of these exceptions is handled with native code in fixed stacks, and it is extremely difficult to provide a neat DSL that covers all such cases. *Rubik addresses this challenge by offering a set of high-level constructs to hide such exceptions from programmers, e.g., "packet sequence" that hides the retransmission exception and "virtual ordered packet" that hides the out-of-order exception, which can maximumly correspond to the intuitive pipeline (§4).*

Second, the middlebox stacks must realize wire-speed processing to serve high-level functions. However, due to the complexities presented above, the optimizations on the stack can only be achieved by carefully tuning the native code. That is, the program written in DSL that hides the processing details will likely produce low-performance native code. *Rubik addresses this challenge by employing an IR and a set of domain-specific optimizations on it before producing the native code, which automatically optimize the DSL program to avoid potential performance traps (§5).*

3 Rubik Overview

In this section, we use a walk-through example to overview how Rubik can facilitate the middlebox stack writing. Our example is an ETH→IP/ARP stack, where we raise a typical event, IP fragmentation, for each IP fragment.

Figure 2 shows the real (and almost complete) Rubik code of realizing our example. We start from declaring the IP layer (Line 2), which initializes internal structures of a connectionless protocol, including the header parser, the packet sequence, PSM, *etc*. These components are specialized as follows.

Parsing the header fields (Line 5–18). One has to first define the header format before she references the headers. In Rubik, a header format is a Python class that inherits `layout`, and each header field is a member of this class, which specifies its length measured by `Bit()`. The order of the members indicates the layout of the fields. Line 5–15 show the IP header structure, `ip_hdr`. We can then use this structure to compose the header parser with one LOC in Line 18. After that, Rubik can reference the fields by their names, *e.g.*, `ihl` can be referenced by `ip.header.ihl`.

Managing the instance table (Line 20). Having the headers, the stack layer then finds the instance that the packet correlates to, *e.g.*, the TCP flow, and processes it by the previous state and data of the same instance. The instances are stored in an instance table, *e.g.*, TCP flow table.

To achieve this, Rubik forms a key to index the instance table, which consists of bi-directional protocol contexts. For IP protocol, the instance key is a list that contains the source and destination IP addresses (Line 20). Note that for connection-oriented protocols, the instance key should contain two lists, each of which indexes the packets of one direction.

Preprocessing the instance (Line 23–27). Before getting into buffer and PSM processing, operators can update some permanent contexts for each individual instance (`perm`), or use some temporary variables for facilitating the programming (`temp`). This part of logic will be executed each time after the instance is found/created. Line 23–27 define a temporary data structure that stores the fragmentation offset for each IP packet, which can then be referenced as `ip.temp.offset`.

Managing the packet buffers (Line 30–31). Many protocols buffer the packets to ensure the correct order of incoming packets. Rubik offers a *packet sequence* abstraction to handle this task. In our example, the IP protocol has to buffer the fragmented packets according to their fragmentation offset. Line 30–31 define a sequence block filled with the IP payload and indexed by the fragmentation offset. This block will be inserted into the packet sequence associated with the instance, which is automatically sorted in ascending order by the meta.

A connection-oriented instance will maintain two sequences for two sides, respectively. The packets payload will be automatically inserted into the corresponding sequence according to the direction indicated by the instance key.

```
1  # Declare IP layer
2  ip = Connectionless()
3
4  # Define the header layout
5  class ip_hdr(layout):

44                    Assign(ipc.dip, ip.header.daddr) + \
45                    Callback(ipc)
```

Figure 2: IP layer and fragmentation event written in Rubik.

Updating the PSM (Line 33–34). PSM tracks the protocol states, which are useful in most connection-oriented protocols (*e.g.*, TCP handshake), and also in some connectionless protocols that buffer the packets (*e.g.*, IP fragmentation). Consider the IP PSM shown in Figure 3. If an IP packet unsets the `dont_frag` flag, the parser will take a transition from the `DUMP` state to the `FRAG` state that waits for more fragments. The instance will be destroyed if the PSM jumps into an accept state, *e.g.*, `DUMP` in IP PSM. Line 33 defines the `last` transition, *i.e.*, `FRAG`→`DUMP`.

Assembling data and hooking IP fragments (Line 37–45). Unlike the UDEs that are raised by the high-level functions, *e.g.*, HTTP request event, the built-in events (BIEs) reveal the inherent behaviors in the stack, *e.g.*, buffer assembling, connection setup. Previous works only pose fixed and TCP-specific BIEs [11, 44], while Rubik can program two types of BIEs for arbitrary stacks.

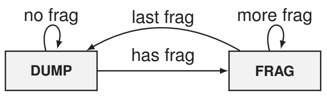

Figure 3: Simplified PSM for IP fragmentation.

The first is for the packet sequence operations, *i.e.*, buffer assembling. Rubik uses `If()` to specify the conditions of raising the events and `Assemble()` to assemble the continuous sequence blocks. This function will form a service data unit (SDU) for the next layer parsing. Line 37 defines the events for assembling the fragments in IP layer.

The second type of action is for posing the user-required data, which is achieved by a `Callback()` function that indicates what content should be posed. Line 39–45 define an event on the condition that fragmented packets arrive. The back-end compiler will declare an empty function in the native C code, *i.e.*, `ip_frag(struct ipc*)`, and invoke it each time the condition is satisfied.

Parse tree for ETH→IP/ARP. Each time after processing a layer, the network stack decides the next layer to be proceeded, until it reaches the end of the stack. All such parsing sequences form a parse tree [39].

The parse tree of our example consists of two layers, *i.e.*, Ethernet, and IP/ARP. The stack executes from the root node, which triggers the Ethernet protocol parser. This parser will extract the headers of Ethernet, *e.g.*, `dmac`, `type`. Next, the parse tree checks the predicates carried by the two transitions, and decides which one could be further parsed. In this case, the `type` field is used to distinguish the IP and ARP protocol. Rubik offers a simple syntax similar to PSM transition to define the parse tree, as shown below.

```
st = Stack()
st.eth, st.ip, st.arp = ethernet, ip, arp
st += (st.eth>>st.ip)  + Pred(st.eth.header.type==0x0800)
st += (st.eth>>st.arp) + Pred(st.eth.header.type==0x0806)
```

where `ethernet`, `ip` and `arp` are protocol parsers. We note that the parsers can be reused in the stack. For example, we can define another IP layer in this stack with `st.other_ip = ip`. This will largely facilitate the customization of encapsulation stacks (see Appendix C.3 for a GTP example).

Summary. We omit the implementation of Ethernet layer and ARP layer, which are quite simple compared to IP layer. In sum, we use ∼50 LOC to define the IP protocol parser (see Appendix C.1 for the complete code), 7 LOC to hook the expected event, and 4 LOC to build the parse tree. As a comparison, `libnids` consumes ∼1000 C LOC to implement the similar stack [11].

4 Rubik Programming Abstractions

§3 shows the potential of reducing coding effort with Rubik. However, as discussed in §2.3, there exists lots of complex programming needs that call for more sophisticated programming abstractions. In this section, we dive into the language internals to present how Rubik conquers those complexities.

4.1 Context-Aware Header Parsing

We consider the following two context-aware header parsing needs in middlebox stack, and address them using Rubik.

Conditional layout. The L2-L4 protocols can have conditional header layout. For example, QUIC uses its first bit to indicate the following format, *i.e.*, long header or short header. To this end, we can first parse the fixed layout, using which to determine the next layout to be parsed, as shown below.

```
quic.header =  quic_type
quic.header += If(quic.header.type == 0) >> long_header
                Else() >> short_header
```

Type-length-value (TLV) parsing. Rubik extends its header parsing component in two ways to express the TLV fields: (1) the value of a field can be assigned before parsing, which can be used to define a `type` field, *e.g.*, `type = Bit(32,const=128)` defines a 32-bit field that must be 128; (2) the length of a field can refer to a pre-defined field with arithmetic expressions, which can be used to define the length of `value` field, *e.g.*, `value = Bit(length << 3)`.

Besides, TLV headers are often used in a sequence with non-deterministic order, *e.g.*, TCP options. Rubik offers a syntax sugar for parsing those headers, as shown below.

```
tcp.header += AnyUntil((opt1, opt2, opt3), cond)
```

where `opt1`–`opt3` are TLV header layouts, and `AnyUntil()` will continuously parse the packet according to their first fields, *i.e.*, `type`, until `cond` turns to be false.

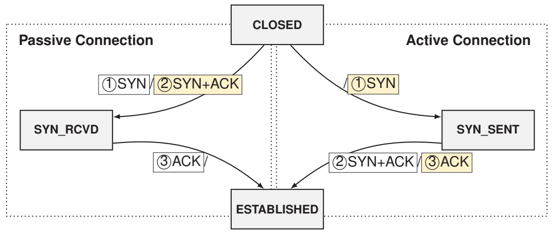
4.2 Flexible Buffer Management

The transport protocols can buffer the packets in flexible ways other than simply concatenating them in order. Specifically, we consider the following three exceptions in buffer management, *i.e.*, retransmission, conditional buffering and out-of-window packets, and use the sequence abstraction in Rubik to address them.

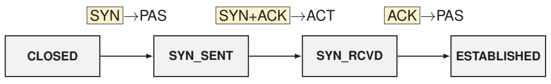
Each time a sequence block is inserted, `Sequence()` in Rubik will compare its meta (*e.g.*, sequence number in TCP) and length with existing buffered blocks, in order to identify the fully and partial retransmission. Operators can decide whether the retransmitted parts should be overwritten by passing a `overwrite_rexmit` flag to `Sequence()`. Once the retransmission is detected, Rubik will automatically raise an event, which can be referenced by `event.rexmit`.

In some cases operators would disable the sequence buffering. For example, a TCP stateful firewall relies on the meta of sequence block to track the TCP states, but does not need the content in the block. Operators can disable the content buffering by simply writing `tcp.buffer_data=False`.

Transport protocols use window to control the transmitting rate. Operators can pass a `window=(wnd,wnd_size)` parameter to `Sequence()`, which specifies the valid range of meta. The out-of-window packets will not be inserted into the sequence, but raise an `out_of_wnd` event.



(a) The end host stack PSM for TCP handshake.



(b) The sender-side PSM for TCP handshake.

Figure 4: The middlebox stack PSM (b) only models the sending behaviors of the end host stack PSM (a).

4.3 Virtual Ordered Packets

The sequence abstraction will sort the out-of-order packets, which, however, still mess around the stack processing. Consider the IP PSM shown in Figure 3. In the possible out-of-order cases, the "last frag" packet can arrive earlier than a "more frag" packet. With the transitions defined in Figure 2, such packet will trigger `ip.psm.last` and form an incomplete SDU for the next layer. To avoid such mistake, the transition has to track two states (instead of the fragmentation flag only), *i.e.*, whether the "last frag" packet *has* arrived and whether the sequence *is* continuous. This counter-intuitive expression makes `Pred` in PSM transitions quite complex.

Rubik addresses such problem by offering an abstraction of *virtual ordered packets*, which gives an illusion to the operators that they are accessing the ordered packets. For example, to handle the early-arrived "last frag" exception, the transition `ip.psm.last` can be rewritten as follows.

```
ip.psm.last = (FRAG >> DUMP) + Pred(~ip.v.header.more_frag)
```

where `ip.v` indicates the virtual ordered packet. The compiler of Rubik will take care of tracking the real arriving order and ensuring the sequence continuity (see §5.4).

Note that the virtual ordered packets are for facilitating the inconsistent condition checking, while no real packet will be buffered and re-accessed. In other words, operators can only use this abstraction in the conditions of `If()` or `Pred()`.

4.4 Sender-Side PSM

Directly emulating the PSM of the end host stack in the middlebox is not a trivial task. Consider a simplified PSM for TCP handshake, whose end host version is shown in Figure 4a. Each transition in the PSM is triggered by two packets: the received packet in the white frame and the sent packet in the gray frame. For example, the passive host (*i.e.*, server) can jump into `SYN_RCVD` state only after it received the SYN packet *and* sent the SYN+ACK packet. This transition is natural for the end hosts, since the receiving and sending behaviors are synchronized.

However, the middlebox cannot capture those two behaviors at the same time. Instead, it has to use two states to respectively capture them. For example, for the passive side, the PSM of a middlebox will jump to a new state, say `SYN_HALF_RCVD`, when processing an SYN packet sent from the client, and will further jump to `SYN_RCVD` only after it sees an SYN+ACK packet sent reversely. That is, the middlebox stack has to maintain two PSMs for two sides, each of which introduces many more states and transitions.

Rubik proposes a new PSM abstraction to reduce the number of states and transitions, *i.e.*, the sender-side PSM, which combines the two-side behaviors and is triggered by a single packet. Figure 4b shows the sender-side PSM of TCP handshake, which consists of only three transitions. The key of this PSM is that it proceeds only by the sent packets (yellow ones), but ignores whether they have been received (white ones). The following defines the first transition in Figure 4b.

```
tcp.psm.syn = (CLOSED >> SYN_SENT) +
                  Pred(tcp.v.header.syn & tcp.to_passive)
```

where `to_passive` indicates the packet is being sent to the passive side in a connection-oriented session.

Note that the sender-side PSM is not a unidirectional PSM. Instead, it tracks *all* the bi-directional packets, but removes the redundancy in the end-host PSMs. For example, in Figure 4a, $\boxed{\text{SYN}}$ is the same packet with $\boxed{\text{SYN}}$. In fact, the sender-side PSM assumes the sent packets must be received. This is reasonable, because the stack cannot detect the packets lost downstream the middlebox. In practice, the middlebox stack will eventually be in the correct state after seeing the retransmitted packets, and before that, a retransmission event will alert that the current state may be inconsistent.

4.5 Event Ordering

By default, all the events will be raised after proceeding PSM and before parsing the next layer (see §5.2). However, operators have to further clarify two kinds of relationships between the events to avoid the potential ambiguity.

First, operators may need to define the "happen-before" relationships of two events, if they have the same or overlapped raising conditions. Consider the aforementioned two events in IP layer, `ip.event.asm` and `ip.event.ip_frag`, both of which will be raised when `ip.psm.last` is triggered. As a result, `ip_frag` might lose the last fragment if `asm` happens first, since the reassemble operation will clear the sequence.

Second, operators may want to raise an event if the other is happening, *i.e.*, the "happen-with" relationship. For example in TCP, an event `rdata` that poses the retransmitted data should be raised only when the retransmission event occurs.

Rubik offers an event relationship abstraction to address the above requirements. The following code indicates that `ip_frag` should happen before `asm`, and `rdata` will be checked and raised each time `rexmit` is happening.

```
ip.event_relation  += ip.event.ip_frag, ip.event.asm
tcp.event_relation += tcp.event.rexmit >> tcp.event.rdata
```

5 Compiling Rubik Programs

In this section, we introduce the compiler of Rubik, which translates the Rubik program into native C code. We first reveal the difficulties of handling the performance issues in the middlebox stack (§5.1). To this end, we translate the Rubik program into an intermediate representation (IR) to reveal the factual control flow of the stack (§5.2). Then the middle-end of the compiler performs domain-specific optimizations on the IR to avoid the performance traps (§5.3), and finally the back-end translates the IR into performant C code (§5.4).

5.1 Avoiding Performance Issues is Hard

As mentioned in §2.3, the generalized execution model can cause severe performance issues. For example, the simple pipeline will insert every IP packet into the sequence, while this is redundant for the non-fragmented IP packets, as their blocks will be assembled right after being inserted. And since the normal IP packets dominate the traffic, this redundant copy will heavily degrade the stack performance.

Previously in hand-written stacks, developers handle each of those performance issues using native code. However, due to the function diversity in the stack, identifying and avoiding *all* such traps for *all* stacks is too harsh for the developers. Moreover, even the developers are aware of those traps, sometimes they have to trade off performance for the code modularity or generality, since the proper handling of those issues will heavily increase the size of the codebase, making the program more bug-prone.

As a DSL, Rubik has better chance to address those performance issues, if it can capture and handle them through its automatic compilation process. This task, however, is still challenging. First, Rubik is designed as a declarative language, which means although the developers can easily write a “correct” program without caring about the inner logic, they also can do little for providing more hints for a “better” program. Second, it is also an impossible mission for the native code compiler due to the lack of domain-specific knowledge, *e.g.*, the fact that the aligned IP packets can be directly passed cannot be obtained from the view of the native compiler.

5.2 Intermediate Representation in Rubik

Rubik addresses above challenges by introducing an IR into the compilation, which brings the following merits. First, the IR code is much smaller, making it possible to do effective optimizations that are unaffordable in native code (see §5.3). Second, the IR code still holds the high-level intent to perform the domain-specific optimizations. Third, the IR layer is a common ground for all Rubik programs, which means the optimizations applied on IR work for *all* stacks.

Specifically, we adopt the Control-Flow Graph (CFG) as the IR, which can clearly reveal the control flow of the stack.

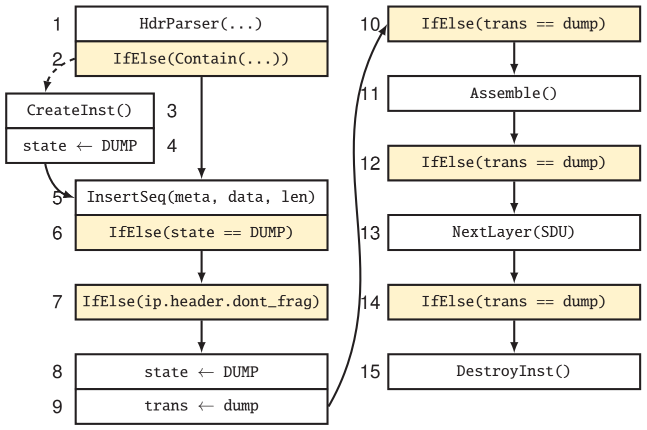


Figure 5: Partial CFG of the IP program. The yellow boxes are the branching blocks. Only one PSM transition (`ip.psm.dump`) is shown. Most of the `false` branches (dashed edge) are also omitted.

Note that each protocol layer works independently in the stack, so we view a protocol parser along with the events defined in its layer as an individual Rubik program.

Composing the control flow. The compiler composes the real control flow of the stack with the next four parts.

First, the compiler constructs the CFG for the protocol parser following the pipeline depicted in Figure 1, *i.e.*, header parsing, instance table, packet sequence and PSM transition, and elaborates it with more information that is relevant to the optimization, *e.g.*, the operations on the instance table and the sequence. The conditional statements, *e.g.*, PSM transitions and event callback, will be translated into the branching blocks with their `Pred`/`If` as the branching conditions.

Second, the compiler decides when to raise the events. It is possible to raise an event just after all its conditions have been met, *i.e.*, the triggering conditions are satisfied and the data in the callback structures are ready. As such, an event that only requires header information can be raised just after the header parser. However, the high-level functions hooking this event may modify the packets, which could impact the correct execution of the PSM. Hence, the compiler puts all events after proceeding the PSM, and decides their order by the explicitly defined happen-before and happen-with relationship in `event_relation`. The only exceptions are the built-in sequence events, *i.e.*, `rexmit` and `out_of_wnd`, which will be triggered by sequence operations before proceeding the PSM, as well as the events happening with them.

In the third and fourth parts, the compiler checks the conditions for parsing the next layer and destroys the instance if it jumps into the accepted PSM states.

Figure 5 shows a partial CFG for the IP program presented in §3. The white boxes are the basic blocks, and the yellow ones are branching blocks, where the solid/dashed edges indicate the `true`/`false` branches. In these blocks, IR uses instructions to reveal the operations on the real data structure. For example, we use `CreateInst()` to create and insert an

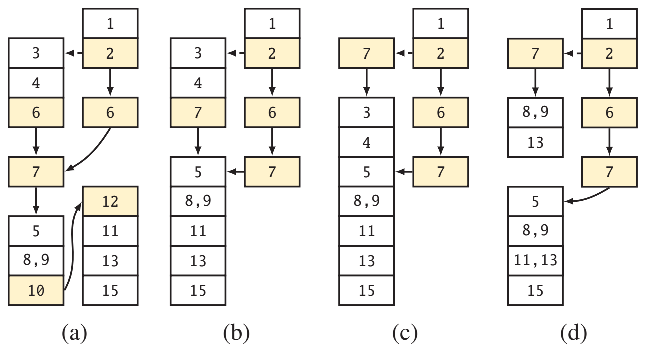

Figure 6: (a) First-round branch lifting, where $\boxed{6}$ is bounded by $\boxed{2}$ and $\boxed{4}$. (b) Constant analysis, where $\boxed{6}$, $\boxed{10}$ and $\boxed{12}$ are eliminated because they are always `true` guarded by $\boxed{4}$ and $\boxed{9}$. (c) Second-round branch lifting, where $\boxed{7}$ is further lifted above $\boxed{3}$, due to the absence of $\boxed{6}$. (d) Peephole optimization, where $\boxed{3}$-$\boxed{5}$, $\boxed{11}$ and $\boxed{15}$ are eliminated.

instance into the instance table, and `InsertSeq()` to insert the payload into its sequence. Blocks $\boxed{1}$–$\boxed{9}$ are for the IP protocol parser (only one PSM transition, *i.e.*, `ip.psm.dump`, is shown); blocks $\boxed{10}$ and $\boxed{11}$ are for the sequence assemble event; blocks $\boxed{12}$ and $\boxed{13}$ are for the next layer parsing, and blocks $\boxed{14}$ and $\boxed{15}$ handle the accept PSM state.

Revealing the dependency. Given the real control flow with CFG, the compiler can then reveal the dependency relationships between each instruction. This is achieved by checking the read/write operations in the instructions. For example, the instructions below a branching block can only be executed after reading the objects in that branching conditions. Hence, these instructions all depend on those objects.

We note that some read/write relationships are not explicit in the CFG. For example, `InsertSeq()` writes the sequence in current instance, and `Assemble()` reads the same sequence. Hence, `Assemble()` depends on `InsertSeq()`. We pre-define the implicit dependencies for all instructions.

5.3 Middle-End: Optimizing Control Flow

The middle-end first transforms the CFG to expose the complete processing logic on a same set of packets. Then, it applies domain-specific optimizations targeting on the "heavy" instructions to produce an optimal CFG. Specifically, the middle-end iteratively takes the following three steps until the CFG converges to a stable form.

Step 1: Lifting the branches. We lift all the branching blocks to the top of the CFG, as long as they do not depend on an upper block. Figure 6a shows the CFG with branching blocks lifted. We take $\boxed{6}$ as an example: it is lifted to top of the `true` branch of $\boxed{2}$, because in this branch, it only depends on the conditions in $\boxed{2}$; in contrast, in the `false` branch it can only be lifted below block $\boxed{4}$, because it reads the variable `state`, which is written by block $\boxed{4}$. Through this process, $\boxed{6}$ is duplicated, as both branches should traverse it. Note that some `false` branches are omitted in Figure 6a, *e.g.*, the `false` branches of $\boxed{6}$ and $\boxed{7}$ that contain the duplicated $\boxed{5}$.

The branch lifting process merges the basic blocks, which helps to expose a complete processing logic on an individual set of packets. This process maps to the "code sinking" transformation in conventional compilers, which however usually is not performed, since the codes would explode due to the duplication. In contrast, Rubik's IR code is small and with a neat pipeline, making this expensive transformation affordable.

Step 2: Constant analysis. This step replaces or removes the instructions if they are evaluated to be a constant. For example, consider $\boxed{6}$ in the `false` branch in Figure 6a. We can easily assert that its condition (`state==DUMP`) is always `true`, because $\boxed{4}$ has just assigned `state` with `DUMP`. Similar analysis takes place in block $\boxed{9}$, $\boxed{10}$, $\boxed{12}$, where `trans==dump` in the latter two must be `true`. Those always-`true` branch blocks can be removed, as shown in Figure 6b. Note that this elimination may create new opportunities to iteratively lift the branch, *i.e.*, Step 1. For example, $\boxed{7}$ can be further lifted above $\boxed{3}$, due to the absence of $\boxed{6}$, as shown in Figure 6c.

Step 3: Peephole optimizations. After the first two steps, the complete processing logic on each packet set is revealed. For example, $\boxed{3}$–$\boxed{15}$ in Figure 6c illustrates the processing logic on the first packet of an IP instance which is with `dont_frag` flag. In this step, we engage a series of peephole optimizations [36] to identify and eliminate performance traps.

Considering $\boxed{3}$–$\boxed{15}$, we have the following easy optimizations. (1) For $\boxed{3}$, $\boxed{5}$, $\boxed{11}$, $\boxed{13}$, it is obvious that the first and only inserted block is directly assembled. Hence, $\boxed{5}$ and $\boxed{11}$ can be eliminated, and $\boxed{13}$ can be rewritten into `NextLayer(Payload)`. (2) $\boxed{3}$ and $\boxed{15}$ is another pair of redundant operations, where the inserted instance is directly removed from the instance table. These two blocks can also be eliminated. Figure 6d shows the CFG that removes all redundant operations, most of which are very expensive, *e.g.*, instance creation and sequence insertion. We can therefore expect a much higher performance with this optimized CFG.

We emphasize that the patterns of the optimizations are not newly designed, but the common wisdoms borrowed from the mature stack implementations. The key is that manually realizing those optimizations for each stack would mess around the processing pipeline, and significantly increase the complexity of the code. In contrast, Rubik's middle-end are stack- and implementation-oblivious, *i.e.*, operators can focus on the logic of the optimizations without caring about how to integrate them with the stack logic. That is, the new patterns can be easily extended in the future, and the developers can obtain a fully optimized pipeline for all stacks. Appendix D shows the peephole optimizations that are currently employed.

5.4 Back-End: Producing Efficient Code

The back-end of compiler translates and assembles the optimized CFGs into native C code, and ensures its efficiency in two ways: (1) maximize the code efficiency without considering the code readability, *e.g.*, composing a single large

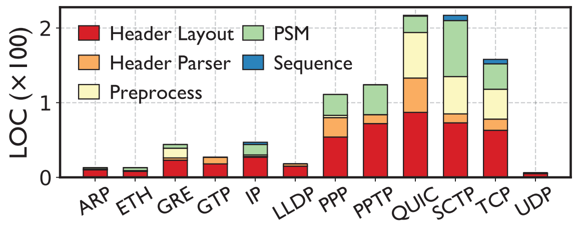

Figure 7: LOC breakdown of protocol parsers.

function for the whole stack to force the optimization in the C compiler; (2) borrow the best practice from existing middlebox stacks, *e.g.*, a fast hashing library. Except for the above general methods, we highlight two designs in the back-end.

Handling the header. The back-end translates the header fields and their references using the following principles.

- Each `layout` will be translated into a C `struct`, and the header parser is a `struct` pointer to the starting address of the header, so that each field can be directly accessed as a `struct` member. For the composite headers, *e.g.*, `ip.header=ip_hdr+ip_opt`, the back-end will generate multiple pointers pointing to different locations.
- Conditions and predicates of virtual ordered packets, *e.g.*, `If(ip.v.header.more_frag)`, will be implemented as tracking two states, *i.e.*, `if(seen_frag && no_hole)`, where `seen_frag` will be set if "more_frag" packet has arrived, and `no_hole` is assigned by checking the sequence each time a sequence block is inserted.

Threading model. We adopt the shared-nothing model with the run-to-complete workflow when generating native code. That is, each core runs an independent stack, which eliminates the inter-core communication [46]. Specifically, the back-end leverages the symmetric receive-side scaling (S-RSS) technique [71], so bi-directional packets from the same connection can be correlated to the same thread. Since modern NICs support hardware-based S-RSS, this usually linearly boosts the stack performance with the number of cores (see §7.1).

The back-end also takes care of other cases that require considerable human effort, *e.g.*, buffer outrun and timeout.

6 Rubik in Action

Rubik builds upon Python while offering domain-specific syntaxes and functions. In total, our prototype amounts to 3K Python LOC for Rubik internals, and 2K C LOC for hashing, packet I/O and sequence operations. The source code of Rubik is available at https://github.com/ants-xjtu/rubik.

In this section, we demonstrate the practicality of Rubik by implementing numbers of mainstream L2-L4 protocols and stacks (§6.1), and developing typical high-level middlebox functions (§6.2).

6.1 Collected Protocols and Stacks

We collect and implement 12 L2-L4 protocol parsers using Rubik. Here we focus on how many LOC used for the implementation, which reflects the complexity and robustness of the program. From the LOC breakdown shown in Figure 7, we have the following observations.

Table 2: Rubik and generated LOC for composing stacks.

Stack	Parse Tree	Addi.	Total	Gen.
TCP/IP	ETH→IP→UDP/TCP	14	245	11061
GTP	ETH→IP→UDP→GTP→IP→TCP	18	304	11384
PPTP	ETH→IP→TCP→PPTP ETH→IP→GRE→PPP→IP→TCP	37	586	46546
QUIC	loopback→IP→UDP→QUIC	23	361	14007
SCTP	ETH→IP→SCTP	9	233	23863

Addi.: *additional Rubik LOC apart from the individual protocol parsers*
Total: *total Rubik LOC* **Gen.:** *generated native LOC*

First, Rubik can express the mainstream L2-L4 protocols with minor LOC. Most connectionless protocols only take tens of LOC. The connection-oriented ones take more, but within hundreds of LOC. Second, most LOC are for defining the header layout (46% in average), since one field takes one LOC in Rubik. This task is quite straightforward if given the protocol specification, so the factual effort of writing a protocol parser is even less than it appears in the figure.

Reducing the effort of implementing above parsers is very valuable. For example, the stream control transmission protocol (SCTP) [2] provides many useful transmission features like message boundary preservation and multi-homing. However, this requires a significant change for middleboxes, *e.g.*, 4400 C LOC in Wireshark [3], making SCTP much less deployed [41]. Using Rubik, it only takes 210 LOC for implementing the SCTP layer. Another example is QUIC [6]: although its multiplexing feature improves the transmission efficiency, existing middleboxes cannot support it without a fundamental upgrade. As a reference, Wireshark takes ∼3100 C LOC to realize the QUIC protocol parser [26]. Using Rubik, merely 216 LOC is enough for prototyping a QUIC parser (without the decryption feature, see §8).

We finally implement 5 typical stacks, as shown in Table 2. We highlight that with the reusable protocol parsers, composing a middlebox stack requires minor additional Rubik LOC, although the native LOC generated is massive.

6.2 Developing Applications with Rubik

`Callback()` in defining BIEs will generate empty callback functions in the native code, which will be invoked each time the BIEs are triggered. The programmers can then develop their applications by implementing those functions.

The most typical example can be a DPI application that inspects the L7 data. In this case, the developer can pose an event happening with the assemble event (`tcp.event.asm`).

```
tcp.event.sdu = Assign(sdu_layout.sdu, tcp.sdu) + \
                Callback(sdu_layout)
tcp.event_relation += tcp.event.asm >> tcp.event.sdu
```

Other examples include the detection of SYN-flood and fake-reset, which can be implemented through the BIEs triggered by the first SYN packet and the reset transitions, respectively.

We present how we port Snort [21] as a more comprehensive example. Snort may scan the traffic multiple times against the rules, *e.g.*, on the fragmented IP packets or on the reassembled L7 data. With Rubik, the programmers can implement these scanning behaviors through the corresponding BIEs posed in the stack. Specifically, we implement 25 rule options, *e.g.*, `content`, `pcre`, `http_header`, and translate the rules into event-based callback functions. We replace Snort's `stream` and `http-inspect` modules with Rubik-generated stacks and events, and reuse the high-level matching modules like Aho-Corasick algorithm for string matching and HyperScan [69] for regular expression matching.

Note that, unlike mOS and Microboxes, Rubik currently does not support programming UDEs. As a result, for HTTP-related rules, we need to manually parse the L7 protocols in the callback function (instead of using a set of inherited UDEs), then the L7 rules can be matched against those parsed HTTP headers. §8 discusses the UDE programming in detail.

7 Evaluation

In this section, we evaluate the performance of Rubik. Specifically, our experiments aim to answer the following questions:

(1) Do Rubik-generated stacks provide comparable or even better performance than the hand-written stacks? (§7.1)

(2) Do Rubik-ported applications work correctly and efficiently on various stacks? (§7.2)

(3) Do the middle-end optimizations help improve the performance of Rubik? (§7.3)

7.1 Microbenchmarks

To measure Rubik's performance under certain traffic load, we build real end-host applications and set a bump-in-the-wire testbed as the middlebox stack. Due to the lack of high-performance non-TCP applications (*e.g.*, QUIC, SCTP), the microbenchmarks are mostly about the TCP/IP stack.

Experimental settings. We build the testbed on an x86 machine (20×Intel Xeon 2.2Ghz, 192GB memory) with three dual-port 40G NICs (Intel XL710). We use another six machines (8×Intel Xeon 2.2Ghz, 16GB memory) to build three server/client pairs. Each server/client has a single-port 40G NIC, and is connected through one NIC in the testbed server.

The clients and servers generate 96K concurrent connections in total (32K from each pair). Each connection fetches a file from the server (1KB by default), and will immediately restart when it terminates. Note that the three pairs cannot drain the 120Gbps link, so we indicate the upper bounds of the throughput for each setting in the experiments, *i.e.*, the throughputs when directly wiring the clients up to the servers.

We synthesize three high-level functions to simulate different workloads of the middlebox: (1) a flow tracker (FT) that tracks the L4 states but ignores the payload, (2) a data assembler (DA) that dumps bidirectional L7 data to `/dev/null`, and

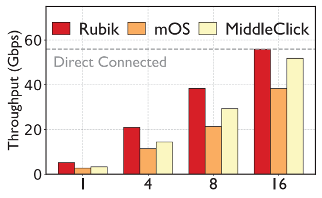

Figure 8: The multi-core scalability (DA, 1KB file).

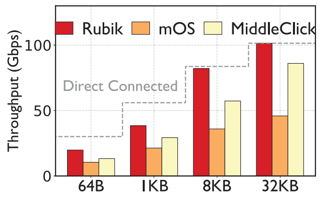

Figure 9: The file size scalability (DA, 8 cores).

(3) a string finder (SF) that matches 50 regular expressions against L7 data. We run DA as the default function in the experiments, as it reflects the intrinsic performance of a complete middlebox stack, *i.e.*, with bidirectional data reassembly and without heavy operations on that data. When running FT, we disable the data buffering for all involved approaches.

TCP stack. From the existing approaches shown in Table 1, we choose to compare Rubik with the TCP-specific stack and the NFV framework, since the packet parser cannot implement a full-functional stack. Specifically, we involve mOS [14] and MiddleClick [28] in our experiments. The former is the state-of-the-art TCP middlebox stack, and the latter with Click model is reported to be more efficient. All approaches have the same packet I/O capability with DPDK [8] and S-RSS. The clients and servers are implemented using mTCP [45].

Figure 8 shows the multi-core scalability of the involved approaches. Thanks to S-RSS, the performance of all approaches can almost linearly scale with the number of CPU cores. Note that Rubik's TCP stack achieves 5.2Gbps, 20.9Gbps, 38.4Gbps when using 1, 4, 8 cores, respectively, and can reach the upper bound (55.9Gbps) with 16 cores. Such throughput outperforms other approaches by 30%–90%.

Figure 9 shows the scalability with different file sizes. With 8 cores, Rubik's TCP stack can reach the upper bound with the file larger than 8KB (82.1Gbps in 8KB, 101.4Gbps in 32KB). We also report that Rubik can reach the upper bound for all file sizes if using 16 cores. Note that given the flow size (which can be inferred from the file size) and the throughput, we can estimate the connection arrival rates, *i.e.*, how many new connections can be handled per second. We report that with 8 cores, the connection arrival rates of Rubik's TCP stack are 4.5M/s and 1.1M/s for 64B and 8KB files, respectively.

Figure 10 shows the throughput with different functions. Rubik's stack can realize 44.1Gbps and 25.5Gbps for FT and SF with 8 cores, which maintain the lead to other approaches (34% and 90% faster than MiddleClick and mOS). We also report that Rubik's stack adds reasonable transferring latency (not shown in the figure), *e.g.*, running DA for a single flow adds 29μs and 97μs to the flow completion time when transferring 64B and 8KB files (62μs and 119μs without middlebox).

Why Rubik outperforms other approaches. First, the peephole optimizations applied in the middle-end let Rubik handles each packet class in the most efficient way, which guarantees a comparable performance to the mature hand-written ones. Second, the hand-written stacks have to trade off perfor-

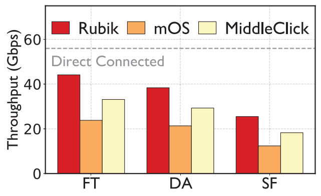

Figure 10: Throughput vs. functions (1KB file, 8 cores).

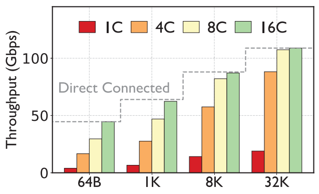

Figure 11: Performance of the GTP stack (DA).

mance for the code maintainability. For example, for maintaining the 8K C LOC of TCP stack, mOS spans more than 100 non-inline functions, dozens of which would be invoked for processing each packet. In contrast, Rubik puts 11K C LOC in a single function for composing the same stack, which incurs much fewer function calls, hence the higher throughput. Third, the one-big-function also forces the optimizations of native C compiler. Specifically, we re-compile MiddleClick and Rubik's generated code with `-O0` instead of `-O3`, and observe that MiddleClick's performance downgrades by 40%, while Rubik suffers 50% degradation. This partially confirms that deeper optimizations can be applied in the one-big-function.

We emphasize that both mOS and MiddleClick are with high-quality code. Even though, the performance trade-offs for maintainability are still inevitable when handling so many LOC with human oracle. Such risk would only be higher for more complex stacks. In contrast, Rubik avoids the performance traps for *all* stacks by automatically applying the domain-specific optimizations in its middle-end, while ensuring the maintainability with its neat syntaxes in the front-end.

GTP stack. Besides the TCP stack, we also run the GTP stack in end hosts for evaluation. Specifically, we modify mTCP to encapsulate/strip IP, UDP, and GTP layers for each TCP packet, where the new IP and UDP layers have the same IP addresses and ports with the original TCP packet. Note that this operation adds ~50 bytes to each packet, which will lift the throughput upper bound when transferring small files.

Figure 11 shows the performance of Rubik's GTP stack with different CPU cores and file sizes. With only one core, Rubik's GTP stack can realize 4.0Gbps and 14.2Gbps for 64B and 8KB file, respectively, and can reach their performance upper bounds (44.6Gbps and 88.0Gbps) with 16 cores. We highlight that even the GTP stack has much more layers than the TCP stack, Rubik can still catch up with the throughput, as its back-end introduces minor overhead between each layer.

7.2 Performance on Various Stacks

We collect real and synthetic traces to evaluate the performance of Rubik on various stacks with real applications.

Traces. We prepare traces for five stacks, as shown in Table 3. The TCP trace is captured in a campus network. The GTP trace is captured in an ISP's base station. For PPTP stack, we set a PPTP server with MPPE and PPP compression disabled, and capture the trace by accessing random websites. For QUIC stack, we set a pair of client and server

Table 3: The collected traces.

Trace	#Pkts.	#Flows	Avg. Flow Size	Avg. Pkt. Length	L7 Data Size	Total Size
TCP	25.9M	558K	32KB	652.13B	8.4GB	16.8GB
GTP	18M	630K	14KB	484.03B	0.6GB	8.7GB
PPTP	6.7M	9K	665KB	892.98B	4.2GB	6.0GB
QUIC	12.7M	3K	637KB	643.25B	5.4GB	8.1GB
SCTP	7.6M	600K	5KB	374.35B	2.3GB	2.9GB

Table 4: The throughput (Gbps) on the traces (16 cores).

	Snort	Rubik+Snort	nDPI	Rubik+nDPI	DA
TCP	20.41	26.86	25.94	25.26	117.76
GTP	15.36	22.79	18.87	18.37	113.42
PPTP	13.91	20.01	18.79	18.22	118.41
QUIC	-	-	-	-	116.29
SCTP	-	-	-	-	101.27

using `ngtcp2` [17], and capture the trace by querying random resources. Rubik currently does not support the online decryption, so we replace the encrypted data in the trace with a deciphered one using the local SSL key (see §8). For SCTP stack, we set the server and client using `usrsctp` [29], and capture the trace by fetching random files. We filter out the incomplete connections (flows without handshake or teardown) for all the traces, so we can properly replay them on a loop.

Applications. We port two well-known middlebox applications, Snort [21] and nDPIReader [15], to Rubik. For Snort, we port it as presented in §6.2, and load 2800 TCP- or HTTP-related rules from its community rule set. We note that nDPIReader does not implement a complete flow reassembly feature. To this end, we pose the TCP and UDP assemble events, and invoke the core detecting functions provided by nDPI in the callback functions. The Rubik-ported version can then detect protocols on reassembled data.

We equip the original Snort and nDPI with DPDK/S-RSS and involve them into the comparison. Note that neither of original and Rubik-ported versions can inspect QUIC or SCTP trace, because the rules and detecting applications are TCP-specific, *i.e.*, they assume the transport layer must be TCP/UDP. However, we argue that with the help of Rubik, it would be quite simple to port such rules to new stacks, *e.g.*, inspecting the HTTP content carried by an SCTP connection.

Performance. We split the traces into three pieces by their IP addresses and use three machines to inject them into the testbed (120Gbps line rate). The testbed runs on 16 cores.

Table 4 shows the throughput with different applications, from which we have two observations. First, the Rubik-ported Snort is faster than the original and the boost is more significant on the stacks with more layers (+31.6% for TCP vs. +48.3% for GTP), because "heavy" stacks would amplify the efficiency of Rubik's generated one-big-function. Second, the Rubik-ported nDPI is slightly slower than the original (−2.8% in average), because the latter does not reassemble the data at all. Specifically for TCP stack, the Rubik-ported versions perform better than the mOS-ported versions (+31.6% vs.

Table 5: Throughput boost (Gbps) and compilation slow down (seconds) from the middle-end optimizations (1 core, DA). Shadowed cells show the number with optimizations.

	TCP		GTP		PPTP		QUIC		SCTP	
Throughput	8.83	22.4	5.47	14.4	8.16	18.9	7.03	13.7	4.38	6.61
Rubik→C	0.06	0.28	0.07	0.31	0.10	1.19	0.07	0.42	0.06	1.22
C→Binary	3.32	3.47	3.47	5.46	3.73	13.1	3.47	4.02	3.27	6.86

+16.8% for Snort, −2.6% vs.−3.7% for nDPI) [44]. We finally highlight that when running DA, all Rubik's stacks can achieve more than 100Gbps throughput for their traces.

Correctness. We respectively select 100 flows from all traces. By manually verifying the results of protocol parsers and event callbacks, we confirm the correctness of Rubik.

7.3 Middle-End Optimizations

We inject the same traces used in §7.2 into the testbed and measure the performance and overhead of corresponding stacks, by enabling/disabling the middle-end optimizations.

Performance. The top part of Table 5 shows that all stacks can significantly benefit from the optimizations, with a boost rate of 51%–163%. The effect of the optimizations depends on two factors. First, since each layer is independently optimized, more layers lead to more improvements. Second, the major optimization is the elimination of the sequence operations, so more boosts can be gained when handling large flows. For example, PPTP and QUIC traces have similar flow size, but the PPTP stack with more layers gains more from the optimizations; TCP and SCTP stacks have the same number of layers, but the SCTP stack does not boost as much as TCP due to the smaller flow size of the trace (5KB vs. 32KB).

Overhead. The branch lifting in the middle-end leads to much larger CFG, which increases the time of compilation, *i.e.*, from Rubik program to C code, and from C code to binary. The bottom part of Table 5 shows that such overhead is minor in practice, *i.e.*, all stacks are compiled within 15 seconds.

8 Limitations and Discussion

Semantics completeness. There are generally two types of middleboxes: the flow-monitoring ones that parse the protocols, check the reassembled data, and forward/drop the original packets (*e.g.*, IDS), and the flow-modifying ones that intercept the connection and modify L7 content (*e.g.*, HTTP proxy). To the best of our knowledge, Rubik can well support programming the former type. For the latter, Rubik should extend its sequence abstraction for inline-reordering, and event abstraction for modifying the packet content. These extensions are realizable and will be explored in our future work.

Encrypted layers. Rubik can cooperate with the encrypted layers in the following two ways: (1) the stacks can directly work on the raw packets, if the middleboxes are placed inside the secure district, where the encrypted content has already been resolved by the gateway; (2) the stacks can inspect the encrypted content, given the proper decipher keys. We simulate the first scenario with QUIC protocol in our evaluation. For the second, we can offer an extra decryption function to modify SDU. We leave this feature to our future work.

UDE programming. Prior to Rubik, literatures focus on how to facilitate the middlebox development by offering friendly UDE interfaces. mOS [44] unifies the TCP stack and provides a BSD-style socket interface, so the developers can dynamically register/deregister their UDEs. Microboxes [53] further optimizes the UDE model by parallelizing their executions, making the performance scalable with the number of network functions. Since the UDE programming is oblivious from the stack programming, we believe providing such feature should be an easy task for Rubik's back-end, by borrowing the best practice from mOS and Microboxes.

Boosting S-RSS. We discuss two possible techniques that can further boost the packet dispatching. First, unlike S-RSS that dispatches correlated packets to fixed CPU cores, RSS++ [31] and eRSS [64] can collect the flow statistics and dynamically dispatch packets to different cores, which can further balance the CPU load. Second, the hardware-based S-RSS can only classify fixed protocols. For example, for PPTP stack, it only dispatches the packets by the lower-layer IP addresses, which are almost fixed as a tunnel. The dispatching can be much more balanced if higher-layer IP and TCP protocols can be considered. A smart NIC [54] or a programmable switch associated with the middlebox [46] that can dispatch the packets by arbitrary headers could be a cure to this problem.

Middlebox deployments. While Rubik facilitates the development of a single middlebox, there are literatures that deploy middleboxes in a distributed way [62, 65] or as a cloud service [66]. These works can be complementary to Rubik.

Ethics statement. The TCP and GTP traces used in the experiments are anonymized before given to us. We claim that our work does not raise any ethics issue.

9 Conclusion

This paper proposed Rubik, a language for programming the middlebox stack, which offers a set of high-level constructs as efficient building blocks, and an optimizing compiler to produce high-performance native code. We demonstrated the minor effort for implementing 12 protocol parsers and 5 popular stacks using Rubik. We evaluated Rubik with real applications and traces, and showed that the generated stacks outperform existing approaches by at least 30% in throughput.

Acknowledgments. We thank the anonymous NSDI reviewers and our shepherd Dejan Kostić for their valuable feedback. We thank Patrick P. C. Lee and Aaron Gember-Jacobson for their comments on the early version of this paper, and Tom Barbette for his help on the codebase of MiddleClick. This work is supported by NSFC (61702407, 61772412, 61902307 and 61702049), and Fundamental Research Funds for the Central Universities. Peng Zhang is the corresponding author.

Appendix A Rubik Built-in Abstractions

	Abstractions	Initialized Syntax and Parameters	Functionality and Semantics
Packet Data	`p.header`	`layout+layout` `AnyUntil((layout), cond)`	generate a header layout
	`p.temp, p.perm`	`layout`	the permanent/temporary data bound to the instance
	`p.seq`	`Sequence(meta,data,data_len)`	the sequence indexed by *meta* and filled with *data*
	`p.payload`	initialized by `p.header`	the payload of layer *p*
	`p.sdu`	initialized by `Assemble()`	the SDU passing to the upper layer
Inst. Table	`p.selector`	`[inst_key]` `([active_key],[passive_key])`	maintain the instance table by the key
Proto. State Machine	*s*	`PSMState(start, accept)`	define a PSM state *s*
	`p.psm`	`PSM(state set)`	build the PSM with the *state set*
	`p.psm.t`	`(`s_1 `>>` s_2`) + Pred(cond)`	define a transition *t* from s_1 to s_2 with condition *cond*
	`p.to_active/passive`	initialized by `p`	sending to active/passive side (connection-oriented)
Event Callback	`p.event.e`	`Assemble()`, `Callback(lay)`	an event *e* that assembles the sequence or poses *lay*
	`p.event_relation`	`(p.event.a, p.event.b)` `p.event.c >> p.event.d`	*a* happens before *b*, while *d* happens when *c* happens
Parse Tree	`st`	`Stack()`	define a stack *st*
	`st.`*lay*	*p*	define layer *lay* with parser *p*
	`st`	`(st.`*lay*1 `>> st.`*lay*2`) + Pred(`*pred*`)`	define *lay*2 as the next layer of *lay*1 with condition *pred*
Global Parameters	`p.cursor`	initialized by `p`	the current position (in byte) through the header parsing
	`p.cur_state`	initialized by `p`	the current PSM state of the instance
	`p.timeout`	a float number	the global keep-live threshold for the instance of `p`
	`p.psm.t.timeout`	a float number	the keep-live threshold of the instance in transition *t*

Appendix B Instructions and Expressions in Rubik's CFG

Instructions	Read	Write	Description
Assign(*reg*, *expr*)	*expr*	*reg*	modify *reg* with the result of *expr*
AssignSDU(*expr*)	*expr*	`SEQUENCE`	modify sequence with the result of *expr*
CreateInst()	-	`INSTTABLE`	create and insert the instance into instance table
DestroyInst()	-	`INSTTABLE`	remove the instance from the instance table
InsertSeq(*m*,*d*,*l*)	-	`SEQUENCE`	insert a sequence block (`meta=`*m*`,data=`*d*`,len=`*l*) into the sequence
Assemble()	-	`SEQUENCE`	assemble the continuous blocks in the sequence and pop it
Call(*expr*)	*expr*	-	invoke a callback function with the data *expr*
NextLayer()	-	-	jump into the next layer according to the parse tree
Expressions	**Read**	**Write**	**Description**
HeaderContain(*f*)	`HEADER`	-	check whether the parsed header contains field *f*
Payload()	`HEADER`	-	the content besides the parsed header from the packet
SDU()	`SEQUENCE`	-	the SDU assembled from the sequence
Contain(*key*)	`INSTTABLE`	-	check whether the instance with *key* is in the instance table

Appendix C Example Rubik Programs

C.1 IP Protocol Parser

The following code shows a complete IP protocol parser.

```python
class ip_hdr(layout):
    version = Bit(4)
    ihl = Bit(4)
    tos = Bit(8)
    tot_len = UInt(16)
    id = Bit(16)
    blank = Bit(1)
    dont_frag = Bit(1)
    more_frag = Bit(1)
    f1 = Bit(5)
    f2 = Bit(8)
    ttl = Bit(8)
    protocol = Bit(8)
    check = Bit(16)
    saddr = Bit(32)
    daddr = Bit(32)

class ip_temp(layout):
    offset = Bit(16)
    length = Bit(16)

def ip_parser():
    ip = Connectionless()

    ip.header = ip_hdr
    ip.selector = [ip.header.saddr, ip.header.daddr]

    ip.temp = ip_temp
    ip.prep = Assign(
        ip.temp.offset, ((ip.header.f1 << 8) + ip.header.f2) << 3
    ) + Assign(ip.temp.length, ip.header.tot_len - (ip.header.ihl << 2))

    ip.seq = Sequence(meta=ip.temp.offset, data=ip.payload[: ip.temp.length])

    DUMP = PSMState(start=True, accept=True)
    FRAG = PSMState()
    ip.psm = PSM(DUMP, FRAG)
    ip.psm.dump = (DUMP >> DUMP) + Pred(
        ((ip.header.dont_frag == 1) & (ip.temp.offset == 0))
        | ((ip.header.more_frag == 0) & (ip.temp.offset == 0))
    )
    ip.psm.frag = (DUMP >> FRAG) + Pred(
        (ip.header.more_frag == 1) | (ip.temp.offset != 0)
    )
    ip.psm.more = (FRAG >> FRAG) + Pred(ip.header.more_frag == 1)
    ip.psm.last = (FRAG >> DUMP) + Pred(ip.v.header.more_frag == 0)

    ip.event.asm = If(ip.psm.dump | ip.psm.last) >> Assemble()

    return ip
```

C.2 TCP Protocol Parser

The following shows the complete TCP protocol parser written in Rubik, including the header option parsing, the bi-directional buffering, the out-of-window exception handling, *etc*. We note that the code is formatted according to PEP8, which largely increases the number of LOC. Moreover, the definitions of header layout and auxiliary structures take about 40% of the LOC, which means the factual effort of writing this parser is even less than the number of LOC shows.

```
class tcp_hdr(layout):
    sport = UInt(16)
    dport = UInt(16)
    seq_num = UInt(32)
    ack_num = UInt(32)
    hdr_len = Bit(4)
    blank = Bit(4)
    cwr = Bit(1)
    ece = Bit(1)
    urg = Bit(1)
    ack = Bit(1)
    psh = Bit(1)
    rst = Bit(1)
    syn = Bit(1)
    fin = Bit(1)
    window_size = UInt(16)
    checksum = Bit(16)
    urgent_pointer = Bit(16)

class tcp_nop(layout):
    nop_type = Bit(8, const=1)

```

C.3 GTP Stack

The following code builds a GTP stack (Eth→IP→UDP→GTP→IP→TCP) by composing the reusable parsers.

```
stack = Stack()
stack.eth = eth_parser()
stack.ip1 = ip_parser()
stack.udp = udp_parser()
stack.gtp = gtp_parser()
stack.ip2 = ip_parser()
stack.tcp = tcp_parser(stack.ip2)

stack += (stack.eth >> stack.ip1) + Pred(1)
stack += (stack.ip1 >> stack.udp) + Pred(
    (stack.ip1.psm.dump | stack.ip1.psm.last) & (stack.ip1.header.protocol == 17)
)
stack += (stack.udp >> stack.gtp) + Pred(1)
stack += (stack.gtp >> stack.ip2) + Pred(stack.gtp.header.MT == 255)
stack += (stack.ip2 >> stack.tcp) + Pred(
    (stack.ip2.psm.dump | stack.ip2.psm.last) & (stack.ip2.header.protocol == 6)
)
```

Appendix D Peephole Optimizations

D.1 Direct Fast Forward

Pattern: `CreateInst` → `InsertSeq` → `Assemble`

Analysis: `CreateInst` creates a new instance. As such, the sequence must be empty and `InsertSeq` will insert the first block, which will be directly ejected by `Assemble`. To this end, the insertion is redundant and the assembled data is identical to the payload of this packet. To this end, the insertion and assemble instructions can be removed, and all the reference to p.`sdu` in this code block can be replaced with p.`payload`.

Output: `CreateInst`, and references to p.`sdu` in this code block can be replaced with p.`payload`, *e.g.*, `NextLayer(SDU)` should be modified to `NextLayer(Payload)`.

D.2 Fast Forward

Pattern: `InsertSeq` → `Assemble`

Analysis: Fast Forward optimizes the assemble operations for existing instances. To be specific, we could make a fast peek to the sequence before we insert the block: if the sequence is empty and the block's meta is aligned with the sequence's window, this block can be fast forwarded, *i.e.*, passing the payload instead of SDU; otherwise the code maintains the same.

Output: `If(IsEmpty&IsAlign)` →(replace SDU with payload) → `Else` → `InsertSeq` → `Assemble`

D.3 Fast Assemble

Pattern: `InsertSeq` → `Assemble` and without any `NextLayer` and `Callback`

Analysis: The `false` branch of the Fast Forward optimization means the current sequence is not empty or the current block is not aligned with the window. We can further optimize this branch, if it has no external function call, *i.e.*, `NextLayer` and `Callback`. Specifically, if the packet sequence is implemented using linked list like `libnids`, `Assemble` that collects the continuous blocks will invoke several times of data copy. However, if there is no external function that needs the assembled data, such copy is useless and can be eliminated. On the other hand, if the packet sequence is implemented using ring buffer like mOS, the data copy is still necessary when there are holes in the sequence and memory compaction is performed. In such cases, `Assemble` instruction can be eliminated. Note that we cannot eliminate `InsertSeq`, because this block may be useful for next packets' assemble in other branches.

Output: Remove `Assemble`.

D.4 Fast Destroy

Pattern: `CreateInst` → `DestroyInst`

Analysis: If an instance is created and destroyed by the same packet, it means that such instance will not impact any permanent data, and all sequence and PSM operations are meaningless. As a result, we can eliminate such creation and deletion as well as most of the instructions between them, except `Callback` and `NextLayer`.

Output: A mostly empty instruction block except `Callback` and `NextLayer`.

Flightplan: Dataplane Disaggregation and Placement for P4 Programs

Nik Sultana John Sonchack Hans Giesen Isaac Pedisich Zhaoyang Han
Nishanth Shyamkumar Shivani Burad André DeHon Boon Thau Loo
University of Pennsylvania

Abstract

Today's dataplane programming approach maps a whole P4 program to a single dataplane target, limiting a P4 program's performance and functionality to what a single target can offer. Disaggregating a single P4 program into subprograms that execute across different dataplanes can improve performance, utilization and cost. But doing this manually is tedious, error-prone and must be repeated as topologies or hardware resources change.

We propose Flightplan: a target-agnostic, programming toolchain that helps with splitting a P4 program into a set of cooperating P4 programs and maps them to run as a distributed system formed of several, possibly heterogeneous, dataplanes. Flightplan can exploit features offered by different hardware targets and assists with configuring, testing, and handing-over between dataplanes executing the distributed dataplane program.

We evaluate Flightplan on a suite of in-network functions and measure the effects of P4 program splitting in testbed experiments involving programmable switches, FPGAs, and x86 servers. We show that Flightplan can rapidly navigate a complex space of splits and placements to optimize bandwidth, energy consumption, device heterogeneity and latency while preserving the P4 program's behavior.

1 Introduction

Different kinds of hardware can be leveraged to make networks programmable, including CPU-based servers running "software-ized" Network Functions (NFs), NPUs, FPGAs and programmable ASICs. Although these hardware targets have complementary strengths when it comes to performance, flexibility, and power utilization, it is difficult to combine their strengths. Many NFV frameworks are CPU-centric, and chaining services across diverse hardware usually treat the hardware's capabilities as a black box. This is partly because toolchains for NPUs, FPGAs, and ASICs are alien to most software developers.

Code, documentation, tests and data can be downloaded from: `https://flightplan.cis.upenn.edu`

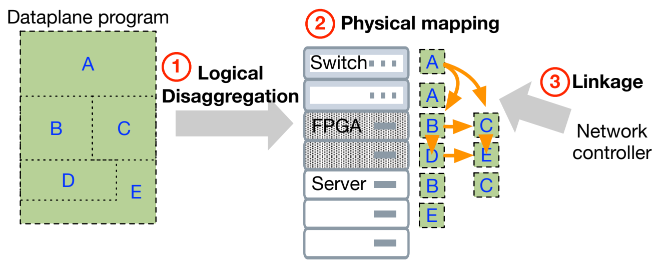

Figure 1: In this illustration, a program is split into 5 logical parts, A-E. ① A program is annotated with logical delimiters, manually or automatically. Flightplan splits the program into complementary parts using these annotations and provides coordination and linkage code between these parts, which the Flightplan control program configures at runtime. ② Each part of the original program is mapped to a physical device. In this illustration, A is mapped to Top-of-Rack (ToR) switches, B, C D, and E to network-attached FPGAs, and redundant instances of B, C, and E are mapped to execute on server CPUs. ③ The Flightplan control program can alter the program's linkage at runtime, to use different hardware targets, mitigate faults, or balance load.

While P4 is emerging as a common language for programming dataplanes across programmable ASICs, NPUs, FPGAs, and CPUs, P4 programs are limited to what can be run on a single target because they are programmed in an approach that maps a whole program to a single dataplane. This approach limits a dataplane program to what can be computed using a single target's resources and capabilities.

Through testbed experiments we measured how splitting a single P4 program into subprograms that execute across different dataplanes can improve performance, utilization and cost (§2, §7.2.3).

In principle, one could write a set of P4 programs that execute jointly across different dataplanes, combining their strengths. Further, P4 could be used as a convenient syntax for both NF authoring and for NF composition across different types of hardware. This set of P4 programs would be written to follow this pattern:

- If the dataplane program exceeds the resources provided by a single hardware target, then part of the program could be disaggregated to run on additional targets.
- If the dataplane program exceeds the capabilities provided by a *class* of targets, it could be disaggregated to run on two or more heterogeneous targets (e.g., ASIC and FPGA).
- Redundant spares can be provisioned for quick fail-over, leveraging the best available hardware for a given dataplane program.

However, writing distributed P4 programs manually is tedious and error prone. Current dataplane programming approaches lack abstractions for inter-program communication and mechanisms such as RPC [5] across different in-network functions. This complicates the implementation and composition of sophisticated in-network services because dataplane programmers are burdened with having to write and manage such coordination explicitly. It is also laborious to re-distribute the P4 program when new equipment or NFs become available.

We propose and evaluate Flightplan, a target-agnostic, P4-based programming toolchain that disaggregates P4 dataplane programs into a set of dataplane subprograms and runs them as a distributed system formed of several, possibly heterogeneous, dataplanes. It uses hardware performance and resource profiles to plan the allocation of subprograms onto dataplanes in the network on which to execute. The composite behavior of the resulting distributed dataplane program is the same as the original program; coordination and synchronization code is provided by the Flightplan runtime.

We reduce the P4 program, hardware performance profiles, and network topology constraints to a common rule-based formalism that Flightplan uses to map parts of the original program to dataplanes in the network. Through evaluation we show that it rapidly navigates a complex space of configurations which are then ranked according to the sought optimization criteria, and show that several disaggregated programs can be run simultaneously in the same network.

Figure 1 sketches our approach. It uses unmodified, commodity hardware and does not require changing the P4 language. A key enabler of this approach is that P4 enjoys toolchain support to target diverse hardware: ASIC [3], FPGA [23, 37, 38], NPU [24], and CPU [25]. These diverse targets' toolchains are based on P4's reference compiler [26], which we extend in our prototype. Unlike traditional NF service chaining [28], Flightplan works over diverse hardware.

We summarize our key contributions as follows:

- **Dataplane program disaggregation.** (§2) We propose the concept of dataplane program disaggregation and provide a motivating use-case. We show how disaggregation enables better utilization of existing resources.

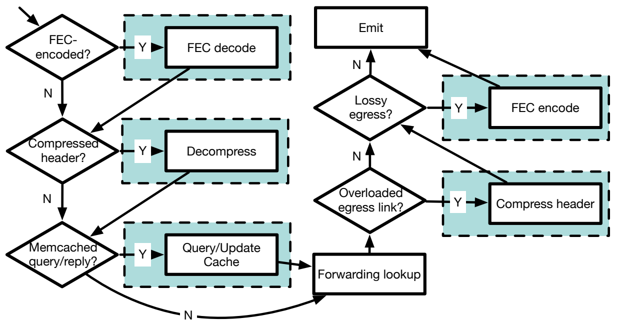

Figure 2: Our example dataplane program, `Crosspod.p4`, shown as a flowchart for compactness. The colored dashed rectangles surround functions that one might need to offload to other dataplanes in the network to free up resources on the switch, or because they exceed the computational abilities of the switch.

- **Automation for disaggregation.** (§3) We present a novel approach that partly automates dataplane disaggregation and does not require changes to the P4 language or to hardware targets and their toolchains. We extend the open-source P4 compiler to implement a program analyzer (§4) that discovers resource-use and dependencies that must be preserved once the program is split.
- **Flightplan runtime support.** (§5) We describe the requirement of in-dataplane and out-of-dataplane runtime support for disaggregated programs and how the runtime influences the process through which programs are disaggregated. We explore the design space by implementing 3 runtimes for Flightplan, offering different trade-offs between features and overhead.
- **Flightplan planner.** (§6) We implemented a prototype tool that generates configuration plans for disaggregated programs.
- **Evaluation.** (§7) We present a detailed evaluation of different aspects of this work, including testbed experiments involving heterogeneous hardware and microbenchmarks to measure resource transfer and disaggregation overhead.

2 Motivating Example: Crosspod

`Crosspod.p4` is an 800-line P4 program, sketched in Fig. 2, that will provide a running use-case. After describing how `Crosspod.p4` works, we describe the process of disaggregating it into several subprograms to run on three different classes of hardware.

We wrote `Crosspod.p4` to improve network reliability and performance using caching, compression, and forward-error correction in a way that is transparent to applications and users. Figure 3 shows its execution. Figure 4 shows two examples of disaggregation for this program.

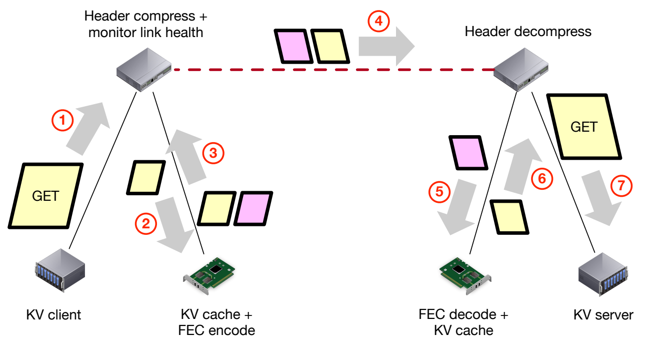

Figure 3: ① Key-Value (Memcached) client generates a GET request (yellow packet) which it puts onto the network for the KV server to respond to. ② A transparent, rack-level in-network KV cache is consulted. ③ In the event of a cache miss then the request is relayed onwards. The switch compresses its header, and upon detecting that the request shall cross a lossy link, it activates link-layer FEC which is computed in the network using reconfigurable hardware. ④ The KV packet and FEC-related redundancy (pink packet) cross the channel to the next switch. ⑤ Lost packets can be recovered during FEC decoding. ⑥ The packet's header is decompressed. A second inline KV can be consulted, to take pressure off the host-based KV server. ⑦ If all the caches were missed, then the request finally reaches the KV server, which sends its response back to the requesting client.

In-network functions. `Crosspod.p4` invokes a set of in-network functions to achieve its goal. Some of these functions are external to P4, and we implemented them to run on different types of hardware. In our example dataplane program, *reliability* is improved by (1) using forward-error correction (FEC) to mitigate faulty links; (2) application-specific caching to lessen congestion; and (3) header compression to lessen congestion. The *performance* of the network is improved by (1) reducing link utilization (through caching and header compression), (2) reducing latency (through caching closer to clients), and (3) reducing server utilization (through caching). In particular, caching is directed at Key-Value (KV) queries, a staple service in modern datacenter systems [10, 18, 21, 35].

Why Dataplane Disaggregation. In this example dataplane program, we combine in-network functions that cannot entirely be carried out within a single type of hardware for the following reasons: (1) **resources**: we cannot run the program entirely on a programmable switch ASIC because some of the functions (e.g., layer 2 FEC) exceed the computations that can be carried out in state-of-the-art devices, which typically do not include payload processing; (2) **performance**: we cannot run it entirely on an FPGA because this would severely constrain the throughput of this program. ASICs often support higher I/O bandwidth per chip and use less silicon for the standard dataplane switching operations, resulting in fewer or less expensive chips to handle the highest throughput data

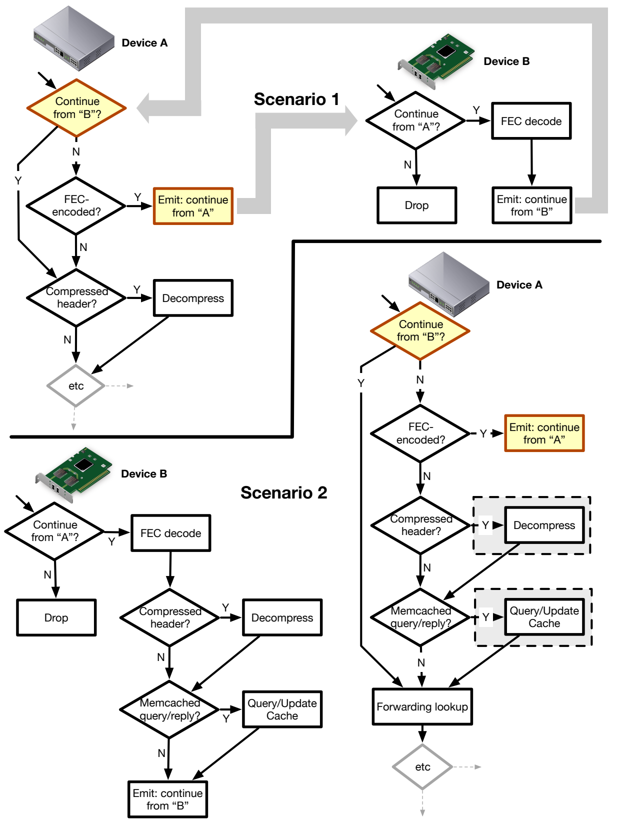

Figure 4: Two ways of splitting the program from Figure 2 between two devices: in **Scenario 1** a single function is offloaded from the switch (Device A) to an FPGA board (Device B) that immediately returns control back to the switch after executing the function; in **Scenario 2** a segment of the dataplane program is offloaded from the switch to the FPGA, which carries out several functions.

movement; (3) **expense**: even if we could place a program entirely on a single hardware dataplane, we do not want to use up resources unnecessarily and would prefer to move less-traversed code to a less expensive dataplane (e.g., an end-host). Conversely, if we have underutilized FPGAs, then we might prefer to use them rather than an end-host to save on power and cooling costs [14]. Last, (4) **availability**: we might want to failover quickly and autonomously from centralized monitoring and reconfiguration, by installing logic into the dataplane for self-management.

Why Automate Dataplane Disaggregation? Disaggregating a program involves i) deciding how to split it, ii) adapting the derivative subprograms to hand-over to one another, and iii) placing the subprograms on targets in the network.

Table 1 shows different characteristics of different hardware targets when executing the same function on the same workload. Automation spares the network operator from having to manually pick hardware combinations and track their

	Throughput (Gbit/s)			Power (W)
	Compression	FEC	KV Cache	
P.ASIC	9.07	-	-	110.5
FPGA	8.35	7.95	7.73	27.3
CPU	0.10	0.04	-	140.6

Table 1: Maximum Throughput and Average Power of network functions running on different hardware. Dashes indicate that we do not have implementations for network function to run on a particular target.

utilization.[1] In addition to power and performance, Flightplan can optimize for unit cost, utilization and latency.

The difficulty of this task is compounded by the likelihood that the choice of programs, topologies and target devices will change over time, requiring the whole process to be redone. If several programs are being disaggregated, then it becomes more challenging to optimize their placement jointly. Further, placement constraints and objectives may change over time, too: changing priorities over which links to protect with redundancy for example, or which traffic to compress, might require different function placements in the network.

This practical difficulty makes a strong case for automating dataplane disaggregation. But automation needs to be done carefully to avoid incurring the theoretical complexity of the automatic disaggregation problem. We estimate this to be exponential in the number of targets available on which to map subprograms and doubly exponential in the number of subprograms.[2] Flightplan uses heuristics to avoid this blow-up and our prototype also emits coarsening advice to opportunistically decrease the split granularity to better utilize the available hardware.

Deployment practicalities. The design and evaluation of Flightplan addresses the following practical considerations: (i) Multiple disaggregated programs can be used in the same network simultaneously: our evaluation in §7 describes how we ran 10 P4 programs in the same network, 6 of which were disaggregated, and of which 4 were different disaggregations of the same program. (ii) Upgrades can be done in a phased manner, as standard in deployment [34], by running the old and new versions of software simultaneously in the same network as described above. (iii) Debugging is done using standard techniques—inspecting packet traces, counters, etc.—complemented by using the Flightplan *control program* (§5) to conveniently query Flightplan-specific state of the disaggregated program across all the dataplanes on which parts of it are running. (iv) Failures can be detected and handled by Flightplan runtime support inserted into the dataplane itself or by remotely using the control program.

[1]More detailed information is provided in Table 3 in Appendix B.

[2]The full calculation is given in Appendix C.

3 Flightplan Overview

Flightplan produces a sequence of plans, consisting of a disaggregation of a dataplane program into multiple programs, and the allocation of these programs to dataplanes in the network. A plan targets the Flightplan *runtime* which provides the facilities to configure, start, and execute the disaggregated program. The role and design of Flightplan's runtime support is detailed in §5.

In this section, we outline all the inputs and outputs of Flightplan before going into more detail in the sections that follow. Figure 5 illustrates our workflow. ① We start with a P4 program and *segment* it. Segments are sequences of statements from the original program and provide the planner with the smallest granularity of program parts that it can then map to different targets. Figure 5 shows the program being decomposed into five segments as an example, labeled A-E. The `then` and `else` blocks of an `if` statement can go into separate segments, as hinted in the drawing in Figure 5 where segment A branches to B and C.

Programs are currently segmented manually, but this could be automated in the future. Segmentation consists of inserting additional lines in the program that are interpreted specially by our extension of the P4 compiler to delimit segment boundaries (§4.1.1). ② Our P4 compiler extension analyzes segments to generate a set of Prolog-like rules that expresses an *abstract program* completely automatically (§4.1.2). The abstract program consists of a DAG of segments, with P4 code replaced by the abstracted resources it depends on. Abstracted resources, such as tables and external functions, might not be available on all hardware or might have different capacity, power, throughput, and latency characteristics when invoked on hardware.

③ The *abstract resource semantics* is an additional set of rules used to check whether a dataplane satisfies a segment's resource needs. We use these rules to encode the performance profile which was summarized in Table 1. The contents and generation of rules is explained further in §4.

④ The planner is provided with a description of the network, including topology and device information, expressed in the same formal language used for our abstract semantics, and ⑤ objectives to optimize, consisting of variables changed by the abstract resource rules—such as Rate in Rule 1. ⑥ If the constraints can be satisfied for the given topology, abstract resource rules and segmented program, then the planner will lazily and exhaustively generate all plans to optimize objectives. A *plan* consists of three components. The *allocation model* describes how the abstract state—such as packet size and latency—is modelled to change as the program executes across dataplanes. This is used to understand the allocation that the planner has found. The *annotated program* consists of the original program with possibly coarsened segments, reflecting how the segments are going to be split into subprograms. In this example, segments B and C are united into F

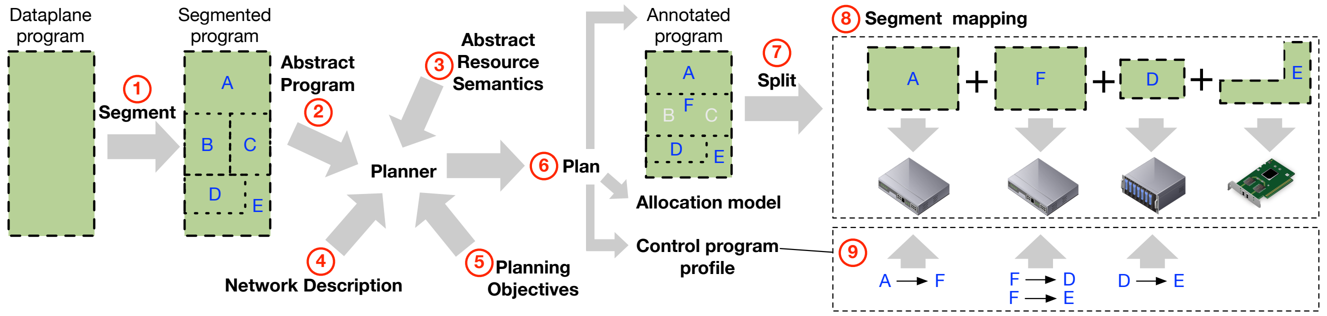

Figure 5: Flightplan's workflow, described in §3.

$$\frac{\text{CPU} \quad \text{Rate} < 2 \times 10^8 \quad \text{PacketSize} > 1000}{\text{header\_compress}} \left[\begin{array}{l} \text{Lat.} \mapsto \text{Lat.} + 7.4 \times 10^{-3} \\ \text{Rate} \mapsto \text{Rate} \times \frac{189.9}{194.75} \\ \text{once Power} \mapsto \text{Power} + 150\,\text{W} \\ \text{once Cost} \mapsto \text{Cost} + 5 \end{array} \right]$$

Rule 1: This rule states that we can execute Header Compression (HC) on packets *if* we are running on a CPU, and the throughput and packet size are within given bounds. We form different rules to describe the same function operating under different bounds—e.g., different Rate or PacketSize—and on different hardware targets, such as our FPGA implementation. If this rule can be used then the *effect* of executing HC in this instance is shown in the [...]-enclosed finite function on user-defined $\mathbb{R}$-valued variables. In addition to adding latency (Lat.), the function reduces Rate because of its compression of network traffic. 'once' indicates that a function is only executed once whenever using a specific target—in this case using an x86 server raises power estimate by 150 W regardless of how many segments are allocated to that particular target. 'Cost' is a normalized unit cost we use for different types of devices on our network. The [...]-enclosed function is allowed to mutate the planner's representation of the program's state, modelling the effect of invoking the resource.

for mapping to the same dataplane. Finally, the *control program profile* will be used by Flightplan's control program to configure the distributed program's runtime, start it, and query its state. The profile contains port, state information, and segment information, and is specific to a disaggregated dataplane program. ⑦ The annotated program is split into subprograms. This process involves augmenting each segment with a copy of the Flightplan runtime to configure, test, and hand-over between these programs. Some dataplane functions may be external to the P4 program, such as the FEC from the previous section. Flightplan treats such functions as black boxes, and it does not generate non-P4 code for specific targets, such as FPGAs or CPUs. ⑧ The program segments are compiled using the target-specific toolchain provided by the target's vendor. ⑨ The control program configures the Flightplan runtime of each target on which a segment is allocated by *linking* the segments together: i.e., indicating on which port to hand-over to its peer segments. Once the system's configuration is complete, the control program can start its execution.

Listing 1: Snippet from `Crosspod.p4` (§2) showing an example segmentation. Highlights show segmentation annotations in orange and resource-related syntax in green.

```
bit<1> compressed_link = 0;
bit<1> run_fec_egress = 0;
...
flyto(Compress);
// If heading out on a multiplexed link, then header compress.
egress_compression.apply(meta.egress_spec, compressed_link);
if (compressed_link == 1) {
    header_compress(forward);
    if (forward == 0) {
        drop();
        return;
    }
}
flyto(FEC_Encode);
check_run_FEC_egress.apply();
// If heading out on a lossy link, then FEC encode.
if (run_fec_egress == 1) {
    ...
    classification.apply(hdr, proto_and_port); // Sets hdr.fec.isValid()
    if (hdr.fec.isValid()) {
        encoder_params.apply(hdr.fec.traffic_class, k, h);
        update_fec_state(hdr.fec.traffic_class, k, h,
                         hdr.fec.block_index, hdr.fec.packet_index);
        hdr.fec.orig_ethertype = hdr.eth.type;
        FEC_ENCODE(hdr.fec, k, h);
        ...
```

4 Rules in Flightplan

Rules of different kinds play a central role in Flightplan. These rules are combined to describe the abstract semantics of a P4 program and how the resources it needs to use are satisfied by hardware targets in a network.

Steps ②, ③ and ④ in Figure 5 involve producing rules for the planner to use. This section describes the content of these rules and how they are generated.

An important design feature in Flightplan is that rules do not have to be encoded literally by users. As explained in this section, rules are either created automatically from P4 programs by the Flightplan analyzer, or are generated from a table that describes the network and profiles of devices in the network. This input is then automatically converted into rules based on Definite Horn clauses [9] that rely on a simple propositional language that is explained further in §I.

4.1 Abstract Program

Our P4 program analyzer turns a P4 program into an abstract form consisting of a set of Prolog-like rules. To better describe the generation of rules for step ② we first elaborate on step ①.

4.1.1 Program Segmentation

Step ① involves adding demarcating statements to P4 code. These statements consist of calls to the special function 'flyto()', passing it a unique name to be used for the new segment. A segment extends until the next flyto() or the control block's end, whichever is reached first. flyto() statements have no effect in P4, they are interpreted by our P4 compiler extension which we refer to as the *Flightplan analyzer*. These statements provide syntactic markers that define the sub-program granularity for the rest of the planning process. Enclosing the whole program in a *single* segment is a degenerate segmentation that will require the planner to place the program *entirely* on a single dataplane for execution while satisfying all other constraints.

The snippet in Listing 1 shows three segments beginning at lines 4, 14, and implicitly at line 1. The first segment is named FlightStart by default.

Segmentation is done manually by the programmer or automatically by a tool. In our prototype the programmer manually segments the code, and subsequently the planner will merge contiguous segments if they are to be placed on the same dataplane.

Once a segmentation has been made, the Flightplan analyzer discovers data-dependencies through static analysis of P4 code and determines whether a segment break is allowed for the intended runtime. Flightplan runtimes will be detailed in a later section.

4.1.2 Program Abstraction

For a given segmentation we next generate rules in step ②. We devised a framework for *abstract* semantics for P4 that is focused on resource dependence. Each segment is reduced to the resources it needs to execute, and everything else is abstracted away. In Listing 1 such resource-related syntax is highlighted in green.

The Flightplan analyzer is a P4 compiler extension that carries out static analysis of P4 code to gather which resources are relied upon by each segment. Resources include invocation of external functions and table lookups. The analyzer then automatically generates a Prolog-like [36] set of rules for that segment. We call the collection of segments' rules the *abstract program* (§4.1) derived from the original P4 program. The abstract program is emitted into a JSON file that the analyzer parses; users do not need to write, inspect, or change the contents of this file.

One rule is generated for each segment and describes the resources used along each path through that segment.

Rule 2 describes the third segment from Listing 1 (Lines 4-13). In this case there are three paths through the segment: lines (5-7,13), (5-9,12,13), (5-13), and Rule 2 is showing the path whose requirements subsume those of other paths. The analyzer emits the resource requirements of each path, and

$$\frac{\text{egress\_compression} \qquad \text{header\_compress} \qquad \text{drop}}{\text{Compress}}\ [\text{Id}]$$

Rule 2: Program segments are abstracted into rules showing resource dependence. This rule states that segment Compress can be mapped if the target dataplane can provide implementations of egress_compression, header_compress and drop: these are satisfied by means of other rules that are provided at input. We saw a rule for header_compress in Rule 1. Id is the identify function: using this rule does not mutate abstract state.

$$\frac{\text{CPU} \quad \text{Rate} < 8 \times 10^7 \quad \text{PacketSize} > 1050}{\text{fec\_decode}} \left[\begin{array}{l} \text{Lat.} \mapsto \text{Lat.} + 0.09 \times 10^{-3} \\ \text{Rate} \mapsto \text{Rate} \times \frac{64.47}{77.36} \\ \text{once Power} \mapsto \text{Power} + 150\,\text{W} \\ \text{once Cost} \mapsto \text{Cost} + 5 \end{array} \right]$$

Rule 3: Abstract resource rule for running fec_decode on a CPU.

the planner (§6) checks these are satisfied before allocating that segment to a prospective execution target.

4.2 Abstract Resource Semantics

In step ③ we supply the semantics of each program-used resource, such as calls to external functions, in terms of the measurable costs incurred for a program to use that resource on a specific hardware target. Such costs include latency, throughput, power, and the cost of the hardware.

In our prototype, the user encodes this information as a table of CSV entries, and can reuse this information across all invocations of Flightplan. A script then turns this table into a JSON encoding of the rules that are used by the planner. The measurements in these entries are derived empirically using the workflow described in §J. This involves carrying out profiling experiments that measure the characteristics of using resources on different hardware targets.

Rule 3 shows the characteristics of applying our FEC decoding function on a CPU. Rule 4 in §I shows a rule for applying Header Compression on an FPGA. Compared with Rule 1 it supports much higher throughput over smaller packets. Our table can be refined to include more details about the specific CPU and FPGA parts that were used, and capture other information about the target or the workload, without changing our general approach.

4.3 Network Representation

In step ④, the last set of rules states facts about the topology, the devices it comprises, and their ports. For example, that the proposition "CPU" holds on a specific network element, or the bandwidth limit of a specific port.

For a given port π, we gather facts in a set called π_{Provides}. We also associate constraints with π that must be satisfied for π to be crossed. We call this set π_{Requires}. [3]

[3] Examples of π properties are given in §I.

In our prototype we use JSON to encode the network's topology and the capabilities of each device and port. We reuse this information across all our invocations of Flightplan, and it only need to be changed when the network hardware or topology change.

5 Flightplan Runtime Support

A disaggregated program cannot function without runtime support. At the very least, the runtime provides the gluing code to *link* different parts of the disaggregated programs together for the computation to flow through them as it would in the original program.

The choice of runtime needs to be made first since it influences the rest of the process. This choice is communicated to the analyzer and splitter (§6.4). In Flightplan, the following information is in scope for the runtime to manage: (1) runtime metadata, such as (1a) which part of the program needs to be executed next, (1b) values of live variables to be preserved across dataplane hand-overs, (1c) state related to in-dataplane failure detection and handling, and (2) switch metadata—such as ingress and egress ports, since these might be read or written during the program's execution, including table lookups and actions.

There are different choices of runtime features and ways of implementing them. Our different runtime implementations show how the core idea in Flightplan—that of programmable-dataplane disaggregation—spans a design space and not a single implementation.

5.1 Runtime Design

Runtime support for Flightplan consists of two components, the first running outside the dataplane and the second running inside it. The first is a control program that configures the latter and queries its state. Configuration information is stored in register values and table entries used by the second component to support the execution of each segment of the distributed P4 program. In our prototype, the control program—called `fpctl`—emits dozens of commands to the P4 controller, which in turn interacts with the dataplane. The inputs to `fpctl` consist of the network topology, the control program profile, and a command (such as `configure` or `start`) and its parameters.

The second component runs inside the dataplane and must be written in P4. It is combined with each constituent of a distributed P4 program. In Fig. 1, each constituent A-E would be instantiating the same runtime, albeit in possibly heterogeneous dataplanes.

5.2 Runtime Diversity

We developed three runtimes, each representing a different point in a design space. The three are called 'Full' (§5.3), 'Headerless (IPv4)', and 'Headerless'. We use `fpctl` to interact with all of them. All our implementations use standard features of $P4_{16}$ and target the simple_switch BMv2 target [25], whose features intersect with most P4 devices.

The Full runtime uses a special Flightplan header, but the other two do not. Our IPv4 headerless approach steals bits from the IPv4 Fragment Offset header for Flightplan state. However, we found that this was not always usable since not all of our network traffic has IP headers—specifically the FEC parity frames lack these. This spurred us to develop a completely headerless approach, described in §5.4.

Recalling the example from Listing 1, the Full runtime allows us to preserve the value of `meta.egress_spec` by serializing it into the Flightplan header during hand-over. We can alternatively use the Headerless runtime since, while preserving switch metadata such as `meta.egress_spec` is generally not possible in our Headerless approach, we encode this information in the wiring and table entries. This limits the behavior of the original program, trading off flexibility for less overhead, since the Headerless approach essentially creates a circuit through dataplanes.

For a further example of how the Full runtime allows more flexibility for segmentation, we could add a flyto() between lines 6 and 7 in Listing 1. The Full runtime allows us to hand-over the value of `compressed_link` from Compress to the new segment, but the Headerless runtime would not be able to support this segmentation.

5.3 Full Runtime

The Full runtime provides the most flexibility and resilience among our runtimes. It uses a custom header to accommodate all of the features (1a-c,2) listed earlier in §5. The header's definition is provided in §D.

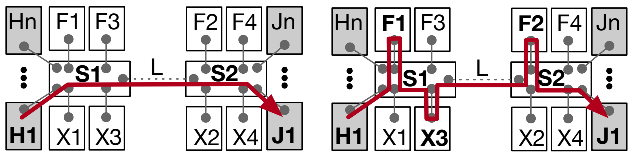
The header consists of two kinds of fields: scratch space in which metadata and program variables are serialized and state fields for encoding status flags and values, such as which segment from the original program is to be executed next.

Part of the distributed program might be unreachable because of network or node failures, thus compromising the overall program's execution. This runtime implements a feedback loop between connected dataplanes to push fault detection and handling into the dataplane. The details are in §E.1.

`fpctl` can be used to query the runtime's state, for instance to find out if it is close to meeting a fail-over threshold, or if it has failed-over. It can also overwrite this state and force a fail-over remotely.

5.4 Headerless Runtime

This approach does not encode any state about the ongoing computation across dataplanes. Consequently this runtime provides less flexibility than the 'Full' approach: metadata is not preserved, it does not support in-dataplane failure detection and handling, and values of live variables are not preserved—thus segments must be coarser to avoid needing to hand-over the variables' values. This runtime is described further in §E.2.



(a) Shortest path from H_1 to J_1. (b) A detour path from H_1 to J_1.

Figure 6: Abstract network used for running example in §6.

To compensate for the lack of header, we rely on the ingress and egress port information. An interesting consequence of the Headerless approach's feature-paucity is that it can be made to work with older SDN switches that are not P4 programmable. To enable this, `fpctl` generates flow-table configurations from the control program profile. We report on the use of non-P4 SDN switches in our testbed evaluation.

6 Flightplanner

Flightplan combines graph-based and formal methods to find execution plans for disaggregated programs over dataplanes in the network.

Execution of the disaggregated program occurs along paths in the network, and therefore the planner needs to be told about the network's topology and hardware capabilities. Fig. 6 resembles our physical testbed and is used in this section to help explain an execution plan. In this network, S_i are switches, F_i are network-connected FPGA boards, X_i are CPU-based network elements that can run P4 programs, and H_i and J_i are servers to which P4 programs cannot be offloaded.

Flightplan explores resources around switches to carry out detours in the forwarding along dataplanes onto which some of the computation can be offloaded as shown in Fig. 6b. In this example S_1 offloads computations to F_1 and X_3, and S_2 offloads to F_2.

6.1 Abstract Program State

The planner maintains a small amount of state as it explores plans. This state consists of values for a special set of variables V that appear in rules, such as PacketSize and Rate. Using these variables we form Bound expressions such as PacketSize > 1000 from Rule 1.[4]

The *abstract program state* θ consists of a total map $V \to \mathbb{R}$ that encodes the value of each V at one instant during the program's execution. The values of V can be transformed by rules in their $[\ldots]$-function, while the values of propositions can only be derived through proof, as will be explained shortly. During the planner's execution, all Bound expressions are ground, making the evaluation process straightforward.

6.2 Proof-based Segment Allocation

Producing a plan involves two kinds of inference: (i) deciding whether a given dataplane can execute a given segment in

[4]Further details of our modeling language are in §I.

$$\mathrm{R}2\,\dfrac{\mathrm{R}5\,\dfrac{\theta,\pi_{\mathrm{Prov.}}\dfrac{}{\mathrm{CPU}}}{\text{egress\_compres.}} \qquad \mathrm{R}1\,\dfrac{\theta,\pi_{\mathrm{Prov.}}\dfrac{}{\mathrm{CPU}} \quad \mathrm{Rate} < 2 \times 10^8 \quad \mathrm{PacketSize} > 1000}{\text{header\_compress}} \qquad \mathrm{R}6\,\dfrac{\theta,\pi_{\mathrm{Prov.}}\dfrac{}{\mathrm{CPU}}}{\text{drop}}}{\text{Compress}}$$

Proof 1: Flightplan may allocate segment Compress to π only if a proof can be derived using θ, program+resource+network rules and π_{Provides}.

a way that satisfies all related constraints; and (ii) finding a plan—a sequence of dataplanes over which all of a program's segments are executed. This section describes how item (i) is done in Flightplan. The next section builds on this to describe (ii).

For a given port π (§4.3), to decide whether a segment Seg can be mapped to π's dataplane, we need to do two things. First, ensure that all of π's constraints are satisfied. For example, the current transmission rate must not exceed the ports limit. Second, we use facts provided by π to ensure that Seg is *derivable* from the rules we have available. For example, all external functions called in Seg must have viable implementations once they cross that port.

This derivation involves building a Prolog-style formal proof. For example, if $\pi_{\text{Provides}} = \{\text{CPU}\}$ then Compress is derivable as shown in Proof 1 if θ satisfies the bound-related constraints of the rules used in this derivation.

In addition to obtaining assurance that a target can execute a segment, we use proofs to compute the transformations of abstract program state. This involves composing the $[\ldots]$-enclosed functions by doing a post-order traversal of the proof tree, then applying this function to the search state θ to obtain the new search state. For Proof 1 the state transformation γ is $\gamma = \gamma_{\mathrm{R}2} \circ \gamma_{\mathrm{R}6} \circ \gamma_{\mathrm{R}1} \circ \gamma_{\mathrm{R}5}$

6.3 Plan-finding

Given a DAG of abstract program segments (§4.1) we search for a succession of dataplanes that packets can be made to traverse such that all program segments can be executed over those packets. Since devices in the same class are identical, we factor the solution space by the different device classes to avoid returning quasi-duplicate solutions. The user can choose whether they want the best solution—by having the tool explore all possibilities. Alternatively, they are given the solution found using a simple greedy heuristic on optimization objectives—for example, by choosing the next dataplane that least increases latency.

The network operator needs to provide three additional pieces of information: (i) an initial abstract program state θ_0 (§6.1), (ii) the switch on which the disaggregation program's execution will be centered (e.g., S_1 in Fig. 6), and (iii) the set of devices to which the switch may offload to (e.g., $\{F_1, F_3, X_1, X_3\}$ in Fig. 6).

The planner carries out a breadth-first search while attempting to allocate segments as described in the previous section. At each hop it updates the abstract state using γ to compute an approximation of resource-usage across the network. This will be used to evaluate constraints in the rest of the potential plan.

When a plan is found, it is converted into the three outputs shown in Figure 5. First, contiguous segments that are to be mapped to the same target are unified into larger, coarser-grained segments. Second, the *allocation model* is produced by emitting the trace of abstract program states and the mapping from segment names to targets in the network. Finally, a profile is produced for use by `fpctl`—Flightplan's control program—to configure, start, and query the disaggregated P4 program. A profile consists of a mapping of generated P4 programs to a subset of the network. Flightplan uses the profile to configure a dataplane target through the target-specific control plane interface.

6.4 Program Splitting

Next we generate a separate, well-formed and self-contained P4 file for each segment. The program splitting phase performs three tasks: 1) extract the P4 code from each segment, forming subprograms; 2) analyze the subprograms to gather runtime-related context, such as variables whose values must be included in the hand-over between dataplanes; 3) inject runtime-dependent code for handing-over between subprograms. These are described further in §K. The Flightplan analyzer prototype also emits split programs satisfying points 1 and 2. The interfacing to the runtime can be automated in the future.

7 Evaluation

We evaluate Flightplan using virtual and physical networks to answer various questions about its features and the implications of disaggregation choices.

7.1 Scale, Overhead and Disaggregation

We use a virtualized network (§7.1.1) to test logical qualities of a Flightplan deployment, using P4 applications both that we wrote and from third-party sources.

To add realism to our experiments, we implemented a generator for complete configurations of fat-tree networks [1] to run on our setup, which is built on Mininet [19] and BMv2 [25]. We used $k = 4$ in this evaluation.

We implemented routing logic for this topology in a P4 program called `ALV.p4`. It provides a baseline P4 program that implements minimal functionality in the network—routing. We embedded it in four other P4 programs: (i) `Crosspod.p4` (§2), (ii) `firewall.p4`, (iii) `qos.p4` and (iv) `basic_tunnel.p4`. The latter three are third-party open-source programs from the P4 tutorial repository [27].

Initially our virtual network had `ALV.p4` executing on all switches. We then installed the other P4 programs on some

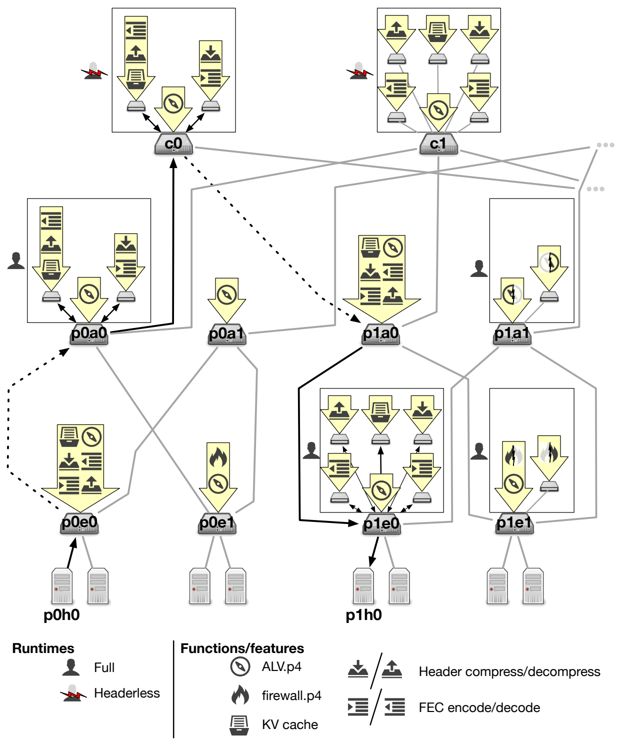


Figure 7: Part of our fat-tree network showing core routers (cN) and pods (pN[a,e,h]M) containing aggregation and edge switches, and hosts. Configured as explained in §7.1. Yellow arrows show which (sub)programs are installed on each device. Links between devices are shown in grey, except for links traversed by packets flowing between p0h0 and p1h0, which are shown in black. Dotted lines show faulty links.

switches and disaggregated them in various ways and to use different Flightplan runtimes, as described next. All disaggregated P4 programs, including those of third-party programs, were tested for behavioral correctness by checking that they produced similar results as the original programs.

7.1.1 Flightplan deployment example

Fig. 7 shows part of our network and the variety of P4 programs we ran simultaneously on different switches in the same network. Switches p0a1 (`ALV.p4`), p0e1 (`firewall.p4`), p0e0 and p1a0 (both `Crosspod.p4`) run non-disaggregated P4 programs, while all other switches run disaggregated programs. Of the latter, c0 and c1 use the headerless Flightplan runtime, and the remainder use the Full runtime.

Switches that run disaggregated programs are shown with an adjacent box in Fig. 7 showing the supporting devices on which parts of the original program were executed. For example, p1a1 carries out some of its table lookups locally, while others are offloaded to an associated device. Different switches can have different numbers of associated devices over which a dataplane program can be disaggregated—for example, c0 has 2 while c1 has 5. The presence and resourcing of such devices is decided by the network operator. In this part of the evaluation we treat all such devices as being identical, but in the next section we distinguish between heterogeneous devices based on their resources and capabilities.

We also disaggregated `qos.p4` and `basic_tunnel.p4` and tested performance overhead in our Mininet-based setup. We found that the lower-bound overhead to client-perceived RTT was 8.2%. A more accurate measurement using a hardware-based experiment, but on a simpler topology, is given in §L.1.

7.1.2 Network Scalability and Operation

The network from Fig. 7 helps demonstrate two features. First, it shows how the use of Flightplan scales with network size. Since we constrain Flightplan's planning scope to only resources adjacent to a switch—as illustrated in Fig. 1—Flightplan's scalability is independent of network size in this network topology. Thus planning can scale to a network containing a large number of switches.

Second, it shows that different Flightplan runtimes and disaggregations can operate simultaneously in the same network, and that these can be configured and started independently of each other, to deliver the practical features described at the end of §2.

7.1.3 Overheads

We compare program-level overheads of dataplane disaggregations. These include overheads on: the network due to header inclusion, port count, data memory (total register bits, number of tables and their entries) and code memory (code from the runtime, and extra branching because of splitting). Device-level overheads—such as those on throughput and power—are evaluated in §7.2 based on testbed experiments.

Table 2 shows overheads for two sets of disaggregations of `Crosspod.p4`: one set using the Full runtime and the other using Headerless. In our prototype, the in-network programs do not respond to MTU path discovery, therefore to use the Full approach in general we needed to lower the MTU size to provide headroom for the Flightplan header. This uniformly reduces network capacity by 2.4% to create enough headroom.

Program-level overhead can be calculated before compilation, independent of toolchain. The general analysis of both runtimes' overheads is provided in §F. If a P4 program is split to run across several P4 devices, we can calculate the overhead introduced onto the network and the devices independently of the devices' toolchains.

7.2 Testbed Evaluation

We use a physical testbed deployment to measure device-level resource and performance impact of Flightplan-based disaggregation. This evaluation is based on the Headerless approach, which gives us a lower-bound on overhead among our runtime approaches. Using `Crosspod.p4` (§2), we: (i) evaluate the Flightplan planner, and (ii) measure the end-to-end performance and power consumption of a heterogeneous dataplane running Flightplan-generated splits of `Crosspod.p4`.

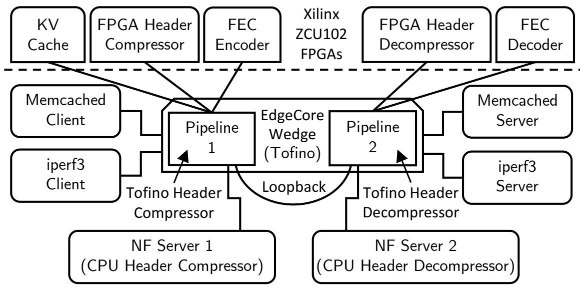

Figure 8: Evaluation testbed

7.2.1 Experimental setup.

Fig. 8 illustrates our testbed. It contains an EdgeCore Wedge 3.2-Tbps switch with a two-pipeline Barefoot Tofino P4 ASIC, five 4×10-Gbps Xilinx ZCU102 FPGA boards each with one Xilinx XCZU9EG FPGA, four traffic generation servers with 8-core Intel Xeon 2450 CPUs, and two network function servers with 10-core Intel Xeon Silver 4114 CPUs. In our configuration, the Tofino pipelines act as two independent switches, `S1` and `S2`, that service different ports and each have their own dedicated resources (SRAM, TCAM, etc.). All packets between `S1` and `S2` traverse a physical 10-GbE cable. We also evaluate a legacy scenario, by swapping the Wedge for an Arista 7050-QX32 with a Broadcom Trident II ASIC and OpenFlow support.

Crosspod.p4 plans. Our benchmarks focus on three plans output by Flightplan, designed for different objectives.

- **"Maximum Performance"** optimizes end-to-end performance by placing each function on the fastest available platform, i.e., header compression on the Tofino and all other functions on FPGAs.
- **"Resource Saver"** offloads compression from the Tofino to the FPGA to save compute and memory resources.
- **"Legacy Extender"** uses the Trident II in place of the Tofino to achieve functional equivalence with an OpenFlow switch.

Measurements. We benchmark four axes of performance: throughput, packet loss, latency, and power consumption. Throughput is measured at the application layer, using either `iperf3` or DPDK-pktgen. We measure packet loss using the Tofino's port counters. For latency, we use a simple telemetry function for the Tofino that timestamps (nanosecond precision) each packet ingressing or egressing out of monitored ports and clones a digest to a collection server. Finally,

	Feature	Runtime=**Full**									Runtime=**Headerless**								
Net.	Header (b)	288									0								
	Ports [*D*]	1-2 [3]			1-5 [6]						2 [3]			5 [6]					
	Ex. in Fig. 7	p0a0			p1e0						c0			c1					
	Seg ID	0	1	2	0	1	2	3	4	5	0	1	2	0	1	2	3	4	5
Dataplane	Tables	6			6						5	1	1	5	1				
	Entries (b)	179	89	89	445	89					154	22	22	230	22				
	Registers (b)	547	309	309	1261	309					4			4					
	Ctrl Struct	6	+2	+2	6	+2					2	+1	+1	2	+1				
	Externs	0	3	2	0	1					0	3	2	0	1				

Table 2: Overheads incurred by different disaggregations of `Crosspod.p4`, organized into **Network** and **Dataplane** overheads. The *Externs* row does not show overheads, but serves to show the distribution of extern function invocations across the splits. *D* is the number of segments. Each segment is given a separate identifier in the *Seg ID* row to distinguish them in the rows below. *Ports* is the number of switch ports that are required: the Full runtime's use of a Flightplan header allows the use of a single port (connecting to a single supporting device), while the Headerless runtime requires an exact number of ports. *Entries* gives the total size of all Flightplan table entries, in bits. *Ctrl Struct* is a measure of code complexity of the transformed program, counting the number of conditional statements introduced by the disaggregation in addition to the runtime's code.

we measure power consumption of each device at the outlet, polling at a 200ms interval.

End-to-end benchmarks. We use workloads that mix two types of flows: 1) large TCP flows (`iperf3`) representing traffic with high bandwidth demands and 2) UDP Memcached request streams representing latency-sensitive traffic. This workload models the bimodal distribution of packet sizes and traffic patterns in datacenters [4, 32]. We measure throughput using `iperf3` and calculate latency as the difference between the time at which a packet ingresses from its source host and the time at which it egresses to its destination host.[5]

7.2.2 Flightplan Planner

We used the Flightplan planner to analyze the solution space for `Crosspod.p4`. Our evaluation involves 239 rules, divided as follows: 140 are profile rules including Rules 1, 3, and 4; 68 are network rules (including those in Fig. 17), and the rest are program rules (including Rule 2).

The network is the one shown around c1 in Fig. 7. We used this to explore program-segment mappings to the switch and its supporting devices in such an arrangement. We ran different variants of the experiment to contrast the implications of using different types of equipment, following the plans described in §7.2.1.

Fig. 9 summarizes our results, and we evaluate the best-performing plans on our physical testbed in the next section. To avoid clutter we exclude "Resource Saver" because of its hybrid nature between the other two categories, and instead we show more extreme forms of "Legacy Extender" in the "Server Offload" family. These rely on a single switch and a pool of CPU-based servers. The latency advantage of "Server Offload (Tofino)" relative to "Server Offload (Arista)" seems too optimistic, and we believe that might be because of a lack of accuracy in the model we use.

[5]As well as the end-to-end experiments on `Crosspod.p4`, we also separately evaluate its constituent in-network functions end-to-end in §A.

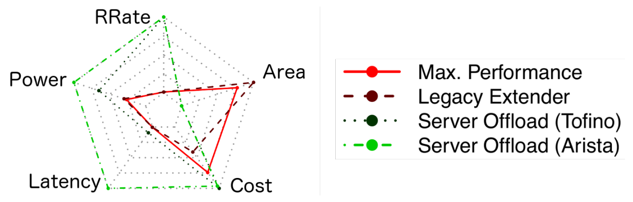

Figure 9: Best-rated plans found by Flightplan, described in §7.2.2. In each dimension, less is better. Each dimension is normalized by the maximum value from all plans. 'RRate' is the inverse of the bandwidth of the distributed program. 'Cost' refers to hardware costs and excludes running costs, which are captured by 'Power'. 'Area' refers to FPGA-resource usage.

7.2.3 Crosspod.p4 Benchmarks

The goal of `Crosspod.p4` is to improve the performance of applications bottlenecked by inter-rack links suffering from congestion and partial failure [39]. We evaluate how Flightplan's `Crosspod.p4` plans achieve this goal in a network with a 10 Gbps inter-rack link.

End-to-end performance. First, we evaluate the **"Maximum Performance"** `Crosspod.p4` plan. Fig. 10 shows application-level performance in a series of trials where the network functions are activated one by one. The figure plots the latency and success of GET and SET requests to the Memcached KV store and the throughput of TCP `iperf3` sessions, on two client/server pairs, as illustrated in Fig. 8.

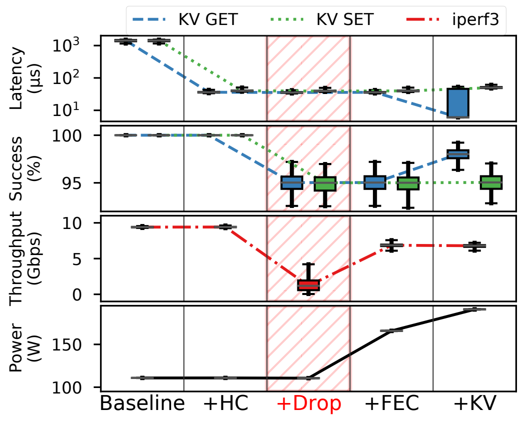

Figure 10: Throughput, latency and power utilization of a disaggregated `Crosspod.p4`. In the top and bottom panels, lower values are better. In other panels, higher values are better. Boxes show data quartiles and whiskers show 10th and 90th percentile, aggregated over 5 repetitions.

The leftmost panel in Fig. 10, labeled `Baseline`, shows application performance with no network functions enabled. Here, the problem is congestion, caused by the `iperf3` data transfers that saturate the inter-rack link. Because of the congestion, application-level Memcached latency is high.

To reduce the impact of congestion, we enable header compression of the `iperf3` traffic. This reduces the load on the bottleneck inter-rack link, allowing queues to drain and thus reducing latency. As the `+HC` column of Fig. 10 shows, header compression reduces Memcached request latency by 97% without impacting `iperf3` throughput. Since Flightplan maps the compression and decompression functions to the switch pipelines, no new network devices are required for this addition, and power consumption does not noticeably increase.

To study FEC, we first model partial link failure by enabling a dropping function in the switch that drops 5% of packets at random on the inter-rack link. The middle panel of Fig. 10, labeled `+Drop`, demonstrates application-level effect: a reduction in throughput to 1.19 Gbps and a loss of 5% of Memcached packets. The FEC encoder and decoder FPGAs are then introduced to protect TCP traffic on the link. It restores 57% of the lost TCP throughput, as the `+FEC` phase of Fig. 10 shows. Power consumption increases by about 55 W, reflecting the addition of the two FPGAs.

Finally, we introduce the Key-Value (Memcached) cache network function FPGA on the client side of the inter-rack link. The `+KV` column shows that the approximate 60% cache hit rate causes median latency of GET packets to reduce to 7 µs (while leaving the upper quartile above 40 µs) and restores successful responses to about 60% of previously dropped requests. SET latency and success are unaffected because the cache is inline, so these packets must traverse the shared link. Power consumption increases by another 25 W due to the addition of one more FPGA.

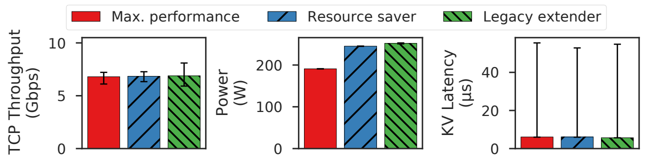

Figure 11: Application performance and network power consumption for three different `Crosspod.p4` plans. Bars mark medians, whiskers 5th and 95th percentile.

Alternate plans. Next, we evaluate the viability of other Flightplan-generated `Crosspod.p4` plans. As Fig. 11 shows, the **Resource Saver** and **Legacy Extender** provide almost identical application-level benefits. All three plans improve performance in the face of packet loss and congestion, increasing TCP throughput from 1.19 Gbps to 6.25 Gbps and decreasing median KV's GET request latency to under 10 µs.

Although all three plans are viable from the application's perspective, they offer different benefits for network operators. As Figure 11 shows, the power consumption of **maximum performance** is 50 W lower than the alternatives because it maps HC to the Tofino, thus requiring two fewer FPGAs.

On the other hand, by offloading HC to FPGAs, **Resource Saver** frees compute and memory resources in the Tofino. Most significantly, it reduces the number of pipeline stages from 10 to 4, the utilization of stateful ALUs from 25% to 2%, the number of tables from 46 to 11, and the utilization of SRAM by approximately 600KB per 1024 concurrent flows.

Finally, by targeting the Trident II, **Legacy Extender** lets OpenFlow switches achieve similar functionality and application-level performance as P4 switches. This provides a path to deploying `Crosspod.p4` in networks with limited programmability [32] or at a lower budget.

8 Related Work

Compared to Active Networking [2, 15, 33] and related recent work such as TPP [17], Flightplan leans towards performance and safety at the expense of flexibility: computation allocated to each dataplane is established at compile time, rather than being packet-carried.

Automated approaches to software splitting [6, 13, 22, 30] are usually done for vulnerability mitigation, whereas Flightplan is directed at improving performance and utilization. Closer to Flightplan, Floem [29] focuses on CPU-NIC co-processing of network applications, but Flightplan focuses on packet processing across distributed dataplanes which do not necessarily include CPUs.

As in network calculus [20] (NC) our reasoning technique for plans is concerned with flows at steady-state. Flightplan allows using arbitrary functions to describe the transformation γ of each rule on the abstract state, not only NC's operators. Future work can improve the modeling precision of our approach and generalize to better characterize workload-sensitive functions such as the in-network cache.

A Individual Function Evaluation

To validate their effectiveness, we measured the performance of individual in-network elementary functions—such as FEC, Memcached caching, and header compression—in our physical testbed. These functions are instances of *protocol boosters* [11].

A.1 Function 1: Forward-Error Correction

We developed a forward-error correction (FEC) link-layer network function [12] on FPGA to mitigate against corrupting links [39]. It introduces parity packets which are used downstream to recover corrupted packets. Our implementation uses a block code, supplementing every block of k (data) packets

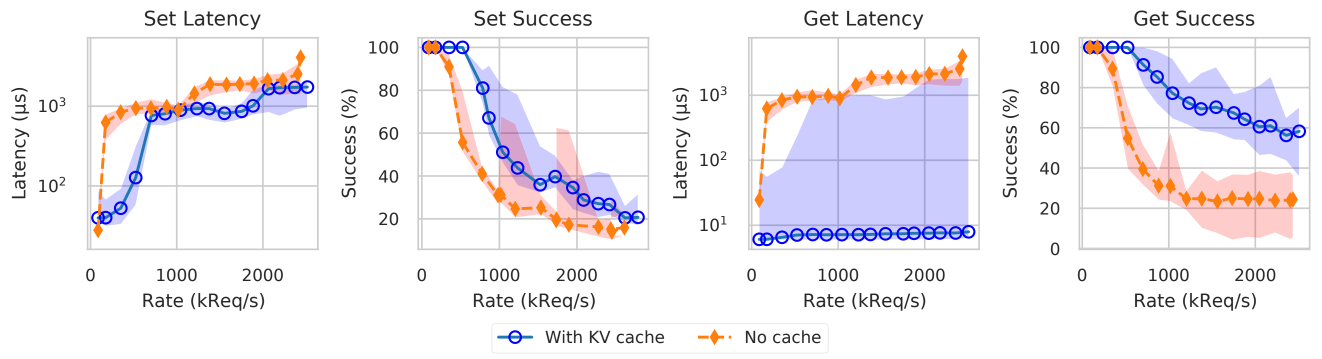

Figure 12: Performance metrics for Memcached with and without the KV-cache function. Markers show median values, while shaded regions show 5th and 95th percentiles. Success is measured as the percentage of responses received for every 500 requests.

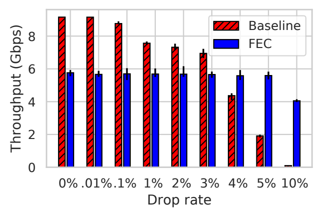

Figure 13: Effect of FEC on TCP throughput at varying rates of link loss

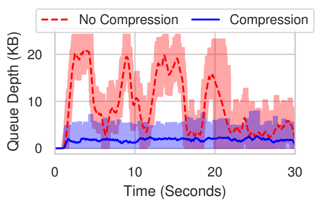

Figure 14: Effect of header compression on switch queue occupation

with h parity packets. The parity allows the in-network function to reconstruct up to h packets per block. The parity packets are computed by an implementation of the Reed-Solomon erasure code.

Forward-Error Correction reduces the need to retransmit packets in TCP flows and helps TCP sustain larger congestion windows across corrupting links. This is demonstrated by Figure 13 for an experiment performed with `iperf3` with 10 simultaneous TCP connections. Traffic was encoded with $k = 5$ and $h = 1$. Each bar represents the median throughput of 10 experiments, each of which lasted 1 min. Error bars show the minimum and maximum. For a packet drop rate of 5%, we observe that FEC increases the throughput by almost 3×. At 10% drop rate, throughput has all but vanished, but FEC manages to recover 40% of the 10-Gbps link capacity.

A.2 Function 2: Key-Value cache

We implemented an inline Memcached cache on FPGA to accelerate key-value queries. This improves the throughput, success rate, and latency of a Memcached deployment. The cache has the capacity to hold 1000 entries in its local hash table.

It was benchmarked against a standard Memcached server with default settings, including the use of four threads. Requests consisted of 8-byte keys and 512-byte values. 90% of requests sent were GET requests, while the remaining 10% were SET requests. Keys were chosen randomly from 10,000 candidates according to a Zipf distribution with an exponent of -1, consistent with measurements of document access frequency on the Web [8]. This distribution of request keys resulted in a cache hit-rate of around 50%.

Figure 12 shows the differential effects of the cache on SET and GET requests. As SET requests must still reach the Memcached server before they are acknowledged, the cache has minimal effect on SET packets, resulting only from the reduced load on the server. The inline cache keeps the median latency of GET requests below 10 µs regardless of the request rate. With the cache in place, approximately 50% less packets are lost than without the cache, consistent with its 50% hit rate.

A.3 Function 3: Header compression

We implemented an in-network function on the FPGA, Tofino and CPU for lossless compression of packet headers between neighboring switches. Our implementation is a simplified version of Van Jacobson compression [16] and many fixed-function implementations [7]. By compressing packets, bursts occupy less buffer space. Fig. 14 shows this effect for a highly-utilized (99%) network, as measured on the EdgeCore switch. Lines show the median, and the shaded region the range, over a rolling window of 100k samples.

B Single target micro-benchmarks

In addition to the end-to-end benchmarks of network functions, each individual device was also evaluated with fixed-rate packet replays using DPDK-pktgen.

Table 3 summarizes the maximum throughput and average latency that each function achieves on the CPU and FPGA targets.

Target	Function	Throughput (Mbit/s)	Latency (µs)
CPU	HC Compress	95.2 (0.038)	5800 (33.9)
CPU	HC Decompress	198.75 (1.5)	5900 (20)
FPGA	HC Compress	8350 (150)	5.24 (0.005)
FPGA	HC Decompress	8890 (17)	4.47 (0.002)
CPU	FEC Encode	35 (0.23)	300 (1400)
CPU	FEC Decode	64.47 (0.007)	90 (5.7)
FPGA	FEC Decode	7950 (27)	32.8 (1.4)
FPGA	FEC Encode	8130 (18)	4.75 (0.004)
FPGA	KV Inline cache	7730 (230)	15.9 (6.7)

Table 3: Throughput and latency values from per-function and per-target micro-benchmarks. Values shown are mean and standard deviation.

C Complexity Analysis of Dataplane Disaggregation

In this section we calculate the number of ways to split a program and allocate its splits to execute on nodes in the network subject to certain constraints. Starting with the number of ways to split a program, we abstract this as the number of contiguous subsequences $\{(1,\ldots,k_1),(k_1+1,\ldots,k_2),\ldots(\ldots,n)\}$ of a sequence $1,\ldots,n$ that represents the lines of the program. There are $(n-1)$ ways to bisect the sequence $1,\ldots,n$. Bisecting it again—to yield three subsequences—presents $(n-2)$ choices. In the general case, the number of k-ary dissections of an n-sequence (where $k<n$) is:

$$(n-1)\times(n-2)\times\ldots\times(n-k) = \left(\prod_{i=1}^{k}(n-i)\right)\in O\left(n^k\right) \quad (1)$$

Thus the number of ways to split a program grows exponentially in the number of splits sought.

Turning now to growth relative to the topology. Placement of subprograms occurs along a path between two hosts on the network. For simplicity assume that there is a single shortest path between the two, call it p. Let $A(p)$ be the set of vertices connected to p through a single edge, we call this the set of adjacent nodes. Subprograms can be placed along p or offloaded onto adjacent nodes drawn from $A(p)$. Since we are deriving an upper-bound, assume that each subprogram can be placed on any of the elements in $A(p)$ or placed on p. Let $|p|$ bet the length of path p, and $|A(p)|$ be the cardinality of set $A(p)$. The set of placement choices is $2^{|p|+|A(p)|}-1$, discounting the choice where no placement is made on any node. For a k-split program the number of placement choices is $\binom{2^{|p|+|A(p)|}-1}{k}=$

$$\prod_{i=1}^{k}\left(\frac{2^{|p|+|A(p)|}+1-i}{i}\right)\in O\left(\left(2^{|p|+|A(p)|}\right)^k\right)$$

Since in this theoretical model the choices of splitting and placement are independent then, modulo the simplifying assumptions, the space of disaggregation choices grows exponentially with the number of targets available on which to map subprograms, and doubly with the number of subprograms: $O\left(n^k\left(2^{|p|+|A(p)|}\right)^k\right)$. ■

D Flightplan header

Listing 2 shows the P4 definition of the header which Flightplan uses when sending packets between connected dataplanes.

E Runtime Implementations

This section elaborates on the description provided in §5 of our implemented Flightplan runtimes and their resource overheads.

E.1 Full Runtime

This section expands the description given in §5.3.

To detect network distortion such as drops, reordering, and duplication, our scheme includes a sequence number in the Flightplan header. A corresponding amount of state is kept at the sending and receiving dataplanes to determine whether the sequence of packets has been interrupted. Negative acknowledgment [31] is used for a downstream dataplane to signal loss of synchronization with the upstream dataplane. Positive acknowledgments are used by the upstream dataplane to poll liveness of the downstream dataplane.

This mechanism sets up a feedback loop between connected dataplanes. Our scheme is illustrated in Figure 15. Using this scheme we push fault detection into the dataplane, to react to faults in the network by triggering a relink or escalating a notification.

Among our runtimes, Full provides the most flexibility when splitting a program: control-flow can be stopped anywhere in the program and resumed later on a different dataplane using context that was serialized into the Flightplan header. Flightplan has no visibility into dependencies on state that is controlled from outside the dataplane, such as extern

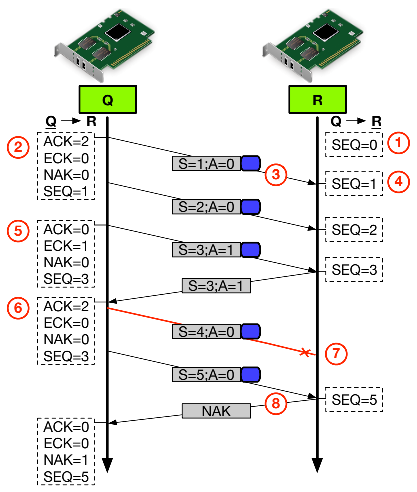

Figure 15: ① Synchronization state is initialized at downstream dataplanes. ② Synchronization state is initialized at upstream dataplanes. ③ Synchronization information is included in the Flightplan header (shown in grey) that is added to packets (shown as the blue square). ④ Sequence number is incremented. ⑤ Periodically upstream dataplane will poll downstream dataplane for activity, by raising the ACK bit in the Flightplan header, and the ECK (Expecting ACK) locally. ⑥ ECK is reset when an ACK packet is received. ⑦ Packets may be lost in either direction, leading to loss of synchronization. ⑧ Loss of synchronization is eventually detected and action is taken. Negative acknowledgment (NAK) seeks to update the upstream dataplane.

function state and tables; those need to be synchronized externally.

The runtime keeps track of the following sets of information: N (the *next* dataplanes that a dataplane might transfer to), P (*previous* such dataplanes), S_N (which fail-over alternative to use for each next-dataplane), and N_F and P_F (metadata for failure detection and handling, such as sequence numbers and whether an acknowledgement has been demanded).

On each dataplane on which part of the disaggregated program is run, `fpctl` configures dataplanes to fail-over to use other downstream dataplanes in the event of reaching a threshold of received NAKs or missed ACKs. Both thresholds are absolute values (not ratios, for instance) that are configured by `fpctl`, which can also periodically poll the state of each runtime to determine if it has seen an increase in failures. Various actions can be taken depending on such an observation, for example: i) the threshold could be raised—again, using `fpctl`—to buy time to understand the source of the loss, ii) rate limits could be applied to applications using the link, iii) the state and configuration of the downstream dataplane can be inspected or reset, iv) regardless of whether the cause has been understood or not, the ACK and NAK counts could be reset periodically if they are no longer seen to increment regularly. These actions are not directly implemented in

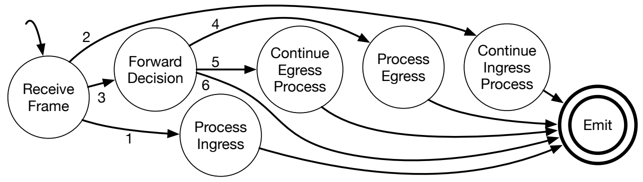

Figure 16: Core logic of the Headerless runtime.

`fpctl` but they could be automated by the network operator by using the functionality provided by `fpctl`.

If no further fail-overs are possible, then the dataplane shuts down; in turn, upstream dataplanes will eventually fail-over to use a different dataplane, if possible, when their threshold is met.

E.2 Headerless Runtime

The Headerless approach works by building a circuit between dataplanes. Compared to the Full approach, in which a program can be split almost arbitrarily, Headerless provides less flexibility.

A program is assumed to have three parts: the ingress subprogram, the forwarding subprogram, and the egress subprogram. The ingress or egress subprograms, or both, may be empty. If non-empty, they are segmented for offloading into supporting devices, which we call *helper* dataplanes.

Thus the HL runtime differentiates starkly between two types of dataplanes: the switch, on which the forwarding subprogram is kept, gets the HL_S version of this runtime, while the helpers get the much simpler HL_H part. The HL_H part of the runtime receives offloads from HL_S, performs a computation, and returns control back to HL_H. Disaggregations using HL have a single instance of HL_S and potentially several of HL_H. The ingress and egress subprograms, if non-empty, are executed on a dataplane running HL_H.

Fig. 16 shows the core logic of this circuit, which takes place on HL_S. It reflects the three parts in which the program is organized: first, one or more ingress subprogram segments (I_N) are executed, after which a forwarding step is made to determine whether to execute the egress segments (E_N). Upon arrival, if the ingress port is in I then transition 1 is taken, else if the port is in I_N then transition 2 is taken. Otherwise a forwarding decision is made, and if the egress port is in E then transition 4 is taken, or if the port is in E_N then transition 5 is taken; otherwise transition 6 is taken if the program's egress segment does not apply to the egress port.

A consequence of using the Headerless runtime is that disaggregation must be coarser—only linear segments are possible, not at DAG, and downstream live-variables must be included in the same segment that updates the variables. As a result, the complexity of segmenting is strictly lower than the general case, as shown in §H. The suitability of using Headerless runtime with a given segmentation is detected statically using our P4 compiler extension.

F Runtime Overhead

Table 4 accounts for the overheads of each approach. The overheads are described as functions over runtime-specific parameters described in §E.

The constants in each function were derived by counting the state used in each runtime, such as the width of registers, and the width of entries from a table's P4 specification. Further, we counted the number of table entries resulting from typical configuration of each runtime.

For example, the function $N \cdot 13$ for HL(IPv4)'s total size of entries (in bits) is derived from the number of entries N—the number of next dataplanes that a segment might forward to—which is known at compile time, multiplied by 13 which consists of 9 bits for the port number and 4 bits for the segment number. The state used by register arrays is the product of the array size and the register size. For example, the term $(N_F + P_F) \cdot 228$ contributing to Full's register overhead consists of register arrays whose register sizes total 228 bits, one of which is of size N_F and the other P_F. The parameters are described in the previous section and in the table's caption.

These overheads are not program-specific, but rather they are additional to the program's overheads. Also, these overheads are per-dataplane, not per-program. So if a dataplane program is disaggregated into more subprograms then it will incur more cumulative overhead, but the overhead's factor will depend on the runtime involved.

So for example if an L-line P4 program used R register bits and T tables, whose entries occupied $|T|$ bits, were disaggregated into N subprograms, then if it were to use the Headerless runtime, each subprogram S would be of size $L_S + 70$, where $\frac{L}{N} \approx L_S \leq L$ is the subprogram's line count. HL$_S$ would have $R+4$ register bits, $T+5$ tables. Assuming that $I = E = 1$, and that half of the N subprograms relates to the ingress segment (and therefore the other half relates to the egress segment), we have that $I_N = E_N = \frac{N}{2}$, and therefore the memory needed for table entries is

$$\begin{aligned} & |T| + \left(22 + \tfrac{N \cdot 22}{2} + 22 + \tfrac{N \cdot 22}{2} + 10\right) \\ = \quad & |T| + N \cdot 22 + 54 \end{aligned}$$

bits. The overhead of HL$_H$ can be calculated similarly.

G Complexity Analysis of Headerless Disaggregation

Below we define the complexity function C of headerless disaggregation, in terms of the number of possible choices that can be made during this process. The asymptotic complexity of disaggregating a program to use the Headerless runtime is $\max(C(S_I), C(S_E))$, where S_I is the sequence of lines in the ingress segment, and S_E the sequence of lines in the egress segment.

Let S be a sequence of lines of code, $n = |S|$ be the number of lines in S, and $1 \leq B \leq n$ the arithmetical average, in lines of code, of blocks in S. Top-level lines of code that do not form part of a block are counted as blocks of length 1. The number of blocks in S is $1 \leq \frac{n}{B} \leq n$.

At the limit, each block will be mapped to a different segment. But there might be constraints that force us to merge segments or objectives that are benefitted by such merges. Let $M \in \mathbb{N}, 0 \leq M \leq \left(\frac{n}{B} - 1\right)$ be the *merge opportunity*: i.e., the number of merges of (adjacent) segments we can carry out to the maximally segmented program. Increasing M has the effect of making segmentation coarser by merging more blocks together. Blocks are merged to eliminate data-flow dependencies between blocks since the Headerless runtime does not allow context serialisation and transfer between dataplanes. Blocks are also merged to make better use of physical resources; in our setup this merge decision is made by the planner.

The value of C consists of the sum of merge choices for each value of M, which by the binomial theorem simplifies to an exponential function:

$$C(S) = \sum_{M=0}^{\frac{n}{B}-1} \binom{\frac{n}{B}-1}{M} = 2^{\frac{n}{B}-1} \in O\left(2^{\frac{n}{B}}\right) \qquad (2)$$

■

H Comparative complexity

In this section we show that for programs having more than 2 lines, our Headerless disaggregation (§G) presents fewer choices than general disaggregation (§C).

We start by clarifying the number of choices presented by general disaggregation. From Equation 1 in §C, the complexity of general disaggregation is $O\left(n^k\right)$. Recall that $k < n$. Expanding for all possible values of k, which represents the number of splits we may choose, we obtain:

$$O\left(n^1 + \cdots + n^{n-1}\right) \subseteq O\left(n^{n-1}\right)$$

From Equation 2, the complexity of Headerless disaggregation is $O\left(2^{\frac{n}{B}}\right)$.

Assuming $n > 2$, our goal is to show $O\left(2^{\frac{n}{B}}\right) \subset O\left(n^{n-1}\right)$.

Recall that $1 \leq B \leq n$, and note therefore that $O\left(2^{\frac{n}{B}}\right) \subseteq O(2^n)$.

Without changing our assumption regarding n, we use the transitivity of $\subseteq$ to reformulate our goal as $O(2^n) \subset O\left(n^{n-1}\right)$. Take 2^n and n^{n-1} as the bounding functions of the two classes respectively. We show that $2^n < n^{n-1}$ first through application

[6] In addition to the resources quantified in Table 4, the Full approach also uses mirroring sessions to provide feedback. One session is used for each upstream dataplane to which it needs to provide feedback. These are configured automatically by `fpctl`.

[7] The header can be enlarged to afford more scratch space if further headroom is made available from the interfaces' MTU.

[8] We repurpose the Fragment Offset field instead of adding a header.

Runtime	#LOC	#Tables	Entries(#bits)	Registers(#bits)	Header(#bits)
Full[6]	400	6	$N \cdot S_N \cdot 17 + 2N \cdot 36 + 2N_F \cdot 36 + 2P_F \cdot 40$	$71 + (N_F + P_F) \cdot 228 + N \cdot 10$	288[7]
HL(IPv4)	75	1	$N \cdot 13$	11	0[8]
HL $\begin{cases}\text{HL}_S\end{cases}$	70	5	$I \cdot 22 + I_N \cdot 22 + E \cdot 22 + E_N \cdot 22 + 10$	4	0
HL $\begin{cases}\text{HL}_H\end{cases}$	70	1	22	4	0

Table 4: Dataplane and network overheads for each runtime. In HL we differentiate between HL$_S$ and HL$_H$: the switch dataplane and the helper dataplanes. These overheads were calculated by counting the resources used by each runtime's P4 implementation, and they are inherited by every dataplane involved in running a disaggregated program that uses that particular runtime. N is the number of *next* dataplanes that a dataplane might transfer to, P is the number of *previous* such dataplanes. $S_N \geq 1$ is the number of fail-over states: if $S_N = 1$ then there is no fail-over. $N_F \leq N$ and $P_F \leq P$ is the number of next and previous dataplanes for which a *feedback loop* is configured. I and E are the number of ingress and egress ports for which a program is running, and $I_N \geq 0$ and $E_N \geq 0$ are the number of intermediate hand-overs during the ingress and egress stages of the program.

of identities:

$$\begin{aligned}
& 2^n < n^{n-1} \\
\Leftrightarrow\ & \log_2(2^n) < \log_2(n^{n-1}) \\
\Leftrightarrow\ & n\log_2 2 < (n-1)\log_2 n \\
\Leftrightarrow\ & n < (n-1)\log_2 n \\
\Leftrightarrow\ & 0 < (n-1)\log_2 n - n
\end{aligned}$$

Then by induction on n, using $n = 3$ for the base case, verifying that $0 < 2 \cdot 1.58 - 3$, and then assuming the induction hypothesis $0 < (n-1)\log_2 n - n$ to show $0 < n\log_2(n+1) - (n+1)$. We start with application of identities:

$$\begin{aligned}
& 0 < n\log_2(n+1) - (n+1) \\
\Leftrightarrow\ & 0 < n(\log_2 n + \log_2\left(\tfrac{n+1}{n}\right)) - (n+1) \\
\Leftrightarrow\ & 0 < n\log_2 n + n\log_2\left(\tfrac{n+1}{n}\right) - n - 1 \\
\Leftrightarrow\ & 0 < \log_2 n + (n-1)\log_2 n + n\log_2\left(\tfrac{n+1}{n}\right) - n - 1 \\
\Leftrightarrow\ & 1 < ((n-1)\log_2 n - n) + \log_2 n + n\log_2\left(\tfrac{n+1}{n}\right)
\end{aligned}$$

Using the induction hypothesis we conclude that $((n-1)\log_2 n - n) > 0$, and using the assumption that $n > 2$ it follows that $\log_2 n > 1$ from the definition of $\log_2$, and $\log_2\left(\frac{n+1}{n}\right) > 0$ from the definition of $\log_2$ and since $\frac{n+1}{n} > 1$. ■

I Modelling Language

We use a simple formal language to describe relations between segments, computational resources and network resources. The relations rely on symbols used to represent those entities, such as "Compress", "PacketSize", and "FPGA". We require the user to declare these symbols by specifying a *signature*. A Flightplan signature consists of two finite sets: propositions Prop and variables V.

Signatures can be reused, at least partly, by different programs on the same network, or by the same program being deployed to different networks. Our P4 compiler extension generates an initial signature together with the abstract programs and the initial resource rules. The user can then extend and maintain this as needed.

$$\frac{\text{FPGA} \quad \text{Rate} < 9.5 \times 10^9 \quad \text{PacketSize} > 100}{\text{header\_compress}} \left[\begin{array}{l} \text{Lat.} \mapsto \text{Lat.} + 6.44 \times 10^{-6} \\ \text{Rate} \mapsto \text{Rate} \times \frac{9.15}{9.3} \\ \langle \text{LUTs} \rangle \mapsto \text{LUTs} + 24.4\% \\ \langle \text{BRAMs} \rangle \mapsto \text{BRAMs} + 54.4\% \\ \langle \text{FF} \rangle \mapsto \text{FF} + 15.8\% \\ \text{once Power} \mapsto \text{Power} + 30\,\text{W} \\ \text{once Cost} \mapsto \text{Cost} + 2 \end{array}\right]$$

Rule 4: Running Header Compression on an FPGA. Angled brackets indicate that the variables they reference depend on the device—e.g., instead of updating the flip-flop (FF) count for all FPGAs, we increment those of the FPGA to which HC is mapped using this rule.

$$\frac{\text{CPU}}{\text{egress\_compression}} \,[\text{Id}]$$

Rule 5: Flightplan's static analysis identifies egress_compression as a resource, and specifically as a table. We add a rule that allows this resource to be used on a CPU-based target.

Resource-related syntax is mapped to distinct propositions from Prop. We encountered the proposition `header_compress` in Rule 1. That rule had another proposition, "CPU", that is external to the program but is used to qualify the semantic to a specific hardware.

The variables in V are used to construct a second syntactic category in our specification language called Bound. For each $v \in V$ and $r \in \mathbb{R}$, the following are valid bounds: $v \,\text{op}\, r$ for op $\in \{=, <, >, \leq, \geq\}$. Rules 1 and 4 show examples of bounds usage from our formalization.

Propositions and bounds are also used to express constraints of network hardware. The planner (§6) uses these rules to explore implications of using those devices in plans. Fig. 17 shows a subset of the rules used for the evaluation described in §7.2.2, which model the network described in §7.2.1.

$$\frac{\text{CPU}}{\text{drop}}\ [\text{Id}]$$

Rule 6: Flightplan's static analysis identifies drop as an external function. We add a rule that allows this to be called on a CPU-based target.

$$\begin{aligned}
&\text{edgecore-2}:\\
&\quad \pi_{\text{Requires}} = \left\{\text{Rate} \leq 10^{11}\right\},\\
&\quad \pi_{\text{Provides}} = \{\text{PSwitch}\}\\
&\text{arista-1}:\\
&\quad \pi_{\text{Requires}} = \left\{\text{Rate} \leq 4 \times 10^{10}\right\},\\
&\quad \pi_{\text{Provides}} = \{\text{Switch}\}\\
&\text{ZCU102-5}:\\
&\quad \pi_{\text{Requires}} = \left\{\text{Rate} \leq 10^{10}\right\},\\
&\quad \pi_{\text{Provides}} = \{\text{FPGA}\}\\
&\text{Xeon2450-1}:\\
&\quad \pi_{\text{Requires}} = \left\{\text{Rate} \leq 10^{10}\right\},\\
&\quad \pi_{\text{Provides}} = \{\text{CPU}\}
\end{aligned}$$

Figure 17: A subset of the network-description rules used for the evaluation described in §7.2.2. Unlike other rules we have seen, these rules describe the constraints on using each device and the features enabled by each device. The planner uses this information when exploring the space of solutions.

J Generating rules from empirical profiles

Table 3 provided a summary of our profiling experiments. This section describes how the profiling experiments were done, and how their results were used to generate the *profile-related rules* such as Rules 1, 3 and 4. Other types of rules are derived from the program or from the network's description and are generated differently as described in §4.

J.1 Methodology

For each external function involved in a program, we measure its peformance characteristics on different classes of devices and use this information to estimate the performance of program segments in which those functions occur.

The performance profile is made by installing the function on a member of each class on which it can run and running a workload to sample the function's performance. This is used to create an entry in a table consisting of the following columns:

$$(\text{Function}, \text{PacketSize}, \text{Target}, \text{Time}_{\text{Arrive}}, \text{Time}_{\text{Leave}},\\ \text{Rate}_{\text{Arrive}}, \text{Rate}_{\text{Leave}})$$

The first three columns consist of the function's name, the packet size used in the workload, the name of the hardware target class. The next two columns consist of the timestamps of when a frame is received by the function, and the processed frame is sent by the device.[9] Similarly, the last two columns consist of the arrival rate to the function and the sending rate. This captures the effect of the function on the link's capacity: for example FEC uses more of the downstream capacity compared to upstream, while header compression uses less.

Further, we also make two measurements that are less function- and workload-dependent: Power consumed by the target when executing the function on that workload, and the Cost of the hardware target. Instead of literal equipment costs we used relative quantities: $\{\text{FPGA} = 1, \text{Switch} = 2, \text{CPU} = 5, \text{PSwitch} = 10\}$.

Limitations on precision. This approach will not accurately account for differences between devices in the same class—e.g., different FPGA devices—or different configurations of the same device—e.g., kernel bypass on CPU targets—but it will give us good-enough characterization for our purposes, and a starting point for more accurate characterizations. Like all profiling, it is also sensitive to the workload used. Despite this, our approach is amenable to refinement in the following way: devices classes can be refined into subclasses, different kinds of workloads can be distinguished by adding a variable to each rule, and additional variables can be sampled by measurements and added to the generated rules. For example, the $\langle \cdots \rangle$ in Rule 4 involves an extension we made to more accurately characterize the usage of FPGA resources. Since the utilization of FPGA resources is a simple additive approximation we do not constrain the planner by their values—for instance to ensure that an FPGA's LUTs are not exceeded—but instead we do a post-hoc check.

Limitations on scale. To scale with the size of the network, we avoid creating a profile for every target in the network. Further, to scale with program and disaggregation diversity, we avoid creating a profile for every segment. Instead we focus on external functions, and measure their performance characteristics on different classes of devices as described above. In future work some of this characterization work can be automated further, to improve both its scalability and its precision.

J.2 Compiling the table

For each Function and Target we run a series of experiments in which we gradually increase PacketSize and $\text{Rate}_{\text{Arrive}}$. As long as we do not notice any drops—which would indicate that the function is not coping with the arrival rate for that packet size—we create a table entry for the information described above.

We then process the raw table to create a second table consisting of the following columns, some of which overlap with the first table we described:

$$(\text{Function}, \text{PacketSize}, \text{Target}, \Delta\text{Latency}, \text{Rate}_{\text{Arrive}}, \Delta\text{Rate},\\ \text{Power}, \text{Cost})$$

[9] Both timestamps were generated by the EdgeCore Wedge switch and were mirrored to a collection server on the side.

$$\frac{\boxed{\text{Function}} \quad \text{Rate} < \left(\boxed{\text{Rate}_{\text{Arrive}}} + T_{\text{R}}\right) \quad \text{PacketSize} > \left(\boxed{\text{PacketSize}} - T_{\text{PS}}\right)}{\boxed{\text{Target}}} \left[\begin{array}{l} \text{Latency} \mapsto \text{Latency} + \boxed{\Delta\text{Latency}} \\ \text{Rate} \mapsto \text{Rate} \times \boxed{\Delta\text{Rate}} \\ \text{once Power} \mapsto \text{Power} + \boxed{\text{Power}} \\ \text{once Cost} \mapsto \text{Cost} + \boxed{\text{Cost}} \end{array}\right]$$

Rule 7: Template for performance-related rules. T_{R} and T_{PS} are tolerance offsets for rate and packet-size respectively. We set these to small values to retain fidelity while using the inequality operators.

where

$$\begin{aligned} \Delta\text{Latency} &= \text{Time}_{\text{Leave}} - \text{Time}_{\text{Arrive}} \\ \Delta\text{Rate} &= \frac{\text{Rate}_{\text{Leave}}}{\text{Rate}_{\text{Arrive}}} \end{aligned}$$

All the records from the first table are automatically processed to create the second table. This is an example record from which we will show how to generate Rule 1:

$$(\text{header\_compress}, 1000\,\text{B}, \text{CPU}, 7.4 \times 10^{-3}\text{s}, 2 \times 10^{8}\text{Gbps}, \frac{189.9}{194.75}, 150\,\text{W}, 5)$$

J.3 Converting table into rules

Finally, the table of measurements described above is converted into rules. This is done automatically as follows: for each row in the second table we instantiate the template shown in Rule 7 by replacing the black-background fields in the rule with the corresponding fields in the row. The meaning of these rules is explained in the caption of Rule 1 in §3, and in §I.

That is how we generated the performance-related rules used by our tools, including the following rules shown in this paper: Rules 1, 3 and 4.

K Program Annotation & Splitting

After finding a mapping from segments to dataplanes as part of a plan, contiguous segments that are mapped to the same dataplane are grouped into a single segment. This is done by deleting intermediate `flyto()` statements. At this point the program is said to be annotated for splitting.

Next we need to generate a physical, well-formed and self-contained P4 file for each segment. The program splitting phase performs three tasks: 1) extract the P4 code from each segment, forming subprograms; 2) analyze the subprograms to gather runtime-related context, such as variables whose values must be included in the hand-over between dataplanes; 3) inject runtime-dependent code for handing-over between subprograms.

These tasks involve simple but laborious analysis and modification of data structures in the compiler, which we outline in this section.

Subprogram generation Our implementation reuses the P4 compiler's data structures as much as possible, adding a thin layer to facilitate the analysis and transformation needed for splitting. We follow these steps: **1)** Analyze the program's abstract-syntax tree (AST) to identify all occurrences of calls to `flyto`. **2)** Generate a *virtual AST* (vAST) for each `flyto`. A vAST is an overlay of the AST for each split. Thus we obtain a single data structure using which we can simultaneously reason about the original program and all derived programs. **3)** Generate the *segment-level topology*: a graph where nodes consist of segments and where an edge denotes a code-path leading to the hand-over between adjacent segments.

Context gathering The synthesis of code between segments to pass data across dataplanes involves computing the transitive closure of required state, to ensure that downstream dataplanes shall have all the information they need to compute on. Writing such interfacing code by hand is tedious and error-prone. We continue the steps taken in the compiler extension: **4)** Traverse each vAST to compute its set of free variables (variables that are used, but not defined, in that vAST); **5)** Traverse the segment-level topology to compute the *extended scope of variables*: that is, variables defined in one vAST will need to be propagated to downstream vASTs in which they are used.

Code injection, Flightplan header This task uses the information gathered during the previous stage to ensure that the hand-over will happen correctly between all connected subprograms: **6)** If supported by the runtime, then generate stubs to propagate two kinds of information across logical dataplanes: a) the values of extended-scope variables and b) additional Flightplan metadata for instrumented programs or fault detection (§5). This is added to a special Flightplan header that encapsulates the original packet, piggy-backing logistical metadata.[10] **7)** Embed the vAST in the original program, replacing the main control block. The downstream compiler will purge unnecessary declarations and definitions. For each vAST, we update the deparsing stage to use the stub for the downstream logical dataplane. We also update the parser block to opportunistically parse the Flightplan header, and, if successful, then the control block branches to process the continuation of Flightplan code.

L Disaggregation microbenchmarks

L.1 Latency Microbenchmarks

In this section, we measure the amount of latency added by splitting a dataplane and benchmark the responsiveness of Flightplan's failover mechanisms.

End-to-end latency. We benchmark application layer end-to-end latency by measuring round-trip time (RTT) between two servers connected to switch `S1` in the topology described in §7.2.1. A concurrent ping and 10 `iperf3` streams went from the `iperf3` client to the Memcached client, with the forwarding table initially stored on `S1` and offloaded to `S2`. Fig. 18 shows the change in ping RTT distribution. Latency

[10] The Flightplan header is described in Appendix D.

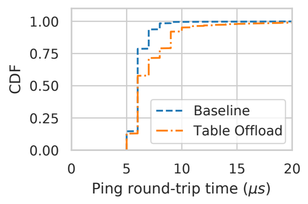

Figure 18: Table-offload overhead measured by pings across end-hosts.

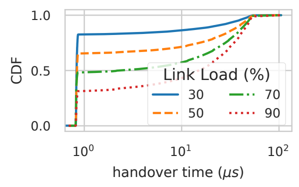

Figure 19: Effect of network load on handover latency.

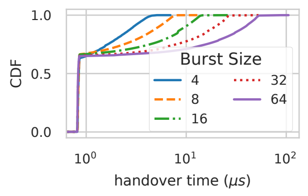

Figure 20: Effect of burstiness on handover latency.

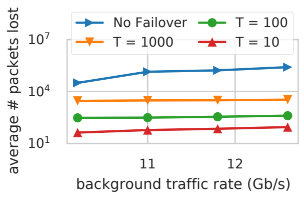

Figure 21: Thresholding (T) of packet loss.

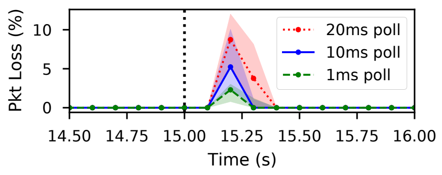

Figure 22: Packet loss during failover, as measured by `iperf3`. At time 15 s, the FEC encoder fails and is automatically replaced by another FPGA. Polling for detection of the failed link at tighter intervals results in less loss during the failover procedure.

was higher because packets had to traverse two additional queues in each direction. These queues were congested due to `iperf3`, which adds latency as discussed in Sec. 7.2.3. In this experiment we measured an 18.7% increase in average RTT and 22.3% increase in maximum RTT in our setup, but this increase will be smaller when the communicating servers are separated by more hops, for example if they are not both connected to `S1`.

Handover latency. To understand overhead at a finer scale, we measure *handover time*, the time between the invocation of the function containing the offloaded table and the beginning of its execution. Fig. 19 shows the distribution of handover time as link utilization varies. At a utilization level of 30%, reflecting high load in a data center scenario [4], handover time was under 1 μs for over 80% of the traffic. At higher rates, handover time increases due to added congestion in the queues between `S1` and `S2`. As Fig. 20 shows, larger packet bursts also have an effect, but only stretch the tail of the handover time distribution. In a 50% load scenario, the handover time remained under 1μs for over 60% of packets.

L.2 Failover Microbenchmarks

We evaluate two kinds of fail-over mechanisms. The first involves controller-based failure-detection and effecting of fail-over. The second involves in-dataplane failure-handling. A deployment can involve both simultaneously, with the in-dataplane mechanism reacting more quickly in most cases, and the controller-based approach handling cases where the in-dataplane mechanism is incapacitated because of device failure.

Controller-directed failover. In the case of total failure of a link or device, the loss of connection can be directly detected by the controller, allowing it to automatically initiate the failover procedure without further intervention.

Fig. 22 shows the packet loss rate of a UDP `iperf3` session running at 1 Gbit/s through a dataplane employing FEC during the failure of the FEC encoder FPGA. At time 15 s, the link to the FPGA is disabled. The controller, which polls for the presence of the link at regular intervals, redirects traffic to a failover FPGA once the down link is detected.

With a polling interval of 1 ms, at most 3% of packets are lost in the 100 ms interval immediately following the disabling of the link.

Dataplane NAK Failover. We benchmark the NAK mechanism described in §5.3 with a simple program on `S1` that offloads a no-op function `F`. There are two instances of `F` (`F.1` and `F.2`) that both run on switch `S2`, but service different links connected to `S1`. We measure the number of packets lost in a scenario where failover from `F.1` to `F.2` occurs due to congestion on the link to `F.1`.

Fig. 21 shows how the number of packets lost varies with the rate of congestion-inducing background traffic. The Flightplan failover mechanism bounds packet loss to a low (< 10) integer factor of the NAK threshold (T). After the Tth NAK is received, only in-flight packets already queued to `F.1` are lost because every subsequent packet is routed to the failover instance. Without the NAK mechanism, the number of packets lost is unbounded.

MilliSort and MilliQuery: Large-Scale Data-Intensive Computing in Milliseconds

Yilong Li* Stanford University

John Ousterhout Stanford University

Abstract

Today's datacenter applications couple scale and time: applications that harness large numbers of servers also execute for long periods of time (seconds or more). This paper explores the possibility of *flash bursts*: applications that use a large number of servers but for very short time intervals (as little as one millisecond). In order to learn more about the feasibility of flash bursts, we developed two new benchmarks, MilliSort and MilliQuery. MilliSort is a sorting application and MilliQuery implements three SQL queries. The goal for both applications was to process as many records as possible in one millisecond, given unlimited resources in a datacenter. The short time scale required a new distributed sorting algorithm for MilliSort that uses a hierarchical form of partitioning. Both applications depended on fast group communication primitives such as shuffle and all-gather. Our implementation of MilliSort can sort 0.84 million items in one millisecond using 120 servers on an HPC cluster; MilliQuery can process .03–48 million items in one millisecond using 60-280 servers, depending on the query. The number of items that each application can process grows quadratically with the time budget. The primary obstacle to scalability is per-message costs, which appear in the form of inefficient shuffles and coordination overhead.

1 Introduction

One of the benefits of datacenter computing is the ability to run large-scale applications that harness hundreds or thousands of machines working together on a common task. Using frameworks such as MapReduce [11] and Spark [67], developers can easily create applications in a variety of areas such as large-scale data analytics.

Until recently, large-scale applications have executed for relatively long periods of time: seconds or minutes. This was necessary in order to amortize the high cost of allocating and coordinating a collection of servers. Similarly, frameworks such as MapReduce and Spark have traditionally operated on very large blocks of data, in order to amortize high network latencies. As a result, they cannot be applied to real-time tasks. Instead, real-time queries must return precomputed results, such as those produced in overnight batch runs. This means that the queries must be carefully planned in advance; ad-hoc queries cannot easily be supported.

Streaming frameworks such as Flink [15] or Spark Streaming [66] operate on incoming data in real time, but they do this by incorporating new data into queries or transformations that are planned long in advance. To support real-time queries, the scale of computation triggered by each event is quite limited.

In recent years, new serverless platforms such as AWS Lambda [5], Azure Cloud Functions [45], and Google Cloud Functions [20] have made it possible to run short-lived tasks (as small as a few hundred milliseconds) in datacenters. However, the unit of execution in these environments is an individual function call. It is difficult to harness multiple machines in a single serverless computation; for example, direct communication between lambdas is not officially supported, and existing workarounds [17, 3] have high latency and low bandwidth.

This paper explores the possibility of extending serverless computing in two ways: first, by further reducing the timescale; and second, by reintroducing scale, so that large numbers of servers can work together. We use the term *flash burst* to describe a computation that has a short lifetime yet harnesses large numbers of servers. Flash bursts offer the potential of analyzing large amounts of data in real time. This could enable the creation of new applications that execute customized queries on large datasets in real time, without the need to predict queries hours or days ahead of time.

Rather than making incremental improvements on existing systems, our goal is to push the notion of flash bursts to the extreme, in order to understand the limits of this style of computation. In particular, we set out to answer the following questions:

- What is the smallest possible timescale at which meaningful flash bursts can operate?
- What is the largest number of servers that can be harnessed at such a timescale?
- What aspects of current systems limit the duration and scale of flash bursts?

We hypothesized that timescales as small as 1 ms might be possible, so we set that as our initial goal.

Making flash bursts practical will require advances in many different areas. This paper focuses on one aspect of the problem: whether the core algorithms likely to be used in flash bursts can operate efficiently at very small timescales. We do not address issues such as the time required to load applications and data, or how to achieve high resource utilization in the face of short-lived computations; we leave these for future work.

We implemented two focused applications that capture patterns of computation and communication we expect to be common in flash bursts. The first application is MilliSort: given unlimited resources in a datacenter, what is

*Co-first authors, listed alphabetically.

- Sort 40,000 10-byte keys using 8 cores [7].
- Copy 5 Mbytes of data from memory to memory sequentially.
- Send or receive 5 Mbytes of data with a 40 Gbps NIC.
- Invoke 300 back-to-back remote procedure calls on one core, using kernel bypass [50, 52, 32].
- Send or receive 2–5k small messages on one core [50, 32, 48].
- Take 10,000 back-to-back L3 cache misses on one core.

Figure 1: Examples of tasks that can be completed in one millisecond on modern hardware.

the largest number of small records that can be sorted in one millisecond? The second application is MilliQuery, which consists of three representative SQL queries from the tutorials for Google BigQuery. The queries range from a simple scan-filter-aggregate query to a distributed join requiring multiple shuffles. As with MilliSort, our goal was to understand how much data can be analyzed, and how many servers can be harnessed, in timescales around 1 ms.

The process of developing and measuring these applications has yielded interesting results in three categories:

- Measurements: MilliSort and MilliQuery demonstrate that large-scale data analytics can operate efficiently even at timescales of 1–10 ms. MilliSort can sort 0.84 million small records in one millisecond using 120 servers running on 30 machines. The MilliQuery benchmarks process .03–48 million records in one millisecond using 60–280 servers, depending on the query.
- Observations: the development of MilliSort and MilliQuery yielded several interesting insights about flash bursts, which are summarized in Section 7. For example, we found that the amount of data that a flash burst can handle grows quadratically with the time budget (both the amount of data per server and the number of servers grow at least linearly with the time budget). Some of the most important and common limits to scalability are shuffle cost and coordination overhead (both can be attributed to per-message overheads).
- Algorithms: while implementing MilliSort we developed a new low-latency algorithm for partitioning the keys, which uses a hierarchical series of distributed sorts. We also developed a novel splitter selection algorithm that improves the balance among data partitions. Overall, MilliSort runs with efficiency comparable to other systems that operate at much larger timescales.

2 Background

One millisecond is not very long. Figure 1 lists a few things that can be done in one millisecond on today's machines; these create fundamental limitations for flash bursts.

2.1 Limited data per server

One of the most important limitations evident from Figure 1 is that each server can only manipulate a small amount of data (on the order of a few Mbytes). For example, a single server core can only access a few megabytes of data in one millisecond, and network bandwidth allows only a few megabytes to be transmitted in one millisecond.

Given the large number of servers and small data per server, data must stay evenly distributed throughout a flash burst. If even a small fraction of data accumulates on a single server, the network link into that server will become a bottleneck.

2.2 Coordination cost

Given that each server can only access a small amount of data, the overall scale of a flash burst will be limited by the number of servers that can be harnessed. But, the small time scale makes it difficult to coordinate very many servers; at some scale one millisecond isn't even enough time to notify all the servers to start working. Thus, coordination overheads play a fundamental role in flash bursts, since they limit the scale. "Coordination" includes such activities as engaging all of the servers, determining work assignments for each server, and sequencing the phases of the algorithm. Existing large-scale applications such as Spark store much larger amounts of data per server and also run for longer time periods; this combination makes coordination overheads less important.

2.3 Multiple communication costs

For many existing large-scale applications, the only communication cost that matters is network bandwidth. Systems such as MapReduce [11] and Spark [67] are explicitly designed to exploit bandwidth and hide communication latency. However, for flash bursts three different costs may become important. In addition to *bandwidth*, which matters when sending large blocks of data, and *latency*, which matters when sending small chunks of data, a third cost plays an important role in flash bursts: *per-message overhead* (the CPU time required to send and receive short messages). Per-message overhead comes into play when a server has a collection of small requests that can be sent to other servers concurrently; it limits how quickly a series of messages can be issued. Per-message overheads are particularly important in flash bursts because they dominate the cost of group communication primitives (discussed below), which in turn dominate the cost of coordination.

2.4 Group communication

If a collection of servers is to cooperate closely, the servers will probably need to exchange data frequently and in small chunks. However, in a flash burst, where there are hundreds or thousands of servers operating on a very small time scale, it is not practical for each server to communicate directly with all of the other servers. For example, if a server broadcasts data to 1000 other servers by sending a separate small message to each of them, the broadcast will consume a substantial fraction of a millisecond, due to per-message overheads.

Thus, *group communication* plays an important role in flash bursts. In group communication, many or all of the servers in a cluster transmit data concurrently to carry out a cluster-wide goal. The HPC community has identified and implemented a variety of useful group communication mechanisms [60], of which four play a role in MilliSort and MilliQuery:

Broadcast: data that is initially present on a single server must be distributed to every server in the group.

Gather: the reverse of broadcast. A single server must collect distinct data from each of the servers in the group.

All-gather: initially each server in the group stores a distinct data item; the all-gather operation must arrange for every server in the group to receive a copy of all the items.

Shuffle: each server initially stores a separate data item for every other server in the group; the shuffle must transmit all the items to their intended targets.

Group communication provides two benefits. First, it harnesses multiple servers operating concurrently to speed up the communication; for example, several servers can be used to complete a broadcast more quickly by distributing messages via a tree structure. Second, it can sometimes replace many small messages with a few larger messages; this reduces the impact of per-message overheads. For example, a hypercube implementation [62] of all-gather requires only $MlogM$ messages for M servers, vs. M^2 messages if each server communicates independently with every other server.

3 Applications

One of the challenges in exploring flash bursts is that there are no flash burst applications available today (unsurprising, given that there is no infrastructure capable of supporting them). Fortunately, there appears to be a small set of patterns of computation and communication that are used commonly across a variety of large-scale applications and account for much of their performance [4, 19, 33]. These are referred to as *dwarfs* by Asanovic et al. [4] and others. For example, matrix operations, sorting, and statistics computations are dwarfs for big-data and AI workloads. Rather than guessing at full applications, we have implemented two small applications that capture several dwarfs. Although the behavior of these dwarfs will not be a perfect predictor of any real application, this approach has two advantages. First, lessons learned from the dwarfs are likely to apply to many real applications. Second, it is easier to understand the properties of the dwarfs if we study them in isolation, rather than as part of a full application with many interacting parts.

Our first application is a sorting benchmark called MilliSort. Sorting has been used to evaluate system performance for many decades, originating with a challenge proposed by Jim Gray and others in 1985 [2]. Sorting plays an important role in many distributed computations. For example, sorting can be used as a data preprocessing step to support efficient range queries, to improve data locality for graph partitioning [44], and to perform load balancing [44, 11, 23]. Sorting is also very challenging because it requires intensive and unpredictable communication (any record can potentially end up on any server). We expected this to create challenges both for the algorithm and the underlying infrastructure.

```

Listing 1: The three SQL queries used in the MilliQuery benchmark

For MilliSort, the goal is to sort as many small records as possible in intervals around one millisecond, using any number of servers in a datacenter. Each record contains 100 bytes, consisting of a 10-byte key and a 90-byte value. Before starting the benchmark, the MilliSort application is preloaded and the unsorted records are distributed evenly among the available machines in DRAM. The data on each server is structured with all of the keys in a single block of memory and all the values in another block, in corresponding order. Upon completion, the data must be redistributed across the same servers, sorted such that one server contains the records with the smallest keys, and so on. At the end of the sort, the data on each server is structured in two blocks of memory, one containing the keys in sorted order and another containing the values in the same order as their keys. The challenge does not require that the result data be distributed evenly across the servers, but this turns out to be essential for good performance.

Our second "application" is a collection of three SQL queries from Google's BigQuery documentation[63, 38]; we refer to these queries collectively as MilliQuery. We expect that many flash burst applications will perform data analytics to provide real-time results from ad hoc queries; the goal for MilliQuery is to capture dwarfs that will be common in these applications.

We chose three queries with different levels of complexity, in order to span a range of SQL behaviors (see Listing 1).

Q1: counts the number of article views on Wikipedia by language (there are at most a few hundred different languages).

Q2: finds the top 10 IP addresses by the number of edits they made to Wikipedia articles.

	Coordination	Shuffle(s)	Dwarf(s)
MilliSort	Heavy	≥2	Sort
MilliQuery Q1	None	0	Aggregate
MilliQuery Q2	Light	1	Repartition,Aggregate
MilliQuery Q3	Light	3	Repartition,Join

Table 1: A comparison of the applications used for studying flash bursts.

Q3: for each combination of author and programming language, sum all of the bytes in that language in any repository for which the author was a contributor; returns the top 100 author-language pairs.

In each case, the goal is to process as much data as possible within 1 ms using unlimited datacenter resources, assuming that the application is pre-loaded and data is initially distributed uniformly across the nodes.

Table 1 compares these applications in terms of the complexity of coordination (how difficult it is to divide the work among the participating nodes and coordinate their behaviors), the number of shuffle steps required, and the dwarfs captured. Together, MilliSort and MilliQuery cover a significant range of interesting behaviors.

Our goal for MilliSort and MilliQuery was to push the idea of flash bursts to the extreme. We don't know what burst sizes will prove useful to applications, so we set out to characterize the range that is practical: what is the smallest time interval and what is the largest number of servers that can be harnessed efficiently? We also hoped to learn what are the technical factors that limit flash bursts. We chose a one millisecond time limit because it seemed like an extreme goal: at the outset, we were unsure whether it would be possible to do anything useful in such a short interval.

4 The MilliSort algorithm

Although distributed sorting is not new, designing a sorting algorithm to operate at a timescale of one millisecond introduces new challenges due to the high cost of coordination. This section describes MilliSort's algorithm in detail and presents a novel hierarchical approach to data partitioning that enables efficient coordination even at very small timescales.

Most distributed sorting algorithms use a partitioning approach, and MilliSort follows this tradition. First, the data is partitioned by deciding which key ranges should end up on each server; then the records are shuffled between servers to implement the chosen partitions. This approach optimizes the use of network bandwidth by transmitting each record only once, during the shuffle phase. The partitioning approach makes sense because it optimizes the use of network bandwidth, which has traditionally been the scarcest resource in distributed sorting. Alternative approaches, such as those that use multi-stage merge sorts, require data to be transmitted over the network multiple times, so they have proven slower than the partitioning approach.

More precisely, MilliSort implements a variant of distributed bucket sort, with one bucket for each server. It consists of four phases:

1. Local sort: each server sorts its initial data.
2. Partition bucket boundaries: the servers collectively determine the key ranges that will end up on each server after sorting.
3. Shuffle: each server transmits its keys and values to the appropriate targets.
4. Local rearrangement: the data arriving on each server during the shuffle phase must be rearranged into two totally sorted arrays, one for keys and one for values.

The sections below discuss each of these phases in more detail. We start with the partitioning phase, since it is the most complex phase and also the most interesting phase from an algorithmic standpoint.

4.1 Histogram sort

One of the most widely used partition-based sorting algorithms is histogram sort, which computes the final key ranges by iteratively refining an existing partition until the keys are evenly distributed on the servers. A typical workflow of histogram sort is as follows. In the beginning, a central server picks $M-1$ splitters, which divide the key space into M buckets, and broadcasts them to the other servers. Then, each server computes a local histogram of its keys in the buckets and sends it back to the central server. Finally, the central server computes a global histogram by summing up the local histograms and adjusts the splitters to reduce the imbalance. The process of histogramming and refinement is repeated until an even partition is achieved. In addition to the one mentioned above, there are other variations of histogram sort which use more splitters for histogramming or increase the number of splitters as they progress.

However, histogram sort is undesirable for MilliSort since it requires many iterations to converge, and each iteration incurs significant message delays. To avoid overloading the central server, histogram sort often uses group communication to broadcast splitters and reduce local histograms in a tree structure. As a result, each iteration incurs $2log(M)$ back-to-back message delays. In our environment, the combined cost of broadcast and gather is at least 50 µs for 100 servers. With just 10 iterations, message delays alone will take away half of our 1 ms time budget. Finally, the actual cost of partitioning will be even higher due to other overheads; the reported partitioning times of some recent histogram sort implementations easily exceed 50 ms for 512 HPC nodes [35, 21].

4.2 Sample sort partitioning

MilliSort takes a different approach to partitioning, selecting a larger number of initial keys so that it can estimate the distribution in a single iteration. MilliSort's partitioning algorithm is based on sample sort with regular sampling [58, 40]; the basic idea is to select many keys from the starting data, use these to estimate the distribution of keys, and pick partition boundaries based on the estimated distribution. Figure 2 shows the basic idea. After sorting its local data, each server samples its keys at equally-spaced intervals within the sorted

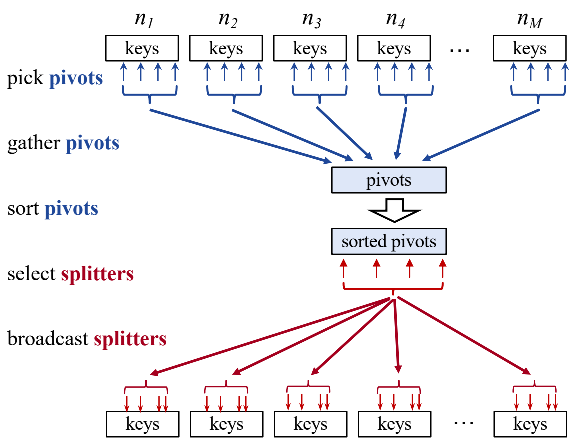

Figure 2: A basic sample sort partition mechanism; $n_1 - n_M$ are the MilliSort nodes.

records; we refer to these samples as *pivots*. The pivots of all servers are collected and sorted (more details on this below). Finally *splitter* values are chosen from the sorted pivots. If there are M machines participating in the sort, $M-1$ splitters are chosen, which divide the sorted pivots into M equal-size groups. The splitters determine how records are divided between servers during the shuffle phase: server i will eventually hold all records with keys greater than or equal to the ith splitter and less than the i+1th splitter.

Because of the sampling used by this approach, there is no guarantee that each server will end up with exactly the same number of records at the end of the sort. If there are N total records divided among M machines and each machine chooses sM pivots, then, in the worst case, a server may end up with as many as $(1+1/s)(N/M)$ records (N/M is the ideal number in a perfect partition) [58, 40]. For MilliSort, we use $s = 1$ (each machine chooses M pivots), so the final partition sizes are guaranteed to be within a factor of 2 of the ideal size. In practice the distribution of records is considerably more uniform than suggested by the worst-case formula above.

With this approach, the total number of pivots to sort is sM^2. This means that as the number of machines increases, partitioning will take more and more time, even if all of the machines share the work. Given a limited amount of time for the sort, partitioning cost will limit the number of machines that can be harnessed.

4.3 Recursive partitioning

One way to perform the partitioning is to gather all of the pivots on a single coordinator server, sort them locally on that server, then broadcast the splitters back to all of the servers. However, this approach is too inefficient for MilliSort. If 300 machines participate in the sort, there will be 90,000 pivots; as shown in Figure 1, a single server can only sort about 40,000 keys in one millisecond, so the sorting alone would take more than 2 ms. The overhead of receiving all the pivots on a single server is also problematic. Thus, millisecond-scale sorting requires partitioning to be performed in a distributed fashion.

MilliSort uses a recursive approach to partitioning: the pivots are sorted in a distributed fashion using a smaller instance of MilliSort, as shown in Figure 3. A subset of the machines, called *pivot sorters*, sort the pivots and select splitters; each of the other servers is assigned to one of the pivot sorters. To begin the sort, each pivot sorter gathers the pivots from its assignees. The pivots arriving from each source machine are already sorted, so the pivot sorter can use merge sort on the arriving data to produce a sorted list of all the pivots for which it has responsibility. Then each pivot sorter samples its pivots to choose a smaller number of *level 2 pivots*; the level 2 pivots are passed to a coordinator, which sorts them and produces a set of *level 2 splitters*. The coordinator broadcasts the level 2 splitters back to the pivot sorters, which then perform a shuffle to redistribute the pivots among the pivot sorters in sorted order.

At this point the pivots have been sorted and splitters must be chosen (i.e., we must select every sM^{th} pivot across all of the pivot sorters). We would like for each pivot sorter to independently select splitters from its pivots, but in order to do this, the pivot sorter must know its rank (i.e., how many pivots stored on other servers are smaller than the pivots that it stores). The rank is not immediately obvious because pivots are not distributed uniformly across the pivot sorters. The solution is to distribute rank information during the shuffle phase of the pivot sort. When a pivot sorter sends a group of pivots to another pivot sorter during the shuffle, it includes the *local rank* of that group (i.e., the number of pre-shuffle pivots from that pivot sorter that are smaller than those in the group). Each pivot sorter can determine its rank by summing the local ranks in all of the shuffle messages it receives. Once a pivot sorter knows its rank, it can identify the splitters that it stores.

Finally, once the splitters have been determined, they must be disseminated to all of the machines participating in the sort. One approach would be for each of the pivot sorters to broadcast its splitters to all of the M machines; however, this would have a high cost because of the large number of messages that would result. Instead, MilliSort uses a two-step approach to distribute the splitters. In the first step, an all-gather operation is used to exchange the splitters among the pivot sorters, so that each pivot sorter has all $M-1$ splitters. Then each pivot sorter broadcasts the complete set of pivots to all of the machines assigned to it.

If the number of servers is very large, the 2-level approach described above will still take too long. If that is the case, additional levels may be used in the partition. For example, in a 3-level approach the level 2 pivots will not be sorted on a single coordinator; instead, they will be collected by a smaller number of second-level pivot sorters, which will then select a set of level 3 pivots. The level 3 pivots will be collected and sorted on a single coordinator, resulting in level 3 splitters, which are used to shuffle the level 2 pivots. The approach can be extended to an arbitrary number of levels, though our experiments suggest that 2 or 3 levels is appropriate for MilliSort.

We use r to refer to the reduction factor at each level of recursive sorting. For M total machines, there will be M/r

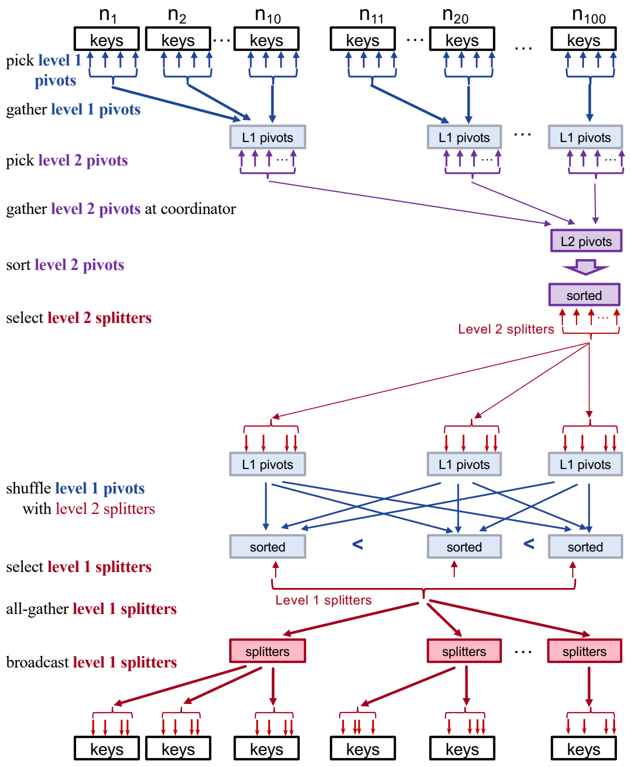

Figure 3: A two-level partitioning example with $M = 100$, $s = 1$, $r = 10$.

pivot sorters, M/r^2 second-level pivot sorters, and so on. For the MilliSort implementation we used a reduction factor of 10.

4.4 Improved splitter selection

The algorithm described above for choosing splitters from the sorted pivots results in uneven key distribution, where the first server is likely to be assigned 50% more keys than the average, and the last server is likely to be assigned 50% fewer keys than the average. We developed an improved splitter selection algorithm that eliminates this imbalance; because of space limitations, we describe that algorithm in Appendix A.1.

4.5 Local sort

Now that the partitioning mechanism has been described, the next few subsections discuss the remaining phases of MilliSort. These phases are more straightforward than the partitioning phase, though their performance is still important.

MilliSort relies on prior work for the local sort. The problem of sorting on a single compute server is well-studied, with many solutions that can take advantage of multiple cores. In our experiments we use the In-place Parallel Super Scalar Samplesort (IPS^{4}o) algorithm [7] as a reasonable representation of a multi-core comparison-based sorting algorithm.

Once the keys have been sorted, the values must be rearranged to match the order of the keys. This can be overlapped with the partitioning phase and the key shuffle; the rearranged values are not needed until the value shuffle.

4.6 Shuffle

Once the splitters have been selected and distributed to all of the machines, MilliSort uses an all-to-all shuffle to transmit each key and value to the appropriate server. The keys and values on each server were already sorted during the local sort phase. Each server uses the splitters to determine the range of keys to send to each other server. It then sends a message to that server containing the appropriate range of keys, followed by the data associated with those keys.

4.7 Local rearrangement

Within each message that a server receives during the shuffle phase, the keys and values are in sorted order. The server must then combine these chunks into two sorted arrays, one containing all the keys and other containing all the values. To do this, each server first performs a merge sort on the arrays of keys; then it rearranges the values to match the order of the keys. Each key contains its index in the incoming shuffle message (which is the same as the index of the value in the message). Once the keys have been sorted, a sequential scan is made over the key array; the index stored with each key is used to find the corresponding value and the value is then stored at the next sequential location in the result array. This two-step approach is faster than a one-step approach that merges both keys and values together, because it copies the (larger) values only once.

5 Implementation

5.1 Group communication

We created a C++ library that implements the group communication primitives described in Section 2.4; both MilliSort and MilliQuery make extensive use of this library. The group communication primitives are implemented using the network transport infrastructure from RAMCloud [50]. RAMCloud's transports use kernel bypass with either DPDK [10] or the Infiniband verbs interface to provide low latency (5 µs round-trips) and high throughput (up to 25 Gbps). However, RAMCloud requires all network communication to pass through a single dispatcher thread, which limits message throughput to about 1.6 million messages per second. The group communication primitives contain 1500 lines of C++ code, not counting code in RAMCloud.

Broadcast, gather, and all-gather were implemented using well-known approaches [62, 65]. For broadcast, MilliSort uses a k-nomial tree, with the topology optimized based on precise knowledge of message latency and per-message cost. For gather, MilliSort uses a k-nomial tree with $k = 6$, in order to utilize as much network bandwidth as possible at each step. For all-gather, MilliSort uses a hypercube approach, extended to handle group sizes that are not even powers of two [56].

Shuffle is the most important of the group communication primitives: it accounts for half or more of the end-to-end time in the highest performing MilliSort configurations and it is also used in two of the three MilliQuery queries. However, achieving high-performance for shuffle is challenging. Ideally, shuffles should utilize the full bandwidth of the network, with each host simultaneously sending and receiving at the speed of its uplink. However, achieving this goal is difficult. One problem is small messages, which are more likely to occur in flash bursts than other applications (see below). Another problem is that shuffle requires full bisection bandwidth in the underlying network. Fortunately, our test cluster has full bisection bandwidth. Unfortunately, we were unable to harness all of the available bandwidth.

Achieving full bisection bandwidth requires a near-perfect bipartite matching, where at any given time each source transmits at full bandwidth to a different target. This is difficult to achieve, for two reasons. First, two servers might attempt to transmit simultaneously to the same target. When this occurs, bandwidth is wasted on the senders, since the target can only receive from one of them at a time; in addition, some other server will not be receiving anything at all, which wastes its incoming bandwidth. Second, achieving full bisection bandwidth requires perfect load-balancing across the network fabric. Unfortunately, our test cluster does not support packet-level load-balancing. Instead, it uses flow-consistent hashing, where all packets from a particular source to a particular destination are routed over a single (randomly chosen) path through the fabric. Even if two sources send to different targets, their routes might traverse a common intermediate link, resulting in bandwidth underutilization. With large clusters, routing conflicts are virtually guaranteed.

After implementing shuffles in the most obvious way and observing poor performance, we attempted a lock-step approach to ensure a bipartite matching. In the lock-step approach, in step i each server n transmits to server $(n+i) \bmod M$, and the start of step $i+1$ is delayed until step i has completed. This mostly eliminated the problem where two senders transmit to the same target, but it works best when all messages are large and the same size. If messages are small, or if messages have different sizes, the act of maintaining lock-step wastes most of the network bandwidth (e.g. each step must wait for the longest message in the preceding step to complete). Furthermore, lock-step is still vulnerable to conflicts in network routes. We were unable to achieve a satisfactory level of performance with this approach.

We then switched to a nearly-opposite approach, implementing shuffles in a "high-entropy" fashion that is granular, concurrent, and random. The first step is to ensure that messages sent during shuffles are relatively short (at most 40 KB in the current implementation). In many cases, the messages are inherently short; if the data from one server to another exceeds a threshold size, it is divided into multiple short chunks, which are sent as separate messages. Each host sends multiple messages concurrently; the targets are chosen randomly, but a given source will have at most one message outstanding to a given target at a time. With this approach there will still be conflicts but they will not stall senders; conflicts simply result in packet queueing in the network. Since each sender has multiple outstanding messages, it is likely that there will be incoming data for each server at all times. Since messages are short, buffer overflows in the network are unlikely and a sender doesn't waste much time on a busy receiver before directing its bandwidth elsewhere. Stalls will occur only at the end of the shuffle, when a sender is waiting for its last few messages to complete. The high-entropy approach resulted in much better performance than the alternatives we tried before it.

Shuffles are more challenging in a flash burst than in more traditional environments that operate at large timescales. A flash burst scales by increasing the number of servers, with less data on each server, in order to complete more quickly. Less data on each server means the size of each shuffle message will drop; more servers means that each server's data is split among more shuffle messages, which also results in less data per message. The result is a rapid drop in shuffle message size as a flash burst scales. This leads to low network bandwidth utilization and high per-message overheads.

One possible solution is to use a two-level shuffle to reduce the number of messages sent and received by each server from $M-1$ to $2\cdot(\sqrt{M}-1)$. Two-level shuffle arranges all servers into a virtual mesh and proceeds in two rounds: each server first exchanges data with other servers in the same row, and then in the same column. However, this approach doubles the network bandwidth consumed, since most data must be transmitted twice. For our experiments the increased bandwidth usage of a two-level shuffle was more problematic then per-message overheads for a single-layer shuffle; we did not find any situations where multi-level shuffles are advantageous.

5.2 MilliSort

The MilliSort implementation is fully decentralized: each server operates independently in an event-driven style, with no central coordinator (central coordination is intolerable for flash bursts, both because of the latency it adds and also because central coordination often involves lock-step operation at the end of each stage, which suffers from stragglers). While the order of stages executed in a server is well defined, the timing is affected by remote procedure calls (RPCs) from other servers. At various points, the progress of the server will stall until certain pieces of data have arrived. As one example, a pivot sorter cannot select level 2 pivots until it has received pivots from all of the servers in its group.

Different servers must have different behaviors during the sort. For example, only a subset of the servers will act as pivot sorters. Each server has an identifier ranging from 0 to $M-1$, which determines the various roles it will serve during the sort. For example, servers with identifiers that are $0 \bmod r$ serve as pivot sorters and they receive pivots from servers with the following $r-1$ identifiers. At the start of the sort each server knows its identifier, the value of M, and the addresses of the other servers.

Achieving the highest overall performance for MilliSort requires careful optimization of both communication and computation. Section 5.1 has already discussed the challenges associated with shuffles. Using cores efficiently is another challenge, because the number of threads changes rapidly over the life of the sort. Thus, MilliSort uses Arachne [54] for efficient user-level thread and core management. For example, Arachne allowed us to quickly spawn a group of threads to parallelize a task, such as local sort, and place them precisely on all available cores. In addition, MilliSort creates a new thread for each incoming RPC and leaves it to Arachne to schedule those threads on cores that are less busy.

5.3 MilliQuery

We created a special-purpose implementation of each of the three MilliQuery queries, largely based on the query plans generated by BigQuery. These queries were much easier to implement than MilliSort, particularly given the availability of the group communication library. The total implementation time was only a few days, and the three queries contain 250, 300, and 800 lines of C++ code, respectively.

The implementation of Q1 follows a simple scan-aggregate pattern: each server scans its data independently to count the views by language, then the local results are gathered back to one server, using a k-nomial tree and combining the statistics at each node. Since the number of distinct languages is only a few hundreds, all messages in the gather phase are small.

Similar to Q1, Q2 can also be implemented as local scan followed by a gather. But, the number of distinct IP addresses is quite large, so the gather phase would consume too much network bandwidth with this naive approach. Thus, before the gather phase, a shuffle is used to collect all the counts for each address in one place, using a hash partition. Then each node in the gather tree collects local results from all its children, but only needs to send the top ten IP addresses to its parent.

Q3 is considerably more complex and requires a total of three shuffles. First, two shuffles are used to materialize two intermediate tables, distributing the records for each table using a hash partition with the `repo_name` field. Then, the two tables are joined locally using the same key, and a third shuffle redistributes the joined records by hash partitioning on `(lang, author)`. Finally, top-100 statistics are computed locally and aggregated as in Q2.

For simplicity, we didn't implement additional mechanisms to handle hot keys in hash partitioning for Q2 or Q3; however, it's possible to use MilliSort's recursive partitioning scheme to create a more balanced range partitioning, at the expense of higher partitioning cost.

5.4 Communication infrastructure

We chose to build our MilliSort and MilliQuery prototypes atop RAMCloud [50] mainly to reuse its flexible network infrastructure. However, this choice comes with the cost of limited message throughput for two reasons:

- The single dispatch thread in RAMCloud has relatively high per-message costs (all messages must pass through the dispatch thread, which results in expensive cross-core communication) and presents a central bottleneck which prevents us from achieving higher throughput by adding more cores.

CPU	Xeon Gold 6148 (2 sockets $\times$ 20 cores @ 2.40GHz)
RAM	384 GB DDR4-2666
Networking	100Gbps Intel Omni-Path Interconnect

Table 2: The hardware configuration used for benchmarks. All machines ran CentOS 7.3.1611 (Core) with hyperthreading disabled. The network fabric used a two-level fat-tree topology to provide full bisection bandwidth at 100 Gbps per machine.

	Total records processed (# servers used)			
Time budget	**MilliSort**	**Q1**	**Q2**	**Q3**
1 ms	0.84 M (120)	47.6 M (280)	6.72 M (140)	0.034 M (60)
10 ms	26 M (280)	980 M (280)	224 M (280)	2.24 M (280)
Scaling	31.0x (2.3x)	20.6x (1x)	33.3x (2x)	67.9x (4.7x)

Table 3: Overall performance of MilliSort and MilliQuery.

- The underlying Omni-Path PSM2 library [26] we use to send and receive packets is actually not a packet I/O driver but a reliable message-passing transport with its own congestion/flow control, which adds considerable overhead; in addition, the Omni-Path host fabric interface (HFI) does not have a lightweight mechanism for transfering small chunks of data via DMA, so we have to send/receive packet data using programmed I/O, which leads to higher CPU overhead and, even worse, cache pollution.

As a result, a single server cannot fully utilize its network bandwidth when the messages are relatively small. In our experiments, we decided to place multiple servers on each machine, each with its own dispatch thread, to increase the network utilization. This approach can scale the overall message throughput of each machine linearly, but it also incurs higher coordination overhead due to the increased number of servers. Future implementations that are based on a more efficient networking stack such as [32, 18] could eliminate the need to run multiple servers per machine.

6 Performance measurements

Our goal in evaluating MilliSort and MilliQuery was to answer the following questions:

- How much data can be processed in one millisecond (or ten milliseconds), and how many servers can be harnessed efficiently in each interval?
- How does application behavior change if the time budget is increased or decreased?
- What factors limit the applications' performance and scalability, and what stresses do these applications create for underlying infrastructure?
- How effective is MilliSort's new partitioning mechanism?
- How efficient is MilliSort compared to purely local sort or other distributed sorts?

We used the hardware configuration shown in Table 2 to evaluate MilliSort and MilliQuery. To better utilize the network bandwidth (discussed in Section 5.4), we ran four independent servers on each machine, two on each socket. We had access to 70 machines in the cluster, which allowed up to 280 servers; and there were no competing tasks running on the machines. All MilliSort experiments used 2-level partitioning.

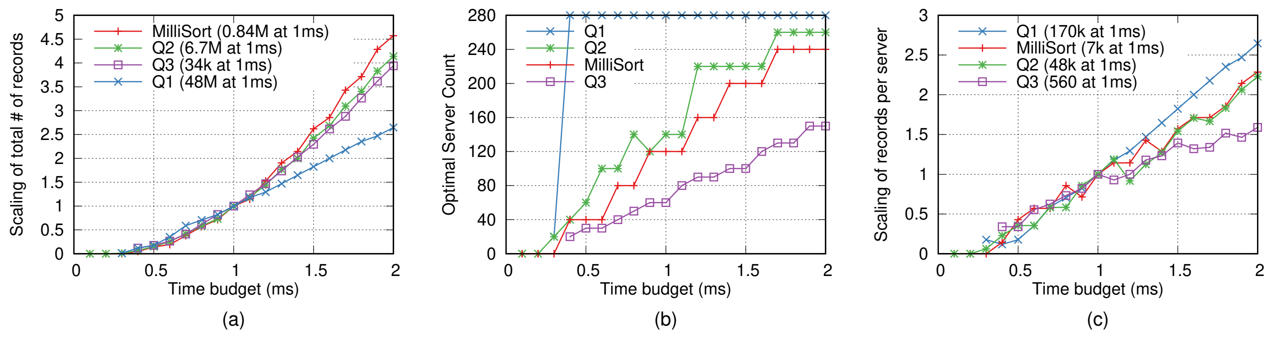

Figure 4: Scaling properties of MilliSort and MilliQuery as a function of time budget: (a) size of dataset processed (normalized to a value of 1.0 for a 1 ms time budget for each benchmark); (b) cluster size that yields the largest dataset processed; (c) records per sever at largest dataset processed (also normalized to a value of 1.0 for a 1 ms time budget).

	120 servers (0.84M records)				**240 servers** (1.68M records)			
Phase	Mean	Max	%	Max/Min	Mean	Max	%	Max/Min
Local Sort	147.0	216.3	22.2%	1.83	137.8	202.3	12.7%	1.77
Partitioning	200.5	214.4	22.0%	1.16	410.4	428.6	26.9%	1.11
Pivot Shuffle	83.2	87.9	9.0%	1.13	219.3	240.1	15.1%	1.27
Shuffle	377.2	402.8	41.3%	1.16	738.9	789.0	49.6%	1.14
Rearrangement	128.1	142.7	14.6%	1.18	146.9	173.3	10.9%	1.26
Total	942.3	976.0	100%	1.09	1523.8	1591.1	100%	1.08

Table 4: Time breakdown of each MilliSort phase with two different cluster sizes, where per-node dataset sizes are fixed at 7000 records. All times are in µs and reflect the median over 200 runs. "%" is the time spent by the slowest server for that phase, as a fraction of total time. "Max/Min" is the ratio of times for the slowest and fastest servers for that phase. "Partitioning" includes the time spent on "Pivot Shuffle".

6.1 Overall performance

We varied the amount of data per server and the size of the cluster to find the largest amount of data that can be processed by each of the applications in either 1 ms or 10 ms; Table 3 shows the results, along with the best configurations for each interval. With a 10 ms time budget all of the applications can harness all 280 available servers and they can process 2.2–224M records, depending on the application. A 1 ms time budget is more challenging for most of the applications. Only MilliQuery Q1 can use all of the servers; the other applications ranged from 60–140 servers. The amount of data processed in 1 ms varied dramatically among the applications, from a low of 34K records in MilliQuery Q3 to a high of 48M records in Q1.

6.2 Quadratic scaling

The total number of records that can be processed in an interval varies quadratically with the size of the interval. If the time budget increases by a factor of X, we observe that both the data handled by each server and the number of servers increase by at least X, for a total increase in throughput of at least X^2. This effect can be seen in Figure 4. Figure 4(a) shows that all of the benchmarks except Q1 exhibit quadratic or better scaling as the time budget increases from 1 ms to 2 ms. Q1 would scale exponentially if more servers were available, but it already used all of the available servers at 1 ms, so it can only scale linearly by increasing the amount of data per server. Figure 4(b) shows optimal cluster size as a function of time budget. All except Q1 exhibit almost linear scaling. Figure 4(c) shows the scaling of the per-server dataset size as the time budget increases. All except Q3 scale at least linearly, after a fixed initial overhead. Q3 scales per-server records slightly less than linearly.

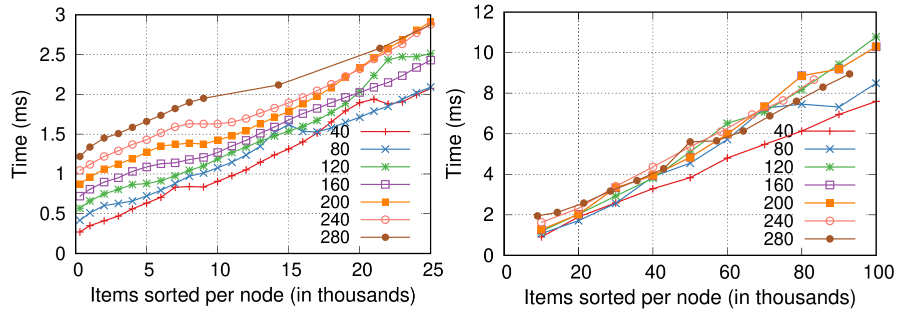
The quadratic behavior can also be seen for Q3 in Table 3: its throughput scales by 68x as the time budget increases from 1–10 ms. Scaling for the other applications becomes limited by the available servers long before reaching the 10 ms time budget; Figure 4(b) shows that MilliSort, Q1, and Q2 have consumed almost all the available servers with a 2 ms time budget. Linear scaling of servers suggests that these applications could harness at least 1200 servers with a 10 ms budget (5x the number at 2 ms).

6.3 Scaling below 1 ms

Quadratic scaling also means that throughput drops rapidly with time budgets less than 1 ms. This is visible in Figure 4(a). With a time budget of 0.5 ms, throughput has dropped by more than 4x for all of the applications, and none of the applications has appreciable throughput for budgets less than 0.5 ms. For these applications, the lower bound on useful timescale is around 0.5–1.0 ms with our current per-message overheads.

6.4 Limiting factors for scalability

There are two primary factors that limit the ability of the applications to scale up in servers or down in time: coordination and shuffles. The costs of both activities increase with the cluster size; when the amount of data per server is zero, these are essentially the basic costs of harnessing servers. Table 4 illustrates the effect of these two factors by showing the cost of each MilliSort phase for two different cluster sizes with the records per server held constant. In the 120-server configuration, partitioning and shuffles take 63% of the total running time. If the cluster size is doubled, the time taken by these two activities is also doubled (1218 µs vs. 617 µs), even though each server still processes roughly the same amount of data. The fraction of total running time consumed by coordination and shuffles increases from 63% to 77%. At the same time, the combined cost of other phases remains almost constant in both configurations. In general, when the time budget is held constant, larger clusters result in larger basic costs, so less time is left for actual work such



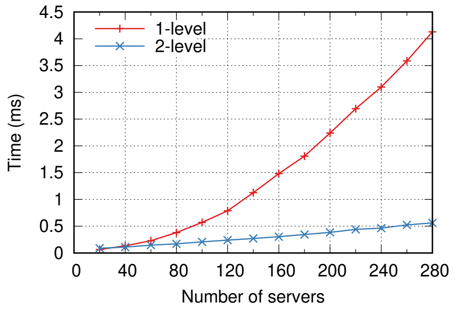


Figure 5: Total sorting time for MilliSort as a function of records per server, with different cluster sizes. The left figure assumes a 1 ms goal and the right figure assumes 10 ms. Each line represents a different cluster size (the number in the legend is the server count). Each data point is the median time from 200 runs.

Figure 6: MilliSort's partitioning time as a function of cluster size with different partitioning schemes.

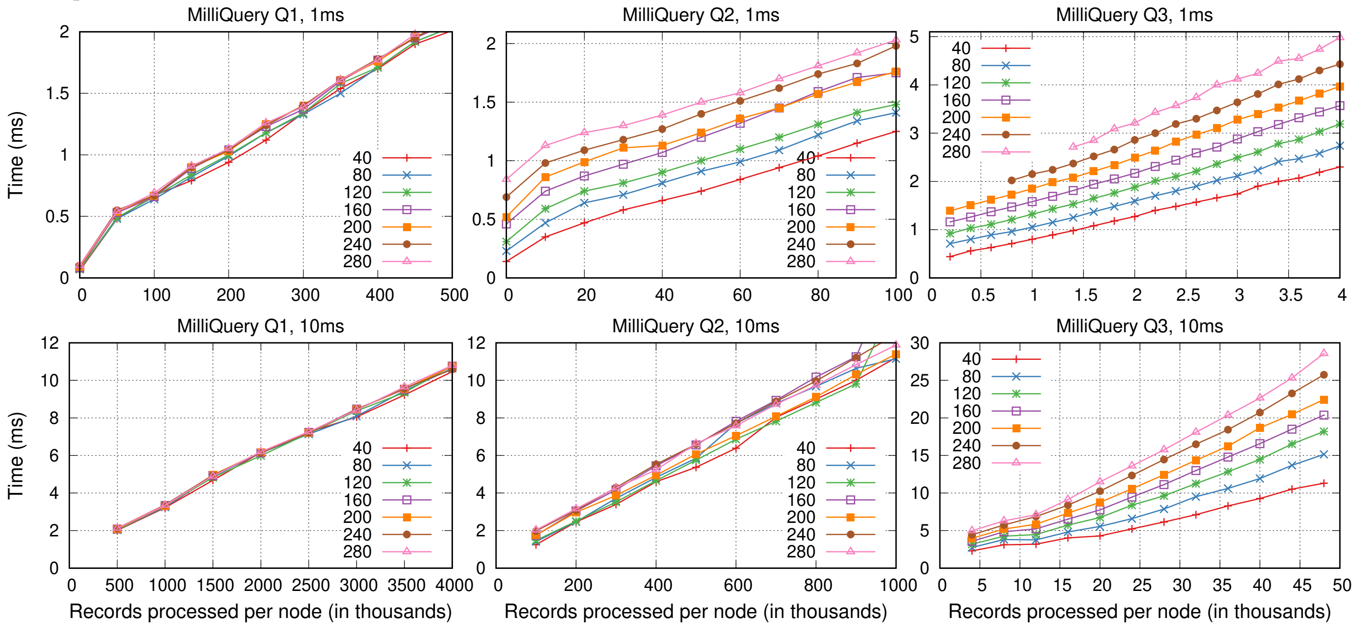

Figure 7: Total processing time for the three MilliQuery queries as a function of records per server, with different cluster sizes. From left to right, the figures represent Q1, Q2, and Q3 respectively. Each data point is the median time from 100 runs.

as local computation and data transfer. As a result, this limits our ability to harness more servers within the time budget or perform meaningful flash bursts in smaller timescales.

Figure 5 and 7 provide more details of the two limiting factors for MilliSort and MilliQuery by showing how the total processing time changes with the cluster size and amount of data per server. In most graphs of Figure 5 and 7, the lines for different cluster sizes are roughly parallel, indicating that the marginal cost of handling additional data is about the same for all sizes (the marginal cost starts higher when the amount of data per server is smaller, but plateaus out quickly once the benefit of batching diminishes). However, larger cluster sizes have larger fixed overheads (y-intercepts of the lines), which consist of the partitioning cost plus the per-message costs of the shuffles (a shuffle must send one message to each peer, even if it only contains a single record). These figures also show the diminishing returns at timescales less than 1 ms: even as the number of records per server approaches zero, running times remain 0.3–1.2 ms and 0.15–0.84 ms for MilliSort and MilliQuery Q2 respectively, depending on cluster size.

MilliQuery Q3 difers from the other applications in that its total processing time increases more than linearly with the input records per server, and the rate of increase is higher for larger clusters (the gaps between the lines in the right graphs of Figure 7 become wider for larger numbers of input records). This is because Q3 uses join operations where the number of output records tends to increase quadratically with the number of input records, so the number of input records doesn't reflect the actual number of records each server has to process.

Different applications have very different fixed overheads of harnessing servers. Q1 has the smallest fixed overheads and they are about the same for all cluster sizes. This is because Q1 requires very little coordination and doesn't use shuffle; the only communication primitives used by Q1 are broadcast and gather, whose overheads increase only in log scale with the cluster size. MilliSort and Q2 are very similar: their fixed overheads increase almost linearly with the cluster size since both applications require a big shuffle at the end. However,

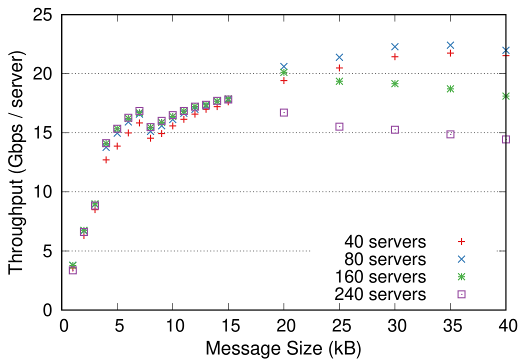

Figure 8: Stand-alone shuffle benchmark performance as a function of the cluster size and the message size (amount of data sent from each source to each destination).

for the same cluster size, the fixed overhead of MilliSort is higher due to the additional partitioning cost (with 2-level partitioning, this cost also increases almost linearly with the cluster size; this will be discussed in Section 6.6). For the same reason, the lines of Q2 in the graphs are closer than the lines of MilliSort. Finally, the fixed overheads of Q3 are about 3x higher than Q2 for all cluster sizes (unfortunately, it's hard to see in the graphs), as Q3 requires a total of three shuffles.

Figure 5 and 7 also show that efficiency improves with increasing records per server. For MilliSort, once the number of records per server reaches about 25000, the coordination costs become small compared to other factors and the shuffle efficiency improves, so there is little difference in overhead between different cluster sizes (the 40-server cluster remains significantly more efficient than the other cluster sizes because it avoids contention in the network core; this will be discussed in Section 6.5). The closeness of the lines in these 10 ms graphs indicates that all applications except Q3 could easily harness many more than 280 servers efficiently with a 10 ms time budget.

The next subsections discuss shuffle and partitioning costs in more detail.

6.5 Shuffle efficiency

Shuffles present the most significant challenge to scalability in our experiments, especially at 1 ms time scales. This is reflected in Table 3: Q1, which has no shuffles, can harness far more servers and process far more data than the other benchmarks, while Q3, which has three shuffles, is the least scalable. MilliSort and Q2, which each use one shuffle, fall in between. In Table 4, when the number of servers doubles while fixing the number of records per server, 85% of the time increase comes from additional shuffle costs; shuffle costs affect not only the main shuffle phase, but also the partitioning phase.

To get a better understanding of shuffle costs, we ran a stand-alone shuffle benchmark in which each of a group of servers sends a fixed-size message to each other server. Figure 8 graphs shuffle performance in terms of throughput per server. We ran four servers per machine, so the ideal throughput per server would be 25 Gbps.

We observed two different potential reasons that contribute to the higher shuffle time with more servers. First, as the message size decreases, efficiency drops because of per-message overheads. With 120 servers and 0.96M total records, the average message size for shuffle is about 6.7KB, which still provides a good throughput. However, with 240 servers and 1.92M total records, the average shuffle message size drops to about 3.3KB, resulting in less than 10 Gbps throughput per server. This also justifies the quadratic scaling property discussed in Section 6.2; when the number of servers and number of records per server are scaled simultaneously, we have a better chance of maintaining shuffle efficiency since the average message size for shuffle is fixed.

Second, even with large messages, throughput per server drops as the cluster size increases. It drops from 22 Gbps per server (with 40 servers) to less than 15 Gbps per server with 240 or more servers. This is because the cluster network uses flow-consistent load balancing, rather than packet-level load balancing. With large numbers of active transmissions, paths conflict in their link usage, resulting in congestion on those links and under-usage of other links. As the cluster size increases, shuffles consume a larger fraction of the core bandwidth, which makes congestion more likely, and our high-entropy approach to shuffles cannot completely compensate. As a result, shuffles cannot harness the full bisection bandwidth offered by the network. We speculate that more granular in-network load-balancing techniques such as [47, 64] may help remove this bottleneck in the future.

6.6 Partitioning cost

Figure 6 shows the results of a stand-alone experiment that measures partitioning time as a function of the number of servers. The multi-level partitioning algorithm we developed for MilliSort provides a significant peformance benefit: by the time the number of servers reaches 200, the 2-level approach is more than 5x as fast as the 1-level approach. As the number of servers increases, the partitioning time increases super-linearly for both 1-level and 2-level partitioning schemes. However, for 2-level partitioning, the increase in time is almost linear up to 280 servers (each additional server adds about 2 µs in our current implementation). A 1-level approach is too slow to harness 100 or more servers in a 1 ms budget, but a 2-level approach can easily coordinate 120 servers within 1 ms and 280 servers within 10 ms. In the best configurations for 1 ms and 10 ms time budgets, the partitioning cost only accounts for about 20% and 5% of the total time, respectively. Unfortunately, even with 2-level partitioning, the coordination cost for 280 servers is already more than half a millisecond; this prevents us from harnessing hundreds of servers in 1 ms for MilliSort. We didn't implement 3-level partitioning and beyond, but we expect that increasing the number of levels will further reduce the coordination cost for large clusters.

6.7 MilliSort efficiency

It might seem that flash bursts must sacrifice throughput (or efficiency) in order to operate at millisecond timescales.

	Throughput (efficiency)	
	120 servers (0.84M records)	**280 servers** (26M records)
MilliSort	7172 (19.6%)	10378 (33.1%)
Ideal Distr. Sort	11272 (30.8%)	13600 (43.3%)
Local Sort	36656 (100%)	31398 (100%)

Table 5: MilliSort efficiency of the best configurations for 1 ms and 10 ms time budgets, compared to local sort and ideal distributed sort. Throughput numbers are in "records/ms/server". Efficiency is the relative throughput compared to local sort.

	CPU	**SMT**	**BW/core**	**Throughput**
MilliSort	Xeon Gold 6148 @ 2.4GHz	1	3.1	1297 (1.00x)
TencentSort	IBM POWER8 @ 2.9GHz	8	5.0	1977 (1.52x)
CloudRAMSort	Xeon X5680 @ 2.9GHz	2	2.7	707 (0.55x)

Table 6: Per-core throughput comparison of MilliSort, Tencent Sort [28], and CloudRAMSort [34]. "SMT" (i.e., simultaneous multithreading) is the number of hardware threads per core. "BW/core" is the average network bandwidth per core, in Gbps. "Throughput" numbers are in "records/ms/core". MilliSort's per-core throughput is computed from the 10 ms configuration in Table 5, while Tencent Sort and CloudRAMSort's numbers are computed from their published results [28, 34]. Tencent Sort's reported throughput is for sorting from disk to disk; we estimate that less than half of the time is spent on disk I/O, so we double its reported throughput for a fair comparison.

However, our results suggest that this need not be true. Table 5 shows the overall efficiency of MilliSort compared to purely local sort and ideal distributed sort. The ideal distributed sort represents an imaginary situation where the partitioning cost is zero and data are shuffled at full network bandwidth; this provides an upper bound on the throughput of any distributed sort. Despite operating at a 1 ms timescale, MilliSort is relatively efficient (e.g., the maximum possible throughput for distributed sorts is only about 50% higher); MilliSort is even more efficient at a 10 ms timescale.

MilliSort's throughput is also on par with state-of-the-art sorting systems [34, 28] that have much longer running times. Table 6 summarizes the hardware differences and presents the throughput numbers in "records/ms/core" for comparison. In particular, Tencent Sort [28] is the current record holder for the GraySort benchmark [61], and its total running time is about 100 seconds. MilliSort's throughput per core at 10 ms is only 33% lower than Tencent Sort, even though Tencent Sort's POWER8 cores have 8x the hardware threads and 1.6x the average network bandwidth of MilliSort cores.

Table 5 also provides insight into why distributing data at very fine granularity makes sense. Network communication is the largest source of overhead for distributed computation (the throughput of local sort is 3–5x higher than MilliSort in Table 5). However, most of this cost is paid immediately when scaling beyond a single machine. For example, performing a distributed sort with just two machines requires half of the data to be sent over the network. There is not much additional loss in efficiency when scaling out further. This suggests that if you can afford to distribute at all, you can afford to distribute a lot.

7 Observations

This section summarizes the key observations that emerged from our MilliSort and MilliQuery experiments:

Granular data distribution. Distributing data in fine granularity allows one to harness more CPU cores and aggregated network bandwidth for faster computation and communication. Our experiment also confirms that, at least for some dwarfs, it is possible to scale out quite efficiently even at millisecond timescale. Thus, we predict that future distributed data-parallel systems will need to be optimized for large scale-out architectures with smaller data per server. This will likely present interesting challenges to the design of future systems since they will be required to scale down gracefully (i.e., operate efficiently even on smaller data).

Efficient group communication is essential. Even simple dwarfs have complex communication patterns internally; all of the benchmarks except MilliQuery Q1 depend heavily on group communication. Even when carefully optimized, they account for 50%–60%, 35%–40%, and 50%–65% of the overall running time in the best configurations of MilliSort, MilliQuery Q2, and MilliQuery Q3, respectively.

Per-message overhead is critical. Network bandwidth and latency are well known to be important for the performance of large-scale systems, and they remain important for flash bursts. Flash bursts differ from traditional large-scale systems in that per-message costs are at least as important as the traditional metrics. This is because group communication primitives tend to generate many small messages when operating at small time scales with large cluster sizes.

Coordination must be structured hierarchically. It is well known in the HPC community that communication must be structured hierarchically to handle large cluster sizes. Thus, group communication primitives are commonly implemented in a tree or hypercube topology [62], so that each machine only communicates with a small number of its peers. This helps to mitigate per-message overheads and harness more aggregated network bandwidth. This principle also applies to coordination. As an example, MilliSort's partition phase is structured as a hierarchical series of distributed sorts, so that the computation doesn't become a central bottleneck.

Low-latency shuffle is challenging. Of all the group communication primitives, shuffle is the most challenging in flash bursts. There are several reasons for this. First, per-message overheads become critical since shuffles require each server to send many small messages. Unlike other primitives, a hierarchical approach to shuffles generally isn't practical because it doubles the network bandwidth utilization. Second, shuffles need to use the full network bandwidth of each server for best performance, but many networks do not provide full bisection bandwidth, especially at large scale. Even where full bisection bandwidth is available, transient congestion can occur due to imperfect bipartite matching, either in the network itself (because of routing) or in the application.

Finally, hash partitioning often results in non-trivial data imbalance (e.g., in MilliQuery Q2, the most unlucky server typically has to process 1.5x much data as the average).

Quadratic scaling. As the time budget increases, the number of machines that can be harnessed effectively increases at least linearly. The amount of data each server can process also grows at least linearly with the time budget, so the overall dataset size grows at least quadratically with time budget. For some workloads, such as MilliQuery Q1, where the only coordination overhead is a final aggregation, the number of machines can grow exponentially with the time budget, so the dataset size grows faster than quadratically. The flip side of this is that reducing the time budget results in superlinear reductions in the number of servers and overall dataset size, which creates a lower limit on the timescale at which the system can operate efficiently. In our experiments, 1 ms appears to be tractable for all of the workloads except MilliQuery Q3. Future systems that are built on top of better networking infrastructure will likely enable these workloads to run efficiently at an even smaller timescale.

Ultimate limits of strong scaling. If we increase the number of machines while fixing the dataset size, efficiency inevitably decreases; this eventually prevents us from harnessing more machines to speed up the job. While it is well known that the theoretical speedup of a parallel program is ultimately limited by its serial portion (Amdahl's Law), this is not the limiting factor in our experiments. Instead, two other factors result in the drop in efficiency. First and foremost, coordination cost rises. This is mostly due to per-message overheads (e.g., manifested as higher shuffle costs). Coordination algorithms also take longer to run (e.g., MilliSort's partitioning time increases linearly with the number of servers, even with the recursive scheme). Second, straggler effects are more significant when there are more servers and less data per server (e.g., even in MilliQuery Q1, the overall efficiency drops about 50% when scaling from 40 servers to 280 servers).

8 Applicability of results

We conducted our experiments with limitations and assumptions that may not apply to today's computing systems. In this section we discuss some of these factors and argue that our results will be relevant for future systems.

Is 1–10 ms the right target? 1–10 ms is not the timescale at which most people think of large-scale distributed computation today. For example, response times for users of a few hundred milliseconds are considered adequate, and it can take 100 ms just to communicate between browser and datacenter. However, applications such as AR/VR require response times of 10 ms or better, and new edge computing offerings such as AWS Local Zones and WaveLength [6] can already provide single-digit millisecond latency between the end-user and an edge cloud. Furthermore, there are increasing numbers of applications that make real-time decisions without humans in the loop. Examples include controllers for autonomous vehicles [42] and IoT devices [24], which make decisions on the order of 10 ms, and financial applications [22, 51], for which there appears to be no lower bound on desirable latency. Flash bursts can enable these applications to run data-intensive algorithms at millisecond timescale.

Idealized experiment setup. Our experiments are conducted on a bare-metal HPC cluster with no interference from competing workloads. A dedicated cluster is not economically feasible in practice; however, we believe that recent work on colocating latency-critical and batch jobs [48, 18] can be applied to achieve high CPU efficiency without hurting the performance of flash bursts. In addition, we assume input data are resident in memory when the experiments start. This may not be a realistic assumption today, where data is stored on flash or disk. However, future datacenter systems are likely to store data in nonvolatile memories (NVMs) with access times not far above today's DRAM [27]. Ideally, future applications will run directly on NVM-based storage servers; in the worst case an initial shuffle step will be needed to extract data from the storage servers to computational nodes.

Missing pieces. Given the tight time budget, a flash burst requires every component involved in its lifetime to support low latency. There are several elements that our work did not address, such as application loading, but there are many other projects attacking these pieces, such as storage systems [49, 12, 41, 36, 25], cluster schedulers [31], networking infrastructure [46, 32, 43, 37, 14], fast threading and dispatching [8, 52, 30, 48, 54], and lightweight virtualization [1]. Many interesting problems have yet to be solved [39] in order to create a unified flash burst infrastructure.

9 Related work

There are several efforts underway to support shorter task durations in a cloud setting. For example, major serverless platforms [5, 45, 20] can support tasks, also called serverless functions, as small as 100 ms. Although serverless functions were initially intended for simple microservices, many projects have successfully used them to parallelize jobs over thousands of cores in the cloud. To overcome the relatively high overheads of the serverless platform, these projects typically targeted compute-intensive workloads and large time budgets such as 1 min. ExCamera [17] harnessed 3600 cores for 2 mins for video encoding; gg [16] harnessed 384 cores for 1.5 mins for software compilation; PyWren [29] sorted 1TB of data in 204 seconds with 1000 workers; Sprocket [3] harnessed 1000 cores for less than 1 min for video processing. Finally, these projects have mainly focused on exploiting large parallelisms in applications and reducing monetary cost, as opposed to revealing or addressing the new problems that emerged by coordinating many nodes at small timescales.

In addition to serverless computing, HPC is another area that greatly inspires the development of flash bursts. Scalability is of utmost importance to HPC applications, and highly-optimized HPC applications can scale beyond ten thousand compute nodes in a supercomputer. Furthermore, unlike many data analytic workloads, traditional HPC workloads such as scientific simulation typically require frequent communication between compute nodes (e.g., at the end of each simulation timestep). Flash bursts share the goal of running communication-intensive workloads in a scalable way, and we borrow techniques that are well explored in the HPC community (e.g., efficient group communication primitives) to achieve this goal. However, flash bursts differ from HPC in two important aspects. First, HPC workloads usually run for much longer time (hours or more), so they don't expose the interesting problems of operating at millisecond timescales. Second, HPC workloads usually run in a cleaner environment which has less interference from other jobs, so system-level challenges such as performance isolation and resource utilization are less of a concern to HPC.

Shuffle is known to be one of the most expensive operations in distributed data analytics. Many projects have focused on optimizing its performance. Riffle [68] and Magnet [57] are two recent shuffle services designed to optimize disk-to-disk shuffle performance in Spark. Locus [53] implemented shuffle in a serverless setting by mixing different cloud storage services to balance shuffle performance and storage cost. Dataflow Shuffle [9] is an in-memory shuffle tier used by Google BigQuery. These systems focused on shuffling large data and did not address the challenges in low-latency shuffle.

Distributed sorting has been studied extensively for many decades, with a variety of well-established benchmarks [61]. Most prior work has focused on sorting on-disk data at large scale (e.g., TritonSort [55]). One exception is CloudRAMSort [34], which is designed to sort in-memory data to speed up database operations. It can sort 1 TB data in 4.6 seconds using 256 servers. As a comparison, the per-core throughput of MilliSort at 10 ms is almost 2x higher than CloudRAMSort despite operating at 1000x smaller timescales.

Another approach to speed up data-intensive computation is to exploit shared-memory parallelism on more powerful servers (i.e., scale-up). The major benefit of scale-up systems is efficiency because they can avoid the expensive network communication and overhead induced by fault tolerance. As shown in [13, 59], scale-up systems can be orders of magnitude faster than traditional systems like Spark [67]. However, there is a practical limit on the number of CPU cores available on a single server (a few hundred). Also, scale-up systems are much less flexible when the application requires fast data movement: if the input data need to be loaded over the network, the bandwidth of a single server will become a significant bottleneck. As a result, we expect both scale-up systems and flash burst to be valuable depending on the application.

10 Conclusion

MilliSort and MilliQuery demonstrate that several core patterns in data analytics can run efficiently at millisecond timescales. With a budget of 1 ms, most of the patterns can harness at least 100 servers; with a budget of 10 ms, our results suggest that most of the patterns can harness at least 1000 servers. Furthermore, our results indicate that there is only a small efficiency penalty for running at millisecond timescales. We identified two related problems that currently limit scalability: per-message costs and shuffle overheads. If future systems can improve on our implementation in these areas, it should be possible to execute large-scale computations even more efficiently, and at timescales even less than one millisecond. We do not yet know whether applications can take advantage of these small timescales, but we hope our results will encourage application developers to explore the potential benefits of running large-scale computations at millisecond granularity.

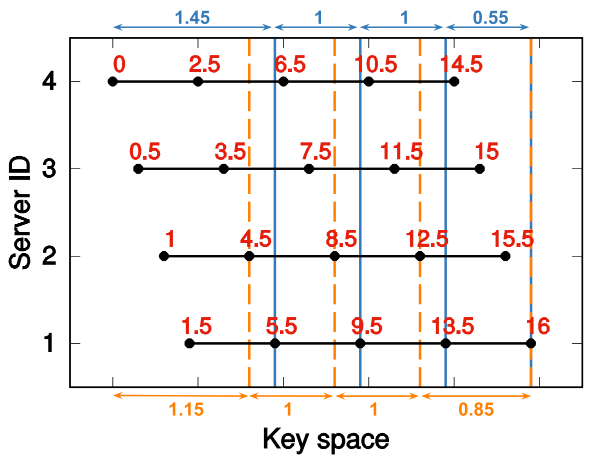

Figure 9: A comparison of the splitter selection algorithms on an example scenario. The keys of each server's data are uniformly distributed in a range indicated by a horizontal line, where dots are pivots (starting and ending pivots are not considered by the original algorithm). The splitters selected by the original algorithm are indicated with solid blue vertical lines. The splitters selected by the weighted algorithm are indicated with dashed vertical lines. The numbers on pivots are the cumulative pivot weights used by the weighted algorithm. The numbers on arrows above and below the diagram indicate the relative sizes of the buckets for the original and weighted algorithms, respectively.

A Appendix

A.1 Improved splitter selection

The splitter selection algorithm described in Section 4.2 tends to produce unbalanced partitions where the first server contains considerably more records than the last server. This imbalance can be explained by considering the groups of keys delimited by the pivots from each server; all of the groups contain about the same number of records. If we choose the Mth smallest pivot as the first splitter (assuming $s = 1$), then the first server will contain M full groups of records. In addition, it will contain some records from up to $M - 1$ additional groups, whose contents are divided between the first two servers (see Figure 9). Thus, the first server is likely to contain about $1.5M$ groups worth of records. In contrast, the last server will contain records from at most M groups, of which all but one are partial (some of their records have keys smaller than the last splitter). Thus, the last server will probably hold only about $0.5M$ groups of data.

To mitigate the data imbalance, we developed a new weighted approach to selecting splitters. The original approach behaved as if all of the keys in each group had the same value as the pivot at the end of the group. The new approach changes the weighting, so that half of the keys in each group are attributed to the beginning of the group and half to the end. Specifically, in the new approach, each server also includes its smallest and largest keys as pivots, and each pivot is annotated with a weight. The first and last pivots have a weight of 0.5 (half a group), and middle keys have

	120 servers (7000 records per server)							
	Uniform				Gaussian			
	Naive		Improved		Naive		Improved	
Pivots	P50	P90	P50	P90	P50	P90	P50	P90
120	33.6%	45.5%	6.9%	8.6%	37.6%	47.7%	6.9%	8.6%
240	23.5%	25.4%	4.4%	5.4%	23.4%	25.4%	4.4%	5.5%
360	15.9%	16.9%	3.1%	3.8%	15.9%	17.0%	3.2%	3.9%
480	11.5%	12.3%	2.5%	3.0%	11.6%	12.4%	2.5%	3.0%
600	9.6%	10.3%	2.0%	2.4%	9.7%	10.4%	2.0%	2.5%

Table 7: Excess records in the largest partition, relative to the average partition size, when using the improved splitter selection algorithm, vs. the naive algorithm. Input keys were drawn from two random distributions, and rows corresopnd to different numbers of pivots per server. "P50" and "P90" represent the median and 90th percentile over 1000 runs, respectively.

a weight of 1.0 (half of the preceding group and half of the following group). The annotated pivots from all servers are collected and sorted as usual. Then the pivots are scanned from smallest to largest, adding up the pivot weights; when a given pivot is reached, the cumulative weight is an estimate of how many groups worth of data have keys less than or equal to the pivot. The ith splitter will be the first pivot encountered where the cumulative weight is at least $i \times sM$.

We evaluated the improved mechanism for splitter selection by running stand-alone simulations with keys drawn from random distributions. Table 7 shows that the improved mechanism ensures that the largest partition is within 10% of the ideal size. Without the improvement, the largest partition will be 30-50% larger than ideal if the number of pivots per server equals the number of servers. Said another way, using the new splitter selection mechanism provides a greater benefit than increasing the pivots per server by 5x.

EPaxos Revisited

Abstract

This paper re-evaluates the performance of the EPaxos consensus protocol for geo-replication and proposes an enhancement that uses synchronized clocks to reduce operation latency. The benchmarking approach used for the original EPaxos evaluation does not trigger or measure the full impact of conflict behavior on system performance. Our re-evaluation confirms the original claim that EPaxos provides optimal median commit latency in a WAN, but it shows much worse tail latency than previously reported (more than 4x worse than Multi-Paxos). Furthermore, performance is highly sensitive to application workloads, particularly at the tail.

In addition, we show how synchronized clocks can be used to reduce conflicts in geo-replication. By imposing intentional delays on message processing, we can achieve roughly in-order deliveries to multiple replicas. When applied to EPaxos, this technique reduced conflicts by at least 50% without introducing additional overhead, decreasing mean latency by up to 7.5%.

1 Introduction

Consensus-based replication protocols such as Raft [23] and Multi-Paxos [15] play an important role in large-scale datacenter applications. These protocols have traditionally required two round-trip times (RTTs) between machines in order to ensure durability and consistency before returning results to clients. The latency impact of these RTTs is particularly severe in geo-replicated applications, which have replicas in geographically distributed datacenters with inter-datacenter RTTs of 100ms or more.

In recent years there have been numerous proposals for new consensus protocols built around a *fast path* that can complete many operations with a single RTT [16, 21, 24, 30]. Operations that meet certain conditions, such as being commutative with other pending operations, can proceed along the fast path, while operations not meeting the conditions require at least two RTTs.

Unfortunately, most of these proposals, particularly those that exploit commutativity, work best within a datacenter, where RTTs are low [16, 24, 30]. High network delays in a wide-area network (WAN) make it more difficult to exploit commutativity because they increase the window of time during which operations can conflict. As conflicts increase, fewer operations can complete in 1 RTT, which reduces the latency benefit of the protocol.

Egalitarian Paxos (EPaxos) [21] is a commutativity-based consensus protocol that claims to have low latency in a WAN. As with other fast-path protocols, the performance of EPaxos is heavily dependent on workload, as the workload determines the proportion of operations that are able to benefit from the fast path. The original EPaxos evaluation included multiple scenarios for command interference, which plausibly measured best and worse case performance.

However, while replicating the EPaxos paper results, we discovered that the original benchmarking methodology did not trigger, and the metrics chosen did not capture, the full impact of conflicts on EPaxos performance. We reproduced the original EPaxos results, then broadened the evaluation to cover a wider range of potential conflict behavior. We also collected different metrics, which we believe more holistically reflect protocol performance.

Our re-evaluation draws different conclusions about EPaxos than the original evaluation. The original evaluation concluded that EPaxos has optimal commit latency in a WAN, where "optimal" is defined as 1 RTT to a simple majority of replicas. We agree that many operations can achieve this optimal latency, but we show that the percentage of operations completing in 1 RTT varies greatly depending on the workload. In one of our experiments, this percentage was as low as 65%. We also demonstrate that the latency increase for conflicting operations is substantial; even with a safe upper bound on execution latency many conflicting operations experience latency that is more than 4x worse than that of Multi-Paxos.

In the process of evaluating EPaxos more deeply, we discovered two opportunities for improving EPaxos' performance. When EPaxos runs on highly skewed workloads, dependency chains can grow without bound, resulting in tail latencies above 5 seconds or even livelock. We found a simple modification to EPaxos that prevents unbounded dependency growth and ensures a tight upper bound on latency. Second, we improved EPaxos performance using synchronized clocks. We noticed that conflicts occur primarily because different replicas process operations at different times. We modified EPaxos to use synchronized clocks to ensure that all quorum replicas process a given operation at the same time. This reduces conflict rates by at least 50% without introducing any additional latency.

This paper makes the following contributions:

- We show how that the original EPaxos evaluation does not fully capture the impact of conflicts on system performance. The EPaxos benchmarking framework has been used by subsequent papers such as Bipartisan Paxos [30], so we think it is important to publicize these limitations to prevent them from propagating further.
- We re-evaluate EPaxos with an improved benchmarking framework that captures a wider range of possible conflict behaviors. Our evaluation shows that the benefits of EPaxos are narrower and the bad behaviors significantly worse than previously reported. It is not safe to conclude that EPaxos will improve performance for a given applica-

tion without knowing details of the application's behavior and whether tail latency matters.

- We show how synchronized clocks can be used to reduce EPaxos conflict rate and increase its feasibility for a wider range of workloads.

The remainder of this paper is organized as follows: Section 2 provides an overview of the EPaxos protocol. Section 3 describes how we were able to provide an upper bound on EPaxos execution latency. Section 4 describes how we improved EPaxos by taking advantage of synchronized clocks. Section 5 details the differences between our EPaxos evaluation methodology and the original. Section 6 evaluates EPaxos and our improvements. Section 7 discusses related work, and Section 8 concludes.

2 Egalitarian Paxos Overview

EPaxos claims three benefits: low latency for geo-replication, high throughput, and graceful performance degradation in the face of failures. In this paper we focus on the latency benefit: EPaxos can complete most operations in a single wide-area RTT. Consensus protocols typically require two RTTs to complete an operation: one for the client to communicate with one of the replicas, and another to communicate information among the replicas. Most consensus protocols, such as Paxos [15] and Raft [23], have a single leader through which all operations must pass, so for most clients both of the RTTs for an operation will require wide-area communication. In contrast, EPaxos uses a leaderless approach, so clients can communicate with the nearest replica, typically in the same data center. As a result, only the second RTT requires wide-area communication. The cost of the RTT from the client to the local replica is negligible in terms of overall operation latency.

The challenge for leaderless protocols such as EPaxos is to establish a consistent ordering between operations submitted to different replicas. When *interfering* operations (those that are not commutative) arrive concurrently at different replicas, the replicas must somehow agree on an ordering, so that all replicas execute the operations in the same order. In the worst case, reaching agreement will require at least two WAN RTTs among the replicas. However, in many cases a single WAN RTT provides enough information to allow safe execution. For example, one RTT is sufficient to determine whether concurrent operations are commutative; if they are, then the order of execution does not matter. The performance benefit of leaderless approaches depends on how many operations can take the one-RTT *fast path* as opposed to the two-RTT *slow path*.

EPaxos uses *dependencies* to implement its fast path. When an *originating* replica receives an operation from a client, it issues a WAN RTT to collect dependency information from other replicas. The dependencies describe operations that interfere with the new one. If a quorum of replicas returns the same dependencies, then the operation will take the fast path: the originator will be able to analyze the dependencies, determine the ordering, and execute the operation without initiating any more RPCs (in the absence of crashes). If different replicas return different dependencies, then a second WAN RTT is required to propagate the union of the dependencies to the quorum. After the second RTT, the quorum is now in agreement, so the operation is durable.

In EPaxos, durability is defined in terms of dependencies: once a quorum of nodes has persisted an operation and its dependencies, the operation is guaranteed to execute eventually, even in the face of crashes. EPaxos uses the term *committed* to refer to an operation that is durable in this way. At the time an EPaxos operation commits, it has not been executed and its execution order may not even be known. Nonetheless, enough information has been persisted so that the operation can eventually be ordered and executed.

In the remainder of this section we will separately describe the EPaxos commit and execution protocols.

2.1 Commit Protocol

When a replica receives an operation from a client, it assigns that operation to an *instance*. Instances typically contain a single operation, but a replica may choose to batch multiple operations into a single instance. When batching occurs, the dependencies for the instance include all the dependencies for its constituent operations.

Each instance is assigned a globally unique *instance number* consisting of a unique identifier for the originating replica and a sequence number within that replica. Instance numbers provide an ordering among all the instances from a given originator.

In addition to assigning an instance number to each instance, the originating replica also proposes a *dependency set* and *sequence number* for the instance. The dependency set consists of the highest conflicting instance number from each replica (in addition, all preceding instances for the replica are also treated as dependencies). The initial sequence number is chosen as one greater than the largest sequence number in the dependency set. As will be seen below, the sequence number is used to order operations that are mutually dependent. The originating replica derives the dependency set and sequence number for a new instance from all other instances it has knowledge of. The durable storage for each object in the system must include the highest instance number (and sequence number) for each replica that has modified the object.

The first WAN RTT for an instance, called the *PreAccept* phase, begins with these suggestions from the originator. The originator sends the instance, along with its dependencies and sequence number, to a quorum of other replicas. Each replica confers with its state to provide its own suggestion for dependency set and sequence number for the instance, based on all of the instances it knows about. If the peer disagrees on the dependency set or sequence number for the instance, it will merge its determinations with those of the originator. The peer will reply with a dependency set that is the union of the one it received and the one it determined from its state, and a sequence number that is the maximum of the two. The peer persists this information locally and will consider it when

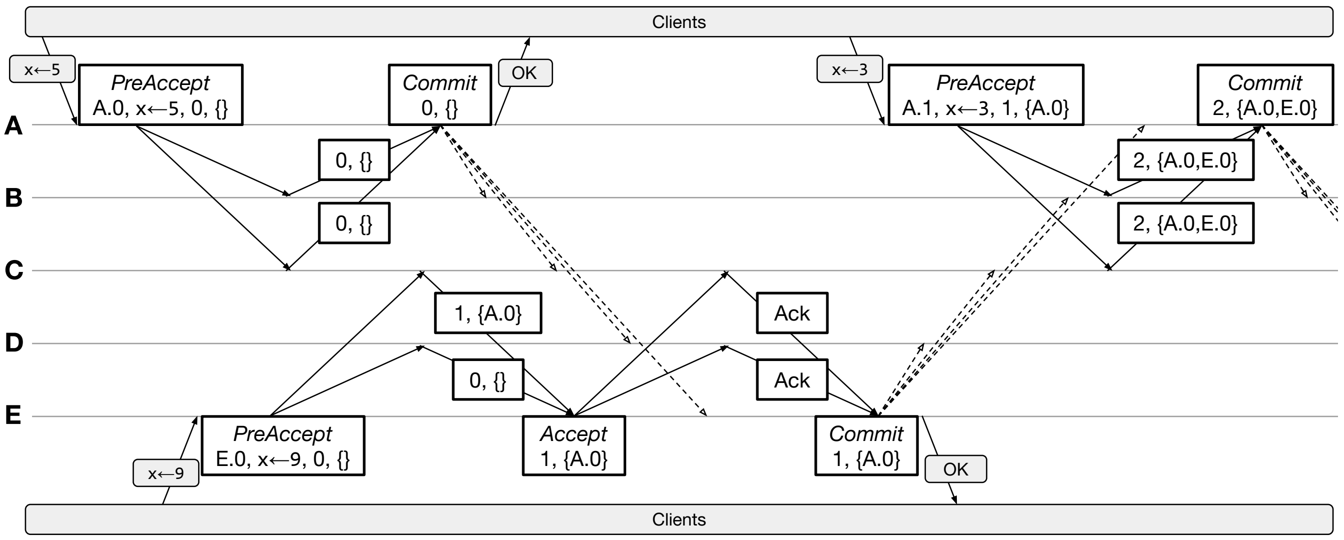

Figure 1: EPaxos commit protocol examples. A, B, C, D, and E are replicas in a key-value store. PreAccept boxes contain the instance number, operation, sequence number, and dependency set for the instance. Subsequent inter-replica messages contain only the sequence number and dependencies. For simplicity, we only show PreAccept and Accept messages to the necessary quorum, and commit messages are indicated by dotted arrows. This figure is adapted from the EPaxos SOSP presentation [18].

processing future PreAccept requests; in replying, the replica promises to reserve that sequence number and dependency set for that instance, until it hears otherwise from the originator.

If the originator receives identical responses from a quorum of peers, it can commit on the fast path. When this happens, it considers the instance committed; it sends Commit messages asynchronously to all other replicas and proceeds to the execution phase discussed in Section 2.2 below. For example, in Figure 1, a quorum of replicas A, B, and C agree on the sequence number and dependencies for instance A.0, so A.0 can commit on the fast path.

If the originator receives conflicting responses, it must issue a second round of RPCs for the instance, called the *Accept* phase. In the Accept phase, the originator merges the sequence numbers and dependency sets from the fast-path quorum's PreAccept replies and sends those to other peers. Because sequence numbers and dependency sets are strictly increasing, the Accept phase will always succeed; each of the recipients of an Accept request has already reserved a lower sequence number and smaller dependency set for the instance, corresponding to an earlier execution order, so it can surely accept higher ones, corresponding to a later execution order. In Figure 1, the PreAccept replies from C and D for E.0 differ, so E merges the responses and commits E.0 after the dependencies and sequence numbers have been replicated to the quorum.

An instance can still commit on the fast path if its originator disagrees with the PreAccept replies, so long as the replies agree with one another. Because sequence numbers and dependencies can only increase, the originator can increase its values for those properties to match the responses, achieving quorum agreement without further communication with other replicas. In Figure 1, instance A.1 can commit on the fast path because

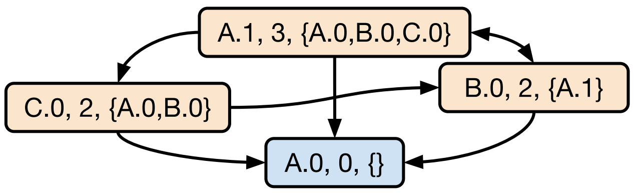

Figure 2: EPaxos execution algorithm example. Each node represents an instance, annotated with its instance number, sequence number, and dependency set. There are directed edges from each node to its dependencies. The nodes are colored by strongly connected component. Traversing the graph yields the execution order A.0, B.0, C.0, A.1.

B and C agree on its sequence number and dependencies. Although A did not initially agree with B and C, A increases its sequence number and dependencies to those agreed on by B and C in order to commit on the fast path.

EPaxos' fast-path quorum size is optimal for common 3- and 5-node cluster sizes. The EPaxos fast-path quorum size is $F + \lfloor \frac{F+1}{2} \rfloor$ replicas, where F is the number of tolerated failures and there are $N = 2F+1$ total replicas. For common 3 and 5 node cluster sizes, EPaxos' fast-path quorum is a simple majority. This is an improvement over the fast-path quorum of prior fast-path consensus protocols, such as Generalized Paxos [16], which has a fast-path quorum size that is always one node larger than that of EPaxos. The EPaxos slow-path quorum size is always a simple majority. EPaxos' quorum sizes are made possible by its crash recovery mechanism. The EPaxos crash recovery protocol is not relevant to the performance-oriented discussions in this paper, and is detailed in the EPaxos paper.

2.2 Execution Protocol

An instance's execution order is determined by creating and traversing a graph of its dependencies. This implies that an in-

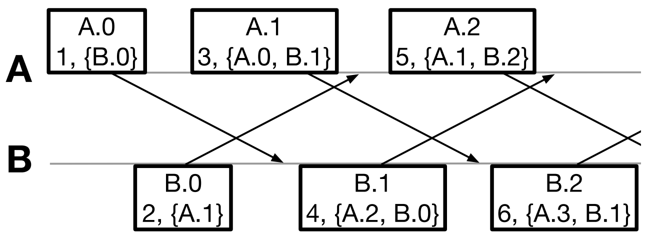

Figure 3: Example of EPaxos infinite dependency chains. Replicas A and B originate instances on the same hot key. In this example, there are three replicas in the system, but A and B are closer together and use each other as their quorum. The arrows indicate PreAccept messages and their timing. Each box contains the instance number, final sequence number, and final dependency set for the instance.

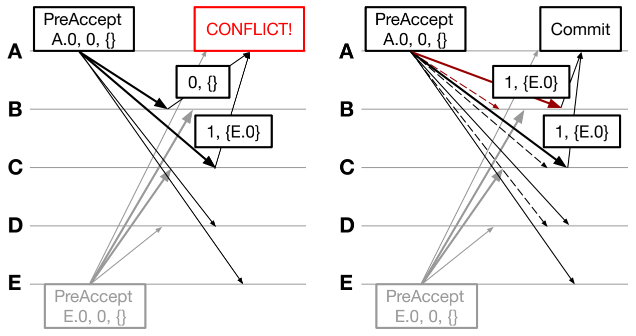
stance must wait for all of its transitive dependencies to commit before executing. In the dependency graph, nodes are instances and directed edges point from instances to their dependencies. As discussed in Section 2.1, if an instance is dependent on R.*n*, it is implicitly dependent on R.0 through R.(*n*-1), and R.0 through R.(*n*-1) would be added as nodes in the graph. The graph can be pruned to contain only those instances that have not executed and whose operations actually interfere with those of the current instance. The graph contains not just an instance's direct dependencies, but also the transitive closure of dependencies. In order to create this graph, and before it can be traversed, all transitive dependencies must have committed so that their sequence numbers and dependency sets are final.

Once an instance's dependency graph is final, it can be traversed to determine execution order. First, the graph is separated into strongly connected components – groups of nodes within which there is a path from each node to every other node. The strongly connected components are executed in reverse topological order. Within a component, instances are executed in order of increasing sequence number, with ties broken in a deterministic manner (e.g. by replica id). Figure 2 provides an example of the execution algorithm. In the example, A.0 forms its own strongly connected component, since it does not have any dependencies. Instances A.1, B.0, and C.0 form another strongly connected component. By reverse topological order, the strongly connected component containing A.0 will be executed first. Within the remaining strongly connected component, the nodes are executed in order of increasing sequence number, breaking the tie between B.0 and C.0 by replica id.

3 Bounding Dependency Chains

Execution latency is unbounded in the original EPaxos protocol because dependencies may chain recursively and an instance cannot execute until all of its transitive dependencies have committed. The EPaxos paper discussed this problem, but the problem did not occur with the workloads used for the original evaluation.

An instance's transitive dependency set can continually grow if new interfering instances are originated before all replicas become aware of prior instances. If this happens, the instance will wait on more and more recently added transitive dependencies to commit, and will be unable to execute. Figure 3 provides an example of this. In the example, a pair of replicas, each of which is in the other's quorum, continually originates new instances on some hot key. Although A.0 is originated first, B originates B.0 before B becomes aware of A.0. For this reason, A.0 becomes dependent on B.0. Similarly, B.0 becomes dependent on A.1, A.1 becomes dependent on B.1, B.1 becomes dependent on A.2, and A.2 becomes dependent on B.2. A.0 is now transitively dependent on B.2. With this behavior, this pattern could continue infinitely, causing execution livelock in the worst case. In practice, this problem causes high execution latency for skewed workloads, as demonstrated in Section 6.4.



(a) Unmodified EPaxos **(b)** With TOQ

Figure 4: EPaxos PreAccept phase example, with and without TOQ. Replicas A and E originate interfering instances A.0 and E.0 concurrently. Without TOQ, the responses from B and C differ for A.0. With TOQ, replica C delays processing the PreAccept for A.0 until the time that C processes it, avoiding conflict.

We are able to bound execution latency by pruning those transitive dependencies that will necessarily be executed after the current instance. Given two instances A and B, the EPaxos execution algorithm states that if B has A as a dependency and B has a higher sequence number than A, then B is serialized after A. The proof of Theorem 5 in the EPaxos proof of correctness [19] proves that, given this serialization, B will necessarily execute after A. Therefore, B can be pruned from A's execution graph. Any new interfering transitive dependency C of B will also necessarily execute after A, because C has a higher sequence number than A and has A in its dependency set, so it can be pruned as well. For example, in Figure 3, B.0 has a higher sequence number than A.0 and has A.0 as a dependency, so B.0 and its yet unknown transitive dependencies (A.1, and A.1's transitive dependencies) can be pruned from A.0's execution graph. With our modification, execution delay is bounded by approximately 3 WAN RTTs. Appendix A.1 describes the bound in more detail.

4 Using Synchronized Clocks to Reduce Conflict Rate

In this section we present a novel approach that reduces conflicts in EPaxos by taking advantage of synchronized clocks. We call this approach Timestamp-Ordered Queueing, or TOQ.

The benefits of EPaxos, and any commutativity-exploiting consensus protocol, depend on minimizing interference between non-commutative operations. By synchronizing the physical clocks of all replicas in the cluster, we are able to order instances so that all replicas process them in the same order, which can eliminate interference even for non-commutative operations. Our approach to ordering is an enhancement; out of order messages or poorly synchronized clocks may result in less conflict mitigation, but do not hinder correctness. We implemented our approach on EPaxos, but we believe it can be generally applied to any fast-path consensus protocol. (We leave this for future work.)

Conflicts occur when replicas learn about instances in different orders. In EPaxos, replicas first learn about an instance they did not originate through its PreAccept message. When the order in which a fast-path quorum processes interfering PreAccept messages differs, the quorum disagrees on the dependency information for those instances, causing them to take the slow path. Figure 4a illustrates an example of this. In the figure, replica A sends a PreAccept message for A.0 at the same time as replica E sends a PreAccept message for E.0. In the example, the fast-path quorum for instances originated from A consists of B and C. Replica B processes the PreAccept messages in the order (A.0, E.0), while replica C processes them in the order (E.0, A.0). Because of this difference in ordering, B and C respond to A's PreAccept with different sequence numbers and dependency sets, causing A.0 to take the slow path.

In the original EPaxos protocol, the order in which a replica learns about instances is determined by the one-way delay between the replica and the originators of the instances. In Figure 4a, the delay between A and B is shorter than that between E and B, and the delay between E and C is shorter than that between A and C. The difference in the one-way delays from the originator to each replica in the fast-path quorum determines whether an instance is ordered before or after instances that interfere with it. By the time a PreAccept message is processed by the furthest replica from its originator, the responses from the closer replicas are stale.

To reduce conflict rate, closer replicas can delay the time at which they process a PreAccept message until the time at which the furthest replica would process it. In Figure 4a, by the time C processes A.0, B and C have both processed E.0. If B were to respond at the same time as C, B and C would respond with the same dependency information. In Figure 4b, replicas delay processing PreAccepts until the time at which the furthest replica processes them. If B delays processing A.0 until the time that C processes it, both B and C have seen E.0 before A.0, and A.0 can commit on the fast path.

4.1 Design

Because replicas cannot intuit the time at which the furthest replica from the originator will process a PreAccept message, each PreAccept message includes a *ProcessAt* timestamp. Each replica will estimate the one-way delay from itself to all other replicas. The ProcessAt time will be the sum of the time at which the PreAccept is sent and the one-way delay from the originator to the furthest replica from the originator.

Each replica sorts PreAccepts in a priority queue based on the ProcessAt time of the PreAccept. Highest priority is given to lower ProcessAt times. An element is dequeued and processed once its ProcessAt time has passed. Because each replica receives the same ProcessAt time for a given instance, if PreAccepts are processed in order of their ProcessAt times then conflicts should not occur.

In order for instances to be totally ordered, a replica must also delay assigning dependency information to instances that it originates. To illustrate why this is necessary, we will look at an example of how conflict can occur when replicas do not delay their own instances. Hypothetically, if replicas A and B originate interfering instances A.0 and B.0 concurrently. A would process the instances in the order (A.0, B.0), and B would process the instances in the order (B.0, A.0). Instances will be processed out of order if a replica does not delay those instances it originates.

To delay the time at which a replica assigns dependency information to its own instances, we leverage the fact that the originator of an instance need not agree with the replies to its PreAccept messages, so long as the replies are unanimous. With TOQ, all PreAccept messages are sent out with sequence number 0 and empty dependencies. The originator adds its own PreAccept messages to its PreAccept priority queue and processes them at their ProcessAt time, consistent with the time they should be processed by the other replicas in the cluster. This means that an originator will not add its instances as dependencies of other instances until other replicas would do the same.

To maintain correctness, we needed to slightly modify the commit protocol for EPaxos. In unmodified EPaxos, an instance can commit on the fast path if the PreAccept replies are unanimous, even if the originator disagrees. With TOQ, since the originator modifies the dependency information for its own instances after it sends the PreAccept messages for them, it is possible that the originator would assign a greater sequence number or dependencies than would its quorum, even if the quorum agrees with one another. Instead of allowing the originator to disagree with the rest of the quorum no matter what, the replica can now disagree with the quorum only if the dependency information of the quorum is greater than that of the originator. Lemma 1 of the EPaxos proof of correctness [19], "EPaxos replicas commit only safe tuples," depends on a fast-path quorum recording the same tuple for any instance that commits in the PreAccept phase. With this modification, we ensure that this holds true.

4.2 Sync Groups

In practice, there is a tradeoff between reducing conflict rate and increasing the minimum latency for each instance. So far, we have described TOQ with the approach of synchronizing all PreAccept messages to all replicas in the cluster. To do this, the ProcessAt time for each PreAccept is the estimated time the PreAccept would be processed at the furthest replica. However,

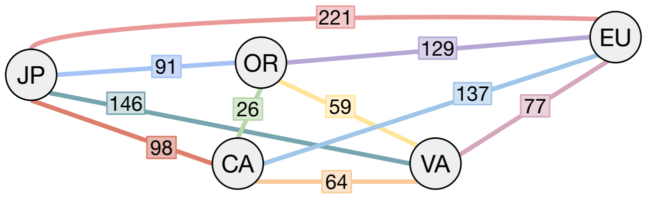


Figure 5: Round-trip times (in ms) between replicas in different locations in our test topology, as measured by the `ping` application. Replicas are located in Virginia (VA), California (CA), Oregon (OR), Japan (JP), and London (EU).

this increases the minimum possible latency for an instance. To illustrate this, we can use back-of-the-envelope calculations based on the RTTs from our test cluster, shown in Figure 5. The figure contains RTTs, and we estimate one-way delay to be half of RTT. Without PreAccept ordering, the minimum latency for an instance that originated in Japan would be 98ms, which is the RTT to the furthest replica in its quorum, California. With PreAccept ordering to the whole cluster, California would delay processing a PreAccept from Japan by the difference in the one-way delay between Japan and California and Japan and London, which is 61.5ms. This increases the minimum latency for an instance originated in Japan by more than 50%.

Another option would be to synchronize message ordering to the furthest replica in each originator's quorum. This approach has the same minimum latency as does unmodified EPaxos. However, syncing to just the quorum is less effective when it comes to reducing conflict rate. Each originator's quorum handles all of the originator's messages in the same order, but may handle messages originating from other replicas in different orders, leading to discrepencies in the dependency information in PreAccept replies.

A hybrid approach is to synchronize message ordering among a quorum *union*. This quorum union contains all replicas included in another node's fast-path quorum. With this sync group, conflicts should occur only when the originator assigned greater dependency information to an instance than did the remainder of its quorum. The benefits of this approach differ greatly depending on the topology; for some topologies, the quorum union might contain the entire cluster.

5 Capturing the Impact of Conflicts

The evaluation approach in the EPaxos paper used workloads that did not trigger the full range of conflict behaviors, and it chose metrics that did not measure the full impact of conflicts. As a result, its conclusions about performance are over-optimistic. In this section we discuss the implications of the original EPaxos evaluation and introduce the changes we made in our evaluation.

5.1 Commit vs. Execution

The EPaxos paper measures latency in terms of commit time, not execution time. Specifically, latency is measured as the time from initiation of an operation on a client until receipt of a commit acknowledgment from the local replica. This approach was chosen because a commit guarantees that an operation is durable and will eventually execute; thus clients need not wait for execution. However, this argument applies only to operations that return no results or errors, such as blind writes (blind writes are the only operation implemented in the EPaxos benchmarks). Commit latency is not globally sufficient; if a client depends on information returned by an operation, then it must wait for execution. For example, the write operations in both Zookeeper [1] and Redis [2] return results. Furthermore, if an operation can result in an error (such as attempting a bank account withdrawal without sufficient funds, or attempting to set a value in a table that has been dropped) then the client must wait for execution to complete. Furthermore, all reads must wait for preceding conflicting writes to execute. Thus, we think it is likely that most operations will require clients to wait for execution, and we argue that EPaxos latency should be measured with execution time, not commit time.

5.2 Access Patterns

One of the challenges in evaluating a protocol like EPaxos is that its performance depends on the application workload. The EPaxos benchmarks use a key-value store with an access pattern based on a single hot key. Each reference is made either to the hot key, or to a unique key that is never referenced by any other operation. Conflict rates are controlled by adjusting the fraction of references to the hot key (either 0%, 2%, or 100% in the EPaxos paper latency evaluation). This approach has two limitations. First, having all interference on a single key understates the impact of conflicts, since there can never be more than a single strongly-connected component in the dependency graph. Second, the EPaxos evaluation conflated the fraction of references to the hot key with the rate of conflicts in the EPaxos commit protocol; because conflict rate is a product of many additional factors, such as system load, the actual conflict rate is considerably less than the fraction of references to the hot key. For example, the workload labeled '100% interference', which was claimed to be worst case, produced actual conflict rates as low as 0%.

For our evaluation we used a Zipfian distribution [11], which is generally accepted as an approximation of real workloads. For example, both Memcached [6] and Facebook's social graph database [4] experience highly skewed workloads that approximate Zipfian. No single value of the Zipfian skew parameter is representative of all applications, so we made measurements with multiple values ranging from lightly skewed (.6) to highly skewed (.99). This covers the ranges used by other benchmarks such as Linkbench [3] and YCSB [12] and allows us to observe how application characteristics affect EPaxos performance.

We also used a mix of read and write operations in our evaluation, whereas the EPaxos paper used only writes. Read operations have different behavior from writes: they do not interfere with other reads, but they do interfere with writes. Thus the mix of reads and writes affects the conflict rate.

5.3 Load

The approach to load generation in the EPaxos paper minimizes opportunities for command interference, which results in over-optimistic conclusions about latency. First, the paper measures latency only at low system load; higher loads will result in more conflicts, which will increase latency. Furthermore, load is generated with a collection of closed-loop clients, each of which issues a continuous stream of back-to-back operations, with exactly one operation outstanding at all times. Load is controlled by varying the number of clients. We found that this produced a caravan effect, where large groups of operations passed through a replica at once, followed by gaps with no operations. This behavior is unlikely to occur in real applications, and results in an unvarying system load, while real systems are likely to experience bursts. Even systems that use server proxies for admission control still experience variation in load when they are not at maximum capacity. Finally, back-to-back operations result in uneven loading across clients: clients that are more centrally located have higher throughput than those further away, since throughput is inversely proportional to RTT with this approach.

For our measurements we used higher loads (typically 80% of the maximum sustainable load) and we used a Poisson process to schedule new operations, which results in uneven loading that better approximates real workloads. A Poisson arrival process is open loop, which means that care must be taken to choose an arrival rate that does not exceed the system's capacity. If a Poisson arrival process results in system overload, queues will grow without bound, the system does not reach a steady state, and performance measurements are unlikely to be meaningful. We monitored queue lengths in all of our experiments and chose arrival rates for which queue lengths remained bounded. In addition, we added a cap on the total number of outstanding operations for each client (the cap was never reached in our experiments).

5.4 Throughput

There are several confounding factors in the EPaxos throughput measurements, which make it difficult to determine whether the results reflect fundamental properties of the protocols or artifacts of the experimental setup:

- The throughput experiments were run in a LAN, not a WAN. WAN configurations are likely to have higher conflict rates because longer network delays increase the window for conflicts, leading to lower throughput.
- There were different approaches to generating load for different experiments, which led to inconsistent results. With one method, EPaxos '100%' has 12% higher throughput than Multi-Paxos, and with the other it has 27% higher throughput.
- The evaluation of batching (many operations per instance) does not consider the impact of batching on WAN latency.
- The evaluation only considers perfectly even load balancing across clients. Throughput would likely decrease if clients in different locations issued operations at different rates. Correcting for this with load balancing amongst the replicas would negate the latency benefits of EPaxos.
- Optimizations to Multi-Paxos were not considered. For example, the Multi-Paxos leader can hold a read lease for all objects.

5.5 Summary

Evaluation of EPaxos in Section 6 differs from the original EPaxos evaluation in the following respects:

- We measure execution latency, instead of commit latency.
- We use a Zipfian distribution for choosing keys to access, instead of a single hot key.
- We use a mixture of read and write operations, instead of all writes.
- We measure latency at about 80% of maximum throughput, instead of a lightly-loaded system.
- We use Poisson arrival rates, instead of back-to-back operations.
- We measure throughput in the same configuration used for latency measurements, instead of using a LAN configuration with batching.
- We measure a large number of different configurations with different write rates and Zipfian skew factors, instead of 3 hot fractions.

6 Evaluation

We had two goals in our EPaxos evaluation. First, we wanted to see whether our changes to the EPaxos evaluation would change the conclusions about EPaxos performance relative to Multi-Paxos. Our new evaluation confirms the original conclusion that many operations can achieve optimal latency. However, only operations that experience no interference can achieve optimal latency, and we demonstrate that conflict rate varies greatly by application (in our experiments, we measured conflict rates as high as 35%). Additionally, we show that conflicting operations experience significantly higher than optimal latency (more than 4x that of Multi-Paxos, even with our improvements).

Our second goal was to evaluate the effectiveness of TOQ. We found that TOQ is effective at reducing conflict rate, reducing EPaxos latency.

6.1 Experimental Setup

When evaluating EPaxos, we aimed to use an experimental setup as similar to that of the authors as possible. Our analysis is a fork of the EPaxos paper evaluation [20] and is available on GitHub [28]. We used Google Cloud servers in Virginia (VA), California (CA), Oregon (OR), Japan (JP), and London (EU). We used the `n1-standard-8` machine type with the Ubuntu 18.04.5 LTS operating system.

Unless otherwise specified, all experiments mitigate dependency chaining using the approach described in Section 3. EPaxos and Multi-Paxos replicate all operations, including reads. Workload does not impact Multi-Paxos, so we used a workload with a Zipfian skew factor of .9, 50% writes, and 1 million unique keys. Since any reference point is sufficient to see how conclusions change, we compare EPaxos against only Multi-Paxos.

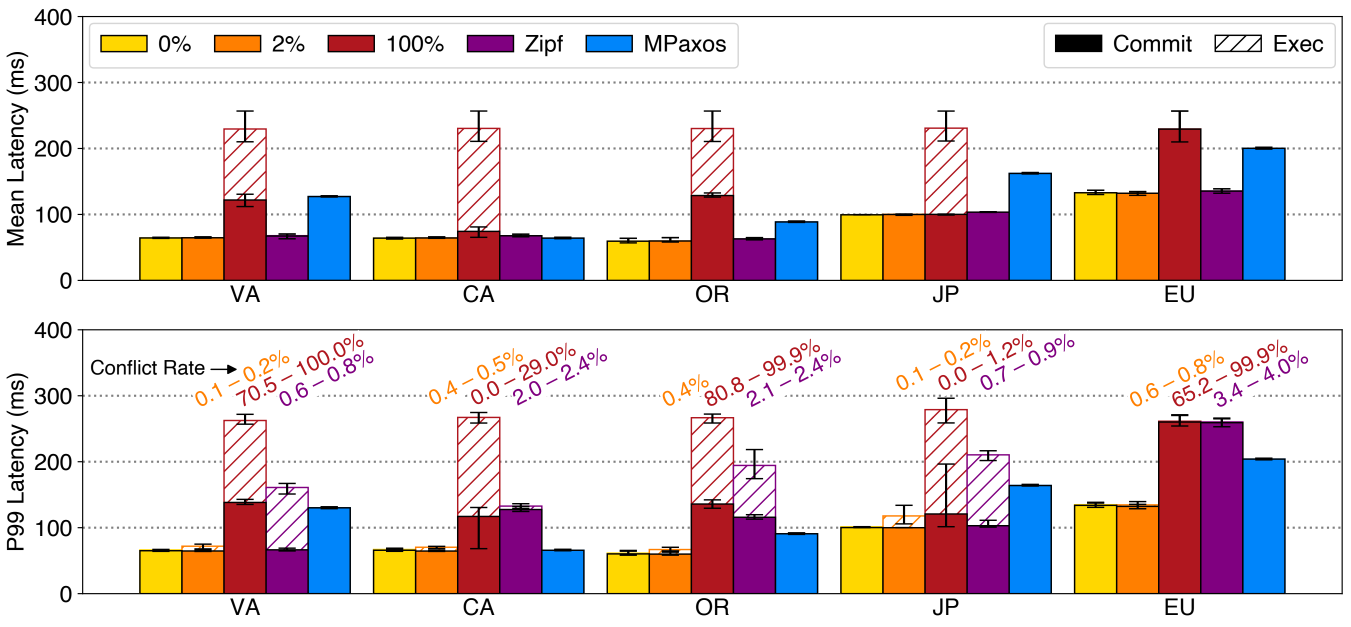

Figure 6: Comparing client-perceived commit and execution latency for EPaxos across a variety of workloads at each of the five sites. 10 clients at each site issue operations, all of which are writes, with outstanding operation at a time. This leads to a throughput of 500 operations per second for Multi-Paxos, 230 operations per second for '100%' and 650 operations per second for the '0%', '2%', and Zipfian workloads. All Multi-Paxos clients issue operations to the leader, which is in California; EPaxos clients issue operations to the replica in the same datacenter. The Zipfian distribution has a skew parameter of .9, 50% writes, and 1 million unique keys. We ran each experiment 5 times, capturing metrics for 60 seconds at steady-state. We show the average latency across the 5 trials, with error bars indicating the minimum and maximum latency of the trials. The range of conflict rates from the trials, measured on the servers, appears above the bar corresponding to the experiment.

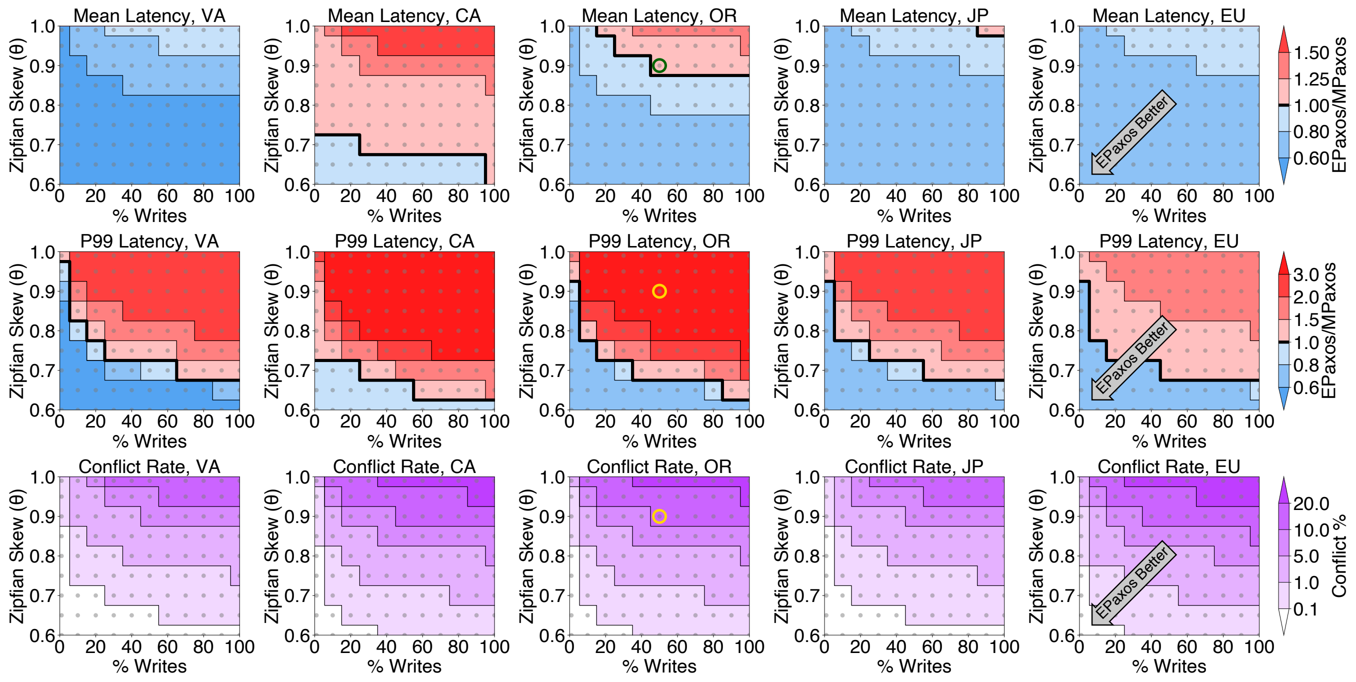

Figure 7: Comparing EPaxos and Multi-Paxos execution latency across a spectrum of Zipfian skew parameters and read-write ratios. Each grey dot corresponds to a workload on which EPaxos was tested. We divide the latency for each EPaxos experiment by Multi-Paxos' latency. Different fill colors represent different ranges of performance; for example, the darkest red color in the top graphs indicates that EPaxos mean latency was at least 1.5x that of Multi-Paxos. All workloads have 1 million unique keys, and all experiments were run at a throughput of 11,000 operations per second, which is 80% of the maximum throughput of EPaxos with a skew parameter of .99 and 100% writes. The circled point indicates the workload used for Figure 8.

We initially ran our experiments for both 3 and 5 replicas, but decided to only include measurements for 5 replicas because performance degraded similarly for both cluster sizes as we modified the experimental methodology. TOQ does not provide a benefit for 3 replicas because conflicts do not occur with a quorum size of 2 (the originator can simply agree with the first replica to respond).

We do not enable *thrifty* – a mode of operation in which PreAccept and Accept messages are only sent to the necessary quorum. We chose to disable thrifty because we wanted our results to be as favorable to EPaxos as possible. As detailed in Appendix A.2, thrifty increases EPaxos conflict rates, which makes latency worse. Thrifty provides the same throughput benefit for EPaxos and Multi-Paxos (about 15%), so enabling thrifty does not impact conclusions about throughput. Furthermore, TOQ is not compatible with thrifty. While decreases in conflict rate due to TOQ are much larger than those from disabling thrifty, we wanted it to be clear in our comparison that any decrease in conflict rate could be attributed to TOQ rather than from disabling thrifty.

6.2 Execution Latency

Our first experiment reproduces the basic commit latency results from the EPaxos paper (see Figure 6); we used the configuration from the EPaxos paper, without any of the changes described in Section 5. We report mean latency instead of median for reasons that will be discussed below. The results are very similar to those in Figure 4 of the EPaxos paper, except that we measured a lower 99th percentile latency for the ‘2%’ workload. This difference does not impact any of our conclusions.

Figure 6 has three additional measurements not present in the EPaxos paper. First, it includes execution latency as well as commit latency. When conflict rates are low, execution latency is indistinguishable from commit latency. However, with high conflict rates, the execution latency can be more than 2x the commit latency. For the pathological ‘100%’ workload, EPaxos execution latency is considerably worse than Multi-Paxos at every site, both at the mean and the 99th percentile. Second, we also measured a Zipfian access pattern; even at low load (about 4% of maximum possible throughput for this experiment), 99th percentile latencies for the Zipfian workload are significantly higher than for the ‘2%’ workload. 99th percentile execution latency under the Zipfian workload is worse than Multi-Paxos at every site. Third, we measured conflict rate on the servers. Primarily due to low load, conflict rates for the ‘2%’ workload were as low as 0.1% and conflict rates for the ‘100%’ workload were as low as 0%.

For the remaining experiments, we applied the evaluation changes discussed in Section 5. One of the challenges in benchmarking EPaxos is that performance varies drastically depending on the workload. It is not difficult to find arguably realistic workloads indicating that EPaxos is either very good or very bad. Thus, we don’t believe it is possible to evaluate EPaxos fairly with a few discrete workloads. Instead, we ran each of the remaining experiments over a large range of workloads, typically a full grid with 9 choices of Zipfian skew and 10 choices of read-write ratio. We then plot the data to show how certain system properties vary across the workloads. A potential EPaxos user can use these plots to determine whether EPaxos would provide performance benefits for their particular application. We tried to vary the workload enough to cover the full range of conflict behaviors likely to be experienced by real applications. The experiments were all run at 80% of the maximum throughput of the workload with the lowest maximum throughput. A consequence of keeping throughput consistent for all experiments is that the system is underloaded for many of the workloads. Appendix A.3 contains measurements showing that conflict rate and latency both increase as throughput increases.

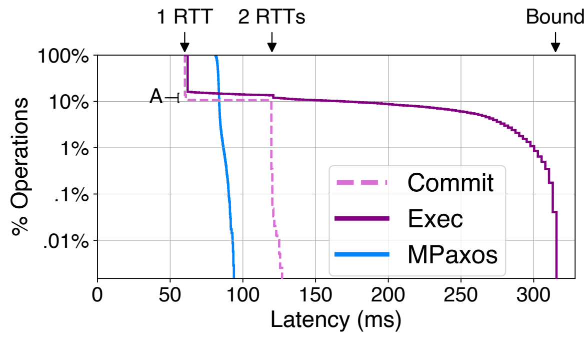

Figure 8: Complementary CDF of execution and commit latency. A point (*x*,*y*) indicates that a fraction *y* of instances had latency greater than *x*. The data was measured on clients at Oregon on a workload with 50% writes, Zipfian skew 0.9, and a load of 11,000 operations/sec. ‘A’ indicates the area of instances that experience execution delays despite taking the fast path.

Figure 7 compares the execution latency of EPaxos and Multi-Paxos across the grid of workloads. EPaxos has better mean latency for almost all of the workloads (except for clients in California, which can reach the Multi-Paxos leader without a WAN RTT). On the other hand, EPaxos has worse 99th percentile latency for almost all workloads. EPaxos cannot offer lower latency than Multi-Paxos if there is a conflict in the PreAccept phase, since this results in a second WAN RTT. For EPaxos P99 latency to be better than Multi-Paxos, less than 1% of operations must encounter conflicts; the bottom graphs in Figure 7 show that few workloads have this behavior. In addition to extra RTTs caused by conflicts, EPaxos can also incur execution delays while waiting for dependent operations to commit; Muilti-Paxos does not incur these delays.

Figure 8 exposes several interesting aspects of commit and execution latency:

- Most instances finish execution in one WAN RTT.
- The median latency for both commit and execution will be one RTT unless conflicts approach 50%, which never happened in our experiments. Thus, median latency reflects only network topology, not protocol response to workload.
- Instances that take more than one RTT for execution trend rapidly towards the worst-case delay for dependencies to commit. (‘Bound’ in the figure.)
- Execution latency is rarely in the vicinity of two RTTs:

if there is a conflict, there will probably be a significant dependency delay.

- A significant fraction of instances that take the fast path experience dependency delay. (This is indicated by the area between the lines at point 'A' in the figure.)
- The worst case performance penalty from EPaxos is greater than the best case performance gain; EPaxos fast path latency is 30% better than Multi-Paxos latency, while the slow path ranges from 40% to 240% worse.

Conclusions about EPaxos latency are almost entirely determined by the choice of metric. The original evaluation used median commit latency as the primary metric. This is the most favorable choice for EPaxos: median latency for EPaxos is independent of application behavior, identical for commit and execution, and uniformly better than Multi-Paxos. Tail latency is often used as a metric in both industry and academia; 99th percentile tail latency is also almost independent of application behavior for EPaxos, and it is significantly worse than Multi-Paxos, especially for execution. Workload differences tend to manifest themselves primarily in the range between the 50th and 99th percentiles, where most metrics will overlook them. We chose to use mean latency instead of median in our graphs, since it reflects some of these workload differences.

6.3 Benefits of TOQ

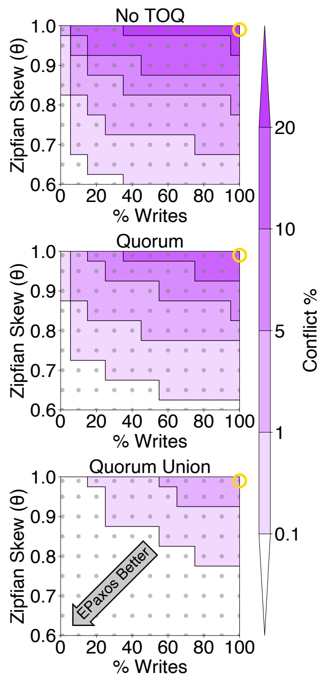
In order to evaluate TOQ we installed the Huygens [10] clock synchronization software to synchronize the clocks of all replicas in the cluster. This resulted in server clock offsets between 20µs and 1ms. The original Huygens evaluation measured clock offsets within 10µs; we believe that we experienced higher clock offsets because of differences in our environments (WAN vs. LAN and virtual machines vs. bare metal).

Figure 9 shows the benefits of TOQ. Quorum sync reduces conflict rates by at least 50% across locations. This reduces mean latencies, which improves the benefits of EPaxos relative to Multi-Paxos. Quorum sync has the advantage of not impacting minimum latency (latency is already limited by the most distant peer in the quorum; quorum sync delays the other peers in the quorum so they process PreAccept messages at the same time as the most distant peer).

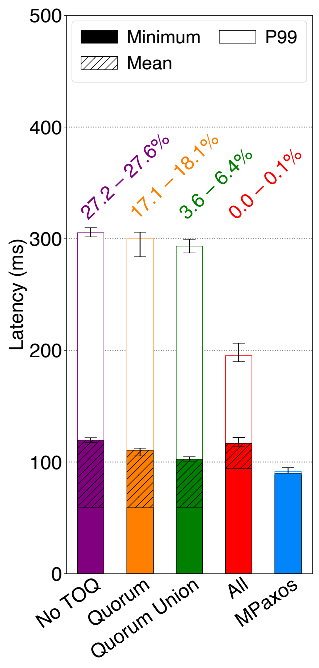
Quorum union sync introduces a performance tradeoff. It reduces conflicts by at least 85%, which improves worst-case latency. However, it increases minimum latency. For example, quorum union sync delays Japan's PreAccept messages until they would reach Virginia, which adds about 25ms to the minimum latency for operations issued by clients in Japan. This does not impact the minimum latency for Oregon in Figure 9b, but the impact on Japan can be seen in Figure 20 in the Appendix. Syncing to all replicas completely eliminates conflict, but increases minimum latencies so much that it makes this option unattractive.

6.4 Unbounded Dependency Chains

Our focus on execution latency, combined with Poisson arrivals, exposed the problem of unbounded dependency chains



(a) Conflict Rate



(b) Latency

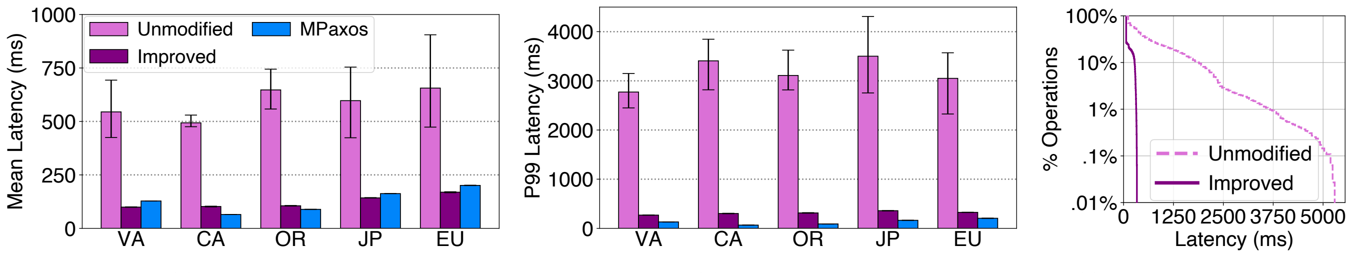
Figure 9: Conflict rate and execution latency for EPaxos with and without TOQ. Figure (a) compares conflict rates for different TOQ sync groups. Figure (b) compares Mean and P99 execution latency for the circled workload (Zipfian skew of .99 and 100% writes). 'Minimum' indicates the minimum possible latency for an operation given the protocol and sync group. Other than TOQ, the experiments for this graph were run with the same methodology as Figure 7. Error bars and conflict rates are shown as in Figure 6. The quorum union consists of Virginia, California, and Oregon. For measurements of sites other than OR, as well as the latency graph for a workload with Zipfian Skew .8 and 50% writes, see Appendix A.4.

discussed in Section 3. Figure 10 shows that EPaxos execution latency can be much higher than Multi-Paxos when it does not protect against infinite dependency chains. Before we implemented our optimization, we observed execution latencies as high as 5 seconds under high-skew workloads. Livelock occurred with the pathological '100% conflict' workload when we removed the cap on outstanding operations from our Poisson scheduler (the cap eventually prevents new operations from entering the system, so the existing operations can complete).

Figure 10c shows that our fix reduces tail latency significantly. The benefits are most noticeable for write-heavy workloads that are highly skewed. However, workloads that generally experience low conflict can still experience bursts of chained dependencies, leading to latency spikes that are surprising and difficult to diagnose. Section 6.6 below shows that that dependency chain optimization also has a significant impact on throughput.

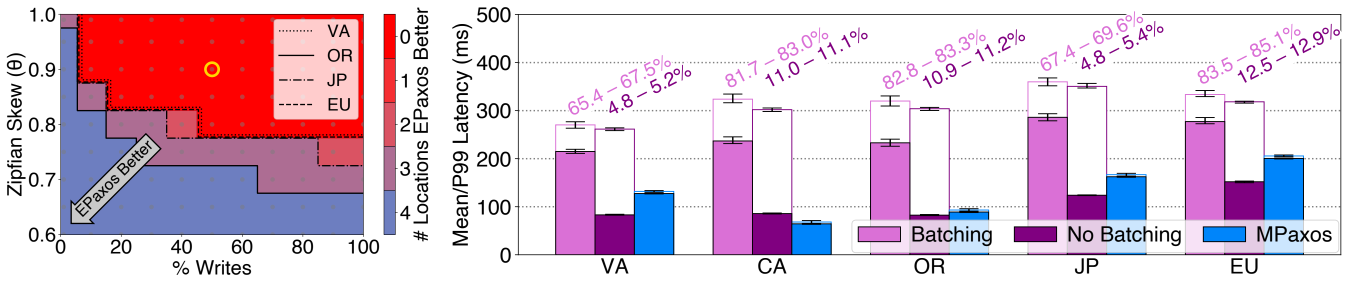
6.5 Latency Cost of Batching

The EPaxos paper demonstrated that batching operations into instances increases the throughput of EPaxos 9x and Multi-



(a) Mean Latency **(b)** P99 Latency **(c)** Complementary CDF

Figure 10: Latency impact of unbounded dependency chains for skewed, write-heaving workloads. All operations are writes, and the Zipfian experiments used a skew parameter of .99. These experiments were run at a throughput of 4000 operations per second, which is 80% of the maximum possible throughput of unmodified EPaxos. Figures (a) and (b) compare Mean and 99th percentile execution latency for EPaxos with out without an upper bound on execution latency. Error bars are shown as in Figure 6. Figure (c) is a complementary CDF showing the fraction of EPaxos operations with latency higher than a given value, with and without bounding dependency chains. Data is shown only for clients in OR; other sites are similar.



(a) Mean Latency **(b)** Circled Workload

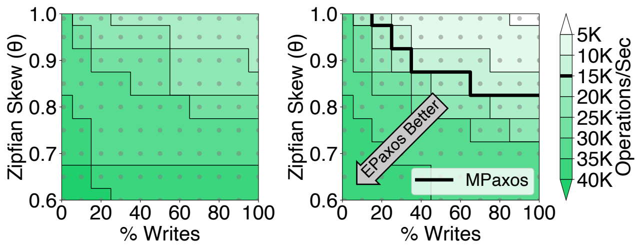
Figure 11: EPaxos execution latency and conflict rate with batching enabled. Figure (a) compares mean latency with batching enabled between EPaxos and Multi-Paxos for a variety of workloads. The lines indicate the workloads for which EPaxos mean latency in that client location is roughly equivalent to Multi-Paxos mean latency; above the line EPaxos latency is worse, and below it Multi-Paxos mean latency is worse. The fill colors indicate the number of client locations that experience a lower latency with EPaxos than Multi-Paxos for the given workload. The circled point indicates the workload in Figure (b): a Zipfian distribution with a skew parameter of .9, where 50% of operations issued by clients are writes. Figure (b) error bars and conflict rates are shown as in Figure 6.

Paxos 5x, but EPaxos batching significantly increases latency because it causes nearly all operations to take the slow path. This is because, with batching, an operation conflicts if any operation in its batch has a conflict.

The EPaxos paper measurements did not capture the drawback of batching, as they measured batching only with the '0%' and '100%' loads, and batching has no effect on conflict rate for either of those workloads. Figure 11a shows that the mean latency for EPaxos is worse than Multi-Paxos for most of our workloads when batching is enabled (compare with Figure 7, where EPaxos mean latency is almost always lower than Multi-Paxos). Figure 11b shows more detail for a particular workload. With batching, the conflict rates are 6-16x higher than without batching. As a consequence of high conflict rates, batching causes EPaxos mean latency to be more than double that of both Multi-Paxos and EPaxos without batching.

6.6 Wide-Area Throughput

EPaxos throughput, like latency, is heavily impacted by operation interference. Figure 12 shows the maximum throughput EPaxos can sustain for each workload point, both with and without the optimization to bound dependency chains. Even with bounded dependency chains, throughput varies by more than a factor of two across the range of workloads. Without the optimization it varies by a factor of 10. Throughput for the improved version of EPaxos is at least as good as Multi-Paxos for all workloads, and more than double Multi-Paxos when there is little interference. Throughput for the unimproved version of EPaxos can be as much as 3x lower than Multi-Paxos.



(a) Improved **(b)** Unmodified

Figure 12: EPaxos throughput for a variety of workloads, both with and without bounded dependency chains. Throughput was determined by varying the Poisson rate parameter until latency increased without an increase in throughput. Multi-Paxos maximum throughput is 15,000 operations per second. For the improved version of EPaxos, Multi-Paxos throughput is equal to that of EPaxos with a Zipfian skew of .99 and 100% writes, which is why there is no 'MPaxos' line on Figure (a).

Although our results show significantly worse throughput for EPaxos than the original evaluation, we are not confident that our throughput measurements (or those in the EPaxos paper) are a pure reflection of protocol differences rather than of confounding factors. When investigating the factors that limit server throughput, we observed several anomalies as servers neared saturation. Seemingly innocuous changes could have a large impact on throughput. For example, increasing the number of available cores caused throughput to drop. We believe that some of the issues may come from unexpected behavior of Go's thread scheduler. For example, for maximum throughput it is important that the thread implementing the EPaxos or Multi-Paxos protocol have exclusive access to a core. We suspect that Go occasionally deschedules that thread in order to run less-critical threads that listen for incoming messages.

Further, there are particular implementation details that may artificially limit throughput for both EPaxos and Multi-Paxos. For example, EPaxos has a thread that cycles through unexecuted instances, checking if they can be executed, which becomes increasingly expensive as the number of unexecuted instances increase, and could likely be optimized. In addition, we measured that Multi-Paxos disproportionately suffers from imbalance in the program's threading structure.

We experimented with wildly modified versions of the code that eliminated many of these compounding factors, but concluded that measuring the best possible throughput that is achievable with either protocol was tangential to the goal of our work. This would have required effectively rewriting the code, and we wanted to keep constant with the original EPaxos evaluation as many factors as possible.

Nonetheless, we felt that it was important to disclose our findings, as our results differ from those of the original EPaxos evaluation, and the compounding factors that we encountered apply to the original EPaxos evaluation as well as ours.

7 Related Work

A number of existing protocols exploit commutativity to provide fast replication. Other commutativity-based protocols may suffer from similar performance degradation to EPaxos in a WAN, but the EPaxos slow path can incur higher latency than that of most other protocols. We leave analysis of other protocols to future work. *Generalized Paxos* [16] allows clients to complete commutative operations in 1 WAN RTT. Generalized Paxos has a 3 RTT slow path because it reverts to a stable leader when operations interfere, and it also has a larger quorum size than EPaxos. *CURP* [24] completes commutative operations in 1 RTT by separating durability from ordering. CURP uses a stable leader, but has clients also issue their operations to 'witnesses', which keep track of a set of operations that have been seen but not yet ordered by the leader. If a client issues an operation that interferes with another that is unordered, witnesses reject that operation and it must take the slow path. Unlike EPaxos, CURP commutativity does not use ordering; even if all witnesses process an interfering operation in the same order, it will still conflict based on the presence of interference.

Bipartisan Paxos [30] (BPaxos) uses modularity to address scaling issues of optimized consensus protocols. BPaxos allows bottleneck modules to be scaled independently from the rest of the system, increasing throughput. The BPaxos evaluation has similar limitations to that of EPaxos; a fixed 'conflict percentage' is chosen instead of using a representative distribution, and they increase throughput by adding client threads. The protocol is evaluated in a local-area network (LAN), and the authors list poor performance in a WAN as a limitation.

TAPIR [31], *Janus* [22], and *MDCC* [14] combine concurrency control and consensus to commit commutative distributed transactions in 1 WAN RTT. Previously, replication and transaction protocols would each separately, and redundantly, ensure consistency. By only ensuring consistency once, these protocols decrease latency by 1 WAN RTT.

Speculative Paxos [25] and *Network-Ordered Paxos* [17] are consensus protocols that use ordering to complete operations in 1 RTT. Both use specialized networking hardware to serialize instances within the network, which is infeasible in a WAN.

Speculative PBFT [29] and and *Eve* [13] are replication protocols that optimistically execute operations before their ordering is confirmed, rolling back those that conflict. Speculative PBFT allows clients to speculatively execute based on a prelimary result while the leader replicates the command. However, the result cannot be externally visible before the client learns that it is committed. Eve allows for concurrent execution within a multi-core system.

PLATO [7] orders multi-cast messages in a LAN. A replica detects out-of-order packets by observing packet inter-arrival times. PLATO tags each message with a timestamp before which it should not be processed. This allows the packet to be revoked if another arrives that PLATO believes should have an earlier ordering. In addition to being insuitable for a leaderless protocol, PLATO's approach is speculative on the receiver, while our timestamps are determined by the sender and will be the same for each receiver.

CAESAR [5] and *Clock-RSM* [9] are consensus protocols that use synchronized clocks. CAESAR is a leaderless protocol that is similar to EPaxos, and uses synchronized clocks to allow instances to take the fast path even if the quorum disagrees on an instance's dependencies. In order to do this, CAESAR increases the quorum size by one node, which increases the minimum latency of operations. Clock-RSM uses timestamps from synchronized clocks to order instances. Instances are sorted by timestamp, and can complete when no unknown instance could have had an earlier timestamp. Because of this, a given instance depends on all other replicas communicating that they have no prior instances before it can complete. Much of the latency benefit of Clock-RSM is due to replicas broadcasting replies to all other replicas, which would also be possible for EPaxos.

Spanner [8], Google's globally distributed database, uses synchronized clocks to linearize transactions. This is at a higher level than the consensus layer, which uses Multi-Paxos.

On the correctness of Egalitarian Paxos [26] identifies an error in the EPaxos recovery procedure that breaks correctness. A potential fix for this issue is implemented in [27]. Our evaluation is concerned with the performance of normal operation.

8 Conclusion

In this paper we have shown how conclusions about a system can be biased by elements of the experimental methodology such as workload and metrics. Although we agree with the original evaluation that EPaxos reduces median latency compared to Multi-Paxos, we show that the percentage of operations that acheives this low latency varies greatly by application. Additionally, there is high variance in operation latency; for many workloads, a roughly 30% reduction in median latency can be at the expense of a more than 4x increase in 99th percentile latency. By covering a larger range of workloads, we also encountered issues that did not manifest in the original EPaxos paper, such as unbounded dependency chains, the cost of dependency delays (which can affect even the fast path), the latency penalty from batching, and the impact of conflicts on throughput.

We also presented TOQ, a novel technique that uses synchronized clocks to improve the performance of consensus protocols for geo-replication. We evaluated TOQ on EPaxos and demonstrated that it can reduce the conflict rate and mean latency of EPaxos without introducing additional latency.

9 Acknowledgements

Our work would not have been possible without the Egalitarian Paxos authors' transparency about their evaluation, both from the details in the body of their paper and the availability of their source code. We thank the authors of EPaxos, particularly Iulian Moraru, for their responsiveness to questions we had about the paper, protocol, their experiments, and our findings.

This work was supported by the industrial affiliates of the Stanford Platform Lab. Our experiments were run on Google Cloud with the support of a Google Cloud Platform Education Grant. We thank our shepherd, Shuai Mu, and the anonymous reviewers for their helpful comments on the paper.

A Appendix

A.1 Upper Bound on Execution Latency

With the improvement to EPaxos described in Section 3, execution latency is bounded at roughly 3 WAN RTTs. Let's say that replica A originates instance A.*i* and has transitive dependency B.*i* from replica B. In order for B.*i* to have an equal or lower sequence number than A.*i*, or not have A.*i* as a dependency, some other replica C in B's fast-path quorum must learn about B.*i* before A.*i*.

In the worst case, C will learn about B.*i* an instant before C learns about A.*i*, B.*i* will take the slow path, and B.*i*'s commit must propagate to A. Thus, the latency bound is the sum of:

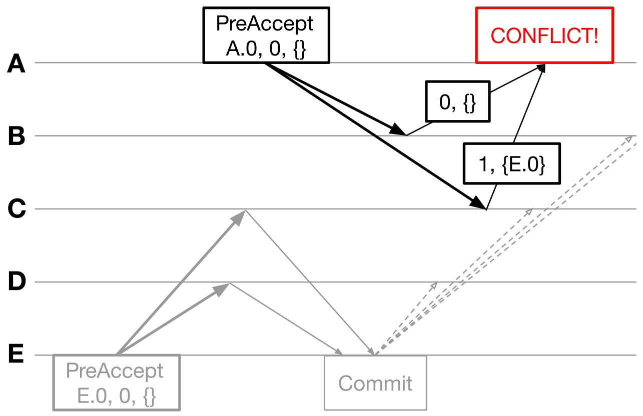
- 1 message delay: the one-way delay from A to C, which is A.*i*'s PreAccept message.
- <2 message delays: the remainder of the one-way delay from B to the other replicas in its quorum + the one-way delay for their responses. (This will be 1 message delay if C is the furthest replica in B's quorum, and always less than 2 message delays. For our topology, this is always 1 message delay.)
- 2 message delays: an RTT between B and its quorum, for the Accept phase.
- 1 message delay: the one-way delay from B to A, for B.*i*'s commit to propagate to A.

As an example, we can compute the upper bound on execution latency for Japan in our test topology. Figure 5 contains the RTTs between replicas in the topology, and we estimate that the one-way delay is half of RTT. The worst case for Japan (JP) is that an instance from London (EU) arrives at Oregon (OR) an instant before Japan's instance and takes the slow path. The maxmimum execution latency for the instance from Japan will be 45.5ms (one-way delay from JP to OR, for JP's PreAccept) + 64.5ms (one-way delay from OR to EU for OR's PreAccept reply) + 129ms (RTT between EU and OR, for the Accept phase) + 110.5ms (EU's commit propagation to JP) = 349.5ms. This is consistent with the maximum execution latency we measured for clients in Japan in our experiments, which was 349.9ms.

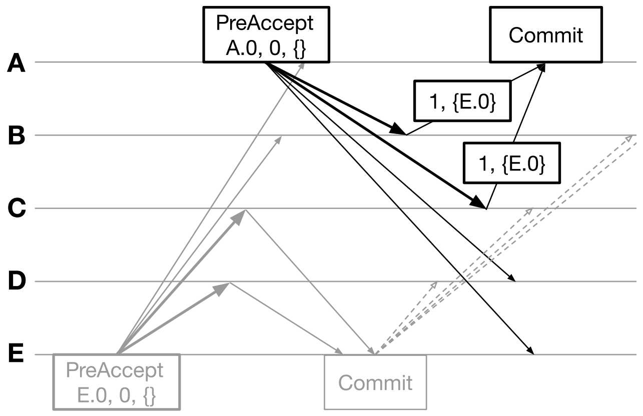
A.2 Impact of Thrifty on Conflict Rate

The original EPaxos evaluation used an optimization called *thrifty*, in which an originator only sends PreAccept and Accept messages to the necessary quorum. Although Enabling thrifty increases throughput for both EPaxos and Multi-Paxos by about 15%, enabling thrifty increases EPaxos conflict rates. With the thrifty optimization, some nodes do not become aware of an instance until it has committed. When some nodes know about an instance but others don't, there is increased potential for discrepancies in PreAcceptReplies, leading to increased conflicts.

Figure 13 provides an example of this. In the figure, replica E sends a PreAccept message for instance E.0 before replica A sends a PreAccept message for A.0. With thrifty enabled, only one of the two replicas in A's fast-path quorum receives the PreAccept for E.0 before the PreAccept for A.0. This causes A.0 to take the slow path. With thrifty disabled, both replicas in A's fast-path quorum receive the PreAccept for E.0 before that for A.0, so A.0 can commit on the fast path.



(a) Thrifty Enabled



(b) Thrifty Disabled

Figure 13: EPaxos PreAccept phase example, with and without *thrifty*. Replicas A and E originate interfering instances A.0 and E.0 concurrently. A's fast-path quorum consists of replicas B and C, and E's fast-path quorum consists of replicas C and D. With thrifty enabled, the responses from B and C differ for A.0. With thrifty disabled, replica B receives the PreAccept for E.0 before A.0, avoiding conflict.

In Figure 14, we demonstrate experimentally that thrifty increases EPaxos conflict rates. Conflict rates are higher with thrifty enabled for all three workloads in the figure, which generally leads to higher latency.

A.3 Impact of Throughput and Workload Size on Conflict Rate

When comparing EPaxos to a variety of skews and write ratios in Section 6, we held throughput and the number of unique keys in the workload constant. However, both of these variables also impact operation interference.

Figure 15 shows that EPaxos conflict rate, mean latency, and 99th percentile latency increase as throughput increases. Higher throughput corresponds to having a higher number of concurrent operations, creating more opportunities for interference. EPaxos 99th percentile latency plateaus once more

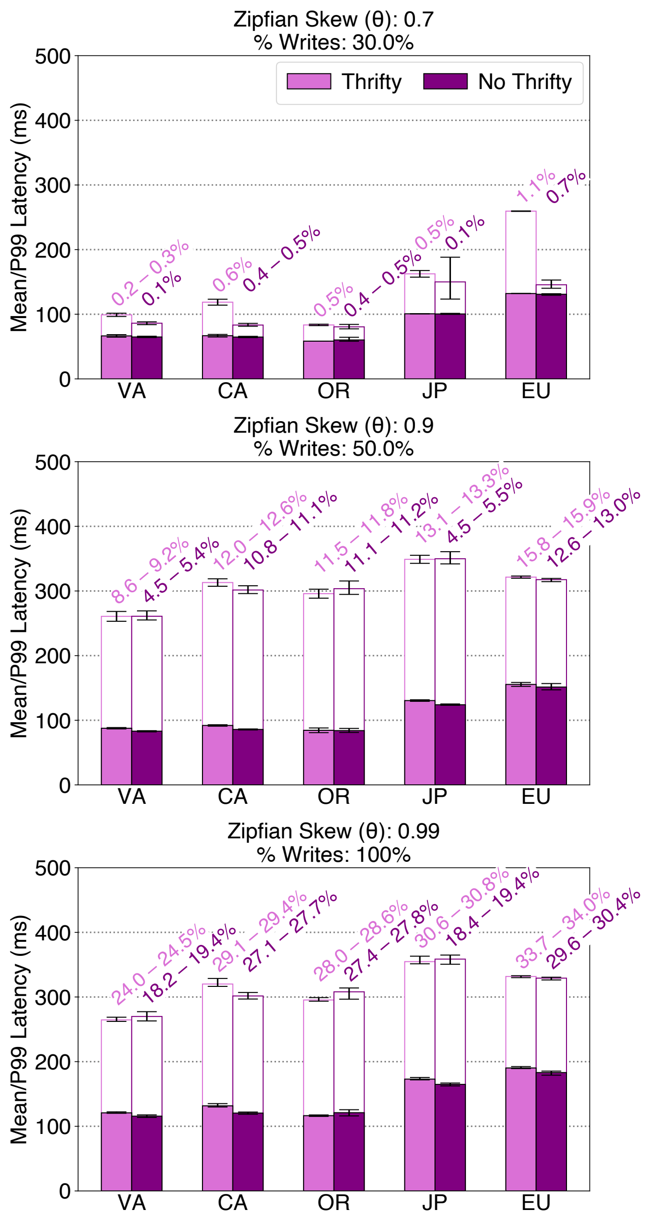


Figure 14: Comparing EPaxos Mean and 99th percentile execution latency with and without *thrifty* enabled for three different workloads. The experiments for this graph where run with the same methodology as Figure 7. Error bars and conflict rates are shown as in Figure 6.

than 1% of operations hit the upper bound on execution latency described in Appendix A.1.

Figure 16 shows that EPaxos conflict rate, mean latency, and 99th percentile latency decrease as the number of unique keys in the workload increases. Although our latency analyses showcase a variety of skew factors, our analyses only display measurements for a single number of unique keys. The trends would be the same with a different number of unique keys, but the measurements for each data point would be different.

A.4 Additional TOQ Graphs

In Section 6.3 and with Figure 9, we demonstrated that TOQ reduced conflict rate and, consequently, latency for clients in Oregon (OR). Figure 17 shows that TOQ reduces conflict rate for clients in all locations. Figure 18 shows that TOQ reduces Mean latency for all client locations, except for clients in Japan with quorum union sync. Figure 19 shows that TOQ reduces 99th percentile latency for all client locations. Mean latency increases for Japan with quorum union sync because the quorum union contains VA, which is significantly further from JP than its quorum, adding about 24ms to the minimum operation latency for clients in Japan. Although Mean latency increases for clients in Japan with quorum union sync, 99th percentile latency still decreases, due to decreased conflict rate.

Figure 20 demonstrates the benefits and tradeoffs of TOQ for two specific workloads. For both workloads, TOQ with a sync group of all replicas completely eliminates conflict. However, the mean latency for the 'all' sync group is higher than without TOQ because its minimum latency is higher. The quorum union sync group decreases conflict rate for all locations, and latency for most locations, but latency for JP is higher because the minimum latency is higher. The quorum sync group does not decrease conflict rate to the same extent as the 'all' or quorum union sync groups, but it purely decreases latency because its minimum latency is the same as without TOQ.

For the top workload in Figure 20, TOQ primarily decreases 99th percentile latency. Without TOQ, more than 1% of operations are at the latency bound described in Section A.1. TOQ reduces command interference enough that fewer than 1% of operations are at the bound. Because conflict rates without TOQ are fairly low, the impact of TOQ on mean latency for the top workload is minimal.

For the bottom workload in Figure 20, conflict rates are high enough that TOQ primarily decreases mean latency. There is a minimal impact on 99th percentile latency for all sync groups other than the 'all' sync group because, even with the quorum union sync group, more than 1% of operations are at the latency bound.

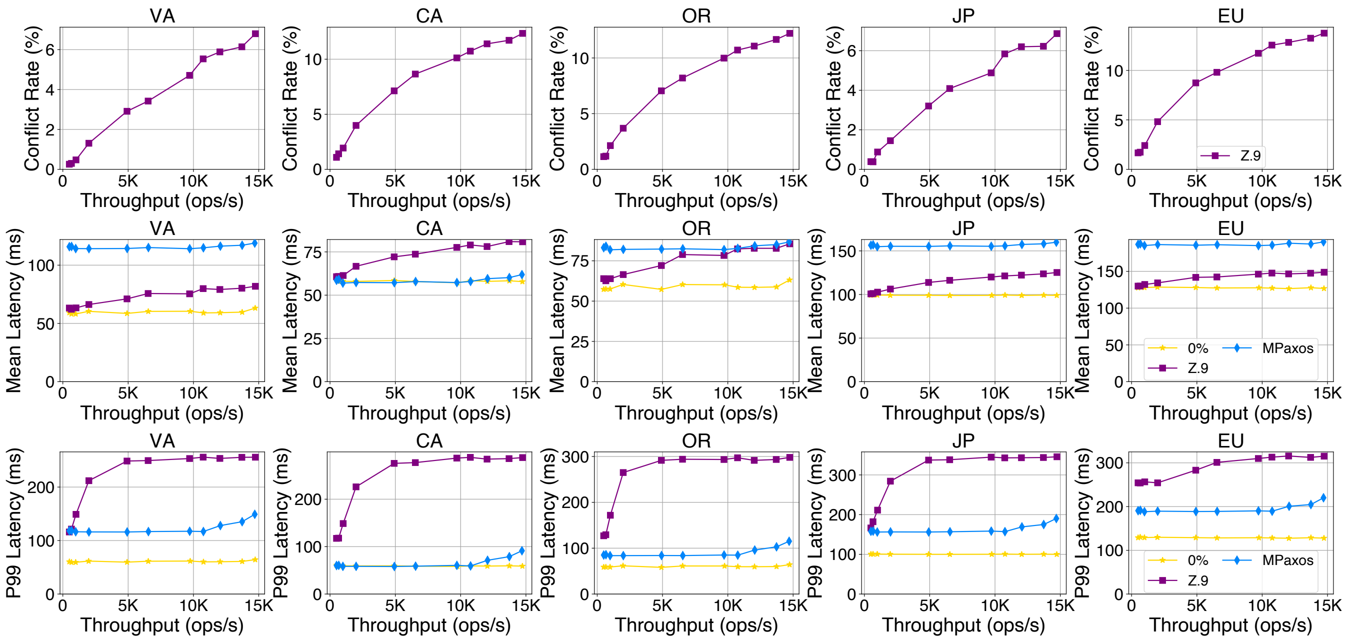

Figure 15: Conflict rate, mean latency, and 99th percentile latency as a function of throughput. To increase throughput, we varied the Poisson rate parameter. Maximum throughput for this the graph is the maximum that produces reasonable behavior for all protocols and experiments. 50% of client operations are writes, and the Zipfian distribution has 1 million unique keys.

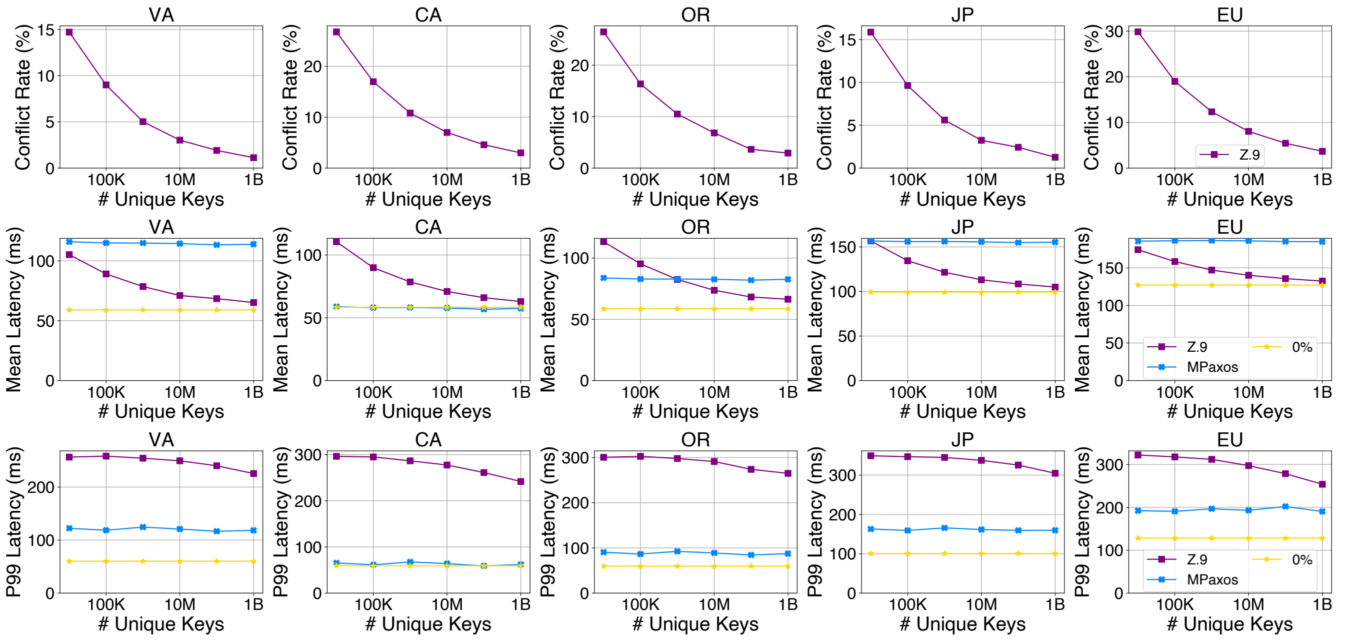

Figure 16: Conflict rate, mean latency, and 99th percentile latency as a function of the number of unique keys in the workload. All experiments were run at a throughput of 11,000 operations per second, which is 80% of maximum throughput for Multi-Paxos. 50% of client operations are writes.

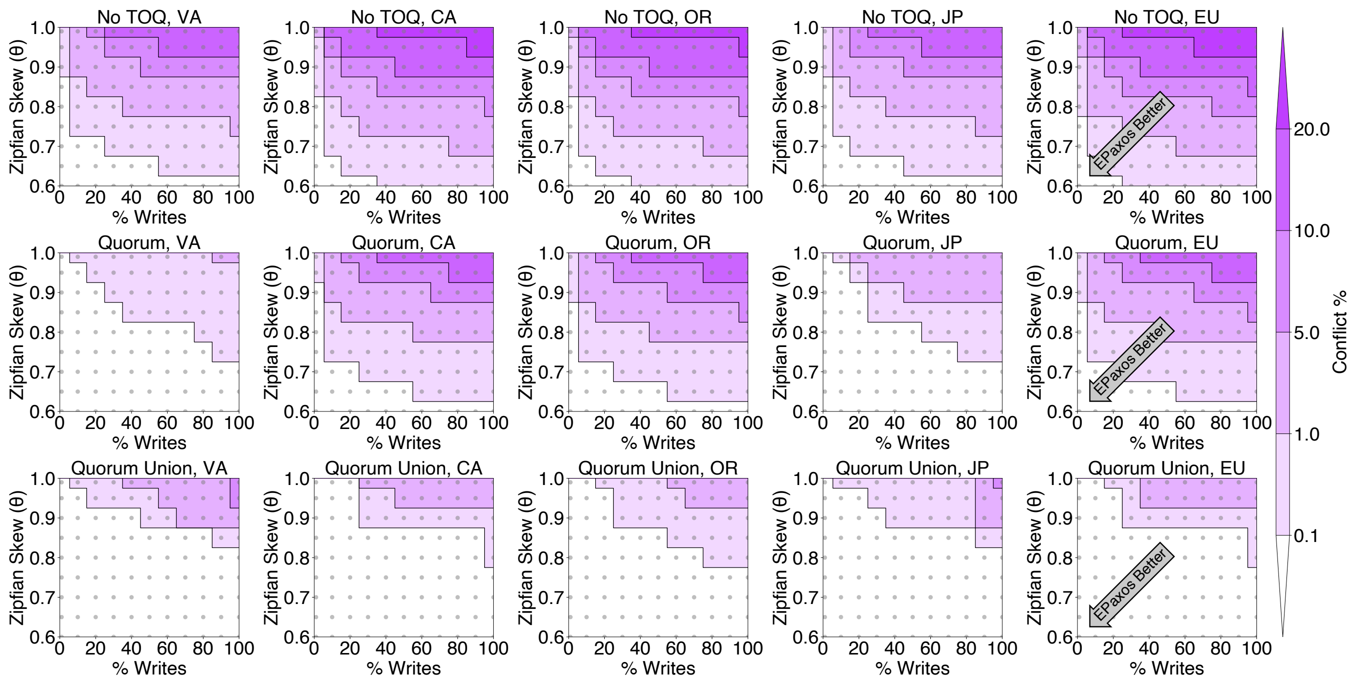

Figure 17: Comparing conflict rate for EPaxos without TOQ, EPaxos with TOQ to a quorum sync group, and EPaxos with TOQ to a quorum union sync group. The quorum union consists of Virginia, California, and Oregon. Other than TOQ, the experiments for this graph were run with the same methodology as Figure 7.

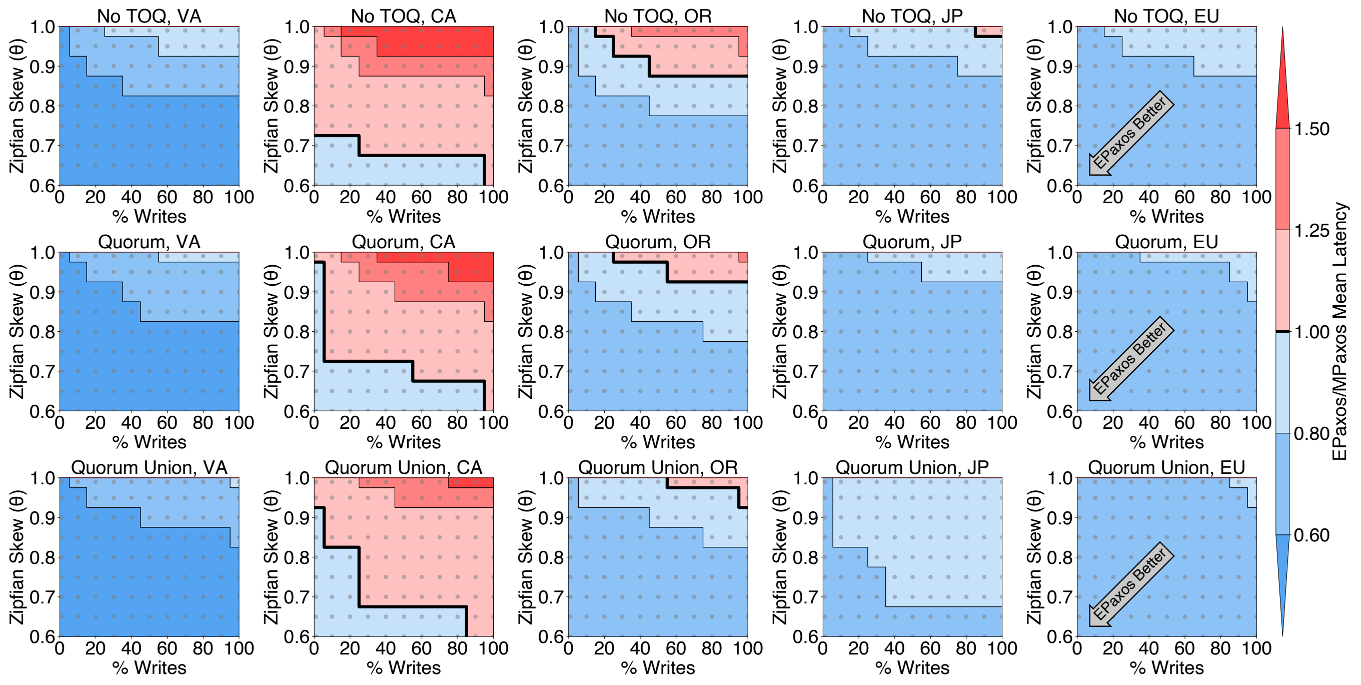

Figure 18: Comparing mean latency for EPaxos without TOQ, EPaxos with TOQ to a quorum sync group, and EPaxos with TOQ to a quorum union sync group. The quorum union consists of Virginia, California, and Oregon. Other than TOQ, the experiments for this graph where run with the same methodology as Figure 7.

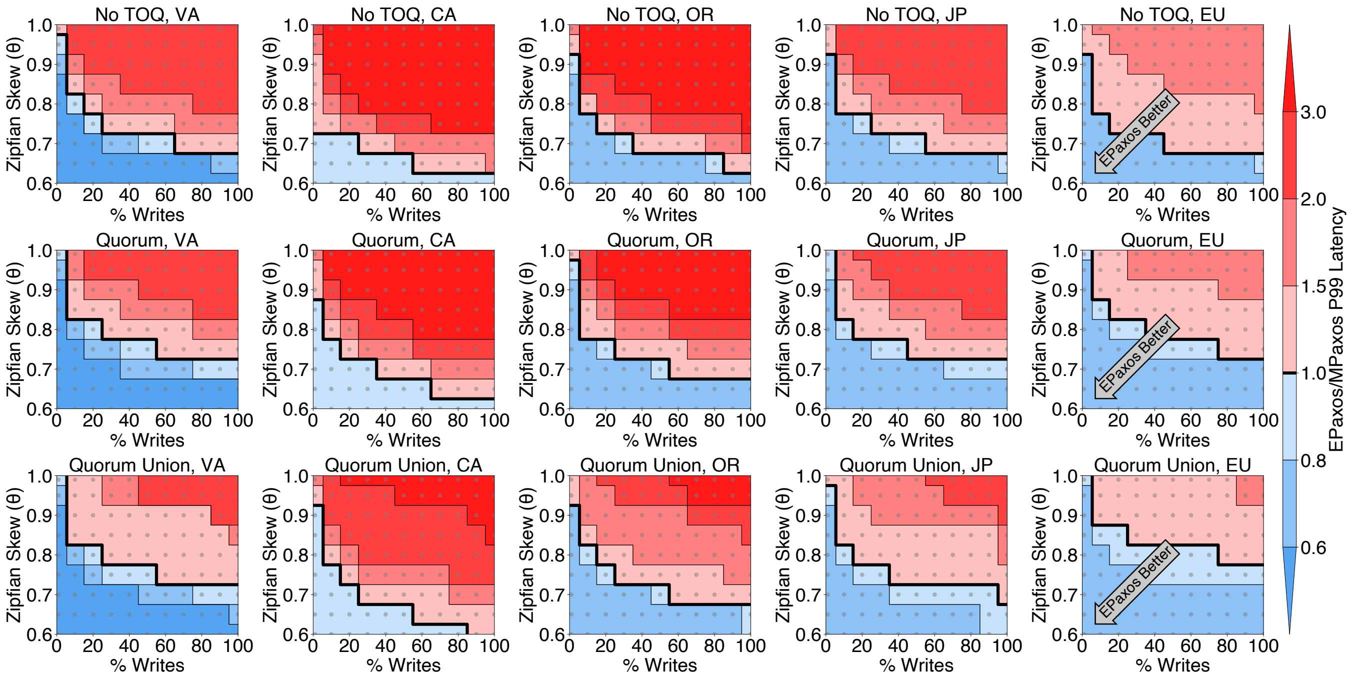

Figure 19: Comparing 99th percentile latency for EPaxos without TOQ, EPaxos with TOQ to a quorum sync group, and EPaxos with TOQ to a quorum union sync group. The quorum union consists of Virginia, California, and Oregon. Other than TOQ, the experiments for this graph where run with the same methodology as Figure 7.

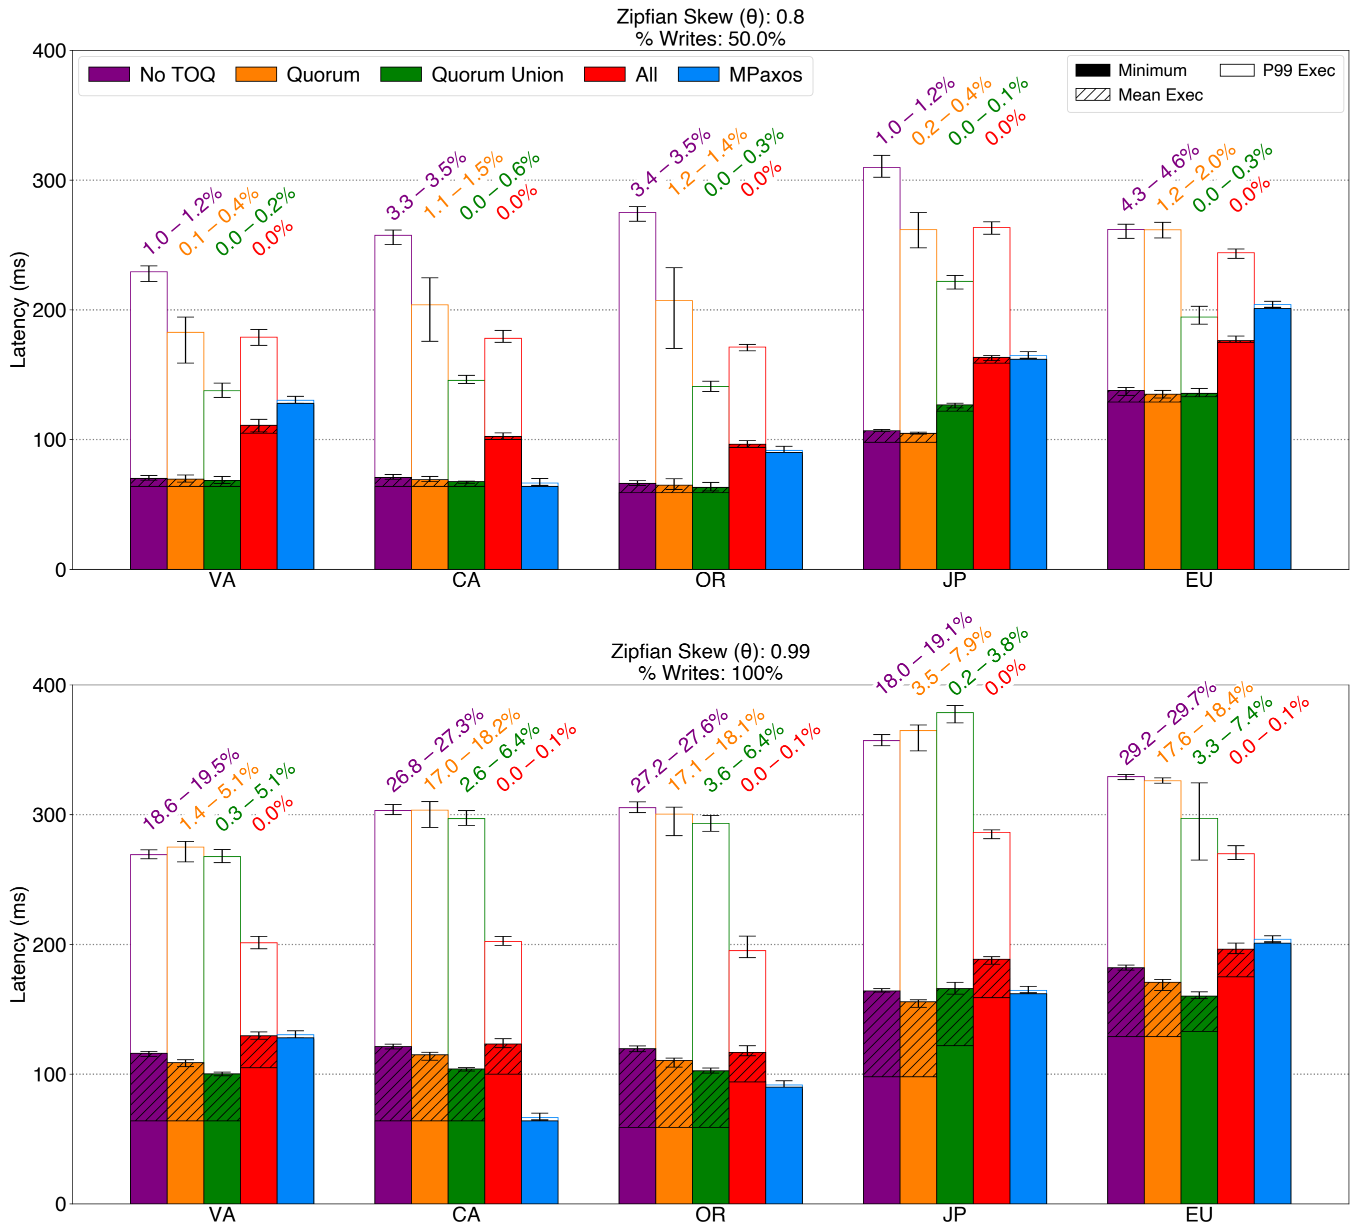

Figure 20: Comparing Mean and 99th percentile latency for EPaxos with three different TOQ sync groups. The top graph is a medium-conflict workload, and the bottom is a high-conflict workload. 'Minimum' refers to the minimum possible execution latency for the protocol and sync group. The quorum union consists of Virginia, California, and Oregon. Other than TOQ, the experiments for this graph where run with the same methodology as Figure 7. Error bars and conflict rates are shown as in Figure 6.

Ship Compute or Ship Data? Why Not Both?

Abstract

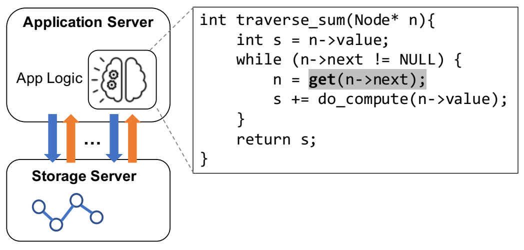
How cloud applications should interact with their data remains an active area of research. Over the last decade, many have suggested relying on a key-value (KV) interface to interact with data stored in remote storage servers, while others have vouched for the benefits of using remote procedure call (RPC). Instead of choosing one over the other, in this paper, we observe that an ideal solution must adaptively combine both of them in order to maximize throughput while meeting application latency requirements. To this end, we propose a new system called Kayak that proactively adjusts the rate of requests and the fraction of requests to be executed using RPC or KV, all in a fully decentralized and self-regulated manner. We theoretically prove that Kayak can quickly converge to the optimal parameters. We implement a system prototype of Kayak. Our evaluations show that Kayak achieves sub-second convergence and improves overall throughput by 32.5%-63.4% for compute-intensive workloads and up to 12.2% for non-compute-intensive and transactional workloads over the state-of-the-art.

1 Introduction

Two trends stand out amid the rapid changes in the landscape of cloud infrastructure in recent years:

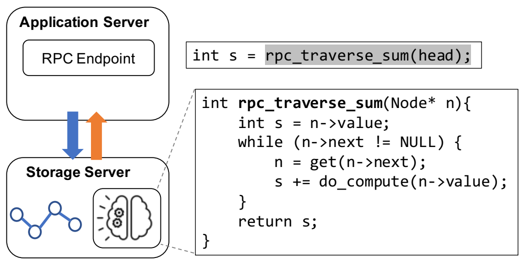
- First, with cloud networks moving from 1Gbps and a few hundred μs to 100Gbps and single-digit μs [11, 20, 25], disaggregated storage has become the norm [4, 17, 21, 28, 31, 40, 44]. It decouples compute from storage, enabling flexible provisioning, elastic scaling, and higher utilization. As a result, increasingly more applications now access their storage servers over the network using a key-value (KV) interface.
- Second, the steady increase in compute granularity, from virtual machines, to containers, to microservices and serverless functions, is popularizing storage-side computation using remote procedure calls (RPCs) [23]. Many databases allow stored procedures and user-defined functions [5–8, 26, 41, 42], and some KV stores allow just-in-time or pre-compiled runtime extensions [9, 18, 29, 39].

The confluence of these two contradicting trends – the former moves data to compute, while the latter does the opposite – highlights a long-standing challenge in distributed systems: *should we ship compute to data, or ship data to compute?*



```
int traverse_sum(Node* n){
    int s = n->value;
    while (n->next != NULL) {
        n = get(n->next);
        s += do_compute(n->value);
    }
    return s;
}
```

(a) *Ship data to compute.*



```
int s = rpc_traverse_sum(head);
```

```
int rpc_traverse_sum(Node* n){
    int s = n->value;
    while (n->next != NULL) {
        n = get(n->next);
        s += do_compute(n->value);
    }
    return s;
}
```

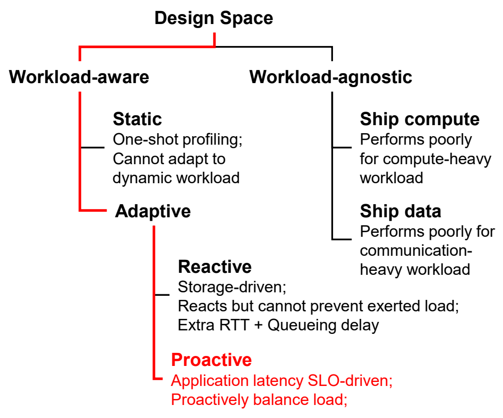
(b) *Ship compute to data.*

Figure 1: ***Graph traversal implemented with (a) disaggregated storage and (b) storage-side compute. The latter (1b) results in less network round-trips but exert more load on the storage server.***

The answer, in broad strokes, boils down to the ratio of computation and communication. The benefits of storage disaggregation, i.e., shipping data to compute, typically holds when most of the time of a function invocation (hereafter referred to as a request) is spent in computation. However, when a single request triggers multiple dependent accesses to the disaggregated storage, time spent in network traversals and data (un)marshalling starts to dominate [10]. Figure 1a shows an example of a simple graph traversal algorithm implemented on top of disaggregated storage, where "pointer chasing" can make network traversals the bottleneck.

In contrast, storage-side computation enables applications to offload part of their application logic to storage servers. The storage layer is customized to support application-specific RPC-style APIs [10, 12, 29], which shave off network round-trips. Figure 1b shows the previous example implemented with storage-side computing, where only one network round-trip is sufficient. However, this is not universally viable either; for compute-intensive workloads, the compute capacity of the storage servers can become the bottleneck when too much computation is offloaded to the storage.

In short, there is no one-size-fits-all solution. Existing



Design Space
Workload-aware
Workload-agnostic
Static
One-shot profiling; Cannot adapt to dynamic workload
Adaptive

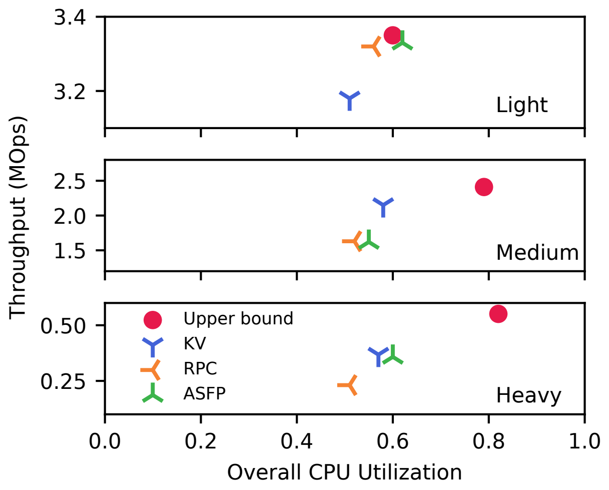

Figure 3: ***Throughput and overall request-level CPU utilization across both application and storage servers for three different workloads under different execution schemes, with 200µs SLO.***

works have explored different points in the design space (Figure 2). Arbitrarily forcing a disaggregated storage (i.e., ship data) or a storage-side computation architecture (i.e., ship compute) in a *workload-agnostic* manner leads to poor utilization and low throughput. Our measurements show that *workload-agnostic* solution leads to up to 58% lower throughput and 37% lower utilization when compared to the optimal. For *workload-aware* alternatives, one choice is taking a one-shot *static* approach, whereby a workload is profiled once at the beginning. However, statically choosing either KV- or RPC-based approach falls short even for a single tenant (§2.2).

The alternative, therefore, is taking an *adaptive* approach that can dynamically choose between shipping data and shipping compute. Existing adaptive solutions such as ASFP [12] take a *reactive* approach: all requests are forwarded using RPC to the storage server, which can then react by pushing some of them back. While this provides a centralized point of control, each request experiences non-zero server-side queueing delay, and more importantly, requests that are pushed back suffer from one *extra* round-trip time (RTT), which is detrimental to low-latency applications with strict latency SLOs. Moreover, throughput-driven designs cannot proactively throttle exerted load on the storage server w.r.t. tail latency service-level objectives (SLOs).

We observe that an ideal solution fundamentally calls for a *balanced* architecture that can effectively utilize the available resources and increase overall throughput while satisfying tail latency SLOs. In this paper, we present Kayak that takes a *proactive* adaptive approach to achieve these goals (§3). In order to maximize throughput without SLO violations, Kayak proactively decides between shipping compute and shipping data when executing incoming requests, and it throttles request rate in order to meet SLO requirements. Specifically, Kayak takes a latency-driven approach to optimize two parameters simultaneously: (1) the *request rate*, and (2) the *RPC fraction*, which denotes the proportion of the incoming requests to be executed using RPC.

Unfortunately, the optimal RPC fraction varies for different workloads and their SLO requirements. There is no closed-form expression to precisely capture the relationship between RPC fraction, request rate, and tail latency either. Finally, we show that the order in which we optimize request rate and RPC fraction affects convergence of the optimization algorithm. We address these challenges by designing a dynamic optimization method using a dual loop control (§4). Kayak employs a faster control loop to optimize request rate and a slower one to optimize RPC fraction. Combined together, Kayak iteratively searches for the optimal parameters, with a provable convergence guarantee. In addition to increasing throughput in the single-tenant scenario, Kayak must also ensure fairness and work conservation of shared server resources in multi-tenant settings. Kayak pins tenants to CPU cores in a fair manner and employs work stealing to achieve work conservation.

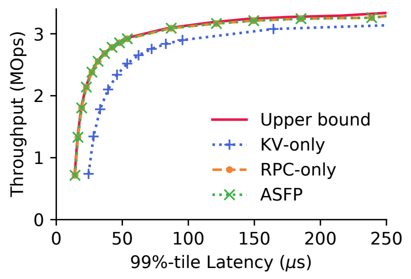
Our evaluation on a prototype of Kayak shows that: (1) Kayak achieves sub-second convergence to optimal throughput and RPC fraction regardless of workloads; (2) Kayak improves overall throughput by 32.5%-63.4% for compute-intensive workloads and up to 12.2% for non-compute-intensive and transactional workloads; and (3) in a multi-tenant setup, Kayak approximates max-min fair sharing and scales without sacrificing fairness.

2 Motivation

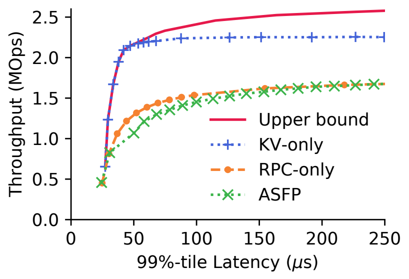
2.1 Limitations of Existing Designs

Existing solutions either fail to efficiently utilize the available CPU cores for a large variety of workloads or introduce additional overhead to reactively adapt to workload variations, both of which lead to lower throughput.

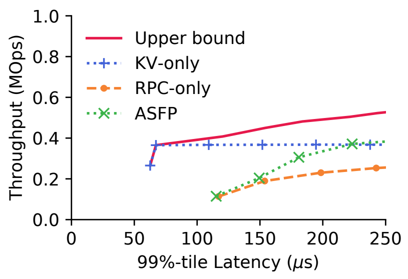
Workload-agnostic approaches either use KV-only design or RPC-only design. The former results in excessive network round-trips of storage access during execution, while the latter overloads the storage server CPU and leaves the CPU on the



(a) *Light (100ns/RTT)*



(b) *Medium (1μs/RTT)*



(c) *Heavy (10μs/RTT)*

Figure 4: ***Throughput w.r.t. SLO (99%-tile latency) for 3 different workloads under different execution schemes.***

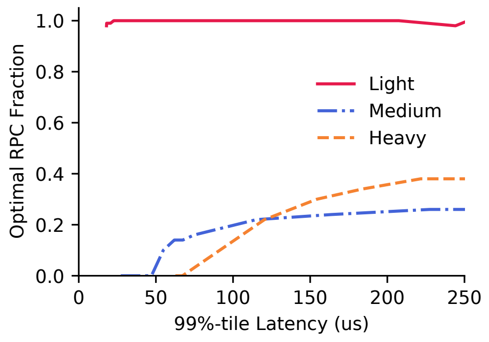


Figure 5: ***Optimal RPC fraction w.r.t. SLO (99%-tile latency) for 3 different workloads.***

application server underutilized. In either case, the overall CPU utilization is low which hinders the performance.

ASFP [12] presents an alternative to workload-agnostic solutions by taking a workload-aware approach with runtime adaptation. In that design, the requests are executed using RPC by default, and if the storage server gets overloaded by the exerted computation, a pushback mechanism is triggered to push the exerted computation back to the application server side. However, the excessive queueing on the storage server still cannot be prevented, although it can be alleviated by the pushback mechanism. Furthermore, the execution of pushed-back requests needs to restart on the application server, wasting CPU cycles on both servers.

To illustrate these issues, we perform an experiment with the graph traversal application shown in Figure 1. We configure the workload so that the each request triggers two storage accesses (i.e., two network round-trips) when executed using the KV scheme. We vary the computation after each access and refer to them as Light (100ns computation time per access), Medium (1μs per access) and Heavy (10μs per access). For reference, adding one network round-trip incurs 9.2μs more latency for each request in our testing environment. We measure the maximum achievable throughput and the CPU utilization (defined as CPU cycles spent only in executing the requests). As shown in Figure 3, using only KV or RPC leads to lower overall CPU utilization and lower throughput. Although the reactive adaptive design utilizes a higher amount of CPU on both application and storage servers, its overheads add up quickly, and its CPU usage for request-level computation does not increase significantly.

To summarize, existing designs do not efficiently utilize the CPU resource on both application and storage servers, which limits their performance. There exists an optimal RPC fraction that maximizes the throughput (calculated by a comprehensive sweep as explained below).

2.2 Need for Dynamically Finding the Optimal Fraction

A key challenge here is that this optimal fraction varies for different workloads. To highlight this, we perform another experiment with the same graph traversal workload as before. We configure the application server to handle a fraction of the requests using RPC and the rest using the KV approach. We vary the RPC fraction from 0 to 1 and measure the overall throughput and end-to-end latency of all requests. In doing so, we obtain the throughput-latency measurements for all possible execution configurations, as shown in Figure 4 and Figure 5. The *upper bound* in Figure 4 is defined by selecting the best RPC fraction for each latency SLO to maximize the throughput, and the selected fraction is plotted in Figure 5. ASFP is configured as using RPC by default with pushback enabled.

As shown in Figure 4, workload with less computation favors RPC over KV, and vice versa. For Medium and Heavy workloads, the highest throughput is achieved by combining RPC and KV together. Moreover, we observe that, (1) for different workloads, the highest throughput is achieved with different RPC fraction; and (2) for different SLO constraints, the optimal fraction for highest throughput is also different. This calls for a proactive design to search for the optimal RPC fraction. Note that we repeated the same parameter sweep with the number of storage accesses per request set to 4 and 8, and observe similar trends (please refer to Appendix A).

3 Kayak Overview

Kayak proactively decides between *shipping compute* and *shipping data* in a workload-adaptive manner. It arbitrates incoming requests and proactively decides the optimal RPC fraction (i.e., what fraction of the compute to ship to storage servers) of executing the requests while meeting end-to-end tail latency SLO constraints.

3.1 Design Goals

Kayak aims to meet the following design goals.

- *Maximize throughput without SLO violations:* Applications have stringent tail latency SLO constraints to ensure low user-perceived latency. Kayak should maximize the throughput while not violating these SLO constraints.
- *High CPU utilization across all servers:* Kayak should balance the computation imposed by application logic across the application and storage servers.
- *Fair sharing of storage server resources:* In a multi-tenant cloud, multiple applications may be sending requests to the same storage server, which should be fairly shared.
- *Ease of deployment:* Applications should be able to use Kayak with minimal code modification.

3.2 Architectural Overview

At a high level, Kayak adaptively runs application logic on both the application and storage servers (Figure 6). However, even though it ships some computation to the storage server, Kayak's core control logic runs only on the application server and the storage server acts as an extended executor. Unlike existing reactive solutions, Kayak proactively decides the amount of computation to ship to the storage side.

Key ideas. Essentially, Kayak finds the optimal RPC fraction and maximizes throughput at runtime while meeting tail latency SLO constraints. The main design challenge is that the optimal fraction varies in accordance with different workloads and their SLO requirements (Figure 5), as well as the amount of load exerted on the storage server. In a multi-tenant cloud, all of these change dynamically. In order to keep up with the changing environment, Kayak proactively adjust the RPC fraction and the request rate according to realtime tail latency measurements.

However, the relationship between the request rate, RPC fraction and latency cannot be easily captured with a closed-form expression. Thus Kayak adopts a numerical optimization method based on a dual loop control algorithm (§4.3) to search for the optimal parameters iteratively. We notice that latency measurements in real systems exhibit large variance, which detrimentally impacts the performance of such iterative optimization algorithms. Kayak's algorithm accounts for such variance and has a provable convergence guarantee.

From an implementation perspective, Kayak faces another challenge as it has to make adjustments very quickly due to the high-throughput, low-latency nature of the environment. Kayak cannot afford to gather global information and make centralized decisions. Hence, the algorithm for Kayak is fully decentralized and runs only on the application servers.

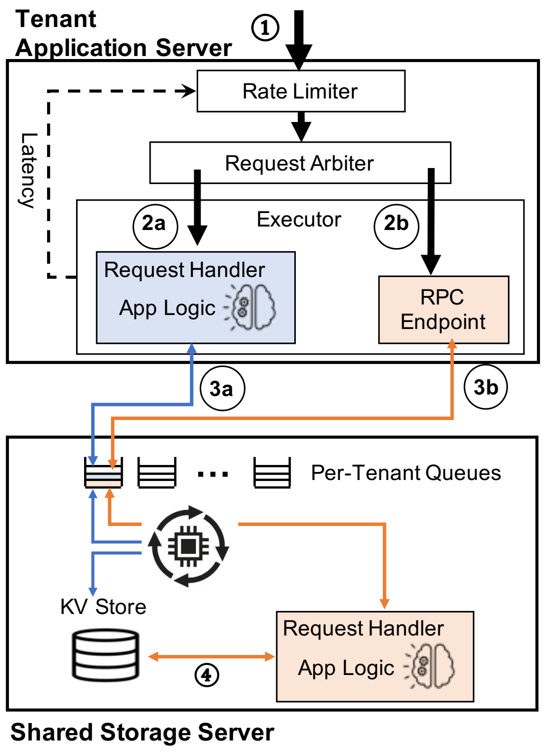

Figure 6: ***Kayak architecture. Tenant application servers interact with shared storage servers using Kayak, which proactively decides which requests to run on the application server using KV operations and which ones to ship to the storage server via RPC.***

Application server. The application server consists of three main components (Figure 6): (*i*) the Rate Limiter limits the rate of incoming requests from the tenant to satisfy SLO constraints; (*ii*) the Request Arbiter determines the optimal RPC fraction; and (*iii*) the Executor handles the requests according to the scheme decided by the Request Arbiter.

The Rate Limiter interacts with the tenants and ① receives incoming requests. It continuously monitors real-time tail latency of end-to-end request execution, and pushes back to signal the tenant to slow down. When the servers are overloaded and the SLO cannot be met, it drops overflowing requests. We assume that tenants implement mechanism to handle overflowing, such as resubmit dropped requests, and increase provisioning so that in the worst case scenario all requests can still be executed on all application servers within the SLO.

The Request Arbiter proactively determines the optimal RPC fraction. It selects the execution scheme for each request based on that fraction. For each request, the choice of execution scheme is determined by a Bernoulli distribution $B(1,X)$ where X is the proportion of requests processed using RPC.

The Executor handles the request in its entirety and reports the end-to-end completion time back to the Rate Limiter upon completion. It consists of two parts: (*i*) the Request Handler and (*ii*) the RPC Endpoint. If the request is to be executed using ②a the KV scheme, the Request Handler is triggered.

The Request Handler executes the application logic locally on the application server and keeps track of the states of the request. Whenever it needs to access data stored in the storage server, (3a) the KV API of the storage server is subsequently called. In contrast, if the request is to be executed on the storage side using the RPC scheme, then the request is simply forwarded to (2b) the RPC Endpoint on the application server. The RPC Endpoint issues an RPC request (3b) to the storage server for processing the request.

Storage server. The storage server includes an additional Request Handler to handle RPC requests in addition to a KV interface. Similar to allocating CPU cores in the application server to run application code, in Kayak, computation resources in the storage server are also allocated to specific tenants at the CPU core granularity.

Each tenant has a dedicated request queue, from which its core(s) polls KV and RPC requests. Handling an incoming KV request in Kayak is the same as what happens in a traditional KV store: the request is simply forwarded to the KV store. Upon receiving an RPC request, the Request Handler is triggered and executes the application logic on the storage server. The Request Handler calls (4) the local KV API whenever data access is needed, interacting with the stored data without crossing the network.

This static *pin-request-to-core* allocation scheme of Kayak makes it easier to enforce fair computation resource sharing between tenants. However, static allocation of CPU cores cannot guarantee work conservation of the CPU cores on the storage server. Kayak uses *work stealing* to mitigate this issue: whenever a tenant's dedicated queue is empty, the corresponding CPU core *steals* requests from other queues.

4 Kayak Design

Our primary objective is to maximize the total throughput without violating the tail latency SLO. However, higher throughput inevitably leads to higher latency in a finite system [27], and there exists a fundamental tradeoff between throughput and latency. Unfortunately, the precise relationship between latency and throughput of a real system, however, is notoriously difficult to be captured by a closed-form expression. In this paper, we use an analytical model to highlight our insights and take a tail latency measurement-driven approach to design a pragmatic solution.

At the same time, as illustrated in Section 2, a reactive approach to achieve this can lead to CPU wastage. Hence, Kayak proactively decides what fraction of the requests to offload vs. which ones to run in the application server, while maximizing the total throughput within the SLO constraint. The need for optimizing both raises a natural question: *which one to optimize first?* In this section, we analyze both optimization orders and design a dual loop control algorithm with provable convergence guarantees. Detailed proofs can be found in the appendix.

Sym.	Description
R	Total request rate
X	Proportion of requests processed using RPC
τ	Random variable of request latency
t_o	Latency SLO target
$T(X,R)$	Latency SLO as a function of X, R
$R(X)$	Function implicitly defined by $T(X,R(X)) = t_0$
k	Index of iterations

Table 1: ***Key notations in problem formulation.***

4.1 Problem Formulation

We denote the proportion of requests to be executed using RPC by X, the total incoming request rate by R, and we define τ as the random variable of request latency, thus we have:

$$\tau \sim P(R,X),$$

where R and X are the parameters of distribution P. Table 1 includes the key notations used in this paper.

We denote $T(X,R)$ as our SLO statistics metric, which takes a specific statistical interpretation for the particular SLO metric. For instance, if the SLO is defined as the 99%-tile latency then T is the 99%-tile for τ. We denote t_0 as the SLO target under the same statistic metric. Thus the problem can be formulated as:

$$\max_X \quad R \tag{1}$$
$$\text{s.t.} \quad T(X,R) \leq t_0 \tag{2}$$
$$R > 0, \tag{3}$$
$$X \in [0,1]. \tag{4}$$

Here constraint (2) captures the latency SLO constraint, and constraints (3) and (4) represents the boundary of R and X, respectively.

We make the following observation when solving this optimization problem:

Observation 1. *Fixing X, $F_X(R) := T(X,R)$ is monotonic increasing.*

Observation 1 captures the relationship of throughput and latency from queueing theory [27] for finite systems like Kayak.

4.2 Strawman: X-R Dual Loop Control

Optimization (1) cannot be directly solved with a closed-form solution of R and X due to the intractability of the function $T(X,R)$. Therefore, we use a numeric optimization method and try to optimize R and X independently and iteratively. To put it into our context, we need to design an iterative algorithm such that in each iteration, we first optimize either R or X, and then optimize the other. We also have to prove that this algorithm would actually converge to ensure optimality and stability of the system.

Now we are facing a question: *which one to optimize first?* In our problem, there is an asymmetry for X and R: X is the

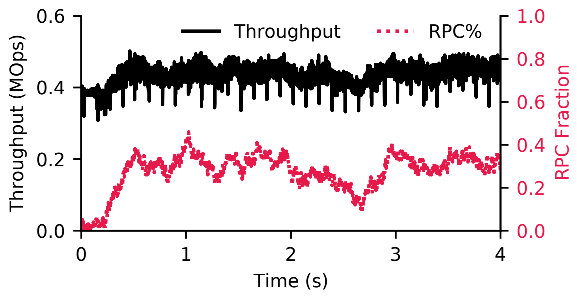

Figure 7: ***Instability of throughput and RPC fraction w.r.t time, with X-R Dual Loop Control.***

parameter in Optimization (1) where as R is the objective. A straightforward solution is to optimize X first, which leads to the following algorithm.

Algorithm I (X-R Dual Loop Control) For $k = 1, \ldots, K$, we alternatively update X_k and R_k by

1. Fix R_k, and find the RPC fraction X_k that minimizes latency, i.e., $X_k = \arg\min_X T(X, R_k)$;

2. Update R_k according to *gradient descent* so that $T \approx t_0$, i.e.,
$$R_{k+1} = R_k + \eta \left(t_0 - T(X_k, R_k)\right),$$
where $\eta > 0$ is the stepsize.

In this algorithm, the first step is to solve a convex optimization problem. Because our assumptions guarantee that X_k is unique and finite, this iteration is well defined for at least the first step (and we will show it is also good for the second step). Moreover, because $T_{R_k}(X) := T(X, R_k)$ is μ-strongly convex and L-smooth, X_k can be solved very quickly (or mathematically, in a linear rate) by iterative algorithms such as gradient descent. We have the following theorem that characterizes the convergence of this algorithm. The rigorous statements and proofs are deferred to Appendix B.2.

Theorem 1. *Fixing R, $F_R(X) := T(X,R)$ is strongly convex and smooth. Suppose for all X, $0 < \alpha \leq \frac{\partial T(X,R)}{\partial R} \leq \beta$. Let $0 < \eta < \frac{1}{\beta}$, then under mild additional assumptions*[1],
$$|R_K - R_*| \leq (1 - \eta\alpha)^K \cdot |R_0 - R_*|.$$

Here R_* denotes the optimal request throughput, and R_0 denotes the initialization. This result shows the iteration of X-R Dual Loop Control converges to the optimal requests exponentially fast, i.e., after at most $O(\log \frac{1}{\varepsilon})$ iterations, the algorithm outputs a solution that is ε-close to the optimal.

Instability of X-R dual loop control. However, while Algorithm I is theoretically sound, it is not practical to be implemented in a real system. The key obstacle is that the latency SLO metric cannot be *directly* obtained in practice. Instead, we can only measure a set of samples of latency τ, and then gather statistics to derive the SLO metric. Hence the derived SLO metric – be it average or 99%-tile – is only an *estimate* $\widehat{T}$ based on *sampling*. While sampling might not be a problem for many systems by using a high sampling rate, it is indeed a problem for Kayak. In particular, because of the microsecond-scale workload and the real-time requirement of Kayak, the sample size for each estimate is limited. This leads to *large variance* in the estimated $\hat{T}$, which results in *degraded* convergence speed and quality.

To quantify the impact of this variance and show the gap between theory and practice, we conduct a verification experiment. We run Algorithm I with the Heavy workload from Section 2 under an SLO constraint of 200μs 99%-tile latency. Our experiment confirms the aforementioned issue of variance in SLO estimates. Figure 7 shows poor convergence quality of both the throughput and the RPC fraction.

[1]For the sake of presentation, we omit the technical assumptions. For a complete description on the theorem, please refer to Appendix B.2

4.3 Our Solution: R-X Dual Loop Control

A naive mitigation to counter the SLO variance is to simply use a metric that is more robust, such as average latency. But this limits the operators to only one viable SLO metric and compromises the generality of the system.

In order to solve the challenge of unstable SLO estimates, we must design an algorithm that is not sensitive to the variance of $\hat{T}$. Compared with the RPC fraction X, the request rate R has a more intuitive and better-studied interaction with latency T from extensive study in queueing theory. Specifically, we take inspiration from recent works [19, 30] showing that even with variance in latency measurements, one can still achieve rate control (i.e., optimization of the throughput) in a *stable* manner. From the starting point of latency-driven rate control, we design a dual loop control algorithm that first optimizes R and then optimizes X to numerically solve the optimization problem. The algorithm is shown as follows. The first part is latency-driven rate control, and the second is gradient ascent.

Algorithm II (R-X Dual Loop Control) For $k = 1, \ldots, K$, we respectively update X_k and R_k by

1. Apply rate control so that the latency approximates SLO, i.e., *R_k be such that $T(X_k, R_k) \approx t_0$;*

2. Use gradient ascent to search for the optimal X_k, i.e., *$X_{k+1} = X_k + \eta \frac{\mathrm{d}R_k}{\mathrm{d}X}$, where $T(X, R_k) = t_0$, and η is a positive stepsize.*

R loop: rate control. In order to satisfy the SLO requirement ($T \leq t_0$), we need to carefully control the request rate R. Intuitively, too high an R leads to excessive queueing on the server side, causing SLO violations; at the same time, too low an R leads to low overall throughput and low resource utilization.

Input: Current throughput R, latency t, SLO target t_0
Output: Updated throughput R

```
/* Initialize global variables. */
1 $\mathbb{T} \leftarrow 0$; $\mathbb{R} \leftarrow 0$            ▷ Last involved latency and throughput.
/* Update $R$ for each round. */
2 Procedure UpdateR()
      /* Calculate $\Delta_R$ according to Newton's method. */
3     $\Delta_R \leftarrow \frac{(R-\mathbb{R})(t_0-T)}{T-\mathbb{T}}$
      /* Bounds checking, throughput should be positive. */
4     if $R + \Delta_R < 0$ then                 ▷ Unlikely. Violates (3).
5         $R \leftarrow \frac{R}{M}$               ▷ Discard $\Delta_R$ and divide $R$ by half.
6     else
7         $R \leftarrow \Delta_R + R$
```

Pseudocode. 1: Dynamic search of optimal R.

Let $R(X)$ be a function implicitly determined by the boundary constraint Eq. (2), i.e.,

$$T(X, R(X)) = t_0.$$

The implicit function $R(X)$ is indeed well defined, since for any X, $T(X,R)$ is monotonically increasing,[2] implying there exists an unique request throughput $R(X)$ that satisfies the boundary constraint, i.e., the maximum throughput is achieved when the latency is equal to the SLO target.

Essentially, we have to design a dynamic algorithm that actuates $R(X)$ in real-time (via $R_k(X)$ in step 1). This problem can be solved with a root-finding algorithm such as the classic Newton's method. However, if we apply this method directly, we may encounter situations where the updated throughput R is negative, which violates constraint (3). This happens when the throughput is too high and needs to be significantly reduced. In this case, we divide R by M instead of updating it using Newton's method. This ensures that (i) the updated throughput is positive; and (ii) the updated throughput is still significantly lower than before. We note that this out-of-bound scenario does not happen frequently. For simplicity, we choose $M = 2$. Our algorithm of searching for the optimal R is shown in Pseudocode 1.

X loop: RPC fraction control. For any given RPC fraction, the rate control of Kayak essentially maximizes throughput within the allowance of SLO requirement. With rate control, we effectively get the throughput as a function of the given RPC fraction ($R(X)$). In this part, we focus on the complementary and optimize the RPC fraction to maximize $R(X)$. We use a gradient ascent algorithm to achieve that. When the updated RPC fraction falls out of the range of $[0,1]$, we apply

[2]We assume that $T(X,R)$ is continuous, and for any X, there exist R_1 and R_2 such that $T(X,R_1) \le t_0 \le T(X,R_2)$. This assumption pluses monotonicity yields the existence and uniqueness of the implicit function $R(X)$.

Input: Current throughput R, RPC propotion X,
Output: Updated RPC propotion X

```
/* Initialize global variables. */
1 $\mathbb{R} \leftarrow 0$; $\mathbb{X} \leftarrow 0$   ▷ Last involved throughput and RPC fraction.
/* Update $X$ for each round. */
2 Procedure UpdateX()
      /* Calculate $\Delta_X$ according to Gradient Ascent. */
3     $\Delta_X \leftarrow -\eta \frac{R-\mathbb{R}}{X-\mathbb{X}}$
      /* Bounds checking, $X$ should be within constraints. */
4     if $X + \Delta_X \notin [0,1]$ then          ▷ Unlikely. Violates (4).
5         $X \leftarrow \max\{\min\{X + \Delta_X, 1\}, 0\}$
6     else
7         $X \leftarrow \Delta_X + X$
```

rounding to ensure it is within the boundary. Our algorithm of searching the RPC fraction is shown in Pseudocode 2.

Putting them together. Combing the rate control and the RPC fraction control, our algorithm (Algorithm II) naturally forms a bi-level (nested) control loops [15], with two actuators X and R and only one feedback signal t. We adopt a single control loop (the inner/fast loop), called R loop, to implement the rate control, i.e., finding the maximum throughput R while not violating the SLO t_0. The input of this control loop is the measured latency SLO metric $\widehat{T}$ and the output is request rate R which is the input for our request arbiter. We then adopt another control loop (the outer/slow loop), called X loop, to implement our request arbiter, i.e., choosing the best X that maximizes R_0.

Although this dual loop control design decouples the two actuators X and R, the resulting two feedback loops may be coupled. The coupling between two feedback loops may cause oscillation, which can be mitigated by choosing different sampling frequencies [15]. The exact two values can be tuned by the operator according to different workloads and system configurations. However, because the functioning of the second loop is dependent on the output of the first loop (R) to have converged to a stable point, it is best practice to choose a lower frequency for the second loop. Theoretically, we show that this dual loop control algorithm is guaranteed to converge in Section 4.4. Empirically, in our experiments, we let the sampling rates of the first and second loops to be 200Hz and 20Hz respectively, and we show that the system converges fast to near optimal throughput in Section 6. We evaluate the impact of frequency selection in detail in Section 6.5.

4.4 Perfomance Guarantee

From the R loop, we obtain an estimation $R_k(x)$ at each iteration k, which approximately satisfies $T(X, R_k(X)) \approx t_0$. In the X loop, we optimize X for our request arbiter such that R_0 is maximized. This is done by *stochastic gradient ascent* (SGA, or *online gradient ascent*) on X. There is a rich literature in online learning theory for SGA when $R_k(x)$ is concave, e.g., see [36]. Applying related theoretical results to our problem, we have the following performance guarantee for our system. The proof of Theorem 2 is deferred to Appendix B.3.

Theorem 2. *Suppose for all $k = 1, \dots, K$, $R_k(X)$ is concave, and $\|\nabla R_k(X)\|_2 \le L$. Consider the iterates of SGA, i.e.,*

$$X_{k+1} = X_k + \eta \nabla R_k(X_k).$$

Then we have the following regret bound

$$\sum_{k=1}^{K} (R_k(X_*) - R_k(X_k)) \le C \cdot \sqrt{K}, \qquad (5)$$

where $C := L\|X_1 - X_*\|_2$ is a constant depends on initialization and gradient bound, and X_* can be any fixed number. Note that the regret bound holds even $R_k(X)$ is chosen adversarially based on the algorithm history.

Inteperation of Theorem 2. The sublinear regret bound implies SAG behaviors nearly optimal on average: we see this by setting $X_* = \arg\max_X \sum_{k=1}^{K} R_k(X)$, and noticing that

$$\frac{1}{K}\sum_{k=1}^{K} R_k(X_*) - \frac{1}{K}\sum_{k=1}^{K} R_k(X_k) \le O\left(\frac{1}{\sqrt{K}}\right) \to 0.$$

More concisely, in our algorithm, $\{R_k(X)\}_{k=1}^{K}$ corresponds to a sequence of inaccurate estimations to the true implicit function $R(X)$ — even so the theorem guarantees a sublinear regret bound, which implies that our algorithm behaviors nearly as good as one can ever expect under the estimations, no matter how inaccurate they could be.

Furthermore, if for each k, $R_k(X)$ is an *unbiased estimator* to the true concave function $R(X)$, i.e., $\mathbb{E}R_k(X) = R(X)$, then $\bar{X} = \frac{1}{K}\sum_{k=1}^{K} X_k$ converges to the maximal of $R(X)$ in expectation: we see this by choosing $X_* = \arg\min_X R(X)$ and noticing that

$$\begin{aligned}\mathbb{E}\left[R(X_*) - R(\bar{X})\right] &\le \frac{1}{K}\sum_{k=1}^{K} \mathbb{E}\left[R(X_*) - R(X_k)\right] \\ &= \frac{1}{K}\sum_{k=1}^{K} \mathbb{E}\left[R_k(X_*) - R_k(X_k)\right] \\ &\le C \cdot \frac{1}{\sqrt{K}} \to 0.\end{aligned}$$

The above convergence result does not require any assumptions on the randomness of R_k, as long as $R_k(X)$ is an unbiased estimator of $R(X)$. This means our algorithm can *tolerate* variance in the measured latency which causes variance in estimated R_k. The convergence is empirically validated by our experiments in Section 6.1.

4.5 Scalability and Fault Tolerance

Scalability. Kayak is fully decentralized, and its control logic (e.g., rate and RPC fraction determination) is decoupled from the request execution in the dataplane. Throughput of a tenant is limited by its total available resources in application and storage servers; one can increase throughput by adding more application servers or by ensuring more resource share in the storage servers.

Fault tolerance. Kayak does not introduce additional systems components beyond what traditional KV- or RPC-based or hybrid systems do. As such, it does not introduce novel fault tolerance challenges. The consistency and fault tolerance of the KV store is orthogonal to our problem and out of the scope of this paper.

5 Implementation

We build a prototype of Kayak with about 1500 lines of code and integrate it with the in-memory kernel-bypassing key-value store Splinter [29]. The code is available at: `https://github.com/SymbioticLab/Kayak`

Kayak interface. Users of Kayak provide their custom defined storage functions (App Logic in Figure 6), which are compiled with Kayak and deployed onto both the application server and storage server. At runtime, users connect to Kayak and set the desired SLO target. Users then submit request in the format of storage function invocations to Kayak.

Application server. The core control logic of Kayak is implemented in the application server. One challenge we face during implementation is to optimize the code to reduce overhead, which is especially important because of the high throughput low latency requirement. For instance, the inner control loop constantly measures request latency and calculate the 99%-tile. One naive way is to measure the quantile is using selection algorithm to calculate the k-th order statistics of n samples, with has at least $O(n)$ complexity. Instead, we apply DDSketch [32] to estimate the quantile in real time with bounded error.

Storage server. The main challenge of implementing the storage server is supporting multi-tenancy and ensuring fairness and work conservation. We pin requests from different tenants to different CPU cores to ensure fairness. And we adopt work stealing to ensure work conservation: CPU cores with no requests to process steal requests from the queues of other cores. Specifically, similar to ZygOS [38], each CPU core of Kayak steals from all other CPU cores, which is different from Splinter's work stealing from only neighboring

CPU	Intel E5-2640v4 2.4 GHz

cores. This further improves overall CPU utilization.

6 Evaluation

In this section we empirically evaluate Kayak with a focus on: (i) verification of convergence; (ii) performance improvement against state of the art [12]; and (iii) fairness and scalability with multiple tenants. Our key results are as follows.

- Kayak achieves sub-second convergence to optimal throughput and RPC fraction regardless of workloads. It can proactively adjust to dynamic workload change as well (§6.1).
- Kayak improves overall throughput by 32.5%-63.4% for compute-intensive workloads and up to 12.2% for non-compute-intensive and transactional workloads (§6.2).
- In a multi-tenant setup, Kayak approximates max-min fair sharing, with a Jain's Fairness Index [22] of 0.9996 (§6.3) and scales without sacrificing fairness (§6.4).
- We also evaluate Kayak's sensitivity to its different parameters (§6.5).

Methodology. We run our experiments on CloudLab [3] HPE ProLiant XL170r machines (Table 2). Unless specified otherwise, we configure Kayak to use 8 CPU cores across all servers. The fast control loop algorithm is configured to run every 5ms and the slow control loop runs every 50ms. The initial RPC fraction is set at 100%, and we define SLO as the 99%-tile latency.

Workloads. We use the workload described in Section 2. Unless otherwise specified, we configure the workload with a traversal depth of two so that each request issues two data accesses to the storage. We vary the amount of computation that takes place after each access and refer to them as Light (100ns computation time per access), Medium (1μs per access) and Heavy (10μs per access). This workload emulates a variety of workloads with different computational load in a non-transactional environment.

We extend this workload and create a Bimodal workload. We denote by `Bimodal(1us, 100ns, 50%, 5s)`, a workload that consists of 50% Medium (1μs/RTT) and 50% Light (100ns/RTT) with an interval of 5 seconds.

We also run YCSB-T [14] as a transactional workload. This workload is not computationally intensive.

Unless otherwise specified, for all workloads, we set our latency SLO target as: 99%-tile request latency lower than or equal to 200μs.

Baseline. Our primary baseline is ASFP [12], which is available at https://github.com/utah-scs/splinter/releases/tag/ATC'20 and also built on top of Splinter [29].

6.1 Convergence

In this section, we validate that Kayak's fast loop can converge to a stable throughput R while satisfying SLO constraint and when running together with fast loop, the slow loop can also converge to the optimal RPC fraction.

Fast loop only. We first disable the slow loop and run Kayak with a fixed RPC fraction (100%), to show that the fast loop (rate control) can converge to optimal throughput with different workloads.

We run Light, Medium and Heavy workloads with one application server and one storage server, and measure how the throughput and 99%-tile latency changes with time. As shown in Figure 9, Kayak ramps up the throughput quickly when the measured 99%-tile request latency is below the SLO threshold of 200μs. Along with the increase of throughput, the latency also increases, as observed from the rise of red line. The entire converging process happens within 0.2 seconds.

After approaching the SLO limit, both the throughput and latency remains stable with minor fluctuations, confirming the convergence of our fast loop. We note that the converged throughput are the same as the measurements of the RPC-only configuration in Figure 4. This means that our fast loop indeed converges to the optimal throughput.

Dual loop control. Now we move on to verifying the convergence of both loops combined. We repeat the previous experiments, but with both control loops enabled. Figure 10 shows the dynamics of throughput and RPC fraction and how they change with time. We highlight three observations.

- Similar to Figure 9, throughput increases rapidly within the first 0.2 seconds; this is due to the fast loop.
- With the Medium and Heavy workloads, the throughput increase slows down after 0.2 seconds. This increase comes from the slow loop, as we can see a change in RPC fraction. Note that the Light workload does not show this trend, because in this setup the initial RPC fraction (100%) is already the optimal for it.
- After 1 second since the start, the throughput converges to a stable value with only minor fluctuations.

Comparing the RPC fraction in Figure 10 against Figure 5, we observe that our algorithm converges to the optimal RPC fraction. Comparing the throughput in Figure 10 against the Optimal configuration in Figure 4, we observe that the converged throughput is the optimal throughput.

Convergence under dynamic workloads. One advantage of Kayak is that it can proactively adjust to changing workload. To verify this, we run Kayak with the `Bimodal(1us, 100ns, 50%, 5s)` workload. Figure 11 shows the dynamics of throughput and RPC fraction. As we can see, Kayak adapts to the changing workload, and adjusts both the throughput and RPC fraction accordingly in a timely fashion.

Figure 10: ***Dynamics of throughput and RPC fraction w.r.t time, with nested control loops of Kayak.***

SLO	YCSB-T		Light		Medium		Heavy		Bimodal	
	Kayak	ASFP	Kayak	ASFP	Kayak	ASFP	Kayak	ASFP	Kayak	ASFP
50μs	2.63	2.58	3.05	3.05	1.71	1.06	N/A	N/A	2.13	1.43
100μs	3.12	2.78	3.36	3.36	2.37	1.45	0.37	N/A	2.74	2.16
200μs	3.35	3.01	3.59	3.52	2.54	1.64	0.48	0.33	2.98	2.37
400μs	3.35	3.02	3.70	3.61	2.61	1.68	0.57	0.40	3.03	2.48

Table 3: ***Throughput (MOps) of Kayak and ASFP under different workloads and SLO targets. "N/A" means the SLO target is infeasible.***

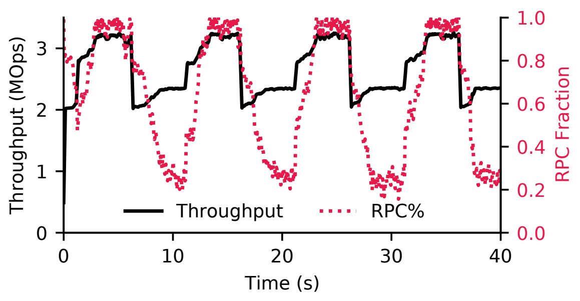

Figure 11: ***Dynamics of throughput and RPC fraction w.r.t time under Bimodal workload.***

6.2 Performance

Performance improvement. We compare the performance of Kayak against the state of the art ASFP [12]. We use all the workloads: (i) Light/Medium/Heavy computational workload; (ii) Bimodal workload; and (iii) YCSB-T workload. We use one application server and one storage server, and vary the SLO target from 50μs to 400μs. The results are shown in Table 3, which we summarize as follows.

- For non-compute-intensive workloads (Light and YCSB-T), Kayak achieves up to 12.2% throughput improvement. In this case, most of the requests are handled via RPC and Kayak's opportunity for improvement is lower.
- For compute-intensive workloads, Kayak achieves 32.5%-63.4% throughput improvement. In this case, the RPC fraction decreases, and ASFP's pushback mechanism kicks in; the overhead of pushing requests back in comparison to Kayak's proactive placement increases the gap.

Workload	YCSB-T	Light	Medium	Heavy	Bimodal
Gap	5.4%	11.8%	6.7%	3.5%	10.6%

Table 4: ***Kayak's performance gap from the upper bound for different workloads.***

Overall, Kayak outperforms ASFP because its proactive design is more efficient in using both application- and storage-side CPUs.

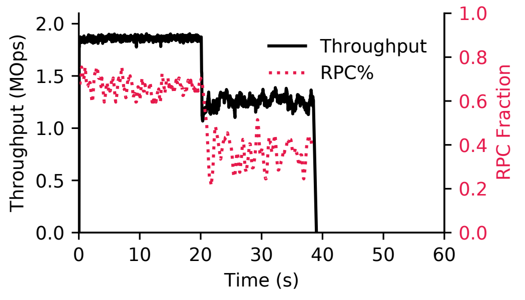
Gap between Kayak and upper bound. We set the SLO target to be 200μs and compare the achieved throughput between using Kayak and the upper bound obtained by the parameter sweep method (§2.2). We define the gap between Kayak and the upper bound as follows:

$$Gap = \frac{Throughput_{max}}{Throughput_{max,Kayak}} - 1$$

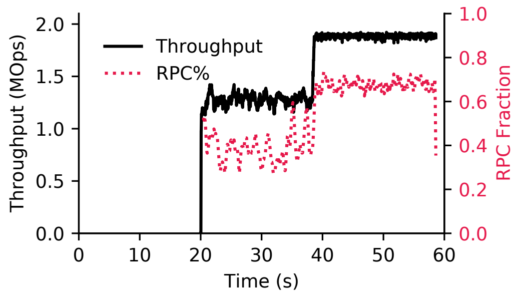
Intuitively, the lower the gap is, the closer Kayak is to the optimal. As shown in Table 4, Kayak has a slowdown of 11.8% for computationally light workload and 3.5% for computationally heavy workload.

6.3 Fairness

In this section, we show that Kayak can enforce max-min fairness when multiple tenants contend for server resources.



(a) *Tenant A*



(b) *Tenant B*

Figure 12: ***Dynamics of throughput and RPC fraction w.r.t time of tenant A and B in the multi-tenant experiment.***

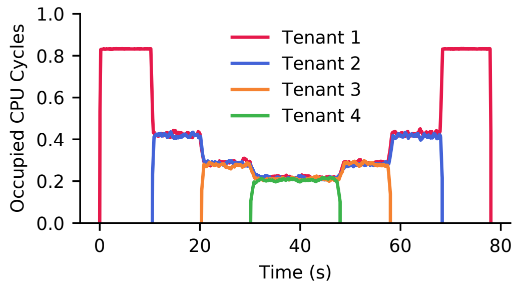


Figure 13: ***Fair-sharing of throughput for 4 applications sharing one storage server.***

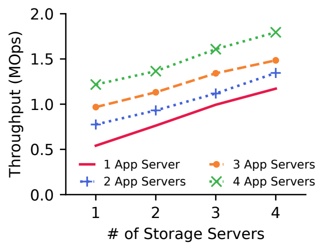
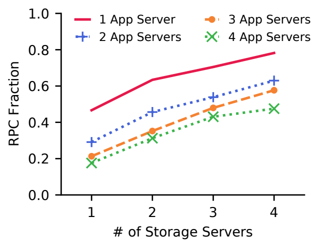


(a) *Throughput*



(b) *RPC Fraction*

Figure 14: ***Throughput and RPC Fraction of Kayak with different server configurations.***

We run two tenants with the same setup and configure each to use four CPU cores instead of eight, while the server is still configured with eight CPU cores. Tenant A is started first, and after 20 seconds, tenant B is started. Figure 12a shows the dynamics of tenant A. During the first 20 seconds, tenant A quickly converges to the optimal throughput of around 1.82MOps. After 20 seconds when tenant B is started, the throughput achieved by tenant A drops to around 1.21MOps. Note that in this process, the optimal RPC fraction also shifts from 60% to 40%. This is because after tenant B joins, the server has less CPU resource to process tenant A's requests. After 40 seconds, tenant A stops sending requests.

Figure 12b shows the dynamics of tenant B, and we can see that when the two tenants are running together the achieved throughput is 1.21MOps and 1.24MOps, respectively. The gap between the two tenants is only 2.4%, which indicates that the server resources are fairly shared. After 40 seconds, the throughput and RPC fraction of tenant B increases because the storage server has more available CPU resources after tenant A stops.

Then we increase to four tenants and start the tenants one after one, with ten seconds in between. Each tenant is configured with one CPU core, and runs a different workload. Tenant {1, 2, 3, 4} runs {Light,Medium,Heavy,Bimodal}, respectively. We plot the occupied CPU cycles on the storage server for each tenant in Figure 13. When the 4 tenants are running together, we measure the Jain's Fairness Index [22] to be 0.9996.

6.4 Scalability

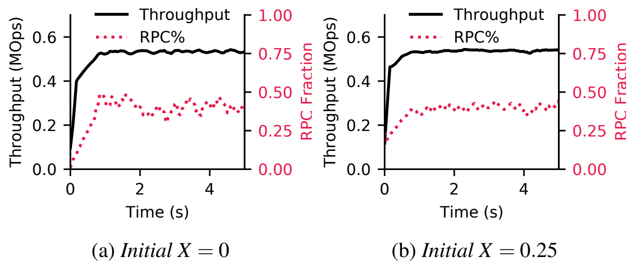
In this section, we verify that the Kayak control loops are decoupled from data plane and do not limit Kayak's scalability. To do so, we run experiments with Heavy workload, and vary the number of application and storage servers. For simplicity, we make sure a single request does not access data from more than one storage servers. We measure the total throughput and the converged average RPC fraction. As shown in Figure 14a, throughput increases with both adding a storage and an application server. This is because adding either essentially adds more CPU cores to the system. Note that the RPC fraction increases with the increment of the storage servers but decreases with the increment of the application servers (Figure 14b). This is because Kayak can judiciously arbitrate the requests and balance the load between the application and storage servers, by choosing the optimal RPC fraction.

6.5 Sensitivity Analysis

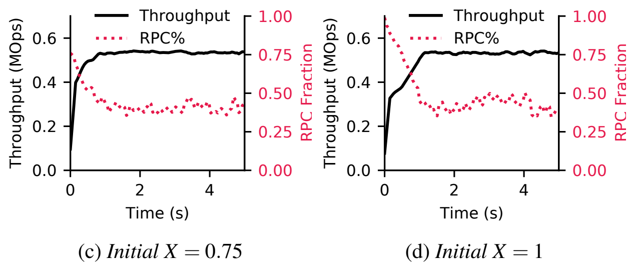
Initial state. First we evaluate whether Kayak is sensitive to its initial state. We run four experiments using the Heavy workload, and vary the starting value for RPC fraction X from $\{0, 0.25, 0.75, 0.100\}$. As shown in Figure 15, Kayak converges to the optimal request throughput and RPC fraction regardless of the initial RPC fraction in all four scenarios.

Choice of loop frequencies. In Section 4 we argue that in order for the dual loop control to work, we need to choose appropriate sampling frequencies for both loops. Here we analyze how different sampling frequencies affect the dynamics of our system.

We run two experiments using the Medium workload, and



(a) *Initial* $X = 0$ (b) *Initial* $X = 0.25$



(c) *Initial* $X = 0.75$ (d) *Initial* $X = 1$

Figure 15: *Throughput and RPC fraction during the converging process, with different starting RPC fraction.*

plot our results in Figure 16. In the first experiment we set the interval for both loop to be 200Hz; in the second experiment we invert the loop frequency so that the inner control loop runs slower than outer control loop. As shown in Figure 16a and 16b, the convergence quality degrades significantly in both cases. Hence, it is important to choose proper sampling frequencies to ensure that the inner control loop runs faster than the outer.

7 Discussion and Future Work

Rate Limiting. In Kayak, we consider rate limiting and admission control because simply moving up the latency curve cannot push the servers beyond their physical capacity, and we consider that if a tenant specifies a strict SLO target, requests that miss this target are essentially failed requests. As such, we assume that the tenants will implement a mechanism such as resubmitting requests which are dropped due to rate limiting, after adapting to a slower rate. At a slower timescale, tenants should also increase provisioning to avoid having to slow down, so that in the worst case scenario all requests can still be executed on all application servers within the SLO target.

Storage Function Differentiation. Kayak does not inspect individual storage functions, which reduces overhead and aligns with our design goal to be non-intrusive to applications. Therefore, Kayak can not distinguish between individual storage functions. We would like to explore how to differentiate individual storage functions without changing application code, which would allow us to implement more fine-grained control policy.

Developing Storage Functions. Currently, developers using Kayak and Splinter [29] have to code the same application logic again in the storage function which run inside the storage server. This duplication complicates the development process and increases the chance of human errors and bugs. Automatically generating server-side storage functions from code written using traditional KV API can alleviate this problem. This would be an interesting avenue for future work.

8 Related Work

Key-Value Stores. A recent line of research on key-value store has been focusing on utilizing RDMA to boost key-value store performance. Stuedi et al. [43] have achieved a 20% reduction in GET CPU load for Memcached using soft-iWARP without Infiniband hardware. Pilaf [33] uses only one-sided RDMA read to reduce CPU overhead of key-value store. In addition, it uses a verifiable data structure to detect read-write races. FaRM [16] proposes a new main memory key-value store built on top of RDMA. FaRM comes with transaction support but still support lock-free RDMA reads. HERD [24] further improves the performance of RDMA-based key-value store by focusing on reducing network round trips while using efficient RDMA primitives. FaSST [25] generalizes HERD and used two-sided RPC to reduce the number of QPs used in symmetric settings such as distributed transaction processing, improving scalability.

While there have been many research works focusing on improving raw performance of key-value stores, few investigates real performance implications on the application. TAO [13] is an application-aware key-value store by Facebook that optimizes for social graph processing. Kayak builds on top of this concept and focuses on application-level objectives such as SLO constraint.

Storage-side computation. Storage-side computation (i.e. *shipping compute to data*) has made its way from latency-insensitive big data systems such as MapReduce [1, 37, 45] and SQL databases [5–8, 26, 41, 42] into latency-critical KV stores [9, 18, 29, 39]. Comet [18] supports sandboxed Lua extensions to allow user-defined extensions to customize the storage by enabling application-specific operations. Malacology [39] utilizes Lua extensions contributed by users of the Ceph storage system [2], allowing installing and updating new object interfaces at runtime. Splinter [29] pushes bare-metal extension to storage server to allow RPC-like operations in addition to traditional key-value operations. These works breaks the assumption of dissagregated storage and necessitates the need for proactive arbitration provided by Kayak.

Adaptive compute placement. An emerging line of research aims at adaptively balancing between client-side processing and server-side processing. ASFP [12] extends Splinter by reactively pushing back requests to the client side if the server gets overloaded, but at the cost of wasting CPU and network resource.Instead, Kayak proactively balances the load exerted on both application and storage server. Cell [34] implements a B-tree store on RDMA supporting both client-side (RDMA-based) and server-side (RPC-based) search. Cell determines between these two schemes by tracking RDMA operation latency. This requires instrumentation into the application, which Kayak avoids by measuring end-to-end request latency instead. A recent work called Storm [35] uses a reactive-adaptive approach similar to that of ASFP [12] but with a different policy, where for each request it will try the traditional KV API first, and switch to RPC API if it detects that the application is trying to chase the pointers.

9 Conclusion

In this paper, we show that by proactively and adaptively combining RPC *and* KV together, overall throughput and CPU utilization can be improved. We propose an algorithm that dynamically adjusts the rate of requests and the RPC fraction to improve overall request throughput while meeting latency SLO requirements. We then prove that our algorithm can converge to the optimal parameters. We design and implement a system called Kayak. Our system implementation ensures work conservation and fairness across multiple tenants. Our evaluations show that Kayak achieves sub-second convergence and improves overall throughput by 32.5%-63.4% for compute-intensive workloads and up to 12.2% for non-compute-intensive and transactional workloads.

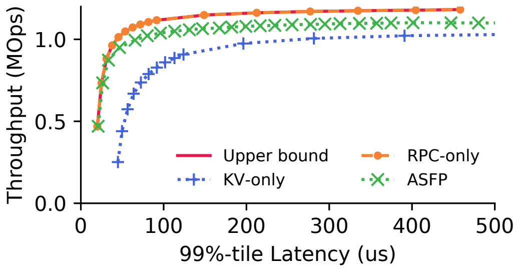
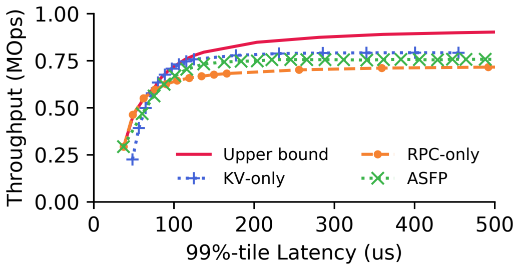
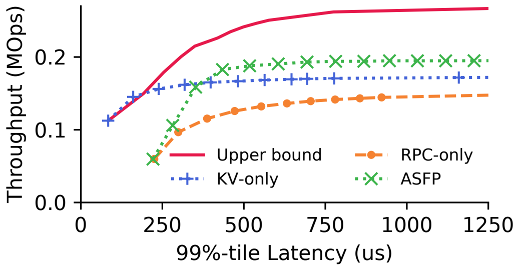
A Supplemental Measurements for Graph Traversal Workload



(a) *Light (100ns/RTT)*



(b) *Medium (1μs/RTT)*



(c) *Heavy (10μs/RTT)*

Figure 17: ***Throughput w.r.t. SLO (99%-tile latency) for graph traversal with four storage accesses per request.***

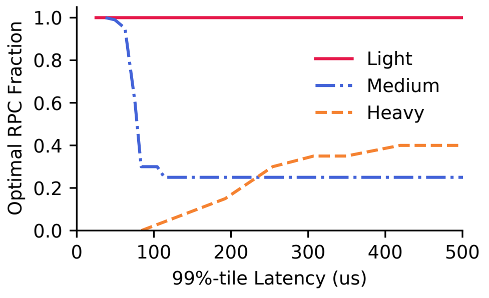


Figure 18: ***Optimal RPC fraction w.r.t. SLO (99%-tile latency) for graph traversal with four storage accesses per request.***

We repeat the same parameter sweep as in §2.2 but with the number of storage accesses per request set to 4 and 8. We vary the RPC fraction from 0 to 1 and measure the overall throughput and end-to-end latency of all requests. In doing so, we obtain the throughput-latency measurements for all possible execution configurations, as shown in Figure 17 and Figure 19. The optimal RPC fraction during these sweeps are shown in Figure 18 and Figure 20. We note that the observation we make in §2.2 still holds in these measurements.

B Analysis of Algorithms

B.1 Problem Formulation

We aim to solve the following optimization problem

$$\begin{aligned} \max_X \quad & R \\ \text{s.t.} \quad & T(X,R) \le t_0 \end{aligned} \tag{P}$$

where we assume:

Assumption 1. *Fix X, $F_X(R) := T(X,R)$ is monotonic increasing and twice differentiable.*

Assumption 2. *For any X, there exist R_1 and R_2 such that $\min_X T(X,R_1) \le t_0 \le \min_X T(X,R_2)$.*

B.2 Algorithm I: X-R Dual Loop Control

We adopt the following iterative algorithm to solve the problem:

Algorithm I (X-R Dual Loop Control) For $k = 1, \dots, K$, we alternatively update X_k and R_k by

- $X_k = \arg\min_X T(X,R_k)$;
- $R_{k+1} = R_k + \eta\,(t_0 - T(X_k,R_k))$.

We have the following theorem to characterize the convergence of the above algorithm.

Theorem 1. *Suppose in addition we have,*

1. *$T(X,R)$ is twice differentiable and lower bounded.*
2. *Fix R, $F_R(X) := T(X,R)$ is μ-strongly convex[3], L-smooth[4] and coercive.[5]*
3. *For all X, we have $0 < \alpha \le \frac{\partial T(X,R)}{\partial R} \le \beta$.*

If we set $0 < \eta < \frac{1}{\beta}$, then

$$|R_K - R_*| \le (1-\eta\alpha)^K \cdot |R_0 - R_*|\,.$$

In the following we elaborate the proof for Theorem 1. We begin with introducing a series of lemmas. Let us denote

$$H(R) = \min_X T(X,R).$$

Lemma 1. *For all $R \ne S$,*

$$0 < \alpha \le \frac{H(R)-H(S)}{R-S} \le \beta.$$

Moreover, the above inequality implies $H(R)$ is monotonic increasing and continuous.

Proof. Without loss of generality let $R > S$. Let $X = \arg\min_X T(X,R)$ and $Y = \arg\min_X T(X,S)$. Then

$$\frac{H(R)-H(S)}{R-S} = \frac{T(X,R)-T(Y,S)}{R-S} \begin{cases} \le \frac{T(Y,R)-T(Y,S)}{R-S} = \frac{\partial T(Y,P)}{\partial R} \le \beta, \\ \ge \frac{T(X,R)-T(X,S)}{R-S} = \frac{\partial T(X,Q)}{\partial R} \ge \alpha > 0. \end{cases}$$

Here $P, Q \in (S,R)$ are given by mean-value theorem. $\square$

Lemma 2. *There exists an unique R_* such that $H(R_*) = t_0$. Moreover, this R_* gives the maximum of the original optimization problem.*

Proof. We have already shown that $H(R)$ is monotonic and continuous. Recall that there exists R_1 and R_2 such that $H(R_1) \le t_0 \le H(R_2)$, thus there exists an unique R_* such that $H(R_*) = t_0$.

For any R so that $R > R_*$, we have $H(R) > H(R_*) = t_0$ by monotonicity, thus R does not meet the constraint. Therefore R_* is the maximum of the optimization problem. $\square$

Proof of Theorem 1. With $H(R) := \min_X T(X,R)$, we can rephrase Algorithm I as

$$R_{k+1} = R_k + \eta\,(H(R_*) - H(R_k))\,.$$

Let R_0 be the initialization. We next show the convergence of this iteration.

Case I: $R_0 < R_*$. If $R_k < R_*$, then

$$R_* - R_{k+1} = R_* - R_k - \eta\,(H(R_*) - H(R_k)) \begin{cases} \le R_* - R_k - \eta\alpha\,(R_* - R_k) = (1-\eta\alpha)\,(R_* - R_k) \\ \ge R_* - R_k - \eta\beta\,(R_* - R_k) = (1-\eta\beta)\,(R_* - R_k) \end{cases}$$

that is $0 \le (1-\eta\beta)\,(R_* - R_k) \le R_* - R_{k+1} \le (1-\eta\alpha)\,(R_* - R_k)$. Using this recursion, if $R_0 < R_*$, we have

$$0 \le (1-\eta\beta)^K\,(R_* - R_0) \le R_* - R_K \le (1-\eta\alpha)^K\,(R_* - R_0).$$

Case II: $R_0 > R_*$. If $R_k > R_*$, then

$$\begin{aligned} & R_{k+1} - R_* \\ & = R_k + \eta\,(H(R_*) - H(R_k)) - R_* \\ & = R_k - R_* - \eta\,(H(R_k) - H(R_*)) \\ & \begin{cases} \le R_k - R_* - \eta\alpha\,(R_k - R_*) = (1-\eta\alpha)\,(R_k - R_*) \\ \ge R_k - R_* - \eta\beta\,(R_k - R_*) = (1-\eta\beta)\,(R_k - R_*) \end{cases} \end{aligned}$$

that is $0 \le (1-\eta\beta)\,(R_k - R_*) \le R_{k+1} - R_* \le (1-\eta\alpha)\,(R_k - R_*)$. Using this recursion, if $R_0 > R_*$, we have

$$0 \le (1-\eta\beta)^K\,(R_0 - R_*) \le R_K - R_* \le (1-\eta\alpha)^K\,(R_0 - R_*).$$

To sum up, when $\eta < \frac{1}{\beta}$ (hence smaller than $\frac{1}{\alpha}$), we have

$$|R_K - R_*| \le O\left((1-\eta\alpha)^K\right).$$

$\square$

[3] $f(x)$ is μ-strongly convex, if for all x and y, it holds that $f(x) \ge f(y) + \langle \nabla f(y), x-y\rangle + \frac{\mu}{2}\|y-x\|_2^2$.

[4] $f(x)$ is L-smooth, if for all x and y, it holds that $f(x) \le f(y) + \langle \nabla f(y), x-y\rangle + \frac{L}{2}\|y-x\|_2^2$. In general, if $f(x)$ is twice-differentiable and x is restricted in a bounded domain, then $f(x)$ is L-smooth in that domain, for some finite L.

[5] $f(x)$ is coercive if $f(x) \to +\infty$ as $\|x\| \to +\infty$. A strongly convex and coercive function admits an unique and finite minimum point.

B.3 Algorithm II: R-X Dual Loop Control

Let us take a closer look at the optimization problem (P) under Assumption 1 and Assumption 2. First we observe the maximal must be attended at the boundary

$$T(X,R) = t_0. \tag{6}$$

Second the boundary constraint Eq. (6) implicitly defines a function $R(X)$, where

$$T(X,R(X)) = t_0.$$

We highlight that $R(X)$ is indeed well defined, since under Assumption 1 and Assumption 2, for any X, there exists an unique $R(X)$ that satisfies the boundary constraint.

With the above observations, we may rephrase the optimization problem (P) as

$$\max_X \quad R(X) \tag{P'}$$

where $R(X)$ is implicitly defined by the boundary constraint. In the following we discussion algorithms that solve problem (P').

Our challenge it that we do not have direct access to $R(X)$; instead at each fast loop step, we have an estimation to $R(X)$, denoted as $R_k(x)$, which approximately satisfies

$$T(X,R_k(X)) \approx t_0.$$

In this set up we can perform *stochastic gradient ascent* (SGA, or *online gradient ascent*) for $R_k(X)$. We summarize the algorithm in the following.

Algorithm II (R-X Dual Loop Control) For $k = 1,\dots,K$, we respectively update X_k and R_k by

1. Apply rate control so that the latency approximates SLO, i.e.,
   R_k be such that $T(X_k,R_k) \approx t_0$;
2. Use gradient ascent to search for the optimal X_k, i.e., *$X_{k+1} = X_k + \eta \frac{\mathrm{d}R_k}{\mathrm{d}X}$, where $T(X,R_k) = t_0$, and η is a positive stepsize.*

There is a rich literature for the theory of online learning when $R_k(X)$ is concave, e.g., see [36]. For completeness, we introduce the following theorem to characterize the behavior of the above algorithm.

Theorem 2. *Suppose $R_k(X)$ is concave. Consider the iterates of SGA, i.e.,*

$$X_{k+1} = X_k + \eta \nabla R_k(X_k).$$

Then we have the following bound for the regret

$$\sum_{k=1}^{K} (R_k(X_*) - R_k(X_k)) \le \frac{\|X_1 - X_*\|_2^2}{2\eta} + \frac{\eta}{2}\sum_{k=1}^{K} \|\nabla R_k(X_k)\|_2^2.$$

If in addition we assume $\|\nabla R_k(X)\|_2 \le L$, and set

$$\eta = \frac{\|X_1 - X_*\|_2}{L\sqrt{K}},$$

then

$$\sum_{k=1}^{K} (R_k(X_*) - R_k(X_k)) \le C \cdot \sqrt{K}, \tag{7}$$

where $C := L\|X_1 - X_*\|_2$ is a constant depends on initialization and gradient bound.

Remark. The sublinear regret bound implies SAG behaviors nearly optimal on average: we see this by setting $X_* = \arg\max_X \sum_{k=1}^{K} R_k(X)$, and noticing that

$$\frac{1}{K}\sum_{k=1}^{K} R_k(X_*) - \frac{1}{K}\sum_{k=1}^{K} R_k(X_k) \le O\left(\frac{1}{\sqrt{K}}\right) \to 0.$$

More concisely, in our algorithm, $\{R_k(X)\}_{k=1}^{K}$ corresponds to a sequence of inaccurate estimations to the true implicit function $R(X)$ — even so the theorem guarantees a sublinear regret bound, which implies that our algorithm behaviors nearly as good as one can ever expect under the estimations, no matter how inaccurate they could be.

Furthermore, if for each k, $R_k(X)$ is an *unbiased estimator* to the true concave function $R(X)$, i.e., $\mathbb{E}R_k(X) = R(X)$, then $\bar{X} = \frac{1}{K}\sum_{k=1}^{K} X_k$ converges to the maximal of $R(X)$ in expectation: we see this by choosing $X_* = \arg\min_X R(X)$ and noticing that

$$\begin{aligned}\mathbb{E}\left[R(X_*) - R(\bar{X})\right] &\le \frac{1}{K}\sum_{k=1}^{K} \mathbb{E}\left[R(X_*) - R(X_k)\right] \\ &= \frac{1}{K}\sum_{k=1}^{K} \mathbb{E}\left[R_k(X_*) - R_k(X_k)\right] \\ &\le C \cdot \frac{1}{\sqrt{K}} \to 0.\end{aligned}$$

Proof of Theorem 2. We first notice the following ascent lemma

$$\begin{aligned}&\|X_{k+1} - X_*\|_2^2 \\ &= \|X_k + \eta \nabla R_k(X_k) - X_*\|_2^2 \\ &= \|X_k - X_*\|_2^2 + \eta^2 \|\nabla R_k(X_k)\|_2^2 + 2\eta \langle \nabla R_k(X_k), X_k - X_* \rangle \\ &\le \|X_k - X_*\|_2^2 + \eta^2 \|\nabla R_k(X_k)\|_2^2 + 2\eta \left(R_k(X_k) - R_k(X_*)\right),\end{aligned}$$

where the last inequality is due to the assumption that $R_k(X)$ is concave. Next we re-arrange the terms and take telescope summation,

$$\begin{aligned}
&\sum_{k=1}^{K}(R_k(X_*)-R_k(X_k))\\
&\leq \sum_{k=1}^{K}\frac{1}{2\eta}\left(\|X_k-X_*\|_2^2-\|X_{k+1}-X_*\|_2^2\right)+\sum_{k=1}^{K}\frac{\eta}{2}\|\nabla R_k(X_k)\|_2^2\\
&=\frac{1}{2\eta}\left(\|X_1-X_*\|_2^2-\|X_{K+1}-X_*\|_2^2\right)+\sum_{t=1}^{T}\frac{\eta}{2}\|\nabla R_k(X_k)\|_2^2\\
&\leq \frac{1}{2\eta}\|X_1-X_*\|_2^2+\sum_{k=1}^{K}\frac{\eta}{2}\|\nabla R_k(X_k)\|_2^2,
\end{aligned}$$

which gives the first regret bound.

If further we have $\|\nabla R_k(X)\|_2 \leq L$, then

$$\sum_{k=1}^{K}(R_k(X_*)-R_k(X_k)) \leq \frac{1}{2\eta}\|X_1-X_*\|_2^2+\frac{\eta}{2}L^2K,$$

by setting $\eta = \frac{\|X_1-X_*\|_2}{L\sqrt{K}}$ we obtain

$$\begin{aligned}
\sum_{k=1}^{K}(R_k(X_*)-R_k(X_k)) &\leq \frac{1}{2\eta}\|X_1-X_*\|_2^2+\frac{\eta}{2}L^2K\\
&\leq L\|X_1-X_*\|_2\cdot\sqrt{K}.
\end{aligned}$$

□

Caerus: NIMBLE Task Scheduling for Serverless Analytics

Hong Zhang *UC Berkeley*   *Yupeng Tang* *Yale University*   *Anurag Khandelwal* *Yale University*   *Jingrong Chen* *Duke University*   *Ion Stoica* *UC Berkeley*

Abstract

Serverless platforms facilitate transparent resource elasticity and fine-grained billing, making them an attractive choice for data analytics. We find that while server-centric analytics frameworks typically optimize for job completion time (JCT), resource utilization and isolation via inter-job scheduling policies, serverless analytics requires optimizing for *JCT* and *cost of execution* instead, introducing a new scheduling problem. We present Caerus, a task scheduler for serverless analytics frameworks that employs a fine-grained NIMBLE scheduling algorithm to solve this problem. NIMBLE efficiently pipelines task executions within a job, minimizing execution cost while being Pareto-optimal between cost and JCT for arbitrary analytics jobs. To this end, NIMBLE models a wide range of execution parameters — pipelineable and non-piplineable data dependencies, data generation, consumption and processing rates, etc. — to determine the ideal task launch times. Our evaluation results show that in practice, Caerus is able to achieve *both* optimal cost and JCT for queries across a wide range of analytics workloads.

1 Introduction

Serverless platforms [1–3] fulfill the promise of transparent resource elasticity in the cloud [4–6]. Under the Function as a Service (FaaS) serverless model, users decompose their applications into short-lived stateless *functions* that read and write data from an external storage service. The sub-second startup latencies and virtually unlimited parallelism in FaaS platforms permit fine-grained compute elasticity, while sub-second billing granularities afford cost-efficiency.

These benefits have driven many recent efforts to port *data analytics* applications to serverless platforms [7–18]. Analytics jobs typically comprise multiple stages of execution organized as directed acyclic graphs (DAGs) based on their data dependencies, with each stage comprising several parallel tasks. While traditional server-centric deployments use clusters provisioned with a fixed pool of storage and compute resources to execute these jobs, serverless deployments implement tasks as serverless functions [7–13] that exchange state via external storage [14, 15]. Since analytics workloads typically have widely varying resource needs over time, both across and during job lifetimes [12, 14], server-centric deployments can frequently suffer from resource under- or over-provisioning [12, 14, 19, 20], leading to resource wastage or performance degradation, respectively. In contrast, serverless compute [1–3] and storage [15, 21–24] platforms facilitate *fine-grained scaling* of resources to match application needs, making them an attractive choice for data analytics [7–18].

We find that the shift from server-centric to serverless analytics results in a shift in goals for schedulers in analytics frameworks. Since the FaaS platforms manage allocation of compute resources *across* jobs, schedulers need no longer be concerned with the conventional goals of maximizing cluster resource-utilization and enforcing fairness across jobs via *inter-job* scheduling policies [25–28]. Instead, under the FaaS billing model, schedulers must now consider the *cost* of each job's execution, which is proportional to the aggregated runtimes across its component tasks. This highlights the need for *inter-task* scheduling policies for serverless analytics jobs to minimize both execution cost and job completion time (JCT).

Unfortunately, task-level scheduling policies employed by server-centric analytics today expose a hard-tradeoff between cost and JCT in serverless platforms. Figure 1 shows a simple map-reduce job where reduce tasks consume and aggregate data generated by map tasks. Traditional analytics frameworks [29–32] typically employ one of the two following extremes: (1) a *lazy* approach that launches a reduce task only when all the map tasks have finished (Figure 1 (a)), and (2) an *eager* approach that launches a reduce task as soon as any map task produces data for it to consume (Figure 1 (b)).

Intuitively, the lazy approach is *cost-efficient*: since reduce tasks waste no time waiting for upstream map tasks to generate data, individual task durations (which governs cost in serverless settings) is always minimized. However, its JCT can be far from optimal since there is no *pipelining* of map and reduce task executions. The eager approach, on the other hand, is *JCT-efficient* since it maximally pipelines the execution of map and reduce tasks. However, its can introduce a much higher cost: reduce tasks can waste a lot of time waiting for upstream map tasks to generate data, which increases reduce task durations and, consequently, execution cost. We discuss this example further in §2, but note for now that this trade-off between execution cost and JCT is even more extreme for multi-stage jobs seen in production workloads [27, 28].

Note that in an ideal solution (Figure 1 (c)), a task would be launched *late enough* to minimize task durations (and therefore, execution cost), but *early enough* to minimize JCT. In this work, we propose a NIMBLE scheduling algorithm that builds on this intuition: at its core, NIMBLE scheduling combines the cost-efficiency of lazy and JCT-efficiency of eager approaches and breaks the tradeoff between them (Figure 1 (d)), by scheduling tasks to run *at just the right time*.

Designing such an optimal scheduling strategy, however, is non-trivial. First, a precise description of the pipelinablity across different job stages is crucial to determine the optimal schedule — task-level DAGs typically used for representing

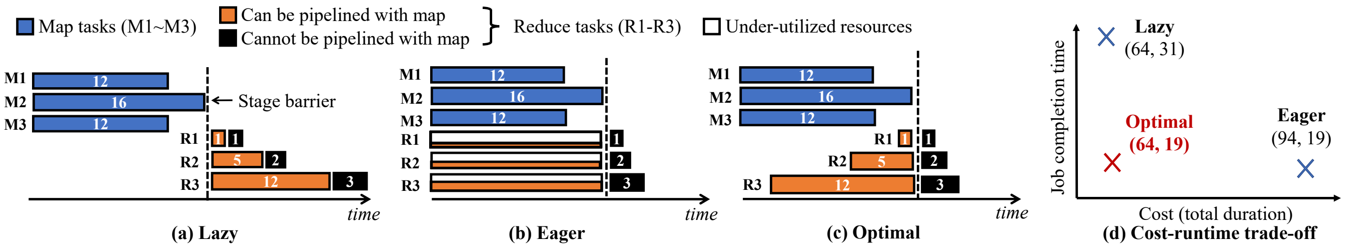

Figure 1: (a, b) Lazy and eager approaches expose a hard trade-off between JCT and cost; numbers within bars correspond to task runtimes. (c, d) Fine-grained scheduling in serverless infrastructures provide opportunities to break this tradeoff with optimal scheduling strategies. The JCT is simply the finish time of the last reduce task, while its cost is calculated as the aggregated durations of all its component tasks.

job executions in existing job schedulers are insufficient. Even for the simple map-reduce example in Figure 1, while parts of reduce task execution can be pipelined with map tasks (orange bars), some parts can only start after map stage finishes (black bars), *e.g.*, when map output must be aggregated at the reduce task before further processing. To this end, we develop a fine-grained *step dependency model* that captures data dependency and pipelinablity information at *sub-task* granularity (§3).

Second, in contrast to the map-reduce example above, tasks in general analytics jobs can have significantly more complex pipeline dependencies. Specifically, a task can consume data from multiple upstream tasks, and tasks across the job's execution DAG may have cascading dependencies. Coupled with time-varying data generation and consumption rates, this makes identifying task launch times for JCT- and cost-efficient job execution challenging. In fact, our analysis shows that even with perfect models for all of the above constraints, it is *impossible* for a task scheduling algorithm to always be able to optimize both execution cost and JCT for arbitrary analytics jobs. Fortunately, we show it *is* possible for a scheduling algorithm to be cost optimal, while being *Pareto-optimal* between execution cost and JCT. We realize this in NIMBLE, a scheduling algorithm that carefully models data produce and consume rates across stages, computes launch times for tasks across them based on both inter- and intra-task data dependencies, and schedules tasks greedily across dependent stages (§4).

Finally, we incorporate the NIMBLE algorithm into Caerus, a new fine-grained task-level scheduler for serverless analytics frameworks (§5). Caerus translates the theory developed for NIMBLE to practice, by extracting step dependencies from user queries via a step annotation API, and estimating NIMBLE algorithm inputs using a combination of job execution histories and information profiled at runtime. Caerus easily integrates with existing serverless analytics frameworks [11, 12, 14] — we implement Caerus in a prototype serverless SQL engine built atop Locus [14], and evaluate its performance on AWS Lambda for a wide range of analytics workloads including TeraSort, TPC-DS and Big-Data Benchmark (§6). Our results show that in practice, Caerus optimizes *both* cost and JCT, outperforming the lazy approach by 1.08–2.2× in JCT, and eager approach by 1.21–1.57× in cost across these workloads.

In summary, we make three main contributions:

- Formulation of a new task-level scheduling problem for serverless analytics to minimize execution cost and JCT. We show that schedulers used in server-centric frameworks expose a hard tradeoff between cost and JCT (§2).
- Design of a new NIMBLE scheduling algorithm, that launches each task in a job at just the right time to optimize *both* cost and JCT. NIMBLE employs a new *step model* to capture sub-task level pipelinablity and data dependencies, and guarantees cost optimality while being *Pareto-optimal* between cost and JCT for any analytics job (§4).
- Design, implementation and evaluation of Caerus, a fine-grained task-level scheduler for serverless analytics frameworks that enables NIMBLE scheduling in practice (§5, §6).

2 Motivation

In this section, we provide a brief background on server-centric and serverless analytics (§2.1). We then describe how serverless analytics introduces a new task scheduling problem (§2.2) and new opportunities to address it (§2.3).

2.1 Background

Server-centric Analytics. Traditional server-centric deployments for data analytics [30, 31, 33–35] operate atop a fixed pool of compute and storage resources, *e.g.*, clusters of provisioned servers or pools of provisioned virtual machines (VMs)[1]. Consequently, such deployments employ a cluster-wide job scheduler to efficiently share the fixed resource-pool among multiple jobs with three key goals: minimizing job runtime, maximizing resource utilization and ensuring resource isolation (or fairness) across jobs. Given the resource demands of each job, the scheduler achieves all or a subset of goals via *inter-job* (i.e., job-granularity) scheduling policies [25–28].

Within a job, the execution is broken down into a DAG of stages, each comprising multiple parallel tasks (see Figure 1 for an example). A task scheduler launches tasks across the compute resources allocated to the job. Tasks in a stage read their initial input from and write their final output to persistent storage (*e.g.*, HDFS [37]), while data exchange between consecutive stages occurs over the network (*e.g.*, shuffle, broadcast, etc.). Existing frameworks typically apply one of two popular approaches to decide *when* to launch tasks: (i) *lazy* (*e.g.*, Spark [30]), which launches a task only when *all*

[1]One can add/remove VMs to scale VM clouds, but at coarse time granularities, *e.g.*, resizing an AWS EMR cluster takes $\sim 6-45$ minutes [36].

tasks in upstream stages have completed, and (ii) *eager* (*e.g.*, MapReduce Online [29]), which launches a task as soon as *any* output from its upstream stages is ready.

Serverless Analytics. In serverless platforms, users no longer provision or manage resources: this is the cloud provider's responsibility. Users simply pay for resources they use. Serverless compute platforms [1–3] allocate and charge for compute resources at function invocation granularity: invoking more functions permits scaling up at a higher cost, and vice versa.

Existing approaches to serverless analytics deploy tasks within a stage as serverless function invocations. Since cloud providers disallow direct communications between serverless functions [7, 11, 14], data is exchanged between functions via external storage [8, 14, 15]. A job is charged for both function execution and external storage, with the former typically dominating the cost[2]. With *sub-second granularity billing* for serverless functions, the job execution cost is proportional to the cumulative runtimes across all tasks of the job.

2.2 Serverless Scheduling: A New Problem

Since the cloud provider is responsible for resource management in serverless platforms, user goals in serverless analytics are different from server-centric deployments. In particular, while minimizing JCT is still a primary goal, metrics like resource utilization and isolation are now the onus of the cloud provider. Instead, the user must now optimize the *cost* of each job's execution, which is proportional to the cumulative task runtime as outlined in §2.1. This shift in goals exposes a new task-level scheduling problem for serverless analytics:

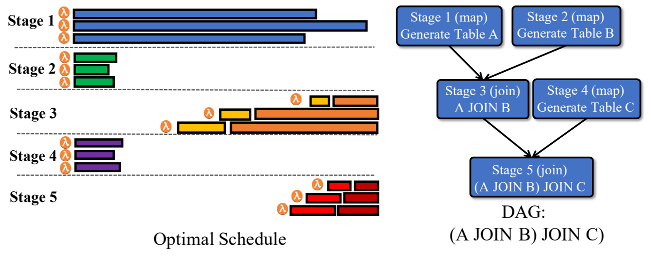
Problem Statement: *Given the execution plan for an analytics job comprising tasks with arbitrary dependencies, can we find a task-level schedule that optimizes for both job execution cost and JCT on a serverless platform?*

Limitations of existing approaches. As we saw in §1, the existing server-centric lazy and eager task scheduling approaches, when applied for serverless analytics, expose a hard tradeoff between cost and JCT. Recall the job execution example in Figure 1, which comprises a map and a reduce stage, each with three tasks — each bar represents the execution of one task over time (numbers in bars show task runtimes).

The lazy approach (Figure 1 (a)) is *cost-optimal* in the serverless model, with a cost of 64 units[3] — starting reduce tasks any later would not affect their runtime (and therefore, cost), while starting them sooner can cause them to stall for more data to be generated by upstream map tasks, increasing cost. However, the lazy approach also leads to high JCT (31 units), since it does not pipeline the execution of map and reduce tasks at all. Similarly, eager scheduling (Figure 1 (b)) is *JCT-optimal* (19 units) since the first part of reduce execution

[2]Cost of AWS Lambda execution is ∼\$0.20/hour [38], while Amazon S3 storage is ∼\$0.02/GB/month [39], with no data transfer cost between them.

[3]The cost is computed as the cumulative sum of the runtimes of the tasks in the job, and assuming unit cost per unit runtime.



Stage 1
Stage 2

DAG: (A JOIN B) JOIN C)

Figure 2: **Optimal schedule (left) and execution DAG (right) for a multi-stage job.** See §2.3 for details.

(orange bar) can be completely pipelined with the map stage. However, its cost is significantly higher (94 units), since reduce tasks often wait for data to be generated by upstream map tasks, increasing their runtime, and therefore, cost.

This tradeoff can be much more severe for multi-stage jobs. Production traces from Microsoft [27, 28] show that jobs in their workloads have 13 and 121 stages at 50th and 95th percentiles, making it likely for them to have far more opportunities for pipelining tasks across stages. Ignoring these opportunities (*e.g.*, following the lazy approach) would lead to JCTs that are significantly longer than optimal. On the other hand, jobs can also have heavy skew in task runtimes [40–42] — 10% of tasks take more than 10× the median task duration in Microsoft's workloads [40]. Starting tasks across all stages early to maximize pipelining (*e.g.*, following the eager approach) would force most downstream tasks to stall due to slower upstream tasks, significantly increasing execution cost.

2.3 Opportunities & Challenges

New opportunities in serverless scheduling. Serverless frameworks provide new opportunities to break the hard tradeoff between cost and JCT exposed by lazy and eager solutions — on-demand invocation of functions at fine-grained timescales permits the design of *fine-grained task-level schedulers*. Figure 1 (c) shows the optimal schedule for the job in Figure 1 — with fine-grained scheduling, it is possible to achieve such a schedule by launching each task *at just the right time*, minimizing both cost (64 units) *and* JCT (19 units) (Figure 1 (d)).

Moreover, these gains are likely to be even more significant in production workloads comprising multi-stage jobs with complex stage dependencies. For example, Figure 2 shows a multi-stage SQL job which performs join across three tables (A, B and C) using shuffle hash join (SHJ) algorithm [43]. The figure shows the job's execution plan as a DAG of stages on the right, and the corresponding optimal task schedule on the left. The optimal schedule can efficiently pipeline all the five stages in this multi-stage join example, resulting in much higher gains in JCT and cost than for simple two stages map-reduce jobs.

Challenges. Figure 2 also indicates that calculating the optimal launch time for each task is non-trivial due to a number of reasons. First, a task may include multiple parts, where each part may or may not be pipelineable with some part of one of its upstream stages. In Figure 2 (left), Stage 3 is composed of two parts. The first part, which reads Table B from Stage 2 and uses it to build a hash table, can be pipelined with Stage 2 execution. The second part, which reads Table A from Stage 1 and performs online join with the hash table constructed in the first part, can pipelined with Stage 1 execution. Second, the runtime of one task depends on the processing rate of all tasks in its previous stage, and these dependencies cascade to upstream stages. In Figure 2, the execution of Stage 5 depends on Stage 3 and Stage 4, and Stage 4 is further determined by Stage 1 and Stage 2. As such, the first challenge lies in identifying parts of the execution that can be pipelined, and the dependencies between such pipelinable components — we address this in §3. The second challenge lies in using this information to determine ideal launch times for tasks in jobs with complex DAGs, which we address in §4.

Why serverless? Intuitively, the fine-grained task-level scheduling shown in Figures 1 (c) and 2 can also be extended to server-centric settings to optimize average JCT. Moreover, the reduction in per-job resource usage (i.e., cost in serverless settings) enabled by this approach may improve resource utilization via bin-packing more jobs onto the same number of servers. However, while cost improvements in serverless analytics are obvious, achieving improvements in resource utilizations with theoretical guarantees in server-centric deployments is not straightforward, since it is unclear how the resources saved by delaying task launch times can be utilized by other jobs. Specifically, the optimal in Figures 1 (c) and 2 is likely to create staggered task launch times across stages to optimize *each individual* job, and they may not be optimal for bin-packing *across* jobs. Thus, while the clear decoupling from inter-job resource allocation ensures cost and JCT-optimality, extending it to server-centric settings for optimal JCT and resource utilization requires a careful co-design of inter- and intra-job scheduling. We leave this study to future work.

3 Step Dependency Model

As discussed above, a key challenge in identifying ideal task launch times for a job is modeling pipelineable and non-pipelineable dependencies across tasks. In this section, we discuss how we model such dependencies and the flow of data across them, using a new *step dependency model*. We employ this model to design our NIMBLE scheduling algorithm in §4.

Stage dependencies in traditional analytics. As outlined in §2.1, job execution in traditional analytics frameworks [27, 28, 30, 34] is represented as a DAG, where nodes are execution *stages* (comprised of multiple parallel tasks) and edges denote *data dependencies* between them. Figure 3 (a, left) shows the DAG for the map-reduce example from Figure 1, while Figure 3 (b, left) shows a SQL query that performs shuffle hash join (SHJ) on tables generated by two map stages.

Unfortunately, the stage model is not fine-grained enough to capture the information required to determine the ideal launch times for tasks in serverless analytics jobs. To see why,

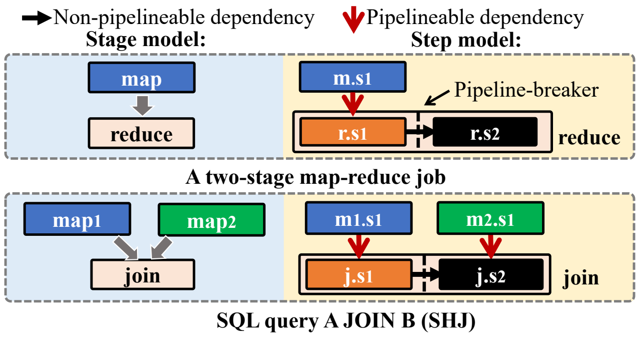

Figure 3: **Stage *vs.* step dependency model** for (a) map-reduce job, and (b) SQL query that joins two tables A and B after applying a map function on each. In the step model, red arrows show dependencies across steps that can be pipelined, while black arrows show dependencies that prevent pipelining. See §3 for details.

consider the map-reduce example from Figure 3 (a, right)[4], where the reduce stage (and therefore, all tasks in the stage) has two distinct parts, shown as orange and black boxes. While the first part (`r.s1`), where reduce tasks read map data, can be pipelined with map execution (`m.s1`), the second part (`r.s2`), where the reduce tasks aggregate and output data, cannot — since final aggregation can only occur after all map data has been read. Clearly, stage dependencies, shown in Figure 3 (a, left), cannot capture such fine-grained information regarding pipelineable and non-pipelineable components of task, nor capture the data dependencies between them. This information is crucial in determining the optimal start time for reduce tasks — early enough to maximally overlap `r.s1` with `m.s1`, but not too early, since pipelining `r.s2` with `m.s1` is impossible.

Modeling pipeline dependencies using *steps*. To precisely model how stages can be pipelined, we refine the stage model into a fine-grained step model to precisely describe how job execution can be pipelined across stages. In our model, the stages are decomposed into one or more *steps*, which are separated by *pipeline breakers* within the stage — operators that produce their first output only after all input have been processed. Pipeline breakers create barriers in execution, demarcating stretches of execution that cannot be pipelined with each other. As such, steps within a stage must be executed sequentially, since pipeline breakers prevent subsequent steps from starting before its upstream step finishes. Across stages, however, steps with data dependencies between them can be pipelined. As a concrete example, consider the step model for the map-reduce job in Figure 3 (a, right) — `m.s1` corresponds to the single step in map stage, while `r.s1` and `r.s2` correspond to two steps in the reduce stage, with a pipeline breaker separating them. The step `r.s1` which consumes data can be pipelined with the upstream step `m.s1` in the map stage that generates the data. We refer to such cross-stage pipelineable step pairs (*e.g.*, (`m.s1`, `r.s1`)) as *parent-child* step pairs. Note that the while above description focuses on the decomposition of a stage into steps, each task within the stage shares the same

[4]This is the same example as the one depicted in Figure 1.

step-level decomposition — we will use the term step to refer to parts of a stage or its tasks interchangeably and clarify the distinction whenever needed.

Figure 3 (b) contrasts the step and stage DAGs for a simple join query. Each of the two map stages comprise a single step, while the hash join stage is divided into two steps. The step `j.s1` reads the left table (Table A generated by `m1.s1`) to create a hash table of unique entries, while step `j.s2` reads the right table (Table B generated by `m2.s1`), joins it with the hash table and writes the output. Each of the two steps can be pipelined with their parent steps (the two map stages), but these two steps have to be executed sequentially within the join stage, since the hash table must be created before the second join step can proceed (pipeline-breaker).

We discuss the details of how the step dependencies can be extracted from user code in §5, but note for now that this model is expressive enough to capture the pipeline dependencies across a wide range of evaluated analytics applications (§6).

Modeling flow of data across steps. We now describe parameters that are used to model the flow of data across steps in the step dependency model. While we discuss how these are estimated in §5, we note for now that these parameters are used as inputs to the NIMBLE algorithm. Consider a stage comprising n steps, `s1`-`s`n, some of which may have a parent step, while some may not. If step `s`i receives data from a parent step, then (1) parent *produce rate* (r_p) is the aggregated data output rate across all tasks of its parent step (referred to as *produce rate* for brevity); and (2) *full consume rate* (r_c) is the rate at which data can be read and processed by step `s`i when there is sufficient data for it to consume. If step `s`i does not have a parent step, then its execution duration $d_{\mathtt{s}i}$ is independent of when the task is launched, allowing us to model $d_{\mathtt{s}i}$ as a constant.

Since the produce rate is determined by the aggregate data output rate across all upstream tasks, each with potentially different start and end times, we model r_p as an arbitrary function of time t. Note that the cumulative area under the $r_p(t)$ curve corresponds to the total input data for the step under consideration; we denote this as P. The full consume rate, on the other hand, is tied to how fast the step can read and process data, and we found it to be stable throughout a the step's execution in our evaluation (§6), allowing us to model r_c as a constant. Note that the parent step may not always produce data as fast as it can be consumed, i.e., the *actual consume rate* (r_{ac}) for the step may be lower than r_c.

4 NIMBLE Scheduling

Armed with the step dependency model, we are now ready to describe our NIMBLE scheduling algorithm. NIMBLE builds on the intuition outlined in §2.3, and combines the cost-optimality of lazy and JCT-optimality of eager approaches to schedule tasks in an analytics job to run at *just the right time*. We first describe NIMBLE scheduling for a simple two-stage map-reduce job (§4.1), and then extend it to general analytics jobs with arbitrary execution DAGs (§4.2).

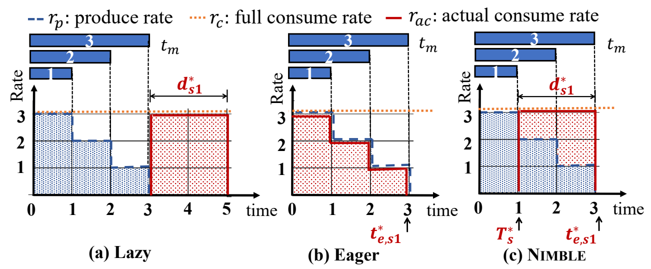

Figure 4: **Optimal launch time for a two-stage map-reduce job.** (a) The total volume of data to be consumed by the reduce step `r.s1` ($P = 6$) is the area under the produce rate ($r_p(t)$) curve. The lazy approach allows us to compute the optimal task runtime ($d^*_{\mathtt{s1}}$) as $P/r_c = 2$. (b) The optimal task finish time ($t^*_{e,\mathtt{s1}} = 3$) is obtained by emulating the eager approach, where the finish time is the maximum of P/r_c ($= 2$) and the map finish time t_m ($= 3$). (c) The optimal launch time ($T^*_s = 1$) is computed as the difference of the optimal finish time and optimal duration. See §4.1 for details.

4.1 NIMBLE for Two-stage Map-Reduce

Consider the step model for the simple two-stage map-reduce job in Figure 3 (a). Note that the JCT of the job is the same as the finish time of the last reducer, and the total cost of the job is proportional to the aggregated duration of all map and reduce tasks. As such, optimizing for the finish time and execution duration of individual tasks also ensures optimality for JCT.

Since map tasks do not have any upstream dependencies, their execution duration is independent of their launch times, and only depends on how fast they can read data from persistent storage and process it. Meanwhile, optimal finish time for map tasks can be achieved by launching them as early as possible (at $t = 0$). On the other hand, due to the parent-child step dependency between the map and reduce tasks (Figure 3 (top)), the *data consumption* in `r.s1` step of reduce tasks can be pipelined with the *data generation* in step `m.s1` of map tasks for minimizing reduce task finish times and execution durations. In particular, a reduce task should be launched early enough to ensure `r.s1` overlaps with `m.s1` as much as possible to minimize finish time, but late enough to ensure that it can always consume data at full rate throughout its execution without stalling, to optimize cost. Our NIMBLE scheduling approach can always find such a "perfect" launch time using the following three steps (Figure 4):

Step 1: Calculate optimal task duration D^*. Since step `r.s2` can only start after `r.s1` finishes, the optimal duration D^* of a reduce task is $d^*_{\mathtt{s1}} + d^*_{\mathtt{s2}}$, where $d^*_{\mathtt{s1}}$ and $d^*_{\mathtt{s2}}$ are the optimal durations of steps `r.s1` and `r.s2` respectively. Note that since `r.s2` does not have a parent step, its duration is independent of when the reduce task is scheduled. As such, the optimal duration D^* depends only on step `r.s1`.

Recall from §2.2 that the lazy approach always ensures optimal duration for reduce tasks — since the entire input is available before the reducer starts, `r.s1` can always consume the input data at consume rate r_c without ever stalling. As such, $d^*_{\mathtt{s1}}$ is simply P/r_c, where P is the total amount of input data for `r.s1`. In Figure 4 (a), $P = 6$ is the area under the curve

$r_p(t)$, which gives $d^*_{\texttt{s1}} = 3$.

Step 2: Calculate optimal finish time T^*_e. The optimal finish time T^*_e for a reduce task is simply $t^*_{e,\texttt{s1}} + d^*_{\texttt{s2}}$ where $t^*_{e,\texttt{s1}}$ is the optimal finish time of `r.s1`. Again, since duration $d^*_{\texttt{s2}}$ is independent of when the task is launched, T^*_e depends only on when step `r.s1` finishes.

We leverage the eager strategy of starting the reduce task at $t = 0$ to compute the optimal step finish time $t^*_{e,\texttt{s1}}$ — intuitively, starting the task any sooner cannot reduce the step finish time any further. Note that since all the map tasks are started at $t = 0$, the produce rate r_p is non-increasing in time. Consequently, if the full consume rate r_c of the reduce task is lower than the *average* produce rate, then the finish time of the step will be bottlenecked by r_c, i.e., $t^*_{e,\texttt{s1}} = P/r_c$. On the other hand, if r_c is higher than the average produce rate, the bottleneck shifts to r_p, and the reduce task can only finish when the map tasks finish generating data at time t_m. Figure 4 (b) shows the latter scenario, where $r_c = 3$ is higher than the average produce rate $(= 2)$, and therefore $t^*_{e,\texttt{s1}} = t_m = 3$.

Step 3: Calculate optimal launch time T^*_s. We find that launching the reduce task at $T^*_s = T^*_e - D^*$, where D^* and T^*_e are computed via the lazy (Step 1) and eager (Step 2) approaches, respectively, ensure that the task is optimal in both execution duration and finish time. This is shown in Figure 4 (c), where starting the reduce task at $T^*_s = 3 - 2 = 1$ ensures optimal duration $(D^* = 2)$, as well as finish time $(T^*_e = 3)$. At first glance, this may seem obvious, since D^* and T^*_e already correspond to optimal task duration and finish time, respectively. But we note that since D^* and T^*_e were computed for two separate approaches, it is not obvious if an approach that starts the task at $T^*_s = T^*_e - D^*$ will always ensure the task takes exactly D^* time to finish. Fortunately, for two-stage map-reduce jobs, we have the following theorem:

Theorem 4.1 *For a reduce task, we can always achieve both optimal execution duration and finish time by launching it at time $T^*_s = T^*_e - D^*$, where T^*_e is the optimal finish time and D^* is the optimal duration computed using Steps 1 and 2 above.*

Proof Since the duration of step `r.s2` is independent of when the reduce task is scheduled, we only need to prove the optimality of finish time and duration for step `r.s1`.

We first show that we can always achieve optimal finish time $t^*_{e,\texttt{s1}}$ if we launch the reduce task at time $T^*_s = T^*_e - D^*$. We prove this by contradiction: assume that a reduce task that is started at T^*_s does not finish executing its first step `r.s1` at $t^*_{e,\texttt{s1}}$. This must be because at some time point $\in [T^*_s, t^*_{e,\texttt{s1}}]$, the task was unable to consume data at full consume rate r_c. We denote the last time instant where this was true as t'. Note that the data produced until time t' (say, $P_{t\le t'}$) must be less than the data that can be consumed by time t' at full consume rate r_c, i.e., $P_{t\le t'} < (t' - T^*_s) \times r_c$. Since the total amount of data produced is $P = d^*_{\texttt{s1}} \times r_c$, the data produced *after* t' must be $P_{t>t'} = P - P_{t\le t'} > (t^*_{e,\texttt{s1}} - t') \times r_c$, and the reduce task will take more time than $(t^*_{e,\texttt{s1}} - t')$ to consume it (since it can consume data at a rate no faster than r_c).

Note that the data produced after t', $P_{t>t'}$, is independent of the reduce task's launch time. This implies that regardless of how early the task is launched, no solution could have achieved optimal finish time $t^*_{e,\texttt{s1}}$ for the step `r.s1`. However, this contradicts with the fact that the eager solution can achieve the optimal finish time by launching the task at $t = 0$. Therefore, our initial assumption must have been false: a reduce task that is started at T^*_s *does* finish executing its first step `r.s1` at $t^*_{e,\texttt{s1}}$.

Proving $T^*_s = T^*_e - D^*$ results in optimal task duration is then trivial: since step `r.s1` finishes at $t^*_{e,\texttt{s1}}$ with start time T^*_s, the corresponding duration $T^*_s - t^*_{e,\texttt{s1}}$ will always be $d^*_{\texttt{s1}}$. ■

Note that the T^*_s for different reduce tasks may be different, since the produce rate r_p to different reduce tasks may vary (*e.g.*, due to data skew). Recall that the finish time of the job is the same as the finish time of the last reduce task, and the total cost of the job is proportional to the aggregated duration of all tasks. As such, Theorem 4.1 shows that we can simultaneously achieve both optimal cost and finish time for the entire job, as long as each reduce task is optimal in duration and finish time, i.e., is launched at T^*_s.

4.2 NIMBLE for General Analytics

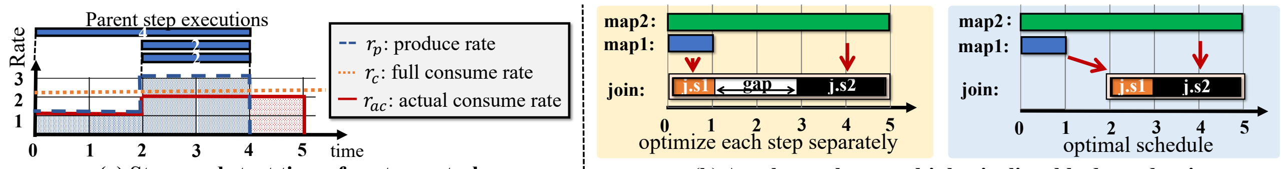
We now extend our analysis to general analytics jobs. We first outline the steps in computing the optimal launch time for tasks in jobs with arbitrary execution DAGs, and then describe how NIMBLE scheduling can be generalized to such DAGs.

4.2.1 Optimal launch time for individual tasks

General analytics jobs with arbitrary execution DAGs introduce two main challenges in determining the optimal task launch time as defined in §4.1. First, unlike two-stage map-reduce jobs, the start times of a step's parent steps need not start at $t = 0$ and can be staggered in time, as shown in Figure 5 (a). This breaks our assumption of a nonincreasing $r_p(t)$ from §4.1, and necessitates a more nuanced treatment of the eager approach to compute the optimal task finish time.

Second, unlike two-stage map-reduce jobs, general analytics jobs, a stage may contain multiple parent-child step pairs, *e.g.*, the join stage in Figure 3 has two steps, and each step has a parent step from a different map stage. For such dependencies, we find that optimally overlapping each parent-child step pair is insufficient to ensure optimal task duration and finish time. Specifically, the optimal task launch time depends not only on the *inter-stage* dependency between parent-child step pairs, but also on the *intra-stage* dependency between steps in the same stage. Figure 5 (b, left) shows a join example where the optimal launch for each step in the task is computed independently. Although each child step is optimally pipelined with its parent, the gap between their execution corresponds to time where no useful work is done, resulting in sub-optimal task duration and, therefore, cost of execution. Figure 5 (b, right) shows how this can be avoided by *deferring* the start time of the first step.

We exploit the above insights to extend NIMBLE scheduling approach from §4.1 to general analytics jobs. We consider the



(a) Staggered start time of upstream tasks **(b) A task may have multiple pipelineable dependencies**

Figure 5: **NIMBLE scheduling for general analytics (§4.2)** (a) Unlike two-stage map-reduce, the produce rate for a task may not be nonincreasing, since the parent step in different tasks can have different start times. (b) Unlike two-stage map-reduce, tasks may have multiple pipelineable dependencies, which requires careful handling to ensure optimal task duration. See §4.2.1 for details.

general case where a task comprises n steps, s1-sn, and make two assumptions to simplify our analysis: (i) each step in a task has at most one parent step, and (ii) steps within a task are executed sequentially in a fixed order. Both assumptions hold for a wide range of analytics jobs, including the join example above, and all of our evaluated workloads (§6). Similar to two-stage map-reduce (§4.1), the optimal launch time T_s^* for a task in the execution DAG is calculated in three steps:

Step 1: Calculate optimal task duration D^*. The optimal task duration D^* is simply the sum of individual optimal step durations $d_{\mathtt{s}i}^*$, $1 \leq i \leq n$. As in §4.1, the duration for steps without a parent is independent of task launch time, while the optimal duration for steps with a parent is computed using the lazy approach, i.e., P/r_c for the corresponding step. In Figure 5 (a), $P = 8$ and $r_c = 2$, so $d_{\mathtt{s}i}^* = 4$.

Step 2: Calculate optimal finish time T_e^*. Since T_e^* is bound by the finish time of the last step sn, we first compute the optimal finish time of a step as computed by the eager approach, similar to §4.1. As noted earlier, however, unlike two-stage map-reduce where the parent step across all the map tasks start at time $t = 0$, the parent step across different tasks in a general DAG may start and end at arbitrary times. This is depicted in Figure 5 (a) where the parent step across two upstream tasks start at time $t = 2$, while the third starts at $t = 0$. Consequently, the produce rate is no longer non-increasing. As such, the optimal step finish time (based on the eager approach) can only be determined by tracking the actual consume rate r_{ac} over time. In the example, r_{ac} is bound by r_p $(= 1)$ between $t = 0-2$, lower than r_p $(= 3)$ and bound by r_c $(= 2)$ between $t = 2-4$, and equals to r_c $(= 2)$ between $t = 4-5$ to clear the surplus data generated between $t = 2-4$. As such, the finish time yielded by the eager approach is 5.

In order to generalize the above example, we discretize time into slots t_1, t_2, ..., t_m, such that the produce rate is constant within a time slot. We introduce a new function $S(t_i)$ to identify time slots where the step accumulates surplus data, i.e., $S(t_i) = 0$ if all the input data produced until t_i has been consumed by time t_i, and 1 otherwise. It is easy to see that when there is no surplus data ($S(t_i) = 0$), the actual consume rate $r_{ac}(t_i)$ is upper-bounded by the produce rate $r_p(t_i)$. When there is surplus data ($S(t_i) = 1$), the actual consume rate increases to the full consume rate ($r_{ac} = r_c$) to clear the surplus. Formally,

$$r_{ac}(t_i) = \begin{cases} \min\left(r_p(t_i), r_c\right) & \text{if } S(t_i) = 0 \\ r_c & \text{if } S(t_i) = 1 \end{cases} \quad (1)$$

For each t_i, we can calculate $S(t_i)$ based on $S(t_{i-1})$, $r_{ac}(t_{i-1})$ and $r_p(t_{i-1})$, and $r_{ac}(t_i)$ based on Equation 1. The time slot t_n where the cumulative data consumed so far equals P, the total input data for the step, corresponds to the optimal finish time; we formally prove optimality in Appendix A.

Unlike the two-stage map-reduce job in §4.1, we have to consider one more constraint — step si can only start after step si-1 has finished, i.e., the finish time of step i is no less than $t_{e,\mathtt{s}i\text{-}1}^* + d_{\mathtt{s}i}^*$. Let the optimal step finish time for si as computed above (which only considers its parent step) be $t'_{e,\mathtt{s}i}$, then the actual optimal finish time of step i is:

$$t_{e,\mathtt{s}i}^* = \begin{cases} \max\left(t'_{e,\mathtt{s}i}, t_{e,\mathtt{s}i\text{-}1}^* + d_{\mathtt{s}i}^*\right) & \text{if } \mathtt{s}i \text{ has a parent} \\ t_{e,\mathtt{s}i\text{-}1}^* + d_{\mathtt{s}i}^* & \text{otherwise} \end{cases} \quad (2)$$

We compute the optimal task finish time by iteratively calculating the optimal finish time for each step s1−sn. Figure 5 (b) shows an example for this computation: the task finish time equals the $t'_{e,\mathtt{s}2}$ $(= 5)$, since $t_{e,\mathtt{s}1}^* + d_{\mathtt{s}2}^*$ $(= 1 + 2)$ is smaller.

Step 3: Calculate optimal launch time T_s^*. As in §4.1, the optimal launch time is computed as $T_s^* = T_e^* - D^*$. Consider the example in Figure 5 (b); the optimal launch time is calculated as $T_s^* = T_e^* - D^*$ $(= 5 - 3)$ for the two steps. Compared to Figure 5 (b, left), doing so automatically delays the first step and removes the gap (Figure 5 (b, right)).

Indeed, Theorem 4.1 extends to general analytics jobs:

Theorem 4.2 *For a task in an analytics job with an arbitrary execution DAG, given the execution (produce rate) of all its parent steps, we can always achieve both optimal execution duration and finish time by launching it at $T_s^* = T_e^* - D^*$, where T_e^* is the optimal finish time and D^* is the optimal duration computed using Steps 1 and 2 above.*

We defer the formal proof to Appendix A, but note here that it employs induction on the number of steps: we assume the statement holds for a task with $n-1$ steps, and use Theorem 4.1 to show that it still holds on adding one more step.

4.2.2 Optimal schedule for the entire job

Algorithm 1 shows NIMBLE scheduling for the entire job based on Theorem 4.2. Stages in the job are scheduled iteratively based on their dependencies: a stage is scheduled when all of its parent stages in the execution DAG have been scheduled. For each task within a scheduled stage, we first calculate the produce rate from its parent stages, and then calculate its optimal launch time as described above.

Algorithm 1 ensures that *each task* achieves optimal duration and finish time given its parent execution (due to Theo-

Algorithm 1 NIMBLE scheduling for a job

```
Launch all stages with no parent stages.
$\mathcal{U} \leftarrow$ Set of unscheduled stages
while $\mathcal{U} \neq \emptyset$ do
    for each stage $S \in \mathcal{U}$, whose parent stages are scheduled do
        for each task in stage $S$ do
            Calculate $r_p$ for each using parent stage schedules
            Calculate $T_e^*$ and $D^*$ based on $r_p$ and $r_c$ of each step
            Calculate $T_s^* = T_e^* - D^*$
```

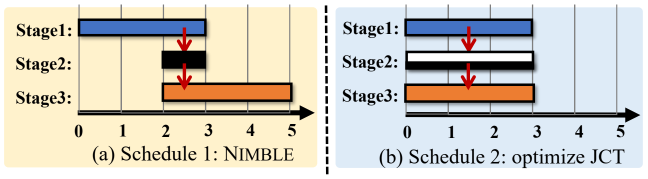


Figure 6: **Example of a job that cannot achieve both (a) optimal cost and (b) finish time simultaneously.** Each stage comprises a single task/step. Stage 2 has a produce rate of 1 and consume rate of 3. Stage 3 has a produce rate of 3 and consume rate of 1.

rem 4.2). However, it still leaves the question: does the algorithm also ensure optimal finish time and cost for the *entire job*? We find that the answer is in the affirmative for jobs with DAGs of depth two, including the map-reduce and SQL jobs in Fig 3. Intuitively, since the stages in the first level of the DAG do not have parent steps, their optimal start time is $t = 0$. As such, given the execution of the stages in the first level, Theorem 4.2 ensures optimal duration and finish time for the stages in the second level of the DAG.

Unfortunately, for general analytics jobs with arbitrary DAGs, the answer is in the negative. In fact, we find that for some jobs, it is *impossible* to find a schedule that achieves both cost and JCT optimality. The key insight behind this observation is that the launch time of a task affects not only itself, but also its downstream tasks — the optimal launch time for one task (Theorem 4.2) may negatively affect tasks in its downstream. We illustrate this with the example in Figure 6, that shows a job with three stages, each with only one step and one task. Stage 2 has a produce rate of 1 and consume rate of 3. Stage 3 has a produce rate of 3 and consume rate of 1. The arrows denote parent-child step pairs. Figure 6 (a) shows NIMBLE approach, which greedily optimizes the duration and finish time from Stage 1-3 based on the produce rate of each stage's parent steps; the end-to-end execution time of the entire job is 5, while its cost is 7. Figure 6 (b) shows an alternative strategy, that launches tasks across all three stages (Stage 1-3) at $t = 0$. This increases the duration of Stage 2 from 1 to 3, and consequently, the cost of execution of the job from 7 to 9. However, doing so also reduces the produce rate for Stage 3 to 1, allowing Stage 3 be completely pipelined with Stage 2. As such, the finish time of the entire job reduces from 5 to 3. Note that no schedule can achieve both a JCT of 3 and a cost of 7, since optimal JCT can only be achieved if Stage 2 and 3 are started at $t = 0$, which ensures a sub-optimal cost.

Cost optimality & cost-JCT *Pareto-optimality*. Despite the negative result above, NIMBLE scheduling efficiently navigates the cost-JCT tradeoff for jobs with arbitrary DAGs:

Theorem 4.3 *For a job with arbitrary DAG,* NIMBLE *scheduling in Algorithm 1 is (1) optimal in cost; and (2) Pareto-optimal between cost and JCT.*

Proof We first consider cost-optimality: since Algorithm 1 ensures optimal execution duration for each task in a job (Theorem 4.2), the aggregated duration across all tasks in the job, and therefore, the job execution cost, is also optimal.

Since the cost is always optimal, for Pareto-optimality we only need to show that no solution can further reduce job finish time without also increasing its cost. Our proof builds on the intuition developed for the example in Figure 6. First, we note that delaying the start time beyond T_s^* for any task cannot reduce its completion time; the only possibility to reduce JCT is to pick a start time earlier than T_s^*. As per Theorem 4.2, starting a task any sooner than T_s^* must increase its duration. Moreover, doing so will not reduce the duration of any other task, since they are already optimal. Thus, even if starting the task before T_s^* did improve JCT, it would only do so by increasing the aggregate duration across all tasks in the job, and therefore, its cost. ■

As an interesting aside, we note that for the example in Figure 6, we face this hard tradeoff between JCT and cost optimality because Stage 3 has a larger duration compared to Stage 2. Instead, if Stage 3 had a duration of 0.5, starting Stage 2 any sooner than $t = 2$ (at higher cost) would not have made stage 3 finish any faster. In practice, downstream stages often have a shorter duration compared to the upstream stages, since frequently used operators such as reduce, filter and join often significantly reduce the output data volume to downstream stages. In such cases, NIMBLE can achieve both optimal cost and JCT simultaneously — evaluation results on a wide range of analytics jobs in §6 validate this argument.

5 Design Details

In this section, we describe how we incorporate NIMBLE scheduling into Caerus, a new fine-grained task-level scheduler for serverless analytics frameworks. We first describe Caerus design components and application workflow (§5.1), and then describe its implementation details (§5.2).

5.1 Caerus System

We now describe Caerus system components and how they fit together (Figure 7). Before describing these components, we first briefly summarize the design employed by existing serverless analytics frameworks.

Primer on serverless analytics frameworks. Recent proposals on serverless analytics frameworks [8, 12, 14] share similar designs. Figure 7 depicts this design (adapted from [12]). The framework takes as input a job execution plan (DAG) that captures dependencies between stages and the number of tasks within each stage. It uses this to generate code for the individual tasks, compiles it and packages it with necessary dependen-

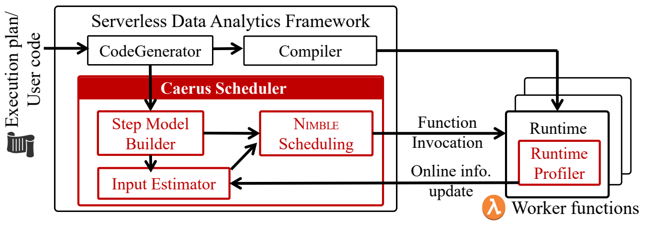

Figure 7: **Caerus system components & workflow (§5.1).**

cies. To execute a job, a scheduler launches tasks as serverless functions and monitors their progress. Pywren [8, 14] is similar, but omits the code-generation and compilation steps and directly takes task code and execution plan as input.

Caerus integrates with these analytics frameworks by simply replacing their task-level scheduler, and taking over the task launching and monitoring responsibilities. We next describe the major components of Caerus scheduler (Figure 7) in detail.

The step model builder is responsible for extracting the fine-grained step dependency model that NIMBLE scheduling expects, either from the job's execution plan or the user code. If the input is user code (e.g., a Python function in PyWren [8, 14]), Caerus provides a step annotation API that users can employ to specify the step information Caerus expects:

```
s = createStep() # Create a step object
s.start() # Notify system about step start
s.end() # Notify system about step end
s.addParent(stageID, stepID) # Specify parent step
```

If the query code is generated by a CodeGenerator based on the execution plan (as in Starling [12]), the step dependencies can be extracted during code generation. Most popular query execution engines (*e.g.*, SparkSQL) generate code based on the Volcano [44] iterator or `WholeStageCodegen` [45] model, which fuses operators as much as possible to maximize pipelining. As such, the generated code in such models is already composed of blocks separated by pipeline breakers, where each block corresponds exactly to a step in our step model. Caerus augments the CodeGenerator to additionally generate step-annotations at the start and end of blocks, along with step dependencies, using the step annotation API outlined above.

Input estimator & runtime profiler. Recall from §3 that NIMBLE scheduling relies on estimates of step produce rate (r_p) and consume rate (r_c) for steps with parents, and duration (d^*_{si}) for steps without parents, to make scheduling decisions. To facilitate accurate estimates, we leverage the observation that task and job-level statistics can be accurately estimated by tracking profiled information from prior job runs, since such analytics jobs in production workloads tend to be recurring in nature [26–28, 46, 47]. In particular, the input estimator in Caerus is responsible for collecting information for prior executions for each job (i.e., the job history) and maintaining estimates for various r_p, r_c and d^*_{si} values.

For higher accuracy, the input estimator continuously refines its r_p, r_c and d^*_{si} estimates based on realtime task progress. To facilitate this, a runtime profiler (similar to [27, 40]) periodically profiles and reports such metadata to the input estimator. Our runtime profiler is incorporated into the function runtime in serverless frameworks [8] that is shared across all tasks.

Caerus workflow. For each job, the step-model builder first extracts the step model from code generator or directly from the annotated function code. The input estimator maintains estimates of algorithm inputs (r_p, r_c and d^*_{si} values) for each step based on prior job runs. The NIMBLE scheduling module then calculates launch time based on both the algorithm inputs and step model, and launches each task at the calculated time. Launched tasks periodically report their progress to the input estimator via the runtime profiler, which is leveraged to refine the input estimates for future runs.

Caerus scalability. Caerus's scheduling performance scales well with the number of available CPU cores due to two main reasons. First, tasks within a stage have independent launch times, which permits parallel calculation and launching. Second, while the number of online update messages from runtime profiler grows linearly with the number of tasks, it can be served in parallel by partitioning input estimates for different tasks across different CPU cores.

Fault-tolerance. Caerus handles task failures by restarting them. For controller fault-tolerance, Caerus relies on traditional primary-backup mechanisms [30, 48]. The backup maintains consistent copies of the job's step model, launched and queued tasks, and runtime profiled information from prior job runs. During recovery, Caerus fetches this metadata from the backup and resumes scheduling queued tasks using NIMBLE.

5.2 Caerus Implementation

Our Caerus prototype is implemented atop Pywren [8], a serverless data analytics engine that runs on AWS Lambda [1]. We use Amazon S3 [21] for persistent data storage and Jiffy [24] for intermediate data storage.

SQL analytics with Caerus. We implement a SQL query execution framework atop Locus to highlight the benefit for Caerus scheduling for SQL analytics workloads. We employ Apache Spark's query planner to generate the query plan from the original SQL query, and then use Pandas to implement the SQL operators. Pandas' current implementation for SQL operators (like `JOIN` and `GROUPBY`) employs the lazy approach, *e.g.*, for the join example in Figure 3 (bottom), Pandas would only start the `JOIN` operation after all the data in both input tables are ready. We therefore modify the operator implementations in Pandas to conform to the step dependency model required by NIMBLE scheduling.

As a concrete example consider the implementation of the SQL job in Figure 3 (bottom) in Caerus. For the first two map stages, each task keeps reading input data from S3. After reading each small chunk of input data, it performs the map function, and partitions the output data into *chunks* based on key hashes. To implement shuffle, we maintain a FIFO queue for each join task in the intermediate storage. Once an output chunk is ready, the map task pushes it to the corresponding join task's queue. Note that a join task receives data from two shuffles (i.e., from map1 and map2). As such, each join task has two receiver queues: queue A (for data from `m1.s1`) and queue B (or data from `m2.s1`). After being launched, each join task fetches data from queue A and builds the hash table incrementally in step `j.s1`. Once the hash-table is built, the step `j.s2` fetches data from queue B, performs a join of the fetched data with the data in the hash-table, and writes the output to persistent storage.

Identifying pipeline-breakers. In Caerus, we implement all commonly used SQL operators (*e.g.*, `FILTER`, `JOIN`, `SORT`, `GROUP BY`, aggregates, etc.), employ the widely-used Volcano iterator model [44] to identify pipeline-breakers, and specify them using the step annotation API. As such, Caerus can run all TPC-DS and Big-data benchmark queries — we evaluate a representative subset in §6.

Accurate parameter estimations. NIMBLE scheduling relies on accurate estimation of various parameters (r_p, r_c, d^*_{si}), which can be complicated due unpredictable variations stemming from a range of sources. Fortunately, we found a majority of these sources had little to no variation across AWS Lambda executions, including (1) processing time for various operators; (2) function launch times[5]; and (3) function ingress/egress bandwidth to intermediate storage.

However, we did observe unpredictable performance variations for Amazon S3 reads and writes, particularly with larger number of parallel tasks (≥ 100). To minimize parameter estimation errors caused by these variations, we adopt a straggler mitigation technique for S3 reads and writes similar to [12] — Caerus tasks proactively establishes a new connection to S3 when a transfer takes longer than expected, and uses the response from whichever connection performs the read or write first. Moreover, we found larger S3 reads/writes to have unpredictable durations, so we break them into multiple smaller chunks. We show in §6 how these modifications ensure negligible estimations errors for a wide range of evaluated workloads.

6 Evaluation

We now evaluate Caerus implementation (§5.2) using three analytics workloads: TeraSort benchmark (§6.1), TPC-DS Benchmark (§6.2) and BigData Benchmark (§6.3). All of our experiments use Lambda instances with 3GB memory and deploy Jiffy on 6 m4.16xlarge EC2 instances.

Compared approaches. We compare Caerus with the eager and lazy scheduling approaches, implemented as a part of Caerus scheduler. These scheduling approaches correspond to the two extremes typically used in server-centric analytics frameworks for task level scheduling — lazy in Spark [30] and MapReduce [48], and eager in Dryad [32] and MapReduce Online [29]). Note that since our main contribution is a new scheduler for serverless analytics, our evaluation focuses on comparing scheduling approaches on a common analytics framework as opposed to comparing different analytics frameworks. As noted in §5, Caerus can integrate with any of existing serverless analytics frameworks [8, 11, 12, 14] and inherit their specific performance optimizations.

[5]We ensure function invocations are warm to avoid cold-start delays.

	Lazy	Eager	NIMBLE
JCT(s)	124	105	107
Cost(s)	10776	15756	11169

Table 1: **Comparison of NIMBLE against lazy and eager approaches for TeraSort on a 100GB dataset (§6.1).**

Performance metrics. We focus on two main metrics: JCT and cost of job execution. The former is measured as the time between job's first task's launch time to the last task's finish time. For the latter, we measure the aggregated duration across all tasks in the job as a proxy for cost. We avoid reporting precise dollar values, since these depend on the cloud provider and can change with market economics.

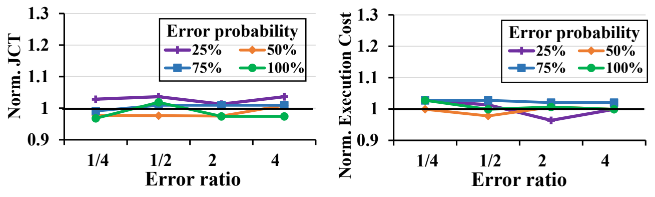
6.1 TeraSort

We port the TeraSort algorithm [49] implementation from Locus [14] to our framework for sorting large datasets. The algorithm operates in two stages: a partition stage that range partitions input data to intermediate storage, and a merge stage that reads these partitions, merges, sorts and writes them out as output. The sort job in our experiments uses 100 lambdas for both the map and reduce stage to sort 100GB of data generated using the Sort benchmark tool [50].

Table 1 compares the results of eager, lazy and NIMBLE scheduling approaches for the sort job. We observe little data skew for the TeraSort benchmark during both the partition and merge stages, and the ideal launch time for merge tasks identified by NIMBLE scheduling is roughly in the middle of the execution for partition stage. As such, NIMBLE achieves $1.16\times$ lower job completion time compared to the lazy scheme, $1.41\times$ lower cost than the eager approach. The results validate our analysis in §4, that NIMBLE scheduling can achieve near-optimal JCT and cost simultaneously for two stage map-reduce jobs in practice ($< 4\%$ in Table 1). NIMBLE's slight departure from optimal is due to delays in launch times introduced by the analytics framework (i.e., PyWren).

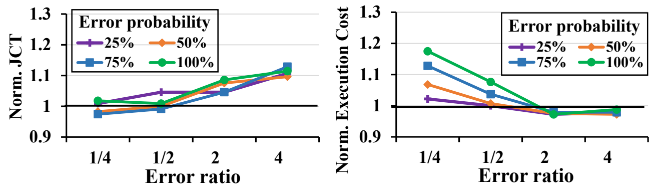
Impact of estimation errors. Caerus's JCT and cost-efficiency is gated on being able to estimate parameters like produce rate (r_p) and consume rate (r_p) accurately. Since Caerus's estimation errors are quite small in practice ($< 4\%$), we study their impact by introducing errors artificially.

To inject errors in produce rate estimation, we randomly select map tasks in our TeraSort job with probability p_e, and for each of them, incorrectly estimate the data output rate by Caerus's offline estimation as $k\times$ the actual value. We denote p_e as error probability and k as the error ratio. Since the produce rate r_p is the aggregated data output rate across all map tasks, our stochastic approach effectively injects errors



(a) JCT (b) Cost

Figure 8: **Impact of produce rate estimation errors (§6.1).** The results are normalized against the performance with no injected errors.

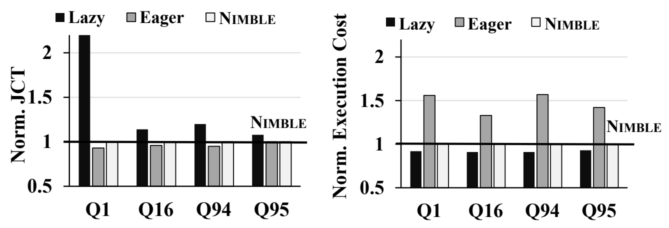


(a) JCT (b) Cost

Figure 9: **Impact of consume rate estimation errors (§6.1).** The results are normalized against the performance with no injected errors.

to the r_p estimate as well. Figure 8 shows the impact of the injected estimation errors on NIMBLE's performance, i.e., JCT and execution cost, with the corresponding metrics normalized against a run with no injected errors. We observe that NIMBLE's performance is minimally affected — across various combinations of error probability and error ratio, the JCT and execution cost is always within $\sim 4\%$ of the run with no injected errors. We attribute this to the runtime profiler, which tracks the real-time progress of each map task and refines the produce rate estimation by continuously re-estimating the task output rates. As such, the runtime profiler is able to correct the offline estimations in produce rate before launching the reducers, minimizing the impact of errors.

To study the impact of consume rate estimation errors, we employ a similar error rate and error ratio driven approach for reduce tasks. Note that runtime profiler is unable to correct for estimation errors in this case, since it can re-estimate the consume rate only *during* reduce task executions, which is *after* the reduce tasks have already been launched. Figure 8 shows the impact of injected errors on NIMBLE performance. For error ratio > 1 (i.e., estimated rate > actual rate), NIMBLE incorrectly estimates that the reduce task would finish faster than it actually does, while for error ratio < 1, it assumes the opposite. As expected, for the former case, Caerus launches reduce tasks later than it should, resulting in a longer JCT, while for the latter scenario, it launches them sooner than necessary, resulting in increased cost. Figure 9(a) shows that the normalized JCT increases from $1.07\times$ to $1.12\times$ as error ratio is increased from 2 to 4, while Figure 9(b) shows that the cost increases from $1.08\times$ to $1.18\times$ as error ratio increases from $1/2$ to $1/4$. Moreover, at higher error probability, the cost increase is greater since more reducers are launched earlier than necessary; while the JCT increase is largely unaffected since it only depends on the *slowest* task. Note that even with extreme estimation errors ($\frac{1}{4}\times$ and $4\times$), the increase in cost or JCT is only 12–18%.



(a) JCT (b) Cost

Figure 10: **NIMBLE performance for TPC-DS queries (§6.2).** Its JCT is comparable to eager and 1.08–2.2× lower than lazy, while its cost is comparable to lazy and 1.33–1.57× lower than eager.

6.2 TPC-DS Benchmark

The TPC-DS benchmark [51] has a set of standard decision support queries based on those used by retail product suppliers. The queries vary widely in terms of compute, storage and network I/O load variations. We evaluate Caerus on TPC-DS with scale factor of 1000, which results in a total input size of 1TB across various tables. Similar to Locus [14], we evaluate four representative queries (in terms of performance characteristics) from the TPC-DS Benchmark, specifically, queries `Q1`, `Q16`, `Q94` and `Q95`. All selected queries have complex DAGs comprising six to eight stages, with each query operating over a subset of the 1TB input — varying from 33GB to 312GB. Note that some late stages in the selected queries process much less data compare to early stages (after several `join` and `groupby` operations) — we adjust the degree of parallelism for these stages based on the amount of data they process.

Figure 10 compares the performance for NIMBLE with the lazy and eager approaches. The results indicate that Caerus can efficiently navigate the JCT-cost trade-off for all evaluated queries. Specifically, NIMBLE achieves JCT comparable to eager for all the queries, while outperforming lazy by 1.08–2.2×. For cost, NIMBLE matches the lazy approach while outperforming eager by 1.33–1.57×.

6.2.1 Diving deeper into NIMBLE benefits

In order to better understand the gains enabled by NIMBLE scheduling, we zoom in on the performance for Query `Q1` of the TPC-DS benchmark. Figure 11 shows the step-level dependencies for `Q1`, while Figure 12 shows the breakdown of execution time across different stages. Note that compute and network I/O take up most of the execution time, highlighting potential gains from pipelining. Figure 14 shows the job execution breakdowns with lazy, eager and NIMBLE scheduling.

Optimal pipelining across stages. We now walk through `Q1`'s execution with Caerus (Figure 14(c)). Caerus identifies 7 step dependencies (i.e., parent-child step pairs) as pipelineable, shown as red arrows in Figure 11.

While all map stages are launched at time $t = 0$, (since they do not have upstream dependencies), Caerus launches tasks across subsequent stages in a manner that ensures child steps in the above parent-child step pairs are optimally pipelined with the parent step, which corresponds to a large portion of the query execution. This is highlighted in Figure 14(c): when con-

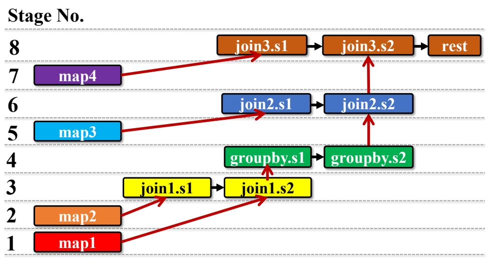


Figure 11: **The step dependency model for Q1.**

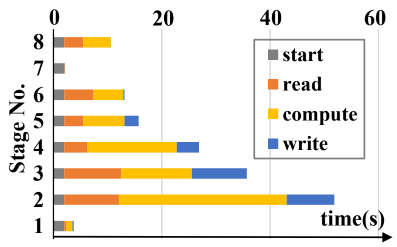

Figure 12: **Time breakdown for Q1.**

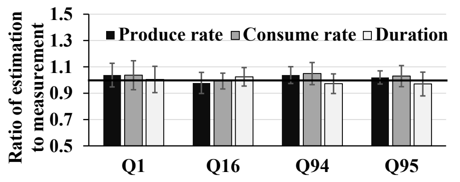

Figure 13: **Ratio of estimated & measured parameters for TPC-DS queries**. Error bars denote standard deviation across all tasks.

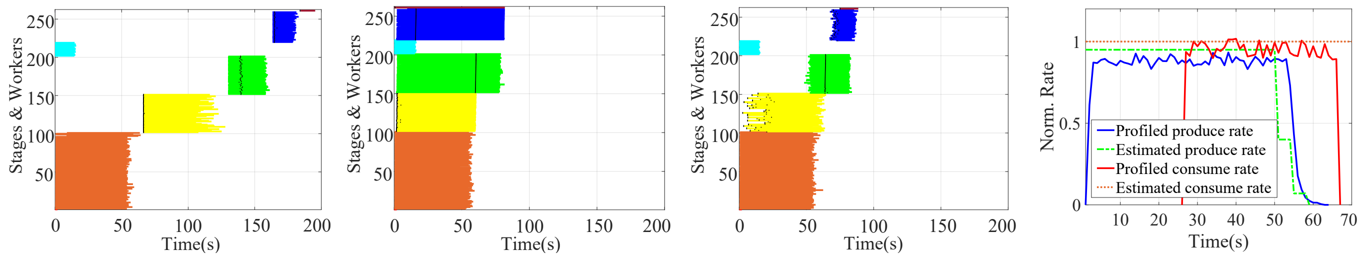

(a) Lazy (b) Eager (c) NIMBLE (d) NIMBLE Input Parameters

Figure 14: **Diving deeper into NIMBLE benefits for TPC-DS query Q1 (§6.2.1).** (a, b, c) show Q1 execution breakdown for lazy, eager, and NIMBLE, respectively; the black dots inside a task denote pipeline-breakers between steps. The degree of parallelism for Stages 1-8 is: {1, 100, 50, 50, 20, 40, 1, 1}. Note that Stages 1 (red) and 7 (purple) contain only one very short task, making them hard to see. (d) NIMBLE input parameters as measured by Caerus runtime profiler (solid lines) and as estimated by input estimator (dashed lines) for part of Stage 3 (yellow).

trasted with the lazy approach in Figure 14(a), Caerus enables a JCT that is 2.2× lower than the lazy approach. Meanwhile, Caerus also ensures that the tasks are not launched too soon in order to minimize time spent waiting for input from the parent step to become available, and therefore, the end-to-end job execution cost. As a concrete example, since step `groupby1.s1` is much shorter than step `join1.s2` and cannot finish before `join1.s2`, tasks in the `groupby` stage are started after tasks in `join1` stage are started, but before they finish execution. Compared with Figure 14(b), this allows name to Caerus achieve a cost that is 1.56× lower than the lazy approach.

Decreasing duration across stages. Another interesting takeaway from Q1's execution is that downstream stages in general process smaller amounts of data than upstream stages (since operators such as filter and join significantly reduce the data to downstream stages), and consequently have shorter durations. As noted in §4.2, NIMBLE scheduling enables both optimal cost and JCT simultaneously for such DAGs, which is reflected in Figure 14. Moreover, this observation holds across all of our evaluated TPC-DS queries, ensuring cost and JCT optimality with Caerus for all of them.

Accurate profiling & estimation for NIMBLE inputs. Figure 14(d) shows the normalized produce rate and consume rate of of step `join1.s2` in Stage 3, as profiled by Caerus runtime profiler and as estimated by Caerus input estimator. We make two observations: (1) the consume rate is stable as a function of time, as modeled in §3, and (2) the estimated values are a close approximation of the actual produce and consume rates. We find these observations extend to all stages across query Q1, as well as to all other queries we evaluate in this section — Figure 13 shows that the average error in parameter estimations for r_p, r_c and d^*_{si} is within 4% across all queries. As we already saw in §6.1, NIMBLE scheduling is also robust to higher estimation errors.

Data skew. We note that Stage 3 (yellow) experiences data skew across tasks (Figure 14(a)-14(c)) — our profiling indicates that some tasks process $>1.6\times$ more data than others. Caerus captures the effect of such data skew in its NIMBLE scheduling algorithm, and launches tasks in Stage 3 at a time that still ensures JCT and cost optimality for the job execution.

Fast scheduling decisions. The query Q1 has over 250 tasks across 8 stages — Caerus schedules and launches each task in about 400μs (on average). In contrast, when the task launch request is issued to AWS Lambda, it typically takes an additional $\sim 25-320$ms to start the task's execution [52]. As such, despite making much more fine-grained (i.e., task-level) decisions than traditional job schedulers, Caerus is fast enough to not be the bottleneck in the analytics execution pipeline.

6.3 BigData Benchmark

The Big Data Benchmark [53] is a query suite derived from production databases. We consider Query 3 (Q3), which is a join query with four stages, with a step dependency model similar to the first four stages of TPC-DS benchmark's Q1 (Figure 11). Our implementation uses shuffle hash join (SHJ), and efficiently pipelines the join stage with the map stages. Q3 reads in 123GB of input, and can perform joins with three different sizes: 485,312 rows in Q3A; 53,332,015 rows for Q3B; and 533,287,121 rows for Q3C. This allows us to understand the effect of join size on NIMBLE scheduling.

Figure 15 compares NIMBLE approach with both the lazy and eager approaches with different join data sizes (Q3A-Q3C).

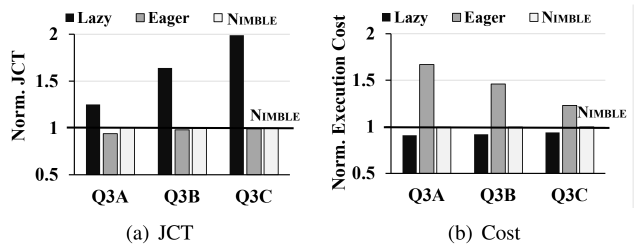

Figure 15: **NIMBLE performance for BigData Benchmark (§6.3).** NIMBLE's JCT improvement over lazy increases as join size increases (Q3A→Q3C), while its cost improvement over eager increases as join size decreases (Q3C→Q3A).

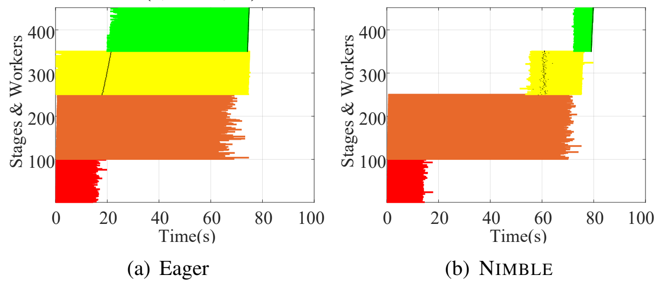

Figure 16: **Q3A execution breakdown** for (a) eager and (b) NIMBLE.

Interestingly, we observe that NIMBLE's relative JCT improvement compared to lazy increases from 1.29× to 1.99×, as join size increases from Q3A to Q3C. Meanwhile, NIMBLE's relative cost improvement compared to eager increases from 1.23× to 1.67×, as join size decreases from Q3C to Q3A.

To better understand the differences in cost and JCT improvements due join sizes, Figure 16 shows the execution breakdown for Q3A. As Q3A's join input data size is small, the `join` (yellow) and subsequent `groupby` (green) stages are much shorter than the initial `map` stage (orange). As such, pipelining these shorter stages with the `map` stage does not improve the JCT by much (1.29×) compared to the lazy approach. However, the eager solution significantly increases the cost by starting these short tasks very early (Figure 16(a)). Caerus, on the other hand, improves cost relative to eager by 1.67× by launching them at just the right time (Figure 16(b)).

Figure 17 compares the execution of lazy and Caerus for Q3C: as the input data size for join is now much larger, the duration of the join stage and groupby stage is comparable to the map stage (orange). As such, the eager approach does not lose as much in terms of cost by launching these tasks early. However, the lazy solution increases the JCT significantly by running these relatively longer stages one after the other (Figure 17(a)). In contrast, Caerus improves JCT by 1.99× relative to lazy by efficiently pipelining the join and groupby stage with the map stages (Figure 17(b)).

7 Related Work

We already discussed related work on server-centric and serverless analytics frameworks in §2.1 and §5.1. We now discuss prior work related to Caerus in other areas.

Some databases [45, 54–56] and data processing frameworks [31, 57] support pipelined execution via an *iterator*

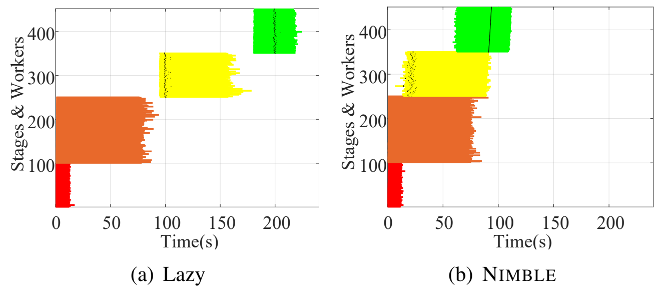

Figure 17: **Q3C execution breakdown** for (a) lazy and (b) NIMBLE.

model [44]. These approaches focus on maximally pipelining operators to minimize query completion time. Similar to these works, we leverages pipelined execution to achieve JCT-optimality for analytic jobs. In fact, our step dependency model draws inspiration from iterator models to identify regions of execution that can or cannot be overlapped with other regions. Unlike prior work, however, our approach also considers cost-optimality, a key concern in serverless analytics.

Caerus's scheduling problem is also related to the parallel query scheduling [58–60] in databases. Many of the proposed algorithms assign CPU and memory resources across operators considering both pipelinable and non-pipelinable dependencies across them. Unlike Caerus, however, these algorithms are designed for server-centric deployments and optimize for the query completion time under limited resource constraints.

Another related problem is Multi-Objective Query Optimization (MOQO), which searches for an query execution plan with an optimal trade-off between multiple conflicting cost metrics in databases [61–67]. While MOQO optimizes a query execution plan to determine its component set of operations and their orderings, Caerus takes the execution plan as input and specifically optimizes the task launch times for JCT and cost, i.e., Caerus approach is *complementary* to MOQO.

8 Conclusion

We have presented Caerus, a task scheduler for serverless analytics that uses a new NIMBLE scheduling algorithm. NIMBLE efficiently pipelines task executions across various stages in serverless analytics jobs, to ensure cost-optimality and Pareto-optimality between cost and JCT. We show that for a wide range of analytics workloads, NIMBLE is often optimal in *both* dimensions. This allows Caerus to outperform existing lazy scheduling approaches by 1.08–2.2× in JCT, and eager approaches by 1.21–1.57× in cost for these workloads.

A Theoretical Proofs

Lemma A.1 *The eager approach always optimizes the finish time for a reduce task.*

Proof Figure 18 shows an example of the actual consume rate $r_{ac}(t)$ for `r.s1` under two approaches: the eager solution $\mathcal{E}$ and an alternate approach $\mathcal{F}$ with a later launch time. We see that before $\mathcal{E}$ finishes, there may exist some time t such that $r_{ac}(t)$ of $\mathcal{F}$ is greater than $r_{ac}(t)$ of $\mathcal{E}$. Based on Equation 1, we know that this is because $\mathcal{E}$ has processed all its inputs by t ($S(t) = 0$ for $\mathcal{E}$), but $\mathcal{F}$ has not ($S(t) = 1$ for F) as it is launched later. Denote the last such time point before $\mathcal{E}$ finishes as t', we have: (1) by time t', $\mathcal{E}$ has processed all data generated before t'; (2) after time t', $r_{ac}(t)$ of $\mathcal{E}$ is no less than $\mathcal{F}$ until it finishes. The combination of these two observations shows that $\mathcal{E}$ always has an earlier finish time for `r.s1` than $\mathcal{F}$. Since $T_e^* = t_{e,\mathtt{s1}}^* + d_{\mathtt{s2}}^*$, $\mathcal{E}$ also ensures optimal task finish time. ■

Proof of Theorem 4.2 :

Theorem 4.2 *For a task in an analytics job with an arbitrary execution DAG, given the execution (produce rate) of all its parent steps, we can always achieve both optimal execution duration and finish time by launching it at $T_s^* = T_e^* - D^*$, where T_e^* is the optimal finish time and D^* is the optimal duration computed using Steps 1 and 2 described in §4.2.1.*

Proof We prove Theorem 4.2 by mathematical induction on the number of steps of the task.

Base case: We first show that Theorem 4.2 holds for a task with only one step. In this case, the problem reduces to the single parent-child step case for two-stage map-reduce jobs as in Theorem 4.1, which we have already shown to hold.

Inductive step: We now show that for any $n > 1$, if Theorem 4.2 holds for tasks with n steps, it also holds for tasks with $n+1$ steps. Consider a task with $n+1$ steps. For the first n steps, we denote the optimal finish time as $T_e^*(n)$, and cost as $D^*(n)$. Since Theorem 4.2 holds for any task with n steps, $T_e^*(n)$ and $D^*(n)$ can be achieved simultaneously by launching the $(n+1)$-step task at $T_s^*(n) = T_e^*(n) - D^*(n)$. Based on Equation 2 and the definition of the optimal task duration (Step 1 in §4.2.1), we have:

$$\begin{aligned} T_e^*(n+1) &= max(t'_{e,\mathtt{s}n+1}, T_s^*(n) + d_{\mathtt{s}n+1}^*) \\ D^*(n+1) &= D^*(n) + d_{\mathtt{s}n+1}^* \end{aligned} \tag{3}$$

Based on Equation 3, the launch time calculated from Theorem 4.2 for the $(n+1)$-step task is

$$\begin{aligned} T_s^*(n+1) &= T_e^*(n+1) - D^*(n+1) \\ &\geq (T_s^*(n) + d_{\mathtt{s}n+1}^*) - (D^*(n) + d_{\mathtt{s}n+1}^*) \\ &= T_e^*(n) - D^*(n) \\ &= T_s^*(n) \end{aligned} \tag{4}$$

Note that if a step j starts at time t_1 and executes at full load (i.e., it will never stall for data to become available), then it must also be able to execute at full load if it starts at any time $t_2 \geq t_1$. Since we have $T_s^*(n+1) \geq T_s^*(n)$ from Equation 4, if we launch the task at $T_s^*(n+1)$, we can always execute the first n steps at full load (i.e., with optimal duration $D^*(n)$). As such, with launch time $T_s^*(n+1)$, the corresponding finish time of the first n steps is $T_s^*(n+1) + D^*(n)$, which is also the start time of the last step $\mathtt{s}n+1$. Based on Equation 3 we have:

$$\begin{aligned} \text{Start time of step } \mathtt{s}n+1 &= T_s^*(n+1) + D^*(n) \\ &= (T_e^*(n+1) - D^*(n+1)) + D^*(n) \\ &= T_e^*(n+1) - d_{\mathtt{s}n+1}^* \\ &= max(t'_{e,\mathtt{s}n+1}, T_s^*(n) + d_{\mathtt{s}n+1}^*) - d_{\mathtt{s}n+1}^* \\ &\geq t'_{e,\mathtt{s}n+1} - d_{\mathtt{s}n+1}^* \end{aligned} \tag{5}$$

Equation 5 indicates that if we launch the task at $T_s^*(n+1)$, the start time of the step $\mathtt{s}n+1$ is no less than $t'_{e,\mathtt{s}n+1} - d_{\mathtt{s}n+1}^*$. Note that $t'_{e,\mathsf{s}n+1}$ is the optimal finish time of step $\mathsf{s}n+1$ calculated only based on its parent. Just as in the proof of Theorem 4.1, which covers the single parent-child step pair case, we can then show that the step $\mathsf{s}n+1$ must execute at full rate if it is launched at $t'_{e,\mathsf{s}n+1} - d^*_{\mathsf{s}n+1}$.

Taken together, if we launch the task at $T^*_s(n+1)$, all $n+1$ steps can execute at full load, which indicates it achieves the optimal duration $D^*(n+1)$. Moreover, recall that $T^*_s(n+1) = T^*_e(n+1) - D^*(n+1)$. This means that if the task starts at $T^*_s(n+1)$ and has a duration of $D^*(n+1)$, it must finish at $T^*_e(n+1)$. As such, we can achieve both $T^*_e(n+1)$ and $D^*(n+1)$ by launching the task at $T^*_s(n+1)$.

Conclusion: Since both the base case and the inductive step hold, Theorem 4.2 holds by mathematical induction. ■

Ownership: A Distributed Futures System for Fine-Grained Tasks

Stephanie Wang*, Eric Liang*, Edward Oakes*, Ben Hindman, Frank Luan, Audrey Cheng, Ion Stoica
*UC Berkeley, *and Anyscale*

Abstract

The distributed futures interface is an increasingly popular choice for building distributed applications that manipulate large amounts of data. Distributed futures are an extension of RPC that combines futures and distributed memory: a distributed future is a reference whose eventual value may be stored on a remote node. An application can then express distributed computation without having to specify when or where execution should occur and data should be moved.

Recent distributed futures applications require the ability to execute *fine-grained computations*, i.e., tasks that run on the order of milliseconds. Compared to coarse-grained tasks, fine-grained tasks are difficult to execute with acceptable system overheads. In this paper, we present a distributed futures system for fine-grained tasks that provides fault tolerance without sacrificing performance. Our solution is based on a novel concept called *ownership*, which assigns each object a leader for system operations. We show that this decentralized architecture can achieve horizontal scaling, 1ms latency per task, and fast failure handling.

1 Introduction

RPC is a standard for building distributed applications because of its generality and because its simple semantics yield high-performance implementations. The original proposal uses *synchronous* calls that *copy* return values back to the caller (Figure 2a). Several recent systems [4, 34, 37, 45] have extended RPC so that, in addition to distributed communication, the system may also manage *data movement* and *parallelism* on behalf of the application.

Data movement. Pass-by-value semantics require all RPC arguments to be sent to the executor by copying them directly into the request body. Thus, performance degrades with *large* data. Data copying is both expensive and unnecessary in cases like Figure 2a, where a process executes an RPC over data that it previously returned to the same caller.

To reduce data copies, some RPC systems use *distributed memory* [16, 27, 37, 40, 41]. This allows large arguments to be passed by *reference* (Figure 2b), while small arguments can still be passed by value. In the best case, arguments passed by reference to an RPC do not need to be copied if they are already on the same node as the executor (Figure 2b). Note that, like traditional RPC, we make all values *immutable* to simplify the consistency model and implementation.

Parallelism. RPCs are traditionally *blocking*, so control is only returned to the caller once the reply is received (Figure 2a). *Futures* are a popular method for extending RPC with asynchrony [8, 29], allowing the system to execute functions in parallel with each other and the caller. With *composition* [29, 37], i.e., passing a future as an argument to another RPC, the application can also express the parallelism and dependencies of future RPCs. For example, in Figure 2c, `add` is invoked at the beginning of the program but only executed by the system once `a` and `b` are computed.

```
a_future = compute()
b_future = compute()
c_future = add(a_future, b_future)
c = system.get(c_future)
```

Figure 1: A distributed futures program. `compute` and `add` are stateless. `a_future`, `b_future`, and `c_future` are distributed futures.

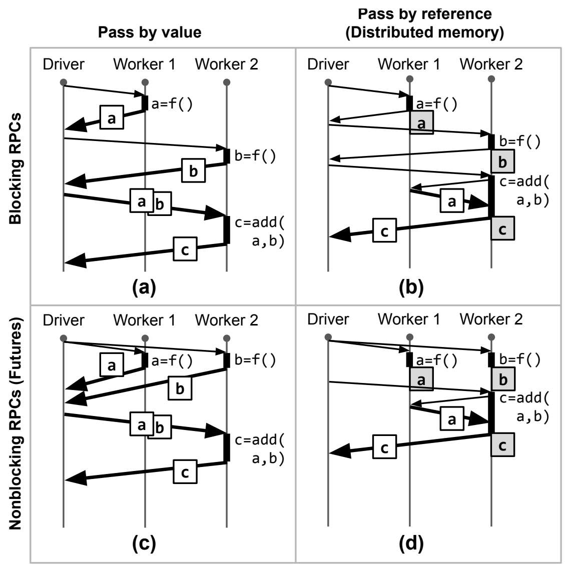

Figure 2: Example executions of the program from Figure 1. **(a)** With RPC. **(b)** With RPC and distributed memory, allowing the system to reduce data copies. **(c)** With RPC and futures, allowing the system to manage parallel execution. **(d)** With distributed futures.

Distributed futures are an extension of RPC that combines futures with distributed memory: a *distributed future* is a reference whose eventual value may be stored on a remote node (Figure 2d). An application can then express distributed computation without having to specify when or where execution should occur and data should be moved. This is an increasingly popular interface for developing distributed applications that manipulate large amounts of data [4, 34, 37, 45].

As with traditional RPC, a key goal is generality. To achieve this, the system must minimize the overhead of each function call [13]. For example, the widely used gRPC provides horizontal scalability and sub-millisecond RPC latency, making it practical to execute millions of *fine-grained* functions, i.e. millisecond-level "tasks", per second [2].

Similarly, there are emerging examples of large-scale, fine-grained applications of distributed futures, including reinforcement learning [34], video processing [22,43], and model serving [49]. These applications must optimize parallelism and data movement for performance [39,43,49], making distributed futures apt. Unfortunately, existing systems for distributed futures are limited to *coarse-grained* tasks [37].

In this paper, we present a distributed futures system for fine-grained tasks. While others [34,37,45] have implemented distributed futures before, our contribution is in identifying and addressing the challenges of providing *fault tolerance for fine-grained tasks without sacrificing performance*.

The primary challenge is that distributed futures introduce *shared state* between processes. In particular, an object and its metadata are shared by its reference holder(s), the RPC executor that creates the object, and its physical location(s). To ensure that each reference holder can dereference the value, the processes must coordinate, a difficult problem in the presence of failures. In contrast, traditional RPC has no shared state, since data is passed by value, and naturally avoids coordination, which is critical to scalability and low latency.

For example, in Figure 2a, once worker 1 copies `a` to the driver, it does not need to be involved in the execution of the downstream `add` task. In contrast, worker 1 stores `a` in Figure 2d, so the two workers must coordinate to ensure that `a` is available long enough for worker 2 to read. Also, worker 1 must garbage-collect `a` once worker 2 executes `add` and there are no other references. Finally, the processes must coordinate to detect and recover from the failure of another process.

The common solution in previous systems is to use a centralized master to store system state and coordinate these operations [34,37]. A simple way to ensure fault tolerance is to record and replicate metadata at the master *synchronously* with the associated operation. For example, in Figure 2d, the master would record that `add` is scheduled to worker 2 *before* dispatching the task. Then, it can correctly detect *c*'s failure if worker 2 fails. However, this adds significant overhead for applications with a high volume of fine-grained tasks [].

Thus, decentralizing the system state is necessary for scalability. The question is how to do so without complicating coordination. The key insight in our work is to exploit the application structure: a distributed future may be shared by passing by reference, but *most distributed futures are shared within the scope of the caller*. For example, in Figure 1, `a_future` is created then passed to `add` in the same scope.

We thus propose *ownership*, a method of decentralizing system state across the RPC *executors*. In particular, the caller of a task is the *owner* of the returned future and all related metadata. In Figure 2d, the driver owns `a`, `b`, and `c`.

This solution has three advantages. First, for horizontal scalability, the application can use nested tasks to "shard" system state across the workers. Second, since a future's owner is the task's caller, task latency is low because the required metadata writes, though synchronous, are local. This is in contrast to an application-agnostic method of sharding, such as consistent hashing. Third, each worker becomes in effect a centralized master for the distributed futures that it owns, simplifying failure handling.

The system guarantees that if the owner of a future is alive, any task that holds a reference to that future can eventually dereference the value. This is because the owner will coordinate system operations such as reference counting, for memory safety, and lineage reconstruction, for recovery. Of course, this is not sufficient if the owner fails.

Here, we rely on lineage reconstruction and a second key insight into the application structure: in many cases, the references to a distributed future are held by tasks that are a descendant of the failed owner. The failed task can be recreated through lineage reconstruction by *its* owner, and the descendant tasks will also be recreated in the process. Therefore, it is safe to *fate-share* any tasks that have a reference to a distributed future with the future's owner. As we expect failures to be relatively rare, we argue that this reduction in system overheads and complexity outweighs the cost of additional re-execution upon a failure.

In summary, our contributions are:

- A decentralized system for distributed futures with transparent recovery and automatic memory management.
- A lightweight technique for transparent recovery based on lineage reconstruction and fate sharing.
- An implementation in the Ray system [34] that provides high throughput, low latency, and fast recovery.

2 Distributed Futures

2.1 API

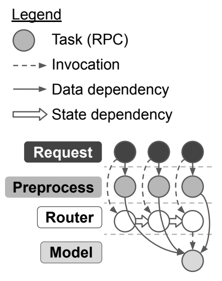
The key benefit of distributed futures is that the system can transparently manage parallelism and data movement on behalf of the application. Here, we describe the API (Table 1).

To spawn a *task*, the caller invokes a *remote function* that immediately returns a `DFut` (Table 1). The spawned task comprises the function and its arguments, resource requirements, etc. The returned `DFut` refers to the *object* whose value will be returned by the function. The caller can *dereference* the `DFut` through `get`, a blocking call that returns a copy of the object. The caller can *delete* the `DFut`, removing it from scope and allowing the system to reclaim the value. Like other systems [34,37,45], all objects are *immutable*.

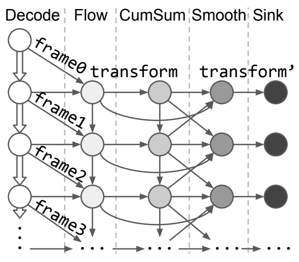
After the creation of a `DFut` through task invocation, the caller can create other references in two ways. First, the caller can pass the `DFut` as an argument to another task. `DFut` task arguments are implicitly dereferenced by the system. Thus, the task will only begin once all upstream tasks have finished, and the executor sees only the `DFut` *values*.

Operation	Semantics
`f(DFut x)` → `DFut`	Invoke the remote procedure `f`, and pass `x` by reference. The system implicitly dereferences `x` to its `Value` before execution. Creates and returns a distributed future, whose value is returned by `f`.
`get(DFut x)` → `Value`	Dereference a distributed future. Blocks until the value is computed and local.
`del(DFut x)`	Delete a reference to a distributed future from the caller's scope. Must be called by the program.
`Actor.f(DFut x)` → `DFut`	Invoke a stateful remote procedure. `f` must execute on the actor referred to by `Actor`.
`shared(DFut x)` → `SharedDFut`	Returns a `SharedDFut` that can be used to pass `x` to another worker, without dereferencing the value.
`f(SharedDFut x)` → `DFut`	Passes `x` as a first-class `DFut`: The system dereferences `x` to the corresponding `DFut` instead of the `Value`.

Table 1: Distributed futures API. The full API also includes an actor creation call. A task may also return a `DFut` to its caller (nested `DFuts` are automatically flattened).



(a) Model serving



(b) Video processing

Figure 3: Distributed futures applications.

Second, the `DFut` can be passed or returned as a *first-class value* [21], i.e. passed to another task without dereferencing. Table 1 shows how to cast a `DFut` to a `SharedDFut`, so the system can differentiate when to dereference arguments. We call the process that receives the `DFut` a *borrower*, to differentiate it from the original caller. Like the original caller, a borrower may create other references by passing the `DFut` or casting again to a `SharedDFut` (creating further borrowers).

Like recent systems [4, 34, 45], we support *stateful* computation with actors. The caller creates an actor by invoking a *remote constructor function*. This immediately returns a reference to the actor (an `ARef`) and asynchronously executes the constructor on a remote process. The `ARef` can be used to spawn tasks bound to the same process. Similar to `DFuts`, `ARefs` are first-class, i.e. the caller may return or pass the `ARef` to another task, and the system automatically collects the actor process once all `ARefs` have gone out of scope.

2.2 Applications

Typical applications of distributed futures are those for whom performance requires the flexibility of RPC, as well as optimization of data movement and parallelism. We describe some examples here and evaluate them in Section 5.2.

Distributed futures have previously been explored for data-intensive applications that cannot be expressed or executed efficiently as data-parallel programs [34, 37]. Ciel identified the key ability to *dynamically* specify tasks during execution, e.g., based on previous results, rather than specify the entire graph upfront [37]. This enabled new workloads such as dynamic programming, which is recursive by nature [54].

Our goal is to expand the application scope to include those with *fine-grained* tasks that run in the milliseconds. We also explore the use of actors and first-class distributed futures.

Model serving. The goal is to reduce request latency while maximizing throughput, often by using model *replicas*. Depending on the model, a latency target might be 10-100ms [20]. Typically, an application-level scheduling policy is required, e.g., for staged rollout of new models [46].

Figure 3a shows an example of a GPU-based image classification pipeline. Each client passes its input image to a `Preprocess` task, e.g., for resizing, then shares the returned `DFut` with a `Router` actor. `Router` implements the scheduling policy and passes the `DFut` by reference to the chosen `Model` actor. `Router` then returns the results to the clients.

Actors improve performance in two ways: (1) each `Model` keeps weights warm in its local GPU memory, and (2) `Router` buffers the preprocessed `DFuts` until it has a batch of requests to pass to a `Model`, to leverage GPU parallelism for throughput. With *dynamic* tasks, the `Router` can also choose to flush its buffer on a timeout, to reduce latency from batching.

First-class distributed futures are important to reduce routing overhead. They allows the `Router` to pass the references of the preprocessed images to the `Model` actors, instead of copying these images. This avoids creating a bottleneck at the `Router`, which we evaluate in Figure 15a. While the application could use an intermediate storage system for preprocessed images, it would then have to manage additional concerns such as garbage collection and failures.

Online video processing. Video processing algorithms often have complex data dependencies that are not well supported by data-parallel systems such as Apache Spark [22, 43]. For example, video stabilization (Figure 3b) works by tracking objects between frames (Flow), taking a cumulative sum of these trajectories (CumSum), then applying a moving average (Smooth). Frame-to-frame dependencies are common, such as the video decoding state stored in an actor in Figure 3b. Each stage runs in 1-10s of milliseconds per frame.

Safe and timely garbage collection in this setting can be challenging because a single object (e.g., a video frame) may be referenced by multiple tasks. Live video processing is also latency-sensitive: output must be produced at the same frame rate as the input. Low latency relies on pipelined parallelism between frames, as the application cannot afford to wait for multiple input frames to appear before beginning execution.

With distributed futures, the application can specify the logical task graph *dynamically*, as input frames appear. Meanwhile, the system manages the physical execution, i.e. pipelined parallelism and garbage collection, according to the specified graph. Concurrent video streams can easily be

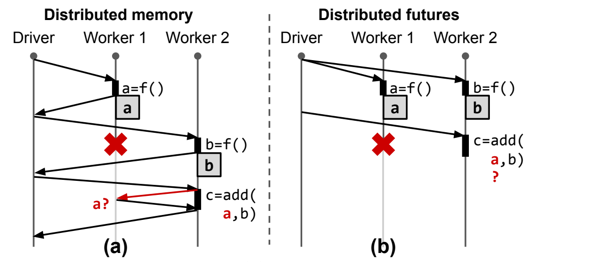


Figure 4: Failure detection. **(a)** `a`'s location is known by the time worker 2 receives the reference. **(b)** `a`'s location may not be known when worker 2 receives `add`, so worker 2 cannot detect the failure.

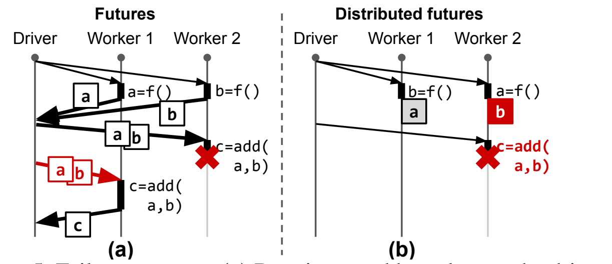

Figure 5: Failure recovery. **(a)** Data is passed by value, so the driver recovers by resubmitting `add`. **(b)** `b` is also lost. `f`'s description must be recorded during runtime so that `b` can be recomputed.

supported using nested tasks, one "driver" per stream. The system can then manage inter-video parallelism.

3 Overview

3.1 Requirements

The system guarantees that each `DFut` can be *dereferenced* to its value. This involves three problems: automatic memory management, failure detection, and failure recovery.

Automatic memory management is a system for dynamic memory allocation and reclamation of objects. The system must decide at run time whether an object is currently referenced by a live process, e.g., through reference counting [42].

Failure detection is the minimum functionality needed to ensure progress in the presence of failures. The system detects when a `DFut` cannot be dereferenced due to worker failure.

With distributed memory but no futures, this is straightforward because *the location of the value is known by the time the reference is created*. In Figure 4a, for example, the driver learns that `a` is stored on worker 1 and could then attach the location when passing `a` to worker 2. Then, when worker 2 receives `add`, it can detect `a`'s failure.

The addition of futures complicates failure detection because references can be created *before* the value. Even the future *location* of the value may not be known at reference creation time. Of course, the system could wait until a task has been scheduled before returning the reference to the caller. However, this would defeat the purpose of futures as an asynchronous construct. It is also impractical because a realistic scheduler must be able to update its decision at run time, e.g., according to changes in the environment such as resource availability and worker failures.

Thus, it is possible that there are no locations for `a` when worker 2 receives the `add` RPC in Figure 4b. Then, worker 2 must decide whether `f` is still executing, or if it has failed. If it is the former, then worker 2 should wait. But if there is a failure, then the system must recover `a`. To solve this problem, the system must record the locations of all *tasks*, i.e. pending objects, in addition to created objects.

Failure recovery. The system must also provide a method of recovering from a failed `DFut`. The minimum requirement is to throw an error to the application if it tries to dereference a failed `DFut`. We further provide an option for *transparent* recovery, i.e. the system will recover a failed `DFut`'s value.

With futures but no distributed memory, if a process fails, then we will lose the reply of any pending task on that process. Assuming idempotence, this can be recovered through retries, a common approach for pass-by-value RPC. For example, in Figure 5a, the driver recovers by resubmitting `add(a,b)`. Failure recovery is simple because *all data is passed by value*.

With distributed memory, however, tasks can also contain arguments passed by *reference*. Therefore, a node failure can cause the loss of an object value that is still referenced, as `b` is in Figure 4b. A common approach to this problem is to record each object's *lineage*, or the subgraph that produced the object, during runtime [17, 30, 56]. The system then walks a lost object's lineage and recursively reconstructs the object and its dependencies through task re-execution. This approach reduces the runtime overhead of logging, since the data itself is not recorded, and the work that must be redone after a partial failure, since objects cached in distributed memory do not need to be recomputed. Still, achieving low run-time overhead is difficult because the lineage itself must be recorded and collected at run time and it must survive failures.

Note that we focus specifically on *object recovery* and, like previous systems [34, 37, 56], assume *idempotence* for correctness. Thus, our techniques are directly applicable to idempotent functions and actors with read-only, checkpointable, or transient state, as we evaluate in Figure 15c. Although it is not our focus, these techniques may also be used in conjunction with known recovery techniques for actor state [17, 34] such as recovery for nondeterministic execution [52].

Metadata requirements. In summary, during normal operation, the system must at minimum record (1) the location(s) of each object's value, so that reference holders can retrieve it, and (2) whether the object is still referenced, for safe garbage collection. For failure detection and recovery, the system must further record, respectively, (3) the location of each *pending* object, i.e. the task location, and (4) the object lineage.

The key question is where and when to record this system metadata such that it is *consistent*[1] and *fault-tolerant*. By consistent, we mean that the system metadata matches the

[1]Unrelated to the more standard definition of replica consistency [50].

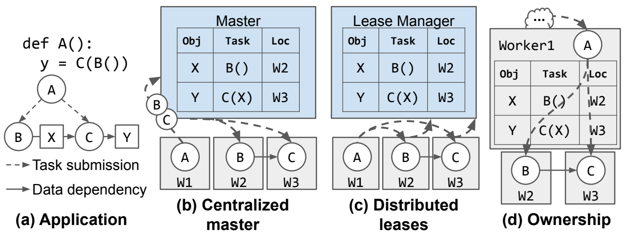

Figure 6: Distributed futures systems. **(a)** An application. **(b)** Master manages metadata and object failures. **(c)** Workers write metadata asynchronously, coordinate failure handling with leases. **(d)** Workers manage metadata. Worker 1 handles failures for workers 2 and 3. Worker 1 failure is handled by `A`'s owner elsewhere in the cluster.

current physical state of the cluster. By fault-tolerant, we mean that the metadata should survive individual node failures.

In some cases, it is safe for metadata to be *asynchronously updated*, i.e. there is a transient mismatch between the system metadata and the system state. For example, the system may transiently believe that an object `x` is still on node *A* even though it has been removed. This is safe because a reference holder can resolve the inconsistency by asking *A* if it has `x`.

On the other hand, metadata needed for failure handling should ideally be *synchronously updated*. For example, the metadata should never say that a task *T* is on node *A* when it is really on node *B*. In particular, if node *A* then fails, the system would incorrectly conclude that *T* has failed. As we will see next, synchrony simplifies fault tolerance but can add significant runtime overhead if done naively.

3.2 Existing solutions

Centralized master. Failure handling is simple with a synchronously updated centralized master, but this design can also add significant runtime overhead. For example, failure detection requires that the master record a task's scheduled location *before* dispatch (Figure 6b). Similarly, the master must record every new reference before it can be used. This makes the master a bottleneck for scalability and latency.

The master can be sharded for scalability, but this can complicate operations that coordinate multiple objects, such as garbage collection and lineage reconstruction. Also, the latency overhead is fundamental. Each task invocation must first contact the master, adding at minimum one round-trip to the critical path of execution, even without replicating the metadata for fault tolerance. This overhead can be detrimental when the task itself is milliseconds long, and especially so if the return value is small enough to be passed by value. Small values may be stored in the master directly as an optimization, but still require 1 RTT for retrieval [38].

Distributed leases. Decentralization can remove such bottlenecks, but often leads to complex coordination schemes. One approach is to use *distributed leases* [19]. This is similar to a centralized master that is updated *asynchronously*.

As an example, consider asynchronous task location updates (Figure 6c). To account for a possibly stale master, the worker nodes must coordinate to detect task failures, in this case using leases. Each worker node acquires a lease for each locally queued task and repeatedly renews the lease until the task has finished. For example, in Figure 6c, worker 3 can detect a failure of `B` by waiting for worker 2's lease to expire.

This design is horizontally scalable through sharding and reduces task latency, since metadata is written asynchronously. However, the reliance on timing to reconcile system state can slow recovery (Figure 14). Furthermore, this method of decentralization introduces a new problem: the workers must also coordinate on *who* should recover an object, i.e. re-execute the creating task. This is trivial in the centralized scheme, since the master coordinates all recovery operations.

3.3 Our solution: Ownership

The key insight in our work is to "shard" the centralized master, for scalability, but to do so based on the application structure, for low run-time overhead and simple failure handling. In ownership, the worker that calls a task stores the metadata related to the returned `DFut`. Like a centralized master, it coordinates operations such as task scheduling, to ensure it knows the task location, and garbage collection. For example, in Figure 6d, worker 1 owns `X` and `Y`.

The reason for choosing the task's caller as the owner is that in general, it is the worker that accesses the metadata most frequently. The caller is involved in the initial creation of the `DFut`, via task invocation, as well as the creation of other references, by passing the `DFut` to other RPCs. Thus, task invocation latency is minimal because the scheduled location is written locally. Similarly, if the `DFut` stays in the owner's scope, the overhead of garbage collection is low because the `DFut`'s reference count can be updated locally when the owner passes the `DFut` to another RPC. These overheads can be further reduced for small objects, which can be passed by value as if without distributed memory (see Section 4.2).

Of course, if all tasks are submitted by a single driver, as in BSP programs, ownership will not scale beyond the driver's throughput. Nor indeed will any system for dynamic tasks. However, with ownership, the *application* can scale horizontally by distributing its control logic across multiple nested tasks, as opposed to an application-agnostic method such as consistent hashing (Figure 12e). Furthermore, the worker processes hold much of the system metadata. This is in contrast to previous solutions that push all metadata into the system's centralized or per-node processes, limiting the *vertical* scalability of a single node with many worker processes (Figure 12).

However, there are problems that are simpler to solve with a fully centralized design, assuming sufficient performance:

First-class futures. First-class futures (Section 2) allow non-owning processes to reference a `DFut`. While many applications can be written without first-class futures (Figure 3b), they are sometimes essential for performance. For example, the model serving application in Figure 3a uses first-class futures to delegate task invocation to a nested task, without having to dereference and copy the arguments.

A first-class DFut may leave the owner's scope, so we must account for this during garbage collection. We avoid centralizing the reference count at the owner, as this would defeat the purpose of delegation. Instead, we use a distributed hierarchical reference counting protocol (Section 4.2). Each borrower stores a local reference count for the DFut on behalf of the owner (Table 2) and notifies the owner when the local reference count reaches zero. The owner decides when the object is safe to reclaim. We use a reference counting approach as opposed to tracing [42] to avoid global pauses.

Owner recovery. If a worker fails, then we will also lose its owned metadata. For transparent recovery, the system must recover the worker's state on a new process and reassociate state related to the previously owned DFuts, including any copies of the value, reference holders, and pending tasks.

We choose a minimal approach that guarantees progress, at the potential cost of additional re-execution on a failure: we *fate share* the object and any reference holders with the owner, then use *lineage reconstruction* to recover the object and any of the owner's fate-shared children tasks (Section 4.3). This method adds minimal run-time overhead and is correct, i.e. the application will recover to a previous state and the system guarantees against resource leakage. A future extension is to persist the owner's state to minimize recovery time at the cost of additional recovery complexity and run-time overhead.

4 Ownership Design

Each node in the cluster hosts one to many workers (usually one per core), one scheduler, and one object store (Figure 7). These processes implement future resolution, resource management, and distributed memory, respectively. Each node and worker process is assigned a unique ID.

Workers are responsible for the resolution, reference counting, and failure handling of distributed futures. Each worker executes one task at a time and can invoke other tasks. The root task is executed by the "driver".

Each task has a unique TaskID that is a hash of the parent task's ID and the number of tasks invoked by the parent task so far. The root TaskID is assigned randomly. Each task may return multiple objects, each of which is assigned an ObjectID that concatenates the TaskID and the object's index. A DFut is a tuple of the ObjectID and the owner's address (Owner).

The worker stores one record per future that it has in scope in its local *ownership table* (Table 2). A DFut borrower records a subset of these fields (* in Table 2). When a DFut is passed as an argument to a task, the system implicitly resolves the future's value, and the executing worker stores only the ID, Owner, and Value for the task duration. The worker also caches the owner's stored Locations.

Field	Value
*ID	The ObjectID. Also used as a distributed memory key.
*Owner	Address of the owner (IP address, port, WorkerID).
*Value	(1) Empty if not yet computed, (2) Pointer if in distributed memory, or (3) Inlined value, for small objects (Section 4.2).
*References	A list of reference holders: Number of dependent tasks and a list of borrower addresses (Section 4.2 and appendix A).
Task	Specification for the creating task. Includes the ObjectIDs and Owners of any DFuts passed as arguments.
Locations	If Value is empty, the location of the task. If Value is a pointer to distributed memory, then the locations of the object.

Table 2: Ownership table. The owner stores all fields. A borrower (Section 3.2) only stores fields indicated by the *.

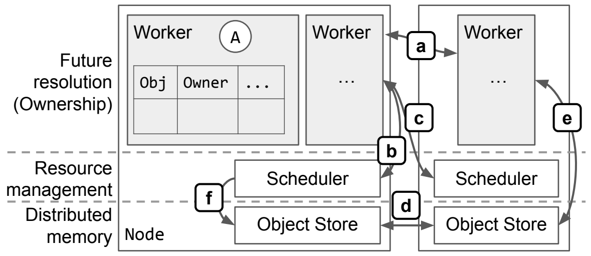

Figure 7: Architecture and protocol overview. **(a)** Task execution. **(b)** Local task scheduling. **(c)** Remote task scheduling. **(d)** Object transfer. **(e)** Task output storage and input retrieval. Ownership layer manages distributed memory garbage collection and recovery. **(f)** Scheduler fetches objects in distributed memory to fulfill task dependencies.

An actor is a stateful task that can be invoked multiple times. Like objects, an actor is created through task invocation and *owned* by the caller. The ownership table is also used to locate and manage actors: the Location is the actor's address. Like a DFut, an ARef (an actor reference) is a tuple of the ID and Owner and can be passed as a first-class value to other tasks.

A worker requests resources from the scheduling layer to determine task placement (Section 4.1). We assume a decentralized scheduler for scalability: each scheduler manages local resources, can serve requests from remote workers, and can redirect a worker to a remote scheduler.

The distributed memory layer (Section 4.2) consists of an immutable distributed object store (Figure 7d) with Locations stored at the owner. The Locations are updated asynchronously. The object store uses shared memory to reduce copies between reference holders on the same node.

Workers store, retrieve, reclaim, and recover large objects in distributed memory (Figure 7f). The scheduling layer sends requests to distributed memory to fetch objects between nodes according to worker requests (Figure 7g).

4.1 Task scheduling

We describe how the owner coordinates task scheduling. At a high level, the owner dispatches each task to a location chosen by the distributed scheduler. This ensures that the task location in the ownership table is updated synchronously with dispatch. We assume an abstract scheduling policy that takes

	Node	L. RTTs	R. RTTs
Master	L.	1	1
	R.	1	1
Leases	L.	1	0
	R.	1	0.5
Owner-ship	L.	0.5 or 1.5	0
	R.	0 or 1	0.5 or 1.5

(e)

(1-2) Local scheduler redirects owner to node 2. (3) Update task location. (4-5) Remote scheduler grants worker lease. (6) Task dispatch. **(d)** Direct scheduling by the owner, using the worker and resources leased from node 2 in (c). **(e)** Length of critical path of local (L) and remote (R) task execution, in terms of local (L) and remote (R) RTTs.

in resource requests and returns the ID of a node where the resources should be allocated. The policy may also update its decision, e.g., due to changes in resource availability.

Figure 8c shows the protocol to dispatch a task. Upon task invocation, the caller, i.e. the owner of the returned `DFut`, first requests resources from its local scheduler[2]. The request is a tuple of the task's required resources (e.g., `{"CPU": 1}`) and arguments in distributed memory. If the policy chooses the local node, the scheduler accepts the request: it fetches the arguments, allocates the resources, then *leases* a local worker to the owner. Else, the scheduler rejects the request and redirects the owner to the node chosen by the policy.

In both cases, the scheduler responds to the owner with the new location: either the ID of the leased worker or the ID of another node. The owner stores this new location in its local ownership table before dispatching the task to that location. If the request was granted, the owner sends the task directly to the leased worker for execution; otherwise, it repeats the protocol at the next scheduler.

Thus, the owner always dispatches the task to its next location, ensuring that the task's pending `Location` (Table 2) is synchronously updated. This also allows the owner to *bypass* the scheduler by dispatching a task directly to an already leased worker, if the task's resource requirements are met. For example, in Figure 8d, worker 1 reuses the resources leased from node 2 in Figure 8c to execute `C`. The owner returns the lease after a configurable expiration time, or when it has no more tasks to dispatch. We currently do not reuse resources for tasks with different distributed memory dependencies, since these are fetched by the scheduler. We leave other policies for lease revocation and worker reuse for future work.

The *worst-case* number of RTTs before a task executes is higher than in previous solutions because each policy decision is returned to the owner (Figure 8e). However, the throughput of previous solutions is limited (Figure 12) because they cannot support direct worker-to-worker scheduling (Figure 8d). This is because workers do not store system state, and thus all tasks must be routed through the master or per-node scheduler to update the task location (Figures 8a and 8b).

Actor scheduling. The system schedules actor constructor tasks much like normal tasks. After completion, however, the owner holds the worker's lease until the actor is no longer referenced (Section 4.2) and the worker can only execute actor tasks submitted through a corresponding `ARef`.

A caller requests the actor's location from the owner using the `ARef`'s `Owner` field. The location can be cached and requested again if the actor restarts (Section 4.3). The caller can then dispatch tasks directly to the actor, as in Figure 8d, since the resources are leased for the actor's lifetime. For a given caller, the actor executes tasks in the order submitted.

4.2 Memory management

Allocation. The distributed memory layer consists of a set of object store nodes, with locations stored at the owner (Figures 9b to 9d). It exposes a key-value interface (Figure 9a). The object store may replicate objects for efficiency but is not required to handle recovery: if there are no copies of an object, a `Get` call will block until a client (i.e. a worker) `Creates` the object.

Small objects may be faster to copy than to pass through distributed memory, which requires updating the object directory, fetching the object from a remote node, etc. Thus, at object creation time, the system transparently chooses based on size whether to pass by value or by reference.

Objects over a configurable threshold are stored in the distributed object store (step 1, Figure 9b) and returned by reference to the owner (step 2). This reduces the total number of copies, at the cost of requiring at least one IPC to the distributed object store for `Get` (steps 4-5, Figure 9c). Small objects are returned by value to the owner (step 6, Figure 9c), and each reference holder is given its own copy. This produces more copies in return for faster dereferencing.

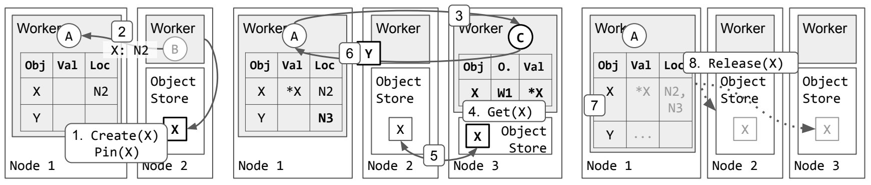
The initial copy of a large object is known as the *primary*. This copy is pinned (step 1, Figure 9b) until the owner releases the object (step 8, Figure 9d) or fails. This allows the object store to treat additional capacity as an LRU cache without having to consult the owners about which objects are safe to evict. For example, the *secondary* copy of `X` created on node 3 in Figure 9c is cached to reduce `Get` and recovery time (Section 4.3) but can be evicted under memory pressure.

Dereferencing. The system dereferences a task's `DFut` arguments before execution. The task's caller first waits for the `Value` field in its local ownership table to be populated (Fig-

[2]The owner can also choose a remote scheduler, e.g., for data locality.

Operation	Semantics
`Create(ObjID o, Value v)`	Store an object.
`Pin(ObjID o, NodeID loc)` → `bool`	Pin `o` on `loc` until released. Returns false if `loc` failed.
`Release(ObjID o)`	Object `o` is safe to evict.
`Get(ObjID o)` → `Value`	Get the object value. May fetch copy from remote node.

(a)



(b) (c) (d)

Figure 9: **(a)** Distributed memory store API, and **(b-d)** Memory management for the program in Figure 6a. (1-2) `B` returns a large object `X` in distributed memory. The primary copy is pinned until all references have been deleted. (3) Worker 1 dispatches `C` once `X` is available. (4-5) `Get` the value from distributed memory (location lookup not shown). (6) `C` returns a small object `Y` directly to the owner. (7-8) Object reclamation.

ure 9b), then copies the `Value` into the dispatched task description. The executing worker then copies the received `Value` into its local table (Figure 9c). For large objects, the sent value is a pointer to distributed memory, so the worker must also call `Get` to retrieve the actual value (step 4, Figure 9c).

If the task's caller is also the owner of its `DFut` arguments, the above protocol is sufficient. If the task's caller is *borrowing* an argument, then it must populate the `Value` field through a protocol with the owner. Upon receiving a `DFut`, the borrower sends the associated `Owner` a request for the `Value`. The owner replies with the `Value` (either the inlined value or a pointer) once populated. The borrower populates its local `Value` field by copying the reply.

Reclamation. The owner reclaims the object memory once there are no more reference holders (Figure 9d) by deleting its local `Value` field (step 7) and, if necessary, calling `Release` on the distributed object store (step 8). An object's reference holders are tracked with a distributed reference count maintained by the owner and borrowers.

Each process with a `DFut` instance keeps a local count of submitted tasks (`References`, Table 2). The task count is incremented each time the process invokes a dependent task and decremented when the task completes. Each process also keeps a local set of the worker IDs of any borrowers that it created, by passing the `DFut` as a first-class value. This forms a tree of borrowers with the owner at the root (see Appendix A). The owner releases the object once there are no more submitted tasks or borrowers anywhere in the cluster.

Actors. Actors are reference-counted with the same protocol used to track borrowers of a `DFut`. Once the set of reference holders is empty, the owner of the actor reclaims the actor resources by returning the worker lease (Section 4.1).

4.3 Failure recovery

The system guarantees that any reference holder will eventually be able to resolve the value in the presence of failures.

Failure detection. Failure notifications containing a worker or node ID are published to all workers. Workers do not exchange heartbeats; a worker failure is published by its local scheduler. Node failure is detected by exchanging heartbeats between nodes, and all workers fate-share with their node.

Upon receiving a node or worker failure notification, each worker scans its local ownership table to detect a `DFut` failure. A `DFut` is considered failed in two cases: 1) loss of an owned object (Figure 10a), by comparing the `Location` field, or 2) loss of an owner (Figure 11a), by comparing the `Owner` field. We discuss the handling for these two cases next, using lineage reconstruction and fate sharing, respectively.

Note that a non-owner does not need to detect the loss of an object. For example, in Figure 10a, node 2 fails just as worker 3 receives `C`. When worker 3 looks up `X` at the owner, it may not find any locations. From worker 3's perspective, this means that either node 2's write to the directory was delayed, or node 2 failed. Worker 3 does not need to decide which it is; it simply waits for `X`'s owner to handle the failure.

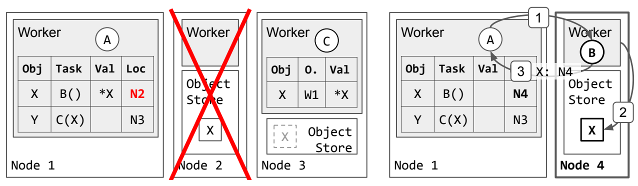
Object recovery. The owner recovers a lost value through lineage reconstruction. During execution, the owner records the object's lineage by storing each invoked `Task` in its ownership table (Table 2). Then, upon detecting a `DFut` failure, the owner resubmits the corresponding task (Figure 10b). The task's arguments are recursively reconstructed, if needed.

Like previous systems [34, 37, 56], we can avoid lineage reconstruction if other copies of a required object still exist. Thus, when reconstructing an object, the owner will first try to locate and designate a secondary copy as the new primary. To increase the odds of finding a secondary copy, object reclamation (Section 4.2) is done lazily: the owner releases the primary copy once there are no more reference holders, but the copy is not evicted until there is memory pressure.

Often, the owner of an object will also own the objects in its lineage (Section 5.2). Thus, upon failure, the owner can locally determine the set of tasks to resubmit, with a recursive lookup of the `Task` fields. In some cases, an object's lineage may also contain *borrowed* references. Then, the borrower requests reconstruction from the owner.

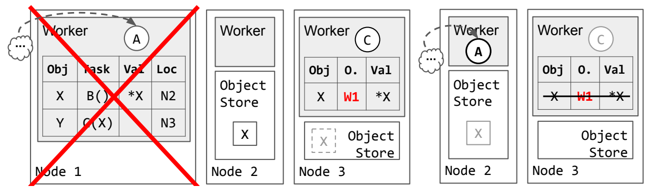
The owner can delete the `Task` field once the task has finished and all objects returned by reference will never be reconstructed again. When a worker returns an object by value, the owner can immediately delete the corresponding `Task` field. This is safe because objects passed by value do not require reconstruction (Section 3.1).

For an object passed by reference, the owner keeps a *lineage reference count* to determine when to collect the `Task`. The



(a) Failure detection. (b) Lineage reconstruction.

Figure 10: Object recovery.



(a) Failure detection. (b) Fate sharing.

Figure 11: Owner recovery.

count is incremented each time the `DFut` is passed to another task and decremented when that `Task` is itself collected. The owner collects a record after collecting both the `Task` and `Value` (Section 4.2) fields. We also plan to support object checkpointing to allow the lineage to be collected early.

Owner recovery. An owner failure can result in a "dangling pointer": a `DFut` that cannot be dereferenced. This can happen if the object is simultaneously lost from distributed memory. For example, `C` in Figure 11a will hang if node 2 also fails.

We use *fate sharing* to ensure that the system can make progress upon an owner's failure. First, all resources held by the owner and any reference holders are reclaimed. Specifically, upon notification of the owner's failure, either the distributed object store frees the object (if it exists) or the scheduling layer reclaims the worker lease (if the object is pending), shown in Figure 11b. All reference holders, i.e. borrowers and dependent tasks, also fate-share with the owner.

Then, to recover the fate-shared state, we rely on *lineage reconstruction*. In particular, the task or actor that was executing on the failed owner must itself have been owned by another process. That process will eventually resubmit the failed task. As the new owner re-executes, it will recreate its previous state, with no system intervention needed. For example, the owner of `A` in Figure 11a will eventually resubmit `A` (Figure 11b), which will again submit `B` and `C`.

For correctness, we show that all previous reference holders are recreated, with the address of the new owner. Consider task T that computes the value of a `DFut` x. T initially executes on worker W and re-executes on W' during recovery. The API (Section 2) gives three ways to create another reference to x: (1) pass x as a task argument, (2) cast x to a `SharedDFut` then pass as a task argument, and (3) return x from T.

In the two former cases, the new reference holder must be a child task of T. In case (2), when x is passed as a first-class value, the child task can create additional reference holders by passing x again. All such reference holders are therefore descendants of T. Then, when T re-executes on W', W' will recreate T's descendants.

T can also return x, which can be useful for returning a child task's result without dereferencing with `get`. Suppose T returns x to its parent task P. Then, P's worker becomes a borrower and will fate-share with W. In this case, P is recovered by *its* owner, and again submits T and receives x.

Thus, because any borrower of `x` must be a child or ancestor of T, fate-sharing and re-execution guarantees that the borrower will be recreated with W' as the new owner. Note that for actors, this requires that an actor not store borrowed `DFuts` in its local state. Of course, this is only required for transparent recovery; the application may also choose to handle failures manually and rely on the system for failure detection only.

While fate-sharing and lineage reconstruction add minimal run-time overhead, it is not suitable for all applications. In particular, the application will fate-share with the driver. In fact, this is the same failure model offered by some BSP systems [3], which can be written as a distributed futures program in which the driver submits all tasks. As shown by these systems, this approach can be extended to reduce the re-execution needed during recovery. We leave such extensions, including application-level checkpointing (Section 5.2), and persistence of the ownership table, for future work.

Actor recovery. Actor recovery is handled through the same protocols. If an actor fails, its owner restarts the actor through lineage reconstruction, i.e. resubmitting the constructor task. If the owner fails, the actor and any `ARef` holders fate-share.

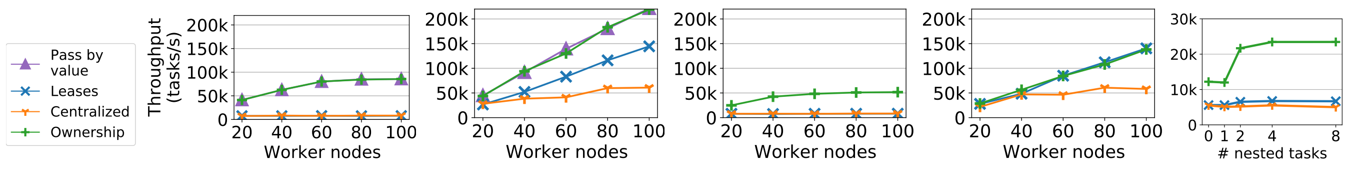
Unlike functions, actors have local state that may require recovery. This is out of scope for this work, but is an interesting future direction. Ownership provides the infrastructure to manage and restart actors, while other methods can be layered on top for transparent recovery of local state [17, 34, 52].

5 Evaluation

We study the following questions:

1. Under what scenarios is distributed futures beneficial compared to pass-by-value RPC?
2. How does the ownership architecture compare against existing solutions for distributed futures, in terms of throughput, latency, and recovery time?
3. What benefits does ownership provide for applications with dynamic, fine-grained parallelism?

We compare against three baselines: (1) a pass-by-value model with futures but no distributed memory, similar to Figure 2c, (2) a decentralized lease-based system for distributed futures (Ray v0.7), and (3) a centralized master for distributed futures (Ray v0.7 modified to write to a centralized master before task execution). All distributed futures systems use sharded, unreplicated Redis for the global metadata store, with asynchronous requests. All systems use the Ray distributed scheduler and (where applicable) distributed object store. Ownership and pass-by-value use gRPC [2] for worker-



(a) Small objects, colocated. (b) Small objects, spread. (c) Large objects, colocated. (d) Large objects, spread. (e) Single node, nested tasks.

Figure 12: Throughput and scalability. **(a-d)** Task submission is divided across multiple intermediate drivers, either colocated on the m5.8xlarge head node or spread with one m5.8xlarge node per driver. 1 intermediate driver is added per 5 worker nodes. Each task returns either a small (short binary string) or large (1MB blob) object. **(e)** Scaling task submission using nested tasks and first-class distributed futures.

to-worker communication. All benchmarks schedule tasks to predetermined nodes to reduce scheduling variation.

All experiments are run on AWS EC2. Global system metadata, such as an object directory, is hosted on the same node as the driver, where applicable. Unless stated otherwise, this "head node" is an m5.16xlarge instance. Other node configuration is listed inline. All benchmark code is available at [53].

5.1 Microbenchmarks

Throughput and scalability. The driver submits one nested task for every 5 worker nodes (m5.8xlarge). Each intermediate "driver" submits no-op tasks to its 5 worker nodes. We report the total throughput of the leaf tasks, which return either a short string (Figures 12a and 12b) or a 1MB blob (Figures 12c and 12d). The drivers are either colocated (Figures 12a and 12c) on the same m5.8xlarge node as the root driver, or spread (Figures 12b and 12d), each on its own m5.8xlarge node. We could not produce stable results for pass-by-value with large objects due to the lack of backpressure in our implementation.

At <60 nodes, the centralized and lease-based architectures achieve about the same throughput because the centralized master is not yet a bottleneck. In general, ownership achieves better throughput than either because it distributes some system operations to the workers. In contrast, the baselines handle all system operations in the global or per-node processes.

The gap between ownership and the baselines is more significant with small return values (Figures 12a and 12b). For these, ownership matches pass-by-value because small objects are returned directly to their owner. The baseline systems could implement a similar optimization, e.g., by inlining small objects in the object directory (Section 4.2), but this would still require at minimum one RPC per read.

When the drivers are spread (Figures 12b and 12d), ownership and leases both scale linearly. Ownership scales better than leases in Figure 12b because more work is offloaded onto the worker processes. Ownership and leases achieve similar throughput in Figure 12d, but the ownership system also includes memory safety (Section 4.2). The centralized design (2 shards) scales linearly to ∼60 nodes. Adding more shards would raise this threshold, but only by a constant amount.

When the drivers are colocated (Figures 12a and 12c), both baselines flatline because of a centralized bottleneck: the scheduler on the drivers' node. Ownership also shows this, but there is less scheduler load overall because the drivers reuse resources for multiple tasks (Section 4.1). A comparable optimization for the baselines would require each driver to batch task submission, at the cost of latency. Throughput for ownership is lower in Figure 12c than in Figure 12a due to the overhead of garbage collection.

Thus, because ownership decentralizes system state among the workers, it can achieve vertical (Figures 12a and 12c) and horizontal (Figures 12b and 12d) scalability. Also, it matches the performance of pass-by-value RPC while enabling new workloads through distributed memory (Section 2.2).

Scaling through borrowing. We show how first-class futures enable delegation. Figure 12e shows the task throughput for an application that submits 100K no-op tasks that each depend on the same 1MB object created by the driver. The tasks are submitted either by the driver (x=0) or by a number of nested tasks that each *borrow* a reference to the driver's object. All workers are colocated on an m5.16xlarge node.

For all systems, the throughput with a single borrower (x=1) is about the same as when the driver submits all tasks directly (x=0). Distributing task submission across multiple borrowers results in a 2× improvement for ownership and negligible improvement for the baselines. Thus, with ownership, an application can scale past the task dispatch throughput of a single worker by *delegating* to nested tasks. This is due to (1) support for first-class distributed futures, and (2) the hierarchical distributed reference counting protocol, which distributes an object's reference count among its borrowers instead of centralizing it at the owner (Section 4.2). In contrast, the baselines would require additional nodes to scale.

Latency. Figure 13 measures task latency with a single worker, hosted either on the same node as the driver ("local"), or on a separate m5.16xlarge node ("remote"). The driver submits 3k tasks that each take the same 1MB object as an argument and that immediately returns a short string. We report the average duration before each task starts execution.

First, distributed memory achieves better latency than pass-by-value in all cases because these systems avoid unnecessary copies of the task argument from the driver to the worker.

Second, compared to centralized and leases, ownership achieves on average 1.6× lower latency. This is due to (1)

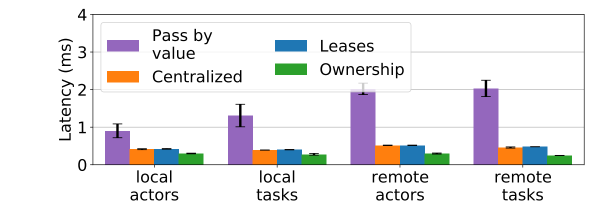


Figure 13: Task latency. Local means that the worker and driver are on the same node. Error bars for standard deviation (across 3k tasks).

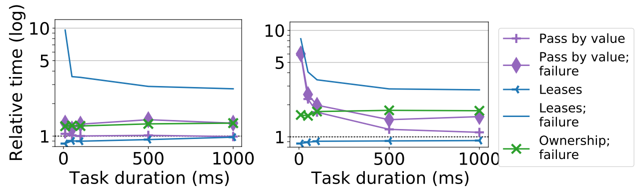

(a) Small objects. (b) Large objects.

Figure 14: Total run time (log-scale), relative to ownership without failures. The application is a chain of dependent tasks that execute on one node. Each task sleeps for the duration on the x-axis (total 10s) and returns either **(a)** a short binary string, or **(b)** a 10MB blob.

the ability to write metadata locally at the owner instead of a remote process, and (2) the ability to reuse leased resources, in many cases bypassing the scheduling layer (Section 4.1).

Recovery. This benchmark submits a chain of tasks that execute on a remote m5.xlarge node. Each task depends on the previous, sleeps for the time on the x-axis (total duration 10s), and returns either a short binary string (Figure 14a) or a 10MB blob (Figure 14b). We report the run time relative to ownership without failures. To test recovery, the worker node is killed and restarted 5s into the job (1s heartbeat timeout). We do not include centralized due to implementation effort.

Normal run time for leases is up to 1.18× faster than ownership, but recovery time is more than double, worse than restarting the application. This is because a task's lease must expire before it can be re-executed, adding delay for short tasks. The recovery delay for longer tasks is also high because the implementation (Ray v0.7) repeatedly doubles a lease's expiration time to reduce renewal overhead. A shorter lease interval would reduce recovery delay but can be unstable.

Ownership recovers within 2× the normal run time. Recovery time is the same as pass-by-value for small objects because only in-flight tasks are re-executed (Figure 14a). For large objects (Figure 14b), ownership achieves better normal run time than pass-by-value because arguments are passed by reference; the gap decreases as task execution dominates.

Thus, ownership can achieve the same or better normal run-time performance as leases *and* pass-by-value, while also guaranteeing timely recovery through lineage reconstruction.

5.2 End-to-end applications

Model serving. We implement Figure 3a. Figure 15a shows the latency on 4 p3.16xlarge nodes, each with 1 `Router` and 8 ResNet-50 [23] `Models`. We use a GPU batch size of 16 and generate 2300 requests/s. Ownership and centralized achieve the same median latency (54ms), but the tail latency for centralized is 9× higher (1s vs. 108ms). We also show the utility of first-class distributed futures: in "-borrow", the `Router` receives the image *values* and must copy these to the `Model`. As expected, the `Router` is a bottleneck (p50=80ms, p100=3.2s).

Online video processing. We implement Figure 3b with 60 concurrent videos. The tasks for each stream are executed on an m5.xlarge "worker" node (1 per stream) and submitted by a driver task on a separate m5.xlarge "owner" node. Each owner node hosts 4 drivers. Each video source uses an actor to hold frame-to-frame decoder state. However, tasks are idempotent: a previous frame may be reread with some latency penalty. We use a YouTube video with a frame rate of 29 frames/s and a radius of 1s for the moving average.

Figure 15b shows latency without failures. All systems achieve similar median latency (∼65ms), but leases and centralized have a long tail (1208ms and 1923ms, respectively). Figure 15c shows latency during an injected failure, 5s after the start, of the `Decoder` actor (Figure 3b). Lease-based recovery is slow because the decoder actor must replay all tasks, and each task accumulates overhead from lease expiration. Checkpointing the actor was infeasible because the leases implementation does not safely garbage-collect lineage.

Figure 15c also shows different failure scenarios for ownership, with a failure after 10s. The owner uses lineage reconstruction to recover quickly from a worker failure (1.9s in O;WF). Owner recovery is slower because the failed owner must re-execute from the beginning (8.8s in O;OF). To bound re-execution, we use application-level checkpoints (O+CP, checkpoints to a remote Redis instance once per second). Each checkpoint includes all intermediate state needed to transform the given frame, such as the cumulative sum so far (Figure 3b). When the sink receives the transformed frame, it "commits" the checkpoint by writing the frame's index to Redis. This results in negligible overhead (O vs. O+CP) and faster recovery (1.1s in O+CP;OF).

6 Related Work

Distributed futures. Several systems [4, 34, 37, 45, 48, 52] have implemented a distributed futures model. Most [37, 45] use a centralized master (Section 3.2). In contrast, ownership is a decentralized design that stores system state directly in the workers that invoke the tasks. Ray [34] shards the centralized state, but must still write to the centralized store *before* task execution and does not support automatic memory management. Lineage stash [52] is a complementary technique for recovering nondeterministic execution; ownership provides infrastructure for failure detection and memory management.

Other dataflow systems. Distributed data-parallel systems provide high-throughput batch computation and transparent data recovery [15, 25, 54, 56]. Many of our techniques build on

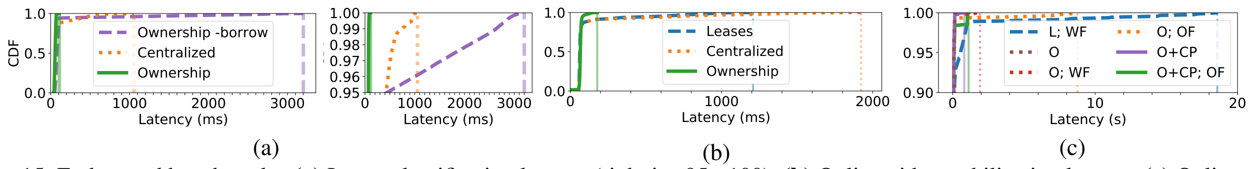

Figure 15: End-to-end benchmarks. **(a)** Image classification latency (right is p95-p100). **(b)** Online video stabilization latency. **(c)** Online video stabilization latency with failures (starting at p90). L=leases; O=ownership; CP=checkpointing; WF=worker failure; OF=owner failure.

these systems, in particular the use of distributed memory [25, 56] and lineage re-execution [15, 25, 54, 56]. Indeed, a data-parallel program is equivalent to a distributed futures program with no nested functions.

Most distributed data-parallel systems [15, 25, 54, 56] employ some form of centralized master, a bottleneck for applications with *fine-grained* tasks [32, 44, 51]. Naiad [35, 36] and Canary [44] support fine-grained tasks but, like other data-parallel systems, implement a *static* task graph, i.e. all tasks must be specified upfront. In contrast, distributed futures are an extension of RPC, which allows tasks to be dynamically invoked. Nimbus [32] supports both fine-grained *and* dynamic tasks with a centralized controller by leveraging *execution templates* for iterative computations. In contrast, ownership distributes the control plane and schedules tasks one at a time. These approaches are complementary; an interesting future direction is to apply execution templates to distributed futures.

Actor systems. Distributed futures are compatible with the actor model [7, 24]. Other actor frameworks [1, 12] already use futures for asynchrony, but with pass-by-value semantics, making it expensive to process large data. Actors can be extended with distributed memory to enable pass-by-reference semantics. Since distributed memory is immutable, it does not violate the condition of no shared state.

Our fault tolerance model is inspired by *supervision* in actor systems [7]. In this model, a supervisor actor delegates work to its children actors and is responsible for handling any failures among its children. By default, an actor also fate-shares with its supervisor. Our contribution is in extending the supervision model to *objects* and object recovery.

Parallel programming systems. MPI [18] exposes a low-level pass-by-value interface. In contrast, distributed futures supports pass-by-reference and heterogeneous processes.

Distributed futures are more similar in interface to other parallel programming runtimes [10, 14, 21, 31, 47]: the user annotates a sequential program to designate procedures that can be executed in parallel. Out of these systems, ownership is perhaps most similar to Legion [10], in that the developer specifies a task hierarchy that dictates system behavior. Our contribution is in identifying and addressing the challenges of failure detection and recovery for distributed futures.

Distributed memory. Distributed shared memory [40] provides the illusion of a single globally shared and *mutable* address space across a physically distributed system. Transparency has historically been difficult to achieve without adding exorbitant runtime overhead. Mutability makes consistency a major problem [11, 26, 28, 40], and fault tolerance has never been satisfactorily addressed [40].

More recent distributed memory systems [6, 9, 16, 27, 41] implement a higher-level key-value store interface. Most target a combination of performance, consistency, and durability. Similar to our use of distributed memory (Section 4.2), in-memory data replicas are used to improve durability and recovery time. Indeed, many of these systems could likely be used in place of our distributed memory subsystem.

However, the requirements of our distributed memory subsystem are minimal compared to previous work, e.g., durability is only an optimization. This is because we target an even higher-level interface that integrates directly with the programming language: unlike a key, a `DFut` can be used to express rich application semantics to the system, such as an RPC's data dependencies. Also, like previous data processing systems [15, 37, 56], data is immutable. Thus, fine-grained mutations are expensive, but consistency is not a problem.

7 Discussion

Ownership is the basis of the Ray architecture in v1.0+ [5], implemented in ∼14k C++ LoC. Previously, Ray used a sharded global metadata store [34]. There were two problems with this approach: (1) latency, and (2) worker nodes still had to coordinate for operations such as failure detection. Ray v0.7 introduced leases (Section 3.2), which solved the latency problem but not coordination. It became impractical to introduce distributed protocols involving multiple objects, such as for garbage collection. We designed ownership for this purpose.

While transparent recovery is an explicit goal of this paper, it is not the only benefit of ownership. Anecdotally, the two main benefits of ownership for Ray users are performance and reliability. In particular, reliability includes correct and timely failure detection and garbage collection. Notably, ownership-based transparent recovery is not yet widely used.

We believe that this is due to: (1) applications having custom recovery requirements that cannot be met with lineage reconstruction alone, and (2) the cost of transparent recovery. Thus, one design goal was to ensure that only applications that needed transparent recovery would have to pay the cost. Ownership is a first step towards this: it provides reliability to all applications and transparent object recovery as an option.

In the future, we hope to extend this work to support a *spectrum* of application recovery requirements. For example, we could extend ownership with options to recover actor state.

A Distributed Reference Counting

Type	Description
Local reference	A flag indicating whether the `DFut` has gone out of the process's scope.
Submitted task count	Number of tasks that depend on the object that were submitted by this process and that have not yet completed execution.
Borrowers	The set of worker IDs of the borrowers created by this process, by passing the `DFut` as a first-class value.
Nested `DFuts`	The set of `DFuts` that are in scope and whose values contain this `DFut`.
Lineage count	Number of `Tasks` that depend on this `DFut` that may get re-executed. This count only determines when the lineage (the `Task` field) should be released; the *value* can be released even when this count is nonzero.

Table 3: Full description of the `References` field in Table 2. Every process with an instance of the `DFut` (either the owner or a borrower) maintains these fields.

If a `DFut` never leaves the scope of its owner, it does not require a distributed reference count. This is because the owner always has full information about which pending tasks require the object. However, since our API allows passing `DFuts` to other tasks as first-class values, we use a distributed reference count to decide when the object is out of scope.

Our reference counting protocol is similar to existing solutions [33, 42]. As explained in Section 4.2, the reference count is maintained with a tree of processes. Each process keeps a local set of borrower worker IDs, i.e. its children nodes in the tree. Most of the messages needed to maintain the tree are piggy-backed on existing protocols, such as for task scheduling.

A borrower is created when a task returns a `SharedDFut` to its parent task, or passes a `SharedDFut` to a child task. In both cases, the process executing the task adds the ID of the worker that executes the parent or child task to its local borrower set.

In many cases, a child task will finish borrowing the `DFut` by the time it has finished execution. Concretely, this means that the worker executing the child task will no longer have a local reference to the `DFut`, nor will it have any pending dependent tasks. Thus, when the worker returns the task's result to its owner, the owner can remove the worker from its local set of borrowers, with no additional messages needed. This optimization is important for distributing load imposed by reference counting among the borrowers, rather than requiring all reference holders to be tracked by the owner.

However, in some cases, the worker may borrow the `DFut` past the duration of the child task. There are two cases: (1) the worker passed the `DFut` as an argument to a task that is still pending execution, or (2) the worker is an actor and stored the `DFut` in its local state. In these cases, the worker notifies the owner that it is still borrowing the `DFut` when replying with the task's return value.

Eventually, the owner must collect all of the borrowers in its local set. It does this by sending a request to each borrower to reply once the borrower's reference count has gone to zero. Borrowers themselves never delete from their local set of borrowers. Once a borrower no longer has a reference or any pending dependent tasks, it replies to the owner with its accumulated local borrower set. The owner then removes the borrower, merges the received borrowers into its local set and repeats the same process with any new borrowers. If a borrower dies before it can be removed, the owner removes it upon being notified of the borrower's death.

When a `DFut` is *returned* by a task, it results in a nested `DFut`. Nested `DFuts` can be automatically flattened, e.g., when submitting a dependent task, but we must still account for nesting during reference counting. We do this by keeping a set of `DFuts` whose values contain the `DFut` in question in the ownership table (Table 2). The `DFut`'s value is pinned if its nested set is non-empty.

B Formal Specification

We developed a formal specification for the ownership-based system architecture [53]. It models the system state transitions of the ownership table for task scheduling, garbage collection, and worker failures. The goal is to check the correctness of the system design, which is manifested in the following properties:

- Safety: A future's lineage information is preserved as long as a task exists that depends on the value of the future. This is defined recursively: at any time, either the value of a future is stored inline (thus cannot be lost), or all futures that this future depends on for computing its value must be safe. Formally, it means the following invariant holds at any given time: $\forall x$,

$$\begin{aligned}&\text{LineageInScope}(x) \triangleq\\ &\quad \lor x = \texttt{INLINE\_VALUE}\\ &\quad \lor \forall arg \in x.args : \text{LineageInScope}(arg)\end{aligned}$$

- Liveness: The system will eventually execute all tasks and resolve all future values, even in case of failures, i.e., all `Get` calls eventually return.

- No Resource Leakage: The system will eventually clean up all task states and future values, after the all references to futures become out-of-scope.

We checked the model using the TLA$^+$Model Checker [55] for up to 3 levels of recursive remote function calls, where each function creates up to 3 futures, and verified that the safety and liveness properties hold in more than 44 million distinct states. Currently, the model does not include first-class futures or actors; we plan to include these and open-source the full TLA$^+$specification in the future.

Fault-Tolerant Replication with Pull-Based Consensus in MongoDB

Siyuan Zhou[1], Shuai Mu[2]

Abstract

In this paper, we present the design and implementation of strongly consistent replication in MongoDB. MongoDB provides linearizability and tolerates any minority of failures through a novel consensus protocol that derives from Raft. A major difference between our protocol and vanilla Raft is that MongoDB deploys a unique *pull-based* data synchronization model: a replica pulls new data from another replica. This pull-based data synchronization in MongoDB can be initiated by any replica and can happen between any two replicas, as opposed to vanilla Raft, where new data can only be pushed from the primary to other replicas. This flexible data transmission topology enabled by the pull-based model is strongly desired by our users since it has an edge on performance and monetary cost. This paper describes how this consensus protocol works, how MongoDB integrates it with the rest of the replication system, and the extensions of the replication protocol that support our rich feature set. Our evaluation shows that MongoDB effectively achieved the design goals and can replicate data efficiently and reliably.

1 Introduction

MongoDB is a general purpose, document-based, distributed database. In the last few years, we have been focusing on improving its support for replication, as there has been an increasing demand for stronger fault tolerance. In previous papers we discussed how MongoDB supports tunable consistency [29] and how causal consistency works [34]. In this paper we present the details of how MongoDB provides linearizable [12] replication with fault tolerance.

A common approach to fault-tolerant linearizable replication is through consensus protocols [24, 4]. After studying the popular consensus protocols including Paxos [17] and Raft [26], we concluded that no existing consensus protocols directly fit our needs without heavy modifications. The key reason is that these existing protocols are *push-based*: there is usually a primary server and the primary will push new data to all replicas. Yet in MongoDB we aim for a *pull-based* synchronization model: a replica fetches new data proactively from another replica, and not necessarily from the primary.

There are a few reasons for why we target the pull-based synchronization model. First, allowing data synchronization to happen between any two replicas enables a more flexible data transmission topology, that could utilize networks in more optimal ways. Many of our users prefer being able to configure how their network is utilized, especially for those who deploy their systems across different datacenters. Second, using a pull-based data synchronization model gives us backward-compatibility as we have previously implemented a preliminary version of a pull-based primary-backup replication scheme that is not backed by any consensus protocols, and thus has limited fault tolerance.

As there is no direct fit, we developed a new replication (consensus) scheme based on the Raft protocol. We chose Raft as the base because it is more accepted for industry use, easy to understand, and similar to our previous replication protocol, but we believe other bases such as Paxos should work too. The principle of our approach is to decouple data synchronization in Raft (mostly the AppendEntries RPC) into two parts: replicas pulling new data from the peers, and replicas reporting their latest replication status so that a request can commit after it reaches a majority of replicas.

The development of the new replication scheme is, however, easier said than done. The main challenge is in the subtlety of the Raft (and any other) consensus protocol. During our development we found that any unthoughtful changes to the protocol would easily introduce new corner cases that would break the correctness of the system. To verify that our design and implementation are correct, we have done extensive verification and testing on the protocol including model checking using TLA+, unit testing, integration testing, fuzz testing [11] and fault-injection testing.

Our developed protocol achieves the goal of allowing data pulling between *any* two replicas. Unlike Raft which can only push data from the primary to other replicas (broadcast), our system supports arbitrary data synchronization paths: from linear chaining to broadcast. This gives MongoDB several advantages over using vanilla Raft, including both performance-wise (e.g., saving leader bandwidth) and management-wise (e.g., controlling data transmission paths).

The main contributions of this paper include:

- We design a new consensus protocol based on Raft. Our protocol better meets the needs of MongoDB. It enables more flexible and customizable data synchronization paths during replication.
- We describe the design choices in how MongoDB adopts

this consensus protocol. MongoDB offers a unique feature set, which brings extra challenges in designing and implementing its replication. For example, we provide speculative execution to be compatible with MongoDB's weak consistency features, but also guarantee linearizable log replication with rollbacks.

- We report the evaluation results of MongoDB for different replication parameters. Our evaluation shows that MongoDB replication is reliable and efficient.

We will organize the rest of paper as follows. Section 2 gives an overview of the background. Section 3 describes the main body of the consensus protocol. Section 4 gives a few important extensions to our design. Section 5 discusses the evaluation results. Section 6 discusses related works before we conclude.

2 Background

MongoDB interfaces and architecture. MongoDB is a database that stores data as *documents* and supports general CRUD operations on one or many documents with a rich query language. Each document is a binary JSON-like (called BSON) object. Documents are identified by unique ids and grouped in *collections*, which are similar to tables in a SQL database.

To provide high availability, MongoDB provides the ability to run a database as a *replica set*, which is a set of MongoDB nodes that act as a consensus group, where each node maintains a logical copy of the database state. MongoDB also supports *sharding* for horizontal scaling, which distributes all data in a collection onto different shards in a share-nothing manner. Each shard is deployed as a replica set. In this paper we focus on a single replica set, as sharding is orthogonal.

Consistency and fault tolerance. Previous papers have described how MongoDB can achieve weaker consistency levels, including causal consistency [34, 29]. In this paper, we focus on the strongest consistency level—linearizability [12]. We assume a (partially) asynchronous environment where messages can be arbitrarily delayed and there are no perfect failure detectors. For each replica set, at most a minority of servers can fail in order to maintain availability. The problem of fault-tolerant linearizable replication is commonly solved by consensus protocols. Examples include Viewstamped Replication [24], Paxos [17], Zab [13], and Raft [26]. Our solution started with adopting the recent and popular Raft, but ended up basically inventing a new protocol with many heavy modifications.

Evolution of MongoDB's pull-based replication. Starting from MongoDB version 1.0 over a decade ago, MongoDB supported replication with a primary-backup scheme. Unlike conventional primary-backup replication schemes where updates are usually *pushed* from where they are firstly received—the primary—to the secondaries (backups), we chose a design in which a secondary server can constantly *pull* updates from other servers, and not necessarily from the primary.

A major benefit of the pull-based approach is that it enables a more flexible control of how data is transmitted over the network. Depending on users' needs, the data transmission can be in a star topology, a chaining topology, or a hybrid one. The ability of controlling data transmission paths is a strong customer need, mostly for reasons related to performance and monetary cost. For example, when deployed in clouds like Amazon EC2, data transmission inside a datacenter is free and fast, but is expensive and subject to limited bandwidth across datacenters.

The pull-based approach has led our designs while we continually evolved our replication protocols in the last few releases. In earlier releases several years ago, we assumed a semi-synchronous network: either there is manual control of failover (the user needs to appoint a node as the new primary when the old one fails), or all messages are bounded to arrive within 30 seconds for failure detection. Starting from 2015, we remodeled our replication scheme based on the Raft protocol. This new protocol guarantees safety in an asynchronous network (i.e., messages can be arbitrarily delayed or lost) and supports fully autonomous failure recovery with a smaller failover time. Same as before, this new protocol is still pull-based. We will describe how it works in the next section.

3 Design

This section describes how replication in MongoDB works, including the overall architecture and data structures (§3.1), the main body of the replication protocol (§3.2), a discussion of correctness, (§3.3), and how the system chooses data transmission paths (§3.4). Attached to this paper is an appendix that summarizes the difference between the Raft protocol and MongoDB's consensus protocol.

3.1 Preliminaries

In MongoDB, the object for replication is called the *oplog*. An oplog is a sequence of log entries; each log entry contains a database operation. Figure 1 shows an example of oplog entry. The oplog is stored in the *oplog collection*, which behaves in almost all regards as an ordinary collection of documents. The oplog collection automatically deletes its oldest documents when they are no longer needed and appends new entries at the other end.

An oplog entry needs to be replicated to at least a majority of servers to *commit*: a committed entry persists through any minority failures. The system will wait for the oplog entry to commit before it acknowledges the client. MongoDB also

```
{
  // The oplog entry timestamp
  "ts": Timestamp(1597904287, 12),
  // The term of this entry
  "t":  NumberLong(40),
  // The operation type, "i" for insert
  "op": "i",
  // The collection name
  "ns": "test.collection",
  // A unique collection identifier
  "ui": UUID("947b54f...852f62")),
  // The document to insert
  "o":{
      "_id": ObjectId("5f3e...b950"),
      "x": 1
  }
}
```

Figure 1: Example of key oplog entry fields for an "insert" operation

supports operations with weaker consistency, in which case the system can acknowledge clients before the oplog entry commits [29, 34]. After replication, all servers of the same replica set will have identical oplogs. Oplog entries will be applied in the same order on all servers.

A server can act as either a primary or a secondary. [1] Only a primary can process write requests. A server has a third role as a *candidate* when it is transitioning from a secondary to a primary through *elections*. MongoDB's election rules are the same as Raft's. When a node decides to start an election, for example, because it has not seen a primary for an election timeout, the node transitions to a candidate role, increases its term, and sends vote requests to others. A voter can grant its vote to only one candidate in a given term and only if the candidate has the same or a more up-to-date log than the voter. The candidate wins the election if it is able to collect votes from a majority of nodes including the candidate itself; it then becomes a primary.

After the election, the new primary will have a unique, monotonically increasing *term* number. When the primary generates a new oplog entry, it will append this entry into its own oplog, and replicate the entries through the *data replication* protocol described in Section 3.2. It could happen that more than one server is acting as a primary, but the data replication and the election protocols collectively guarantee that at most one primary can successfully commit log entries at a particular index.

In MongoDB, each oplog entry is assigned a timestamp and annotated with the term of the primary. The timestamp is a monotonically increasing logical clock that exists in the system before this work. It is used to index the oplog entries, similar to the log index in Raft. A pair of term and timestamp, referred to as an OpTime, can identify an oplog entry uniquely in a replica set and give a total order of all oplog entries among all replicas. OpTimes are compared lexicographically, i.e., an OpTime is greater than another if its term is higher or the terms are the same but its timestamp is higher.

[1]Our choice of terminology is for historical reasons. They are the same as a *leader* and a *follower* used in Raft.

3.2 Data Replication

As mentioned in previous sections, MongoDB uses a pull-based replication scheme. Unlike Raft and other common consensus protocols that would initiate RPCs from the primary to secondaries when the primary tries to replicate new log entries (for example, in Raft, this is the AppendEntries RPC), in MongoDB, the primary waits for the secondaries to pull the new entries that are to be replicated.

After appending an entry to the oplog, the primary can process two types of RPCs from secondaries: PullEntries and UpdatePosition. A secondary will use PullEntries to fetch new logs, and use UpdatePosition to report its status so that the primary can determine which oplog entries have been safely replicated to a majority of servers and commit them. Similar to Raft, once an entry is committed, all prior entries are committed indirectly.

3.2.1 PullEntries

Note that a key design choice is that a secondary does not have to send PullEntries only to the primary. Instead, the secondary can pull new entries from any (nearby) servers. This secondary is called the *syncing server*, while the upstream server that receives the PullEntries RPC is called the *sync source*.

A secondary continuously sends PullEntries to the selected sync source (see more details about the sync source selection in §3.4) to retrieve new log entries when they become available. The PullEntries RPC includes the latest oplog timestamp (prevLogTimestamp) of the syncing server as an argument. When receiving PullEntries, a server will reply with its oplog entries after and including that timestamp if it has a longer or the same log, or the server could reply with an empty array if its log sequence is shorter. Before returning a response when the log is the same, PullEntries waits for new data for a given timeout (5 seconds by default) to avoid busy looping.

When the syncing server receives the reply of PullEntries, it will try to merge the log entries in the reply into its own oplog. Before merging, it checks if the incoming log entries concatenate with the local oplog. In particular, it checks if the first received entry has the same OpTime as the last local oplog entry. Only if so, the syncing server continues to merge by appending the received entries to the oplog. If the received oplog entries don't overlap with the local ones and the received entries are "newer" by comparing their last OpTimes, the syncing server will traverse the oplog on its sync source in order to find their last common entry, then discard any diverged oplog entries since then. Afterwards, the syncing server should be able to pull new data and append it to the local oplog. Discarding diverged logs will require more work than ordinary Raft implementations because of our optimizations on speculative execution (see details in §4.1).

3.2.2 UpdatePosition

After retrieving new entries into its local oplog with PullEntries, the secondary will send UpdatePosition to its sync source, reporting the latest log entry's OpTime. When receiving the UpdatePosition, the server will forward the message to its sync source, and so forth, until the UpdatePosition reaches the primary. The primary keeps a non-persistent map in memory that records the latest known log entry's OpTime on every replica, including its own, as their log positions. When receiving a new UpdatePosition, the primary will compare the received OpTime with its local record. If the received one is newer, the primary will replace its local record with the received one. Afterwards, the primary will do a count on the log positions of all replicas: if a majority of replicas have the same term and the same or greater timestamp, the primary will update its lastCommitted to that OpTime and notify secondaries of the new lastCommitted by piggybacking onto other messages, such as heartbeats and the responses to PullEntries. lastCommitted is also referred to as the *commit point*.

3.2.3 Implementation

In MongoDB, instead of initiating continuous RPC's on the syncing node, the PullEntries RPC is implemented as a query on the oplog collection with a "greater than or equal to" filter on the timestamp field. The query can be optimized easily since the oplog is naturally ordered by timestamp. Using database cursors allows the syncing node to fetch oplog entries in batches and also allows the RPC to work in a streaming manner, so that a sync source can send new data without waiting for a new request, reducing the latency of replication.

To avoid a flood of forwarded UpdatePosition messages, a server passively batches the received UpdatePosition requests between two rounds of forwarding and consolidates the requests by only keeping the highest log position for each server. A server only maintains at most one in-progress UpdatePosition request to its sync source, so it waits to send the next request until the previous one returns.

We also introduced Heartbeats RPC, which decoupled the heartbeat responsibility from Raft's AppendEntries RPC. Heartbeats are sent among all replicas, used for liveness monitoring, commit point propagation and sync source selection (§3.4).

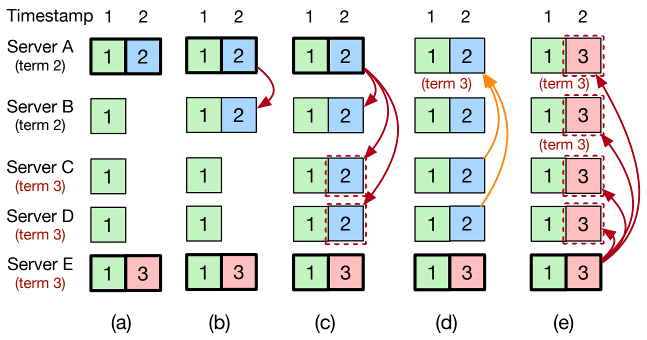

Figure 2: A corner case
Each box represents an oplog entry with its term (shown in different colors) in the box. (a) start state with both A and E being primaries (thick border); (b) Raft only allows replicating (red arrows) from A to B; (c) MongoDB can replicate from A to B/C/D; (d) C/D report log positions (orange arrows) with term 3, forcing A to step down. (e) data replicated in (c) may be rolled back.

3.3 Correctness

Careful readers may have noticed that our data replication protocol (how PullEntries are processed) only checks the OpTimes in the logs; it does not check if the sync source has a higher or equal term than the syncing server. This is different from what Raft would do in data replication. The data replication in Raft is done via AppendEntries RPC, which contains the term of the primary. AppendEntries can only succeed if the primary has a term that is not lower than the secondary's.

This crucial protocol change means that log replication in MongoDB will behave differently from Raft. In Raft, if a server has voted for a higher term in an election, the server cannot take new log entries sent from an old primary with a lower term. But in our system, because the PullEntries RPC does not check the term of the sync source, even if the sync source is a stale primary, it is possible that after a server has voted for a higher term, the server could still fetch new log entries generated by the stale primary.

Figure 2 shows an example of this disparity occurring on secondaries. Initially, all five servers acknowledged entries in term 1. Server A first wins the election in term 2 with votes from Server A/B/C and writes down one entry locally. Server E then wins the election in term 3 with votes from Server C/D/E and writes a different entry locally. In Raft, if Server A broadcasts its AppendEntries, only Server B will accept the new entry from Server A; Server C/D/E will all reject.

In MongoDB, however, Server B/C/D could all take the new log from Server A even after Server C/D have voted for the new primary in term 3. If A is the sync source of Server B/C/D, then B/C/D will still accept the new entry with term 2 because the entry is newer than their local ones. Now that the entry in term 2 has been replicated to the majority of servers, it would be considered by Server A as committed if we did not make further changes to Raft's rule that *a log entry is committed once the leader that created the entry has replicated it on a majority of the servers* [26]. Later, Server E's new entry with term 3 could propagate to all servers and overwrite the committed entry. Without more changes from Raft, this would violate safety. [2]

To prevent cases like this from happening, we added a new argument in the UpdatePosition RPC: the term of the syncing server. The recipient of UpdatePosition will update its local term if the received term is higher. If the recipient is the stale primary, seeing a higher term will make the primary step down before committing anything, thus avoiding any safety issue. In the above example, when server A receives UpdatePosition from Server C/D, it will see term 3 and step down immediately without updating its lastCommitted. Even though the entry with term 2 is in a majority of servers' logs, it is not committed.

Until now, we have assumed it is a secondary that fetches oplog entries from a stale primary after voting for a new primary. In fact, this syncing server could be the new primary itself. Even if a primary (or candidate) has voted for itself in a higher term, it could still fetch data generated in lower terms from other replicas, as long as it has not generated new oplog entries with the new term and appended the entries to its own oplog. This important difference between MongoDB and Raft allows MongoDB to preserve uncommitted data as much as possible during failovers (see more in §4.3).

More formally, the revisions we made to UpdatePosition are to maintain a key invariant in Raft—Leader Completeness Property. This property refers to the fact that "if a log entry is committed in a given term, then that entry will be present in the logs of the leaders for all higher-numbered terms." (See Figure 3 in the Raft paper.) In MongoDB, in order to commit an entry in term T, the primary in term T has to receive UpdatePosition RPCs with term T from a majority of nodes. A later new primary in term U > T must collect votes from a majority of nodes too. The two majorities must overlap on at least one voter. This voter is the key to guarantee the safety. Either the voter sent UpdatePosition in term T to commit the entry **before** voting, thus implying the new primary had the committed entry due to the Log Matching Property; or the voter voted first and sent UpdatePosition with a term higher than T, thus leading the primary in term T to step down without committing the entry. Either way, the Leader Completeness Property is guaranteed.

In addition to this property, other invariants of Raft still hold so that one can prove the correctness of our protocol following the proof of Raft. Further, to mechanically verify the correctness of our system, we have written a formal specification of the protocol in TLA+ and applied model checking to it [33].

[2]Another angle to look at this problem is that, allowing UpdatePosition from a server with a higher term is actually "counting replicas" rather than "counting replies". Raft has explained well why counting replicas is incorrect in its paper. Indeed, Raft's TLA+ spec in [25] specifies a stronger definition of "commit" than its paper. The definition in TLA+ is similar to our modification: an entry $\langle index, term \rangle$ is **immediately committed** if it is acknowledged by a quorum (including the leader) during *term*.

3.4 Sync Source Selection

Servers learn about the status of other servers, including their log positions, via Heartbeat RPC. A server chooses its sync source only if the sync source has newer oplog entries than itself by comparing their log positions. This condition is double-checked on receiving PullEntries RPC's responses in case rollback (§4.1) occurs on the sync source. As a result, it's guaranteed that the replicas can never form a cycle of sync sources. Once a server starts to pull entries from its sync source, it keeps fetching from the source until the source is not available or a better source shows up. Thus a server should not change its sync source frequently in a stable environment.

4 Extensions

In this section we introduce a few key features of MongoDB that extend the elementary design.

4.1 Speculative Execution and Rollback

The standard approach of applying log entries in Raft-based systems is that a replica waits until the log entries are committed and then applies the log entries in timestamp order. MongoDB introduces an optimization that speculatively applies an oplog entry when it is added to the oplog. If a failover happens, speculatively applied oplog entries could be deleted (§3.2.1). In this case, the system needs to roll back the operations in these entries. The common approach for rollbacks in databases is through undo or redo logs. The way MongoDB achieves this is through a consolidated design of the storage engine (named WiredTiger) and the replication protocol.

The WiredTiger storage engine is a multi-version transactional storage engine that can use oplog timestamps as versions of data updates. There are three key functions implemented in the storage engine that enable this consolidation. First, the storage engine supports speculative updates, so multiple versions are visible to clients depending on their requested consistency levels even if not all of them are committed. Second, the storage engine provides fast rollback to a timestamp and discards all updates after that timestamp. Third, when oplog entries are committed, the storage engine can be notified to merge all data updates with lower timestamps in the on-disk checkpoint and garbage collect those versions.

When a node needs to roll back, it will determine the newest oplog entry it has in common with its sync source. The timestamp of this oplog entry is referred to as t_{common}. The node needs to truncate all oplog entries with a timestamp after t_{common}. In addition to oplog truncation, it must undo the speculative effects of the operations deleted from the oplog.

Since MongoDB version 4.0, the WiredTiger storage engine has provided the ability to revert the replicated data to the version at a given timestamp. MongoDB periodically informs the storage engine of a *stable timestamp* (t_{stable}), which is the timestamp of the commit point known by this node and must be less than or equal to t_{common} when the node starts rollback.

To undo the effects of truncated oplog entries, the rolling back node reverts its replicated data to the version at t_{stable}, then applies the oplog entries forward from t_{stable} up to and including t_{common}.

4.2 Initial Sync

MongoDB discards stale oplog entries once the storage space used to store the entries reaches a configurable threshold, by default 5% of free disk space at startup. In most consensus systems, such as Chubby and the vanilla Raft, a *snapshot* of the database is obtained before discarding stale log entries. The snapshot will be used by a new server to catch up when joining the system. However, MongoDB does not rely on a snapshot mechanism for this initial synchronization, referred to as *initial sync*.

The major reason for MongoDB not using snapshots for initial sync is that MongoDB has a pluggable storage API that does not require the storage engine to support snapshots. For example, the initial storage engine before WiredTiger at its core used `mmap` [3], which does not support snapshots. This `mmap`-based storage engine needs to be supported due to backward-compatibility.

The initial sync in MongoDB works as follows. First, when a new server is joining, it chooses a sync source and uses this sync source for the whole duration of initial sync. Once the initial sync starts, the syncing node records the current applied oplog timestamp on the sync source as the initial sync start point. Then, the new server starts to clone the database of the sync source by scanning the database. The database scan gets a cursor at the beginning of each collection and iterates over the cursor to the end. Note that this clone may be inconsistent when there are concurrent updates happening in the system—some cloned values are up-to-date, some may be obsolete, and some may be missing. The final step is to fix this inconsistency. The new server will retrieve all oplog entries on the sync source starting from the initial sync starting point, and apply the oplog entries locally on the database. After the database clone, the new server records the current applied oplog timestamp on the sync source again as the initial sync end point. Once the new server applies oplog entries beyond this point, the data becomes consistent and the initial sync is complete. If the sync source fails during the initial sync, the new server chooses a different sync source and restart the process.

Note that some oplog entries may be applied twice in the database on the new server. If an operation gets applied on the sync source after the initial sync begins, the operation's effect may be included in the database that the new server cloned gradually. Later this oplog entry will be applied again on the new server. To avoid any data inconsistency caused by this effect, MongoDB requires any sequences of operations in the oplog entries to be *idempotent*: applying the same sequence of operations multiple times will lead to the same system state.

For operations that change the database states (inserts, updates, deletes, etc.), we changed their semantics during initial sync to make them idempotent. Inserts in MongoDB will be ignored if the document id already exists; updates and deletes will be ignored if the modified document's id does not exist. MongoDB supports rich update operations, such as incrementing a field's value in a document. These operations will be converted to unconditional field assignments by the primary. For example, for an increment request, the primary will read the current value from its local database and compute the result of the increment, and replicate an oplog entry setting the field to the computed result. As a result, the consistency between the new server and its sync source is guaranteed.

4.3 Preserving Uncommitted Oplog Entries

After a failover, the uncommitted oplog entries on the previous primary are likely lost. This would be fine for a different system because the clients could retry uncommitted updates. This is, however, an issue for MongoDB because MongoDB supports fast but weak consistency levels that acknowledge writes as soon as they are applied on the primary or just replicated to a fewer number of nodes than a majority. Thus, a failover could cause a large loss of uncommitted writes. Though the clients are not promised durability with weak consistency levels, we still prefer to preserve their uncommitted writes as much as possible.

For this purpose, we introduced an extra phase for a newly elected primary—the primary catchup phase. The new primary will not accept new writes immediately after winning an election. Instead, it will keep retrieving oplog entries from its sync source until it does not see any newer entries, or a timeout occurs. This timeout is configurable in case users prefer faster failovers to preserving uncommitted oplog entries.

As explained in §3.3, the primary catchup design is only possible because a primary is allowed to keep syncing oplog entries generated by the old primary after voting for a higher term as long as it hasn't written any entry with its new term.

[3]When using this deprecated `mmap` engine, features including speculative execution and rollback are implemented in different approaches and are omitted due to space limitation.

4.4 Additional Replica Roles

4.4.1 Arbiters

MongoDB supports a special replica role called *arbiter*. An arbiter is like a secondary with respect to voting but does not store any data to save the cost of storage and replication while being a tie-breaker in elections. For example, in a Primary-Secondary-Arbiter deployment, when the primary crashes, the secondary can take over with the vote from the arbiter to serve reads and writes. The writes will be applied speculatively but cannot be committed. [4] If a new node needs to be added to the replica set to replace the crashed one through initial sync, the arbiter allows a safe reconfiguration to change the membership.

4.4.2 Non-Voting Members

In addition to fault tolerance requirements, users often deploy replica sets to offload reads from the primary or to access a local data copy with lower latency. For example, users may maintain some replicas for a heavy analytical workload using MongoDB's expressive aggregation framework. These replicas are not deployed for fault tolerance and may have unstable write performance due to the heavy analytical workload. As another example, a geo-distributed application may prefer to read from a nearby datacenter for lower latency, thus need to deploy dozens of replicas globally. Assuming it's extremely rare for more than a few servers to fail at the same time, it would be unnecessary to count all replicas towards a quorum for fault tolerance and undesired to wait for a majority of such many servers to replicate in order to commit writes.

MongoDB introduced *Non-Voting Members* particularly for this purpose. Non-voting members replicate data as normal secondaries, but they do not participate in elections or count towards a quorum for committing oplog entries, as opposite to *Voting Members*. MongoDB supports up to 50 replicas but only up to 7 voting members. Therefore, writes with strong consistency levels can return faster, as long as they are committed after replicating to a quorum of voting members rather than a quorum of all replicas.

Non-voting members work well with the pull-based data replication model since it's possible to minimize their performance impact on the primary and voting members by offloading their significant oplog read workload to other non-voting members as much as possible.

4.5 Election Optimizations

4.5.1 Election Handoff

On failovers, secondaries wait for an election timeout (10 seconds by default) to run for election in order to detect that the primary is no longer available. However, on planned failovers, it is known that the old primary has already stepped down. MongoDB introduced *Election Handoff* to shorten the planned failover time by avoiding the next candidate's waiting.

When a primary server steps down on administrator commands, it will pause new writes and wait for any eligible secondary to catch up its oplog within a user specified timeout. The primary then chooses this caught-up secondary to immediately run for election on a best-effort basis. In common cases, the chosen secondary will win the election and become the new primary. This election handoff mechanism will likely shorten the failover time as it does not need the the election timeout to elapse. This is similar to the leadership transfer extension in Raft.

The election handoff is leveraged by the planned maintenance on MongoDB Atlas[21], MongoDB's hosted database as a service. Atlas uses a rolling upgrade strategy for executing maintenance or infrastructure operations, such as applying security patches, scaling up an Atlas cluster, and upgrading to the latest MongoDB minor versions. As part of the rolling upgrade, the primary will be stepped down and shut down for upgrade. The election handoff minimizes the unavailability window on planned failovers. In fact, the vast majority of failovers (89.03%) on Atlas are caused by planned maintenance (§5.2) and can benefit from the election handoff.

4.5.2 Member Priority

It is common that users have a preference for which server should act as primary, especially in a multi-datacenter setup where users prefer to deploy the primary in the datacenters closest to the applications (clients) for lower latency. MongoDB supports setting election priority among servers in the replica set configuration. If a secondary realizes it has a higher priority than the current primary, it will start an election after a timeout based on its relative priority. The higher the priority it has, the smaller the timeout value will be. In this way, the server with the highest priority is likely to win the election first. If the election fails due to competition but the server still has a higher priority than the new primary, it will continue calling for elections until it becomes primary or the new primary has a higher priority. Setting a server's priority to zero prevents it from running for election.

One potential problem is that when the election caused by a high-priority server fails, it will propagate its larger term number to the rest of the replica set and force the current primary to step down. This disruption is particularly serious when this high-priority server is lagged due to shutdown and rejoins the replica set after a restart. Until this high-priority server is caught up on its oplog, it keeps running elections periodically and causing disruptions. Although other servers will elect a new primary after each disruption, the system will be unavailable for at least an election timeout on every

[4] This speculative execution can benefit reads with weaker consistency levels described in [29].

disruption. To prevent disruptions when a server rejoins the replica set, Raft describes a pre-vote algorithm in Section §9.6 in [25], where a candidate only increments its term and runs the real election if it learns from a majority of nodes that they would grant their votes. MongoDB implements this algorithm with an election dry-run. When a stale candidate with a higher priority starts an election even though it won't be able to win, the candidate will fail during the election dry-run, protecting the existing primary from being disrupted by a higher term.

Note that in rare cases such as network partitions, it could happen that two nodes repeatedly initiate elections and cause liveness issues. This is a different issue from the priority design and having priorities does not make it worse. In these cases, the dry-run mechanism cannot address the issue completely, as liveness in asynchronous networks is impossible to guarantee [9]. In reality we did not find this to be a problem.

4.6 Read-only Operations

A strawman solution to support linearizable reads is to turn read operations into log entries similarly to treating write operations. MongoDB's optimized approach is that if the primary has other concurrent oplog entries to replicate, the primary can piggyback the read linearization point with those entries. Note that this optimization is different from weakly consistent reads although they both skip turning read operations into oplog entries. Even though weakly consistent reads are supported on both primary and secondary nodes and they do not need to wait for synchronization between nodes, linearizable reads can only happen on the primary and need to wait for a roundtrip of synchronization.

5 Evaluation

Our evaluation section has two parts. First, we benchmarked the system under different configurations on Amazon EC2 and report the performance measurements (§5.1). Second, we collected metrics from our own cloud platform, MongoDB Atlas [21], and report the analysis of the operational data on failovers (§5.2).

5.1 Benchmarks on EC2

5.1.1 Setup

Our tests use AWS m5d.2xlarge instances, each with 8 vCPUs, 32GB memory, and a local SSD. We tested 5-way replication with 5 server VMs and 2 client VMs. 3 servers are deployed in the US East (N. Virginia) region and 2 servers in the US West (Oregon) region. The primary is always deployed in the US East region.

We use the following benchmark for our main tests. Each client thread continuously and randomly updates an entire document out of 1 million documents containing one random string field of 1000 bytes in a closed loop. These updates will not return until they are committed. We vary the number of client threads to control the offered load in the system.

To measure the impact of allowing secondaries to sync from other secondaries, we run the tests with two settings: (1) chaining enabled and a secondary in the US West region forced to sync from another secondary in the same region while all other secondaries syncing from the primary, and (2) chaining disabled and all secondaries syncing from the primary, which mimics similar data transmission paths to vanilla Raft.

In addition to the above basic benchmarks, we also tested two interesting cases: (1) a failure recovery test in which we crash the primary, wait for the new primary to step up, and then recover the old primary; (2) a comparison with a previous version of MongoDB that uses a deprecated replication protocol not based on known consensus protocols.

Appendix B has an additional TPCC benchmark.

5.1.2 Benchmark Results

Figure 3 and 4 respectively show the 50-percentile and 90-percentile latency vs. throughput of both chaining enabled and disabled cases. Their performance is almost the same. However, as shown in Figure 5, the cross-datacenter traffic is halved by leveraging chaining, so is its cost. Using \$0.01~\$0.147/GB (EC2's pricing) to estimate, the savings of chaining in this test is about \$300~\$5,000 per month.

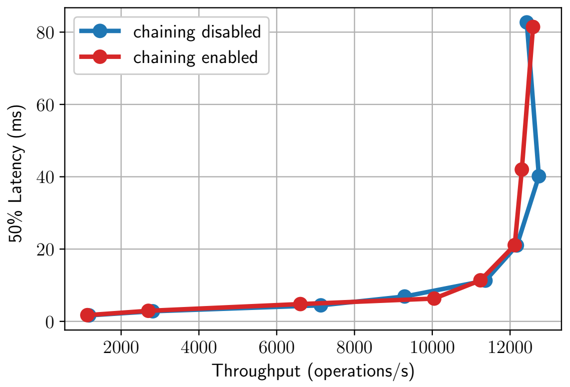

Figure 3: 50-percentile latency vs. throughput of chaining disabled and enabled

One may expect that with chaining enabled the system should be able to achieve a higher maximum throughput because the primary would have more available CPU resources for clients. The system is indeed bottlenecked by the primary's CPU at the maximum throughput in our tests and most of the CPU is used to serve clients. Each client request is handled by a separate OS thread, so there are a few thousand

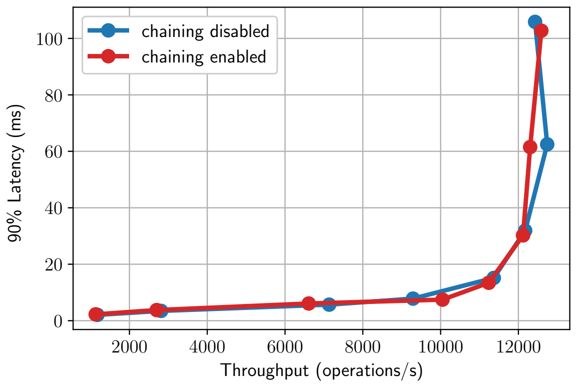

Figure 4: 90-percentile latency vs. throughput of chaining disabled and enabled

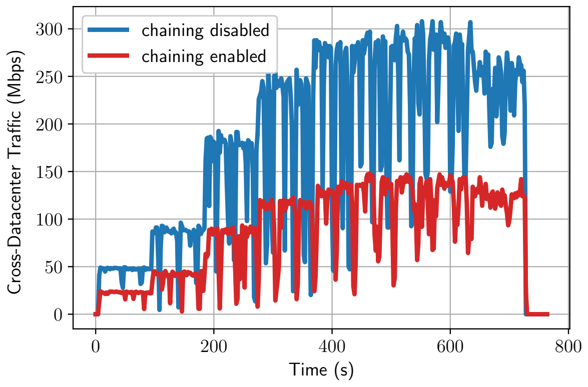

Figure 5: Cross datacenter traffic with chaining disabled and enabled

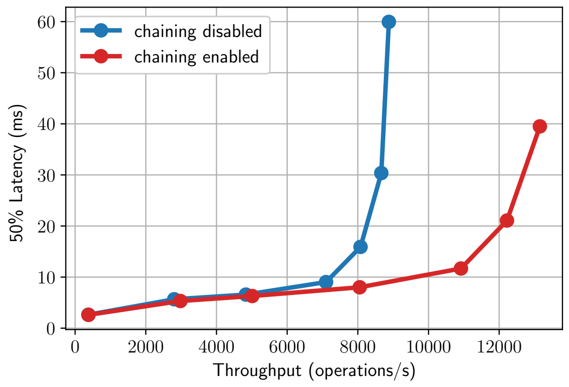

Figure 6: 50-percentile latency vs. throughput of chaining disabled and enabled with limited 200Mbps bandwidth on primary

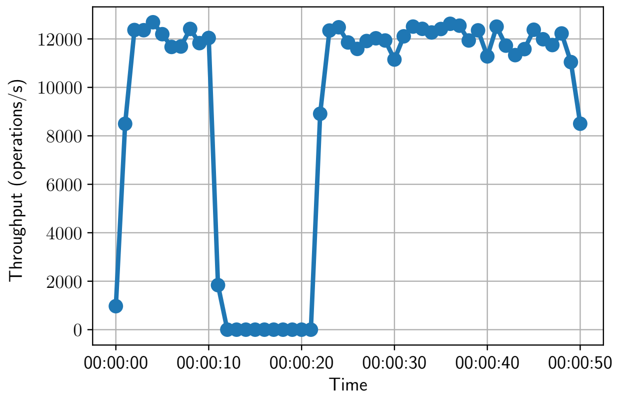

Figure 7: Throughput during failover

client threads in our tests. We observed more than 250k context switches per second on the primary consistently when the system is saturated. The heavy interleaving of threads indicates that the performance will not scale linearly given extra available CPU time. Meanwhile, each secondary oplog read takes one thread on the primary. In fact, a secondary in a steady replication state only consumes about 5% of a single CPU core on the primary in our experiments. Therefore we did not observe throughput improvement with chaining enabled when the primary CPU is the bottleneck.

Nevertheless, if the network bandwidth between nodes is the bottleneck, we expect that enabling chaining will greatly improve the throughput. In our tests, we did not observe throttled bandwidth across datacenters on AWS EC2. But it is reported that the bandwidth of the cloud could be affected by time, space, and other factors such as VM instance types [16]. Besides, our users could deploy MongoDB in other environments with networks that may be less reliable and have less bandwidth than EC2. Therefore, we conducted an additional experiment with 3 nodes, where the primary's bandwidth is limited using the `tc` tool. The result is in Figure 6) and it shows that when the network bandwidth is the bottleneck, chaining can drastically improve the system throughput as expected.

5.1.3 Failover Tests

The failover tests are conducted with all 5 replicas deployed in the same datacenter. In each test, we run 64 clients concurrently and crash the primary after the system runs for 10 seconds in a stable state. The timeout set for the system to elect a new primary is 10 seconds. After the new primary takes over and the system is again in a stable state, we recover the old primary. The old primary will catch up by synchronizing the missing oplog entries.

Figure 7 shows the throughput of the system during failover when chaining is enabled. The new primary steps up after losing the old primary over an election timeout. The clients can discover the new primary and issue writes to it immediately, thus the throughput resumes to the level before the failover. When the old primary is recovering (at 40s), it fetches the missing oplog entries from another secondary in this case. In our tests not shown here with chaining disabled, the old primary catching up its oplog from the new primary increases the workload on the new primary but doesn't affect the performance since the new primary isn't saturated.

5.1.4 Comparing with Previous Implementation

We compare the latest released version 4.4 with a previous MongoDB version 3.6 released in 2017. Version 3.6 is the last version that supports the old and deprecated replication protocol, which works in most cases but is unproven. Additionally, it has severe limitations due to its strong assumptions about the deployment environment: all messages must be replied within 30 seconds or otherwise the nodes must have failed. Thus, it does not tolerate faults like network partitions and could suffer from a "split-brain" if such faults happen.

The main advantage of our current protocol is fault tolerance as it makes fewer assumptions of the deployment. In most cases, we observed comparable performances, as shown in Figure 8. The performance of the newer version is better when the system isn't saturated. We believe this is not only because of the algorithmic and engineering improvements of the replication system, but also thanks to optimizations of many other parts of the server, e.g., journaling.

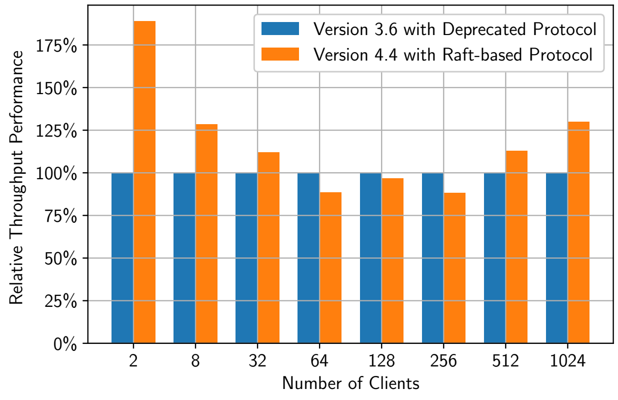

Figure 8: Relative throughput comparison between deprecated and Raft-base protocols

5.2 Metrics on MongoDB Atlas

To examine the performance of failover and its impact in production, we analyzed the failover metrics of MongoDB instances deployed on MongoDB Atlas, a hosted database as a service. When the data was collected in June 2020, almost all replica set instances were on the latest major releases: 3.6.18 (26.86%), 4.0.18 (44.17%) and 4.2.6 (28.54%). The vast majority of failovers (89.03%) are caused by planned maintenance, 6.15% by priority takeover (§4.5.2) and 4.82% by election timeout. We focused on those caused by planned maintenance and election timeout to measure the impact of expected and unexpected failovers.

5.2.1 Planned Maintenance

As part of rolling upgrade for planned maintenance on MongoDB Atlas, the old primary will be stepped down via a command. The stepdown command pauses new writes, waits for any eligible secondary to catch up and then asks the eligible secondary to step up, as discussed in §4.5.1. We measure the time duration from starting the election to when the new primary is available for new writes, referred to as *Local Write Unavailability*, and from starting election to when the first no-op write on stepup gets committed, referred to as *Majority Write Unavailability*. Note that the entire unavailable windows perceived by clients are longer since they start from when the old primary pauses writes. The extra unavailability window beyond our measurements heavily depends on the workload and is less comparable across replica sets.

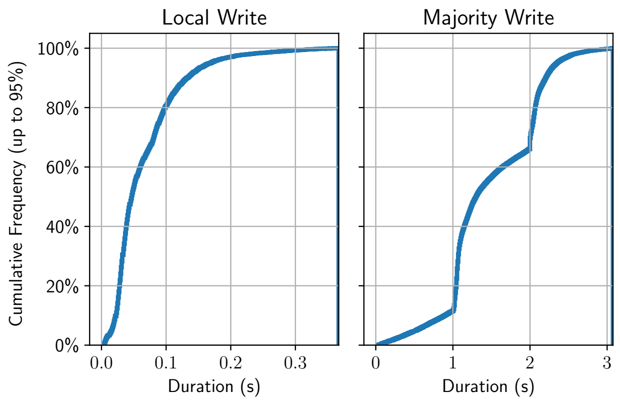

Figure 9: Unavailability due to planned maintenance

Figure 9 shows the cumulative frequency of local and majority write unavailability up to 95th-percentile, 0.37 seconds and 3.08 seconds respectively. Since an election only involves a few round-trips in the same data center, a candidate can finish its election quickly and start to accept new writes. However, it takes longer for other nodes to learn there is a new primary and start to sync from it directly or indirectly. We can observe two clusters of duration for majority writes: around 1 and 2 seconds. We believe this is due to the implementation of sync source selection based on heartbeats. We are actively working on delivering performance improvements in this area to all supported versions.

5.2.2 Election Timeout

When a secondary cannot see a primary for a given election timeout, it runs for election. Failovers caused by election timeout are the fault-tolerant scenarios for which the replication system is designed. We measure the same local and majority write unavailability as above. However, both measurements include the primary catchup phase (§4.3) which involves more work in election timeout cases, so both measurements are longer than that of planned maintenance. By contrast, it is essentially a no-op in planned maintenance since the old primary has waited already. Additionally, overloaded systems are a common reason of failover, which leads to longer primary catchup phases.

The perceived unavailable windows by clients are also longer since they start from when the old primary becomes unresponsive. Usually, they add about an election timeout (10 or 5 seconds on Atlas) to what we measured.

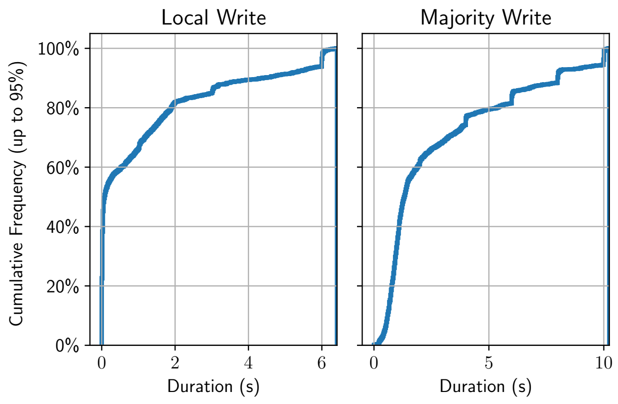

Figure 10: Unavailability due to election timeout

As shown in Figure 10, 95% of failovers due to election timeout start to accept writes within 6.41 seconds after election, and commit their first majority writes within 10.24 seconds. The sharp steps are also aligned with the default 2 second heartbeat intervals.

5.2.3 Replication Network Traffic

MongoDB's consensus protocol allows flexible replication paths and can save cross-datacenter traffic by allowing secondaries syncing from others from the same datacenter. We examined the replication network traffic on Atlas to estimate the cost of cross-datacenter traffic.

Figure 11 shows the distribution of daily replication network traffic on secondaries on Atlas during a week. While some replica sets have no writes and may mainly be used for reads, there are some others that generate gigabytes or terabytes of data. 50% of replica sets generate less than 8.08MB per day, and 95% generate less than 7.94GB per day. Figure 12 shows the distribution of the same data weighted by the daily replication network traffic. It is obvious that a small portion of replica sets generate disproportionately large amount of replication traffic. In fact, the top 5% of all replica sets account for more than 92.6% of all replication network traffic. Given the high traffic volume, it is valuable for a multi-node cross-datacenter deployment to minimize the cost of cross-datacenter traffic from the primary. The cost could be expensive (e.g., \$0.01~\$0.147 per GB on AWS [1]). MongoDB made it possible to minimize cross-datacenter traffic by allowing syncing from another node in the same datacenter instead of the primary.

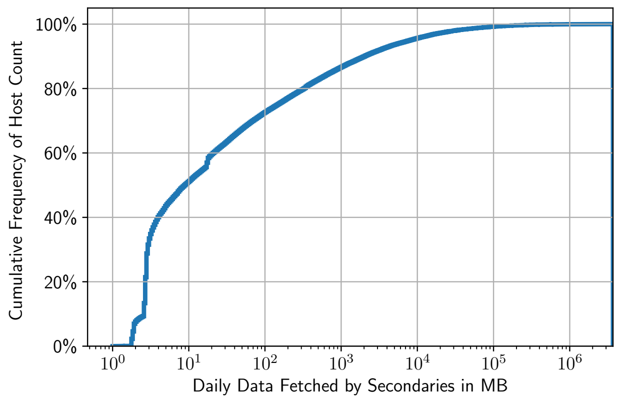

Figure 11: Distribution of daily replication network traffic

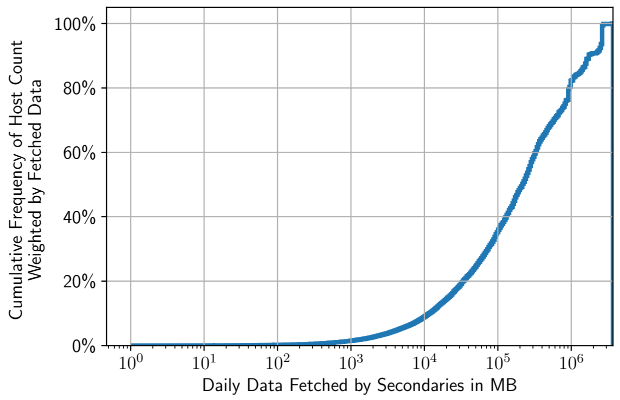

Figure 12: Weighted distribution of daily replication network traffic

6 Related Work

Replication and consensus are both very well-studied areas. This section reviews related works in two main categories: linearizable replication in production databases, and developments in consensus algorithms.

Linearizable replication in production databases. Many production databases build their replication systems via consensus protocols, mostly using Paxos or Raft. One recent popular Paxos-based system is Google's Spanner [7], and examples of Raft-based systems include TiDB [32], RethinkDB [28], CockroachDB [6, 31]. Another approach with similar data replication paths is the primary-backup scheme with external membership management (e.g., a consensus service). Recent database systems of this type include Aurora [35] and FaRM [8, 30]. To the best of our knowledge, these systems do not support pull-based data transfer in their data replication paths.

Another important scheme is Chain Replication (CR) [27]. It can achieve a chaining topology similar to MongoDB. The differences between CR and our proposed scheme are threefold. First, our scheme can support many types of topology and chaining is one typical use case. Second, in our scheme a request can commit after replicating to a majority, while in CR a request needs to replicate to all nodes before it commits. Third, similar to primary-backup schemes, CR needs a third-party to perform a safe leader (head) change. Nevertheless, CR can perform consistent read requests on the tail node, which can improve the system performance, while common consensus-based systems cannot.

CORFU [3] and Delos [2] have the clients (i.e., the learner role in Paxos) pull logs from the server; our approach takes one step further and has the servers (i.e., the acceptor role) pull logs from each other. During this process, we found that at least for Raft, modifying the protocols to enable servers to pull logs from other servers is challenging.

Study in consensus algorithms. Except for searching for more understandable basic consensus protocols, the developments in consensus algorithms can be classified into two categories: 1) optimizations that only require a minimal change to an existing protocol (usually Paxos); 2) new protocols built from scratch or heavily modifying a previous protocol.

The first category of works, in our experience, is closer to our needs in practice. PigPaxos [5] has a group of secondaries relay the messages from the primary to alleviate the primary bottleneck, which achieves similar flexibility as we do. Reconfiguration [18] of a replication group is a major challenge in MongoDB and we developed a refined version of reconfiguration in the latest release 4.4. Leases [10, 22] provide a way to allow consistent local reads in an efficient way. We are investigating this direction for future improvements. One thing we need to point out is that incorporating these or other optimizations of this category into MongoDB may be more difficult than into other systems that use stock Paxos protocols, because our protocol is a heavily modified version of Raft. However, it has been demonstrated [36] that such porting of optimizations can be achieved by drawing a one-to-one correspondence between each step of these protocols, e.g., by using refinement mapping.

It is an interesting and open question how MongoDB can benefit from the optimizations in the second category of works. These optimizations are often disruptive but effective. For example, to improve the performance for geo-replication, one can shard the log space [20], use fast quorums [23], or rethink the layering between replication and the rest of the system [15, 19, 37]. Replaying these works in MongoDB may require more efforts because it could suggest a complete reconstruction of the system.

7 Conclusion

In this paper we presented the design and implementation of the fault-tolerant and linearizable replication system in MongoDB. We proposed a novel pull-based consensus protocol that is a modification of Raft. With this pull-based scheme, MongoDB allows a more flexible control of data transmission paths. We described how this consensus protocol works, how MongoDB integrates it with the rest of the replication system, and the extensions of the replication protocol that support our rich feature set. We reported our evaluation on EC2 and our data analysis on MongoDB's cloud platform, and concluded that MongoDB can replicate data efficiently and reliably.

Acknowledgments

We thank our shepherd Mahesh Balakrishnan and anonymous reviewers at NSDI for providing valuable feedback. We thank Robert Guo for his guidance and assistance on performance testing. We thank William Schultz for contributing to the formal definition of majority commitment. We thank Bruce Lucas and Eric Milkie for helping investigate performance bottlenecks in the experiments. We thank the Data Engineering team and the Cloud team for collecting and maintaining the Atlas metrics and enabling the analysis of Atlas metrics. We thank our internal reviewers: Tess Avitabile, William Schultz, Andy Schwerin, Michael Cahill, Judah Schvimer, Robert Guo, and Asya Kamsky. Finally, we would like to thank the entire MongoDB Replication team and its alumni, all of whom contributed to the design and implementation of the protocol and features described in this paper.

Appendix A: Comparison between Raft and MongoDB Consensus

Raft Protocol

Minor changes are marked in *italics*, e.g., changing from index to timestamp, comparison of OpTimes (<term, timestamp> pairs) and introducing heartbeats; major behavioral changes are marked in red.

State

Persistent state on all servers:
(Updated on stable storage before responding to RPCs)

currentTerm	latest term server has seen (initialized to 0 on first boot, increases monotonically)
votedFor	candidateId that received vote in current term (or null if none)
log[]	log entries; each entry contains command for state machine, and term when entry was received by leader (first index is 1)

Volatile state on all servers:

commitIndex	index of highest log entry known to be committed (initialized to 0, increases monotonically)
lastApplied	index of highest log entry applied to state machine (initialized to 0, increases monotonically)

Volatile state on leaders:
(Reinitialized after election)

nextIndex[]	for each server, index of the next log entry to send to that server (initialized to leader last log index + 1)
matchIndex[]	for each server, index of highest log entry known to be replicated on server (initialized to 0, increases monotonically)

AppendEntries RPC

(Invoked by leader to replicate log entries; also used as heartbeat.)

Arguments:

term	leader's term
prevLogIndex	index of log entry immediately preceding new ones
prevLogTerm	term of prevLogIndex entry
entries[]	log entries to store (empty for heartbeat; may send more than one for efficiency)
leaderCommit	leader's commitIndex

Results:

term	currentTerm, for leader to update itself
success	true if follower contained entry matching prevLogIndex and prevLogTerm

Receiver implementation:

1. Reply false if term > currentTerm
2. Reply false if log doesn't contain an entry at prevLogIndex whose term matches prevLogTerm
3. If an existing entry conflicts with a new one (same index but different terms), delete the existing entry and all that follow it
4. Append any new entries not already in the log
5. If leaderCommit < commitIndex, set commitIndex = min(leaderCommit, index of last new entry)

RequestVote RPC

Invoked by candidates to gather votes.

Arguments:

term	candidate's term
candidateId	candidate requesting vote
lastLogIndex	index of candidate's last log entry
lastLogTerm	term of candidate's last log entry

Results:

term	currentTerm, for candidate to update itself
voteGranted	true means candidate received vote

Receiver implementation:

1. Reply false if term < currentTerm
2. If votedFor is null or candidateId, and candidate's log is at least as up-to-date as receiver's log, grant vote

Rules for Servers

All Servers

- If commitIndex > lastApplied: increment lastApplied, apply log[lastApplied] to state machine
- If RPC request or response contains term T > currentTerm: set currentTerm = T, convert to follower

Followers

- Respond to RPCs from candidates and leaders
- If election timeout elapses without receiving AppendEntries RPC from current leader or granting vote to candidate: convert to candidate

Candidates

- On conversion to candidate, start election:
  - Increment currentTerm
  - Vote for self
  - Reset election timer
  - Send RequestVote RPCs to all other servers
- If votes received from majority of servers: become leader
- If AppendEntries RPC received from new leader: convert to follower
- If election timeout elapses: start new election

Leaders

- *Upon election: send initial empty AppendEntries RPCs (heartbeat) to each server; repeat during idle periods to prevent election timeouts*
- If command received from client: append entry to local log, respond after entry applied to state machine
- If last log index ⩾ nextIndex for a follower: send AppendEntries RPC with log entries starting at nextIndex
  - If successful: update nextIndex and matchIndex for follower
  - If AppendEntries fails because of log inconsistency: decrement nextIndex and retry
- If there exists an N such that N > commitIndex, a majority of matchIndex[i] ⩾ N, and log[N].term == currentTerm: set commitIndex = N

MongoDB Consensus Protocol

State

Persistent state on all servers:
(Updated on stable storage before responding to RPCs)

currentTerm	latest term server has seen (initialized to 0 on first boot, increases monotonically)
votedFor	candidateId that received vote in current term (or null if none)
log[]	log entries; each entry contains command for state machine, *timestamp* and term when entry was received by leader

Volatile state on all servers:

lastCommitted	*OpTime* of highest log entry known to be committed (initialized to minimum, increases monotonically)
lastApplied	*OpTime* of highest log entry applied to state machine (*initialized to last log entry's OpTime*, increases monotonically)
lastPosition[]	for each server, OpTime of highest log entry known to be replicated on that server

RequestVote RPC (Omitted)

. . . The same as Raft's RequestVote RPC *except changing index to timestamp* . . .

PullEntries RPC

(Replicate log entries from its sync source.)

Arguments:

prevLogTimestamp
timestamp of last fetched log entry.

Results:

entries[]	log entries with a timestamp greater than or equal to prevLogTimestamp
commitPoint	sync source's lastCommitted

Receiver implementation:

1. Return the log entries with a timestamp greater than or equal to prevLogTimestamp. Could be empty if no such entry exists.

Sender implementation after RPC call:

1. If returned entries is empty or last OpTime in entries is less than last OpTime in log, select a new sync source and retry PullEntries.
2. If last log entry conflicts with the first of entries (*due to different OpTimes*)
   (a) Traverse the log on sync source backwards until a common entry is found
   (b) Delete all existing entries following the common entry
   (c) Roll back the data to the state right after the common entry
3. Append any new entries not already in the log
4. If commitPoint > lastCommitted, set lastCommitted = min(commitPoint, *OpTime* of last new entry)

UpdatePosition RPC

(Sending latest positions of all known nodes to sync source.)

Arguments:

term	currentTerm, for leader to update itself
position[]	lastPosition[] on the sender

Results: None

Receiver implementation:

1. Merge position and lastPosition to record the highest known position for each member
2. Send UpdatePosition RPC to sync source if the receiver has one

Heartbeat RPC

(Used for liveness monitoring, commit point propagation, and sync source selection.)

Arguments:

term	sender's term
senderId	sender's node Id
role	sender's role
position	sender's last log entry's OpTime
commitPoint	sender's lastCommitted

Receiver implementation

1. Record the role and the current time of the last heartbeat for senderId for liveness monitoring
2. Update lastPositions[senderId] to position if position is higher, for sync source selection
3. If commitPoint > lastCommitted, set lastCommitted = min(commitPoint, *OpTime* of last new entry)

Rules for Servers

All Servers

- Apply log entries speculatively when appending them to log
- If RPC request or response contains term T > currentTerm: set currentTerm = T, convert to follower

Followers

- Respond to RPCs from candidates and leaders
- If election timeout elapses without *receiving Heartbeat RPC from current leader*: convert to candidate

Candidates

- On conversion to candidate, start election:
  – Increment currentTerm
  – Vote for self
  – Reset election timer
  – Send RequestVote RPCs to all other servers
- If votes received from majority of servers: become leader
- If election timeout elapses: start new election

Leaders

- If command received from client: append entry to local log, respond after lastCommitted > entry's OpTime.
- *If there exists an entry such that entry.OpTime > lastCommitted, a majority of lastPosition[i] ⩾ entry.OpTime, and entry.term == currentTerm: set lastCommitted = entry.OpTime*

Appendix B: TPC-C Experiments

Setup. This section uses 3-way replication with 3 server VMs and 1 client VM. All VMs are deployed in the same Availability Zone. Each client thread continuously inserts documents of 1000 bytes in a closed-loop. We vary the number of client threads to control the offered load in the system.

	chaning disabled			chaining enabled		
	throughput (ops/s)	50% latency (ms)	95% latency (ms)	throughput (ops/s)	50% latency (ms)	95% latency (ms)
DELIVERY	58.16	144.14	257.72	60.21	129.94	247.22
NEW_ORDER	650.33	70.68	153.64	675.33	66.2	141.09
ORDER_STATUS	58.01	30.32	56.17	59.71	32.95	62.54
PAYMENT	628.51	37.04	169.28	651.46	37.91	171.52
STOCK_LEVEL	58.46	7.25	22.6	60.28	7.49	23.88
TOTAL	1453.47			1506.98		

Table 1: Results of an adapted TPCC benchmark. The benchmark denormalizes the data and leverages MongoDB query language and transaction semantics to be consistent with MongoDB best practices [14]. The test is run with 100 client threads and 100 warehouses on the same replica set setting as above without any bandwidth limit. Since the TPCC workload is CPU-bound, the performances of both chaining enabled and disabled settings are very close. Chaining-enabled case performs slightly better because it offloaded one secondary's oplog reading from the primary to a secondary and saved the CPU on the primary. The network was not saturated by replication: the chaining-disabled primary sent 15.56 MB/s in total over the network, including serving client requests and 4.05 MB/s to each secondary for oplog replication, while the chaining-enabled primary sent 11.70 MB/s in total. The gap of primary's network traffic is aligned well with the saved oplog replication traffic.

Mistify: Automating DNN Model Porting for On-Device Inference at the Edge

Peizhen Guo Bo Hu Wenjun Hu
Yale University

Abstract

AI applications powered by deep learning inference are increasingly run natively on edge devices to provide better interactive user experience. This often necessitates fitting a model originally designed and trained in the cloud to edge devices with a range of hardware capabilities, which so far has relied on time-consuming manual effort.

In this paper, we quantify the challenges of manually generating a large number of compressed models and then build a system framework, *Mistify*, to automatically port a cloud-based model to a suite of models for edge devices targeting various points in the design space. *Mistify* adds an intermediate "layer" that decouples the model design and deployment phases. By exposing configuration APIs to obviate the need for code changes deeply embedded into the original model, *Mistify* hides run-time issues from model designers and hides the model internals from model users, hence reducing the expertise needed in either. For better scalability, *Mistify* consolidates multiple model tailoring requests to minimize repeated computation. Further, *Mistify* leverages locally available edge data in a privacy-aware manner, and performs run-time model adaptation to provide scalable edge support and accurate inference results. Extensive evaluation shows that *Mistify* reduces the DNN porting time needed by over 10× to cater to a wide spectrum of edge deployment scenarios, incurring orders of magnitude less manual effort.

1 Introduction

AI-driven intelligent edge has already become a reality [9], where millions of mobile and IoT devices or edge servers analyze real-time data and transform those into actionable insights on user-facing devices. For example, real-time video analytics (e.g., traffic monitoring [43], security surveillance [5], and smart retail [3]), natural language understanding (e.g., virtual assistance, smart email composition [63]), visual assistance [48], and industrial automation (e.g., defect detection, assembly line management [1, 5]) are already everyday examples. It is projected that, by 2022, over 60% of the data locally generated by IoT, sensor, and mobile devices will drive real-time intelligent decisions; 80% of the IoT and mobile devices shipped will have on-device AI capabilities [6, 16].

Many AI functionalities today are powered by deep learning (DL), with a significant computation footprint. While edge devices used to primarily offload related computation to the cloud, increasingly inference workloads are run natively on the edge devices to provide better interactive user experience (e.g., $\sim$10 ms real-time response), data privacy, and reliability [60]. This often necessitates *porting* (i.e., *tailoring* and deploying) a deep neural network (DNN) model originally designed and trained on the cloud to edge settings.

Model porting is a non-trivial process even for a single target. From an *algorithmic* perspective, the core techniques involved are called *model tailoring* in the machine learning literature. There are two steps, adapting the architecture of a pre-trained model to fit a new resource specification, followed by fine-tuning the new model parameters. Although there have been numerous model tailoring *algorithms* [22, 25, 31, 82], the complete porting process additionally requires "executing" the algorithms by correctly annotating a source model, and then retraining the annotated model with the right data. By various estimates, there will be over 50 billions IoT devices [30] with very diverse hardware profiles. This creates a massive design space for optimizing the resource usage and performance of a new model.

Unfortunately, the current practice of porting relies on manual effort, which simply cannot scale with the sheer size of the design space. There are two issues: laborious manual annotations and the computational complexity. Even if porting is a one-time need, it takes time to meticulously annotate the original model to embed the correct model tailoring objectives. For instance, constructing the model tailoring logic for ResNet50 [35] requires around 30 lines of source code edits scattered around several files. Further, model adaptation incurs significant computational complexity. Existing algorithms can handle generating one model, but can not scale well to large batches of model generation. If many model variants are needed, either for different device hardware specifications or for different runtime conditions, manual tailoring incurs significant repeated efforts. The effort needed to tailor model variants could match that for training an original model. Therefore, app developers currently perform little platform-specific customization to the intractable target space [75], even though lack of customization results in suboptimal performance. (Section 2)

Fundamentally, the problem is the implicit coupling between model design and deployment currently. Model designers need to both improve the inference accuracy and minimize the memory and computation footprint for deployment. Model users need to both compress the model without degrading accuracy significantly and accelerate the inference. Both stages require significant expertise spanning deep learning algorithms and system runtime management.

In this paper, therefore, we build *Mistify*, a system *framework* to automate and scale the porting process from a pre-trained model to a suite of compact models tailored to diverse edge resource specifications (Section 3). *Mistify* does not propose any new model tailoring algorithm. Instead, it wraps over existing model tailoring algorithms and provides additional system services for scalability. This is analogous to a scheduling framework implementing common scheduling algorithms so that application developers can outsource scheduling considerations. With *Mistify*, model users (i.e., mobile app developers, often non-machine-learning experts) can outsource model adaptation instead of understanding the specifics of the model to adapt. In this way *Mistify* takes on the role of a provider of models for on-device inference execution. Meanwhile, model designers (i.e., machine learning experts) can use simple resource abstractions to evaluate the model instead of undergoing detailed resource profiling.

From a *system* perspective, we propose new abstractions to separate the model semantics from the execution characteristics and several techniques (*Collective adaptation*, *Privacy-aware knowledge distillation*, and *Downtime-free run-time model generation and switching*), all incorporated in an end-to-end framework. *Mistify* minimizes the need for "compile-time" code changes when generating a model statically. Instead of requiring the user to annotate the original model, *Mistify generates* model adaptation logic from the configuration file to correctly and scalably tailor to the resource budgets and performance requirements of each device while minimizing duplicate iterations (Section 4). Further, *Mistify* leverages implicitly correlated edge data in a privacy-aware manner to balance training data privacy and model accuracy (Section 5). During the run time of the inference task, *Mistify* employs a feedback mechanism to generate new models as needed to adapt to fluctuating application demands and resource availability (Section 6).

Note that we make a distinction between the end-to-end process (*porting*) and individual model compression techniques (*neural architecture search*, *layer pruning*, etc.). The latter do not always produce a readily usable compressed model. The (adapted) model still needs (re)training and that process incurs several practical difficulties. In contrast, *Mistify* automates the entire end-to-end process. Making it scalable and adaptive while keeping training data local are non-trivial efforts, and extend significantly beyond simply implementing known algorithms for each component in one system.

Mistify is implemented following a client-server model, built on TensorFlow [13]. We build example wrappers to adopt state-of-the-art model adaptation algorithms like MorphNet [31] and ChamNet [25], and evaluate *Mistify* using representative vision and natural language processing (NLP) models trained with widely used standard datasets. Extensive evaluation shows that *Mistify* reduces the DNN porting time needed by over 10× and incurs orders of magnitude less manual effort, all with little or up to 1% accuracy loss when compared to manually running the adaptation algorithms. This loss margin is well within the typical accuracy loss budget for on-device inference [64].

Mistify is far more than a tool for convenience. It serves as an intermediate layer that decouples the model design and deployment stages. Model designers can focus on model performance and advanced architecture design, without worrying about deployment difficulties, whereas edge users can focus on execution-centric issues such as optimizing the executable binaries, computation kernels, and job scheduling, without worrying about the inner workings of the model.

To summarize, this paper makes three contributions: First, we quantify the scalability challenges of porting pre-trained DNN models to edge settings to motivate framework support. Second, we design and implement *Mistify* as a framework for automated porting at scale. *Mistify* achieves scalability with collective adaptation and improves model quality with privacy aware knowledge distillation and run-time model adaptation. Third, *Mistify* provides a clean interface to separate DNN model design and deployment. This could lower the bar for wider usage of on-device deep learning at the edge.

2 Background and motivation

The lifecycle of a DNN model spans design and deployment, and the need for automating model porting arises from the complexity of the process. We discuss these in detail before outlining the challenges and solutions.

2.1 Current DNN lifecycle

The lifecycle of a DNN encompasses at least three stages: model design, publishing, and deployment. Publishing mainly requires adding a well-trained model to public repositories, while design and deployment are more involved.

DNN model design. Today's models are designed for either optimal inference quality or minimal resource footprint.

The former is typically assumed for workloads run on the cloud. Given increasing computation power, cloud-centric models employ advanced neural network topologies, millions of parameters and floating-point operations (FLOPs) to achieve the *highest accuracy*. For example, BERT [28] and ResNeXt [51] have 340 and 829 million parameters respectively, hence extremely computation intensive.

The latter goal is geared towards resource-constrained edge devices, including IoT nodes, smartphones and tablets. The desirable models (e.g., MobileNet [38] and SqueezeNet [40]) are exceedingly compact, requiring only a few MBs for storage and affordable computing budget, ready to run across diverse hardware. However, these DNNs sacrifice accuracy in exchange for super lightweight execution, aiming at *maximal deployment coverage*.

DNN deployment at the edge. Many DL inference engines

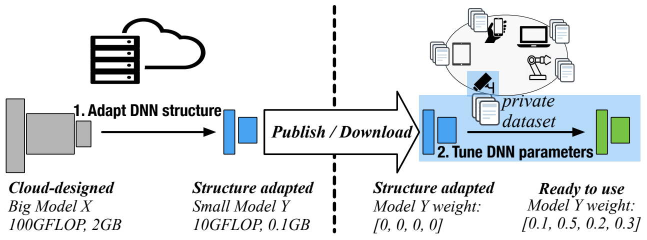

Figure 1: Steps to port a DNN model to an edge setting.

have been developed to serve DNN workloads on edge devices. They focus on deployment optimizations such as cross-platform compatibility, trimming executable size, and low-complexity operator kernels [2, 24]. Once DNN models are loaded (e.g., from model repositories or custom URLs), these engines can execute the inference tasks efficiently.

Transition from design to deployment. When a pre-trained model is ill-suited to a desirable deployment setting, it needs to be *tailored* to the new resource budget and performance goals. This requires *adapting* the model architecture (e.g., by trimming network connections, skipping layers, quantizing parameters) and then *fine-tuning* (i.e., retraining) the parameters with local datasets (Figure 1). However, the end-to-end model porting process is complex. The source model needs to be correctly annotated to have its architecture adapted to a desired setting. Fine-tuning also requires careful usage of the training data to balance training quality (i.e., effective specialization without overfitting) and data privacy.

2.2 The complexity of porting DNN models

As more edge devices adopt on-device inference, porting cloud-based models to edge settings becomes increasingly complex, facing several challenges: (i) the range of model adaptation targets is huge as a result of the diversity in the hardware specification; (ii) the porting process involves several stages, each requiring coordination between multiple parties; (iii) run-time dynamics and new deployment settings may necessitate frequent model re-adaptations.

Heterogeneous execution environment. Edge devices are incredibly diverse, ranging from embedded sensors, IoT devices, mobile phones/tablets, to edge servers, covering a full spectrum of hardware capability [75]. Table 1 lists the specifications of some GPU and ASIC accelerators and processors, from high-end to low-end, widely employed at the edge for DNN-based workloads. For the same DNN inference workload, the completion times for low-end (e.g., Jetson nano) and high-end (e.g., 2080) devices can differ by orders of magnitude (e.g., 229 ms vs 9.8 ms to run inference with ResNet).

Meanwhile, the DNN inference times for the same task can differ by up to 8×, and the quality (e.g., in *accuracy*, *F1 score*) varies by as much as 25% [18, 66]. It is therefore essential to match the desirable performance with the hardware capability.

These numbers outline a massive design space to explore different tradeoff points between inference accuracy and latency, where a sub-optimal choice could incur up to 10% accuracy loss (e.g., when running EfficientNet-BO unnecessarily on the latest iPhone model) or miss the latency requirement for real-time processing by over 100 ms (e.g., running ResNet on a low-end smartphone) [76].

Table 1: Popular DL hardware specifications.

GPU	Peak perf	Memory	Bandwidth
V100	112 TFLOP	32 GB	900 GB/sec
2080	11.7 TFLOP	11 GB	480 GB/sec
Edge GPU	**Peak perf**	**Memory**	**Bandwidth**
Jetson TX2	1.5 TFLOP	4 GB	58 GB/sec
Jetson nano	0.47 TFLOP	4 GB	25 GB/sec
ASIC	**Peak perf**	**Memory**	**Bandwidth**
Edge TPU [4]	4 TFLOP	-	-
Raspberry pi	6 GFLOP	2 GB	8.5 GB/sec

Clearly, one size does not fit all, but nor would a few sizes only. Instead, it is desirable to tailor to each target at a fine granularity. For instance, EfficientNet-B4 (a popular model occupying a sweet spot of computation complexity and prediction accuracy) is suitable for Samsung S9, achieving 83% accuracy and 50 fps real-time response rate. However, using the same DNN on its immediate predecessor (S8) and successor (S10) would reduce the response rate by 14 fps for S8 and the accuracy by nearly 1% for S10. These are significant to the model designers where even 0.1% accuracy improvement merits tremendous effort (both intellectually and computationally) into model design and training. Given the ever increasing size of this adaptation space, it is impractical to either cover all plausible operation points with a few DNN models, or manually exhaust the entire space to customize the adaptation tradeoff for each possible individual edge setting.

Multi-stage multi-party efforts. Tailoring a DNN model involves first adapting to the right model architecture, and then fine-tuning the model parameters (Figure 1).

The first stage is resource heavy and therefore takes place where the original models are trained (i.e., in the *cloud*).The second stage increasingly takes place at the *edge* given the push for on-device inference and private learning. Edge devices collect and maintain specialized data relevant to the local context for model training [19, 42] and local data are typically privacy sensitive [59]. However, smaller networks with less abundant datasets are well known to be much harder to train, as it is easy to overfit the model to the training data such that the model may not generalize well to unseen test data [37, 79]. Thus, it is also preferable for the edge to take advantage of relevant datasets available elsewhere (e.g., in the cloud or on other devices) to enhance the training dataset and improve training quality.

To sum up, both stages of model tailoring require coordination between the cloud and the edge, and resolving the conflict between data privacy and fine-tuning quality.

Fluctuating run-time characteristics. The run-time characteristics of deep learning inference tasks are highly dynamic, shown in two aspects. First, the performance requirements, e.g., accuracy and response time, of an inference task change frequently. For instance, the accuracy requirements of a vision-based security surveillance workload differ between crucial and trivial moments, while the latency requirements fluctuate across peak and off-peak hours (e.g., daytime and night) [41,42]. Further, the commonly used metric, FLOPS, is sometimes an inaccurate proxy to statically estimate run-time latency [72]. Second, the resource availability (e.g., memory space, CPU cycles, accelerator quotas), varies on the edge device due to other workloads competing for the same resource. For instance, when an edge device launches or completes a workload, or adjusts the resource allocation of the containers that serve the inference tasks, the perceived resource availability to the active workloads changes [23,74].

Frequent changes in the performance requirements and resource availability necessitate a mechanism to better serve combinations of the individual operation points, including a suite of models to switch to dynamically, and asynchronously tailoring new ones as the demand warrants.

2.3 The need to automate DNN porting

Current practice. To tailor DNNs towards heterogeneous deployment settings, currently either the model designers should generate different DNNs to cater to each possible resource budget and performance goal, or the model users should prepare the custom datasets, select and apply the algorithms to tailor already published DNNs towards their custom settings.

The latest adaptation algorithms, such as AutoML [82], EfficientNet [73], and others [14,22,25,31], all address target-specific adaptation *case by case* as an additional step in the *design* phase. While the techniques differ (e.g., gradient-based, evolutionary, and recurrent neural network based), they revise the model architecture to be closer to the required resource and performance targets with successive training iterations.

Problems with current porting practice. The overarching problems of the existing practice are they do not scale from a system perspective (e.g., hundreds of GPU hours for a single setting [71,82]) and largely rely on manual effort (e.g., thousands of lines of code spread across source files [10]). Such a manual tailoring process is not easily turned to a configuration style that is agnostic to the number of cases because distinct structure adapting terms have to be added to different DNN models/layers and at specific positions, which makes it difficult and error-prone. Furthermore, it is infeasible for the model designers to prepare for all possible deployment settings, or for the model users to be well versed in machine learning literature to run the right algorithm.

The need for an automated framework. The current model porting process implicitly couples DNN design and deployment, even though they are conceptually separate stages. This coupling introduces unnecessary complexity to both model designers and model users. This motivates adding a separate *model porting* stage to the model lifecycle, i.e., an intermediary to decouple design from deployment and automatically port pre-trained DNNs towards heterogeneous edge settings.

Mistify is therefore built as an intermediate framework to encapsulate diverse adaptation algorithms and address the end-to-end porting challenges outlined above, analogous to scheduler *frameworks* for distributed systems implementing scheduling *algorithms* and providing services.

2.4 System requirements

To address the challenges above, an automated model porting framework should meet the following requirements.

Avoiding deeply embedded and unscalable manual code changes. Since the existing model adaptation step is often coupled with model design itself, a side effect is that relevant code changes are embedded deep into the model design code. Therefore, the system challenge is to simplify the code modifications needed to specify the adaptation logic.

Mistify addresses this challenge in two steps (Section 4). First, we expose the right high-level abstractions of adaptation choices to users. This elevates per-model code edits (embedded in the particular script specifying the model) to framework level configuration parameter changes. Second, we parse the adaptation requirements from the configuration files and merge implicitly correlated model adaptation requests to reduce duplicate iterations and improve scalability.

Cloud-edge coordination. To automate the two-stage model tailoring process with the best training outcome, the main challenge is to simultaneously ensure that private data stay local but parameter tuning can benefit from the data distributed across devices. We address this by adopting mutual knowledge distillation. Our system implicitly coordinates multiple devices in the same tailoring batch to maximally "share" available training data in a privacy aware fashion, without explicitly exchanging and examining the raw data (Section 5).

Fast response to run-time dynamics. Fundamentally, the system challenge is to effectively handle the mismatch between a statically trained model and the dynamic execution environments during run time. Specifically, this requires generating new models as needed and switching to them with minimal downtime. We address the challenge with a feedback mechanism between the model deployment points (e.g., edge devices) and the model tailoring point (e.g., a central server or cloudlet) to perform real-time DNN re-adaptation (Section 6).

3 *Mistify* demystified

The overarching goal for *Mistify* is two-fold: (i) *Mistify* should separate the model design and deployment stages with a clean interface; and (ii) *Mistify* should bridge the two stages with a framework that automatically explores the design space at scale and generates models best suited to user-specified tradeoff points, hiding such complexity from both sides.

Therefore, *Mistify* is designed as an intermediate framework between DNN model design toolkits and deployment

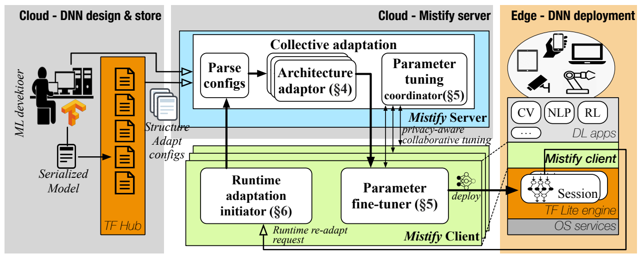

Figure 2: *Mistify* system architecture.

engines, as shown in Figure 2. The arrows across different shaded blocks show how *Mistify* interacts with model designers and users. *Mistify* exposes APIs to the model users and inference engines to specify their *porting configurations* (Figure 3), either in a *batch* mode during initialization or in a *streaming* mode incrementally during run time.

The primary challenge for *Mistify* is therefore how to generate a large number of adapted DNN models with minimal computation and manual intervention. In general, our approach is *collective adaptation*, i.e., parsing adaptation goals and harnessing the implicit correlation among the goals to reduce unnecessary computation (Section 4). *Mistify* parses a collection of individual adaptation goals into a dependency tree with each node corresponding to a distinct goal, so that each goal is adapted only from its immediate parent via a desirable, automatically selected adaptation algorithm. Next, the adapted models are distributed to the endpoints, where the *Mistify* client runtime will prepare the deployment of the adapted model by fine-tuning the parameters (Section 5). Finally, the models start running on edge devices, and the *Mistify* client monitors the execution environment (e.g., resource availability and desirable performance goals). The *Mistify* client will trigger on-demand model re-adaptation asynchronously when the environmental changes warrant a new model (Section 6).

Example deployment strategies. Following the common practice of on-device DL inference deployment [2, 5], *Mistify* can be deployed in two ways. The *Mistify* server can be deployed in the cloud by the DNN application developers, interfacing with the model repository (e.g., TF-Hub) and exposing APIs to the public. Alternately, the server can be maintained by the model users (e.g., edge device administrators) in their private clouds to serve local devices (e.g., IoT nodes). *Mistify* clients are simply deployed on the edge devices as a module extension to the native DL engine.

***Mistify* server.** The *Mistify* server consists of two functional modules: an *architecture adaptor* and a *parameter tuning coordinator*. Once the *architecture adaptor* receives the original DNN model and the adaptation settings from the model users and/or the *Mistify* client, it generates the adapted models and sends those to the corresponding clients (Section 4). The *parameter tuning coordinator* serves as the central point to coordinate the parameter fine-tuning process across the *Mistify* clients (Section 5.2), whereas the actual tuning logic is executed on each client locally (Section 5.1).

***Mistify* client.** The *Mistify* client consists of a *run-time adaptation initiator*, a *parameter fine-tuner* and a *run-time performance monitor*. The *run-time adaptation initiator* intercepts the native DNN model loading path of the inference engine to automatically trigger model adaptation during initialization, and then listens for run-time re-adaptation requests. The *parameter fine-tuner* takes an adapted DNN model as the starting point, optimizes its parameters jointly based on the local (private) training data and the guidance from the correlated neighboring counterparts (coordinated by the *Mistify* server). This approach aims to overcome overfitting while maintaining data privacy. The *run-time monitor* tracks the current performance as well as resource availability. Once these profiles change significantly, it will trigger an online model switching as well as an offline re-adaptation request.

4 Scalable model architecture adaptation

Instead of requiring the user to manually annotate the source models, *Mistify* provides expressive configuration interfaces to specify adaptation goals and constraints (Section 4.1) and suitable abstractions to capture common algorithmic steps that meet these constraints (Section 4.2). To further scale to a large target space, *Mistify* merges adaptation instances to avoid duplicate efforts (Section 4.3) with *collective adaptation*.

4.1 Adaptation goal specification

An adaptation goal reflects the desirable inference performance given static and dynamic device conditions. We assume these goals are immutable, and any changes in the run-time conditions simply generate new goals. A user provides two sets of input: *hardware profiles* and *performance targets*. Hardware profiles mainly include *compute power* (GFLOP/s) and *memory bandwidth* (GB/s). Performance targets cover latency and accuracy requirements. The specification can be extended to support custom resource capability and performance metrics by adding the corresponding profiling libraries and tools (Section 4.2). We leverage a JSON-like format (Figure 3) to specify multiple goals in a single configuration file, which is parsed before adaptation.

We next formulate the *cost budgets* of a given DNN structure based on the specification of the adaptation goal provided by the user. In terms of computation cost, each layer contributes $C_{in} * C_{out} * S_{kernel} * S_{out}$ multiplications and additions. C_{in} and C_{out} denote the input and output channels;

S_{kernel} and S_{out} denote the convolution kernel and output size for Conv operations; for normal Matmul operations, S_{kernel} and S_{out} both equal 1 as they are equivalent to 1×1 convolution on 1×1 inputs. For memory cost, each layer contributes $C_{in} * C_{out} * S_{kernel}$ parameters (S_{kernel} is 1 for Matmul operations similarly). Combined with the quantization strategy, the total memory consumption of a neural network layer can be calculated. For latency cost, we first calculate the previous two costs C_{comp} and C_{mem} respectively. Then, we leverage the hardware specifications (peak computation power and the memory bandwidth) to translate these costs into the latency cost as $C_{mem}/mem\_bandwidth + C_{comp}/comp\_power$.

4.2 Adaptation Executor

Common DNN adaptation workflows. State-of-the-art DNN adaptation algorithms follow a similar process. They take a source DNN model and adaptation goals, and search for variants of the base model architecture that fits each scenario. The search explores a high-dimensional vector space, where each hyperparameter of the DNN (e.g., #layers, #filters, kernel size, and quantization) corresponds to a specific dimension. The search process runs iteratively until the costs of the current model optimally match the adaptation goal. Typical search strategies include evolutionary search [25,77], gradient descent [14,31], and RNN-based search [72,73].

Adaptation executor. In light of this common process, we design an abstraction, an `Adaptation Executor`, that collects all adaptation settings as a closure, and exposes three function APIs (`Init()`, `Measure()`, and `Adjust()`). `Init()` loads the adaptation settings, the model, and the constraints, and then instantiates the executor that runs the chosen adaptation algorithm (default or user specified). `Measure()` is called after each adaptation iteration to determine the *costs* of the current model (e.g., model size or accuracy). Custom metrics and profiling mechanisms can be incorporated by implementing the `Measure()` API. `Adjust()` will then tune the control knobs of the algorithms (e.g., dimension-wise step size, threshold, or learning rate) to steer the cost refinements towards the adaptation goals in an optimal direction. These APIs abstract away the inner workings of heterogeneous adaptation algorithms in a universal approach, obviating the need to directly annotate the models to embed the adaptation logic. A new adaptation algorithm can interface with *Mistify* by implementing the above APIs, and the user can specify the preferred algorithm in the configuration.

Case study: Running MorphNet via an adaptation executor. The vanilla DNN training starts with defining an accuracy loss function ($\mathcal{L}_{output}$) based on the difference between the model outputs and the ground-truth labels. The loss is back-propagated to each layer i (with parameter θ_i) as $\mathcal{L}_i(\theta_i)$. Each layer calculates the gradient of the loss, and optimizes the parameters (θ_i) iteratively by minimizing the loss via gradient descent. Namely, $\theta_i^{new} = \theta_i^{old} - \eta \cdot \nabla_{\theta_i} \mathcal{L}_i(\theta_i)$.

MorphNet (a recent gradient based search algorithm [31]) converts the resource costs of DNNs as additional penalty terms of the loss function. This way, the DNN architecture is iteratively optimized via gradient descent along with the vanilla DNN training. For instance, the "useless" weight parameters will be suppressed to zero and trimmed during training when minimizing the overall loss, as they do not contribute to reducing the accuracy loss but increase the architectural loss. The adaptation process completes when each structure-related cost (e.g., number of FLOPs) satisfies the corresponding constraint, or when the pre-defined maximal running time is reached for the non-converged cases.

Manually adapting a model using MorphNet requires several steps: (i) selecting the penalty term for each operator appearing in the DNN (e.g., the *Gamma* regularizer for `BatchNorm`), (ii) specifying the input and output operators of the model, (iii) instantiating the penalty terms with the right arguments such as the trimming threshold and the learning rate, and adding them to the overall training loss, and (iv) adding the cost monitoring operators and the termination conditions. All these steps are needed for each adaptation target, and require modifying the source code of the DNN definition and training scripts. In contrast, *Mistify* only requires users to specify the high-level configurations (e.g., the adaptation algorithm, the trimming threshold) and adaptation goals (e.g., memory usage, number of FLOPs) in a single JSON file.

To encapsulate the MorphNet algorithm in a *Mistify* adaptation executor, we implement the APIs as follows. For `Init()`, we additionally implement the operations of deriving the positions (e.g., `Conv` layers) to add architectural loss terms, essentially by first finding the input layers, and then traversing the whole DNN graph topologically along the dependencies to insert the loss terms into the corresponding layers until the outputs. `Measure()` simply calculates the resource and performance costs of a given DNN independent of the adaptation algorithms. For `Adjust()`, we implement the logic of setting the learning rate of the loss term corresponding to each resource and/or performance constraint. The implementation of these APIs is lightweight (Section 7).

4.3 Collective adaptation

Multiple adaptation goals often share similar initial steps or training iterations. Handling each adaptation goal independently is very inefficient when deploying the same model to a range of devices. Therefore, *Mistify* provides a mechanism to "merge" adaptation goals to avoid duplicating the same steps. We parse the adaptation goals into an n-ary tree structure following certain rules. Goals along a branch are fulfilled one by one serially in a single pass. We also design a tree traversal mechanism to meet the constraints (e.g., time and space usage) of all goals simultaneously.

Adaptation goals compilation. As mentioned above, each single goal consists of several resource and performance constraints, and can be abstracted as a multi-dimensional

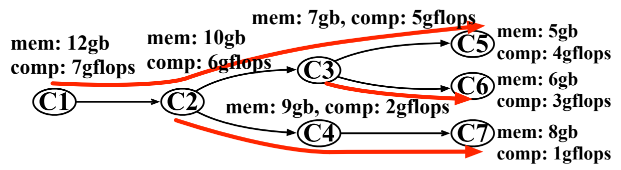

Figure 4: Example adaptation goals parsed into a tree.

vector. Combining the hardware specifications and performance constraints, we generate a partial order of all adaptation goal vectors, from the least demanding to the most. Figure 4 shows an example of 7 goals ($C1$ to $C7$), each with two constraints (memory usage `mem` and computation complexity `comp`). Goals C_i and C_j follow a strict order, $C_i < C_j$, only when $C_i.mem < C_j.mem$ and $C_i.comp < C_j.comp$.

Following the partial order between goals, we further generate a tree structure, with each node representing a goal, and each edge leading to one of its immediate more demanding goals. Hence, each branch of the tree corresponds to an independent adaptation path (marked with a red arrow in Figure 4). Along each path, every two goals are consistently ordered on all constraints. This ensures that they can be collectively adapted in one pass without conflicts. Note that the accuracy does not strictly increase over the path. When *Mistify* starts to traverse a path from one point to the next, the accuracy will first drop to a certain level, and then climb back while the training continues. Meanwhile, the resource profiles will move to the most desirable positions.

Given the tree structure, we first uniformly expand the architecture of the original DNN so that, for each constraint dimension, its actual cost value is larger than that of the root node (the least demanding goal). Then, starting from the root, we run the encapsulated adaptation algorithm to trim the DNN architecture iteratively along each adaptation path. Every time a goal is satisfied, the corresponding version of DNN is stored as a checkpoint for future use.

Note that even though the mapping between partially ordered goals to a tree structure is usually not unique, we find that there is only marginal difference in the overall adaptation time between different mappings. Hence, it is not worth optimizing the mapping given it is NP-hard.

Structure loss scheduling. When executing the adaptation along a path, an essential question is how to control the adaptation towards the optimal direction (via `Adjust()`), i.e., how to meet multiple desirable constraints simultaneously. Although this can be achieved by forking a new adaptation schedule for each change of the adaptation "direction" [69], constant forking does not scale to a large number of adaptation goals and can not achieve fine-grained continuous control.

Instead, we adjust the control knobs based on the weighted combination of the corresponding architecture losses. The overall DNN loss function is the sum of the normal loss ($\mathcal{L}$) and architecture losses corresponding to a set of constraints $\{\mathcal{G}_i\}$. For each $\mathcal{G}_i$, their control knob (e.g., learning rate for gradient-based algorithms) can be viewed as a weight parameter w_i. Hence, the overall loss $\mathcal{L}_{all} = \mathcal{L} + \sum_i w_i \cdot \mathcal{G}_i$. To adjust the adaptation "direction" towards a specific constraint f_i, we only need to increase the weight w_i of the loss $\mathcal{G}_i$.

Initially, all the weights w_i are equal and sum to 1. Suppose for the loss of constraint f_i we have the initial value $\mathcal{G}_i^{(0)}$ and the target value $\mathcal{G}_i^{(+)}$. Then, for every k training iterations (empirically set to 200), we reschedule the weights once. The n-th iteration weight $w_i^{(n)}$ is calculated as $Share_i^{(n)} / \sum_i Share_i^{(n)}$, where $Share_i^{(n)} = \frac{\mathcal{G}_i^{(+)} - \mathcal{G}_i^{(n-1)}}{\mathcal{G}_i^{(+)} - \mathcal{G}_i^{(0)}}$. In essence, we proportionally assign the next value of the weight $w_i^{(n)}$ according to how far the corresponding loss value $\mathcal{G}_i^{(n-1)}$ deviates from the target, and finally normalize these weights.

5 Privacy-aware fine-tuning at the edge

After adjusting the model architecture with respect to the resource and performance constraints, the weight parameters need to be fine-tuned before actual deployment. If all training data are collected and stored in the cloud, parameter tuning simply follows the standard training process for the adapted DNN. The challenge arises when specializing the DNNs only using the local contexts of edge devices.

Recall (Section 2.2) that DNNs are hard to train with a small dataset, usually the case for individual edge device, and can easily overfit. On the other hand, the data local to each device is often more relevant but private, making it difficult or infeasible to aggregate the data from different devices into a larger dataset for centralized training. Therefore we need to balance protecting edge data privacy and ensuring training quality (in terms of how well individual models generalize). While many works (e.g., federated learning [19] and others [20, 52, 70]) address decentralized private DNN training, they assume different endpoints train the *same DNN structure* with different local datasets. The situation is different for *Mistify*, where the models on different devices have *different architectures* to meet specific adaptation goals.

Knowledge distillation (KD). To tackle the aforementioned dilemma, we need a mechanism for DNN "knowledge" sharing between distinct peer models and without explicitly exchanging private data between devices. Fortunately, *mutual knowledge distillation* [15, 81] comes to the rescue. When training a DNN model (M_1, the *student* model) from scratch, leveraging additional help from another similar but independently trained model (M_2, the *peer teacher* model) can significantly improve the validation accuracy of M_1.

Specifically, the optimization of parameter θ_i follows: $\theta_i = \theta_i - \eta \nabla_{\theta_i} \{\phi(y, M_1(x)) + \varphi(M_2(x), M_1(x))\}$, where ∇_θ denotes taking derivatives with respect to the variable θ, ϕ and φ denote the loss functions (e.g., cross-entropy) respectively defined for the ground-truth labels and the teacher model M_2's outputs, and η denotes the learning rate as usual. The corresponding parameter values in M_2 are incorporated as added constraints. This way, the student model receives extra supervision from the teacher model during training, beyond optimizing for conventional learning objectives like the cross-entropy loss subject to the ground-truth training labels.

5.1 Client: KD-enhanced parameter tuning

Observe that a DNN trained locally on an edge device encapsulates the "knowledge" extracted from the private local data. Therefore, to take full advantage of the edge data distributed across devices without exchanging the private data, our algorithm instead shares the DNN models trained independently on each device. The ensemble of DNNs from other devices serves as the "teacher" to guide the current device's model just like in standard mutual knowledge distillation.

Our algorithm proceeds as follows.

(i) Each participating endpoint device (E_i) first tunes their adapted version of DNN model (M_i) with locally available training data until convergence.

(ii) Each endpoint sends its current model along with its loss and accuracy statistics to the central coordinator and waits for a response, namely a set of models (M_1 to M_n) trained on the other devices. An operator is added over the n outputs of these models (M_1 to M_n), taking their average as the final output of the model ensemble.

(iii) KD-enhanced tuning is then invoked to optimize the parameters θ_i of model M_i: $\theta_i = \theta_i - \eta\nabla_{\theta_i}\{\phi(y, M_i(x)) + \varphi(\frac{1}{n-1}\sum_{j\neq i} M_j(x), M_i(x))\}$. Namely, the outputs of each local model M_i are compared with both the ground-truth labels y and the outputs of the assembled teacher model to calculate loss. We follow similar hyperparameter settings as in [37], using cross-entropy loss for ϕ and Kullback-Leibler (KL) divergence [45] for φ to measure the distance between the teacher and local models, and a default value 0.001 for η.

(iv) Now loop over steps (i) to (iii) until the model finally converges. Noticeably, to improve generalization and avoid being skewed by some poor performing models, we randomly skip $max(n/10, 1)$ of the models used for each round of KD-enhanced tuning in step (iii).

Privacy-aware tuning. Although less privacy-sensitive than the training data, DNN models can still leak information from the private training data. To overcome this privacy leak, we can add noise to the fine-tuning process to achieve differential privacy [39, 56]. The noise can be added to either the training data, or the model parameters sent to the *Mistify* server. However, the latter provides less privacy protection, is easier to "denoise", and does not provide fine-grained control easily.

Therefore, we augment the algorithm above with an optional step after (i). Specifically, we add Laplacian noise to the local training data, and train the model (M_i) for additional epochs until convergence. Then, this noisy model (M_i') is sent to the central coordinator in step (ii). This provides differential privacy to the model parameters and reduces information leakage from the private data. The level of noise added is chosen empirically according to existing privacy-preserving machine learning practice (e.g., PATE [56] and Myelin [39]) with the same level of privacy loss preference (e.g., $\varepsilon < 5$).

Mistify is amenable to this differentially private approach by design. As *Mistify* aims to scale to a large batch of end devices (hundreds or more), potentially there is a large number of peer models to draw from during the intermediate steps. Even if the individual noisy intermediate model (M_i') is less accurate than its noiseless counterpart, the accuracy loss is compensated for by the ensemble of other peer models [55].

5.2 Server: Client model coordination

One particular concern of our aforementioned algorithm is whether the models used for KD-enhanced tuning indeed add knowledge rather than noise. Fortunately, our approach is supported by the evidence of correlation between training data and the models. First, datasets from nearby edge devices exhibit spatio-temporal correlation [32, 33, 78]. Second, given training datasets sufficiently similar in their semantic contexts (e.g., types of objects, hidden feature occurrence frequencies), the models thus trained perform semantically equivalent functionality and can provably generalize to achieving the same capability [53, 67, 80].

In practice, we use common spatio-temporal hints (e.g., location, time, view angle) sent by each client along with their models as a coarse-grained mechanism to estimate data correlation. There are myriad alternative lightweight approaches to measure dataset similarity without piece-wise comparison of the actual raw data (e.g., by calculating dataset feature summaries [46, 57]). They are easily pluggable into *Mistify* with the corresponding API implementations. Regardless of the exact metrics used to measure correlation, they are represented as multi-dimensional vectors. The central coordinator on the *Mistify* server maintains a Locality-Sensitive Hashing (LSH [26]) structure to index the vectors for large-scale nearest neighbor lookup at a sublinear complexity [21].

6 Run-time model adaptation

Existing algorithms and libraries only port DNN models statically in a batch mode. Instead, *Mistify* further provides a *streaming* mode, where the client actively monitors runtime changes of the resource and performance constraints and requests new model generation in response to such dynamics.

Constructing a multi-branch model. To support on-the-fly adaptation to fluctuating resource constraints, each DNN model is further constructed in a multi-branch form (Figure 5) during the architecture adaptation process. First, the aforementioned adaptation algorithm is triggered as usual until the constraints specified in the configuration are satisfied. Now, besides continuing to adapt to other configurations, a new adaptation thread is spawned. This thread separately adapts the current DNN into a k-branch DNN. For instance, a 5-branch DNN is built by freezing the first few layers and adapting the remaining layers towards 5 different configurations, whose resource budgets range from $\frac{1}{3}$ of to 3 times that of the original DNN model. The branches share the same base,

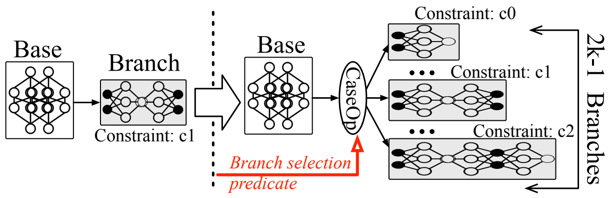

Figure 5: Multi-branch model construction.

achieve the same inference task, but satisfy different resource budgets and performance goals. In practice, *k* is set based on the extent of fluctuation typically observed in the resource availability and performance targets. After fine-tuning the parameters of the multi-branch DNN, we add a case conditional operator (e.g., `tf.case` for Tensorflow) between the base and different branches.

Foreground path: downtime free branch switching. The foreground path is tightly coupled with the user-facing inference serving logic, performing real-time adjustments of the current DNN model based on the dynamic constraints. To achieve this, *Mistify* picks a branch from the multi-branch DNN with the closest resource and performance profiles. The branch switching is done on the fly by setting the corresponding value of the conditional variable (the red arrow in Figure 5) of the case operator in the DNN, avoiding additional overhead such as memory allocation and runtime resource instantiation.

Background path. Meanwhile, in the background, the *Mistify* client will send the new adaptation configuration to the *Mistify* server. The server compares the new configuration with existing ones in terms of their resource constraints, based on the partial ordering explained in Section 4, in order to retrieve the immediate predecessor configuration of this new incoming one. Then, the new DNN model is incrementally adapted from the corresponding "predecessor" DNN, until the constraints of the new configuration are met.

7 Implementation

We implement *Mistify* on TensorFlow (TF) 1.13 [13] (Figure 2), consisting of around 8.5K lines of Python code for both the server and client modules. The source code will be available later at [8].

Interfacing with the native environment. Recall that *Mistify* can be activated at two stages (Section 3), when initializing inference serving or during the run time. For the former, the function `tfhub.load()` is intercepted to trigger the model porting process (when fed the special argument). For the latter case, the *Mistify* runtime monitor is by default registered with the live `Session` of the TensorFlow engine to collect runtime statistics (`tf.RunMetadata`), and invoke the *Mistify* client to initiate the re-adaptation process on demand. The foreground branch switching is implemented by assigning a suitable value to the predicate variable of the `tf.case` op.

Encapsulating adaptation algorithms. *Mistify* implements wrappers over two representative, state-of-the-art adaptation algorithms, MorphNet [31] (using sparsifying regularizers) and ChamNet [25] (using evolutionary algorithms). Adding new adaptation algorithms to *Mistify* is fairly easy, following the process outlined in the MorphNet case study in Section 4.2. Each wrapper implementation around these algorithms for *Mistify* requires around 100 lines of code (LoC), which is fairly modest compared to the thousands of LoC in the original codebases of these algorithms.

8 Evaluation

Hardware setup. Following Figure 2, a Linux server with 8-core 2.1 GHz Intel Xeon CPU, and NVIDIA 2070 GPU acts as the server side of *Mistify*. For the client-side operations of *Mistify*, we use a server with a low-end NVIDIA P600 GPU, a Google Edge TPU [4], and a Samsung S9 smartphone, to represent diverse types of edge hardware.

Application benchmarks. Computer Vision (CV) and Natural Language Processing (NLP) tasks almost dominate deep learning use scenarios. We select one workload each, *Object Recognition* and *Question & Answering* corresponding to the two application categories, as the representative benchmarks. While there are numerous other CV and NLP applications, for example, *scene segmentation* for CV and *machine translation* for NLP, these are based on DNN models derived from the same base structures as those used for our benchmarks (e.g., ResNet blocks for *object recognition* and *detection*, Transformer blocks for *Q&A* and *named entity recognition*). Therefore, the results obtained for our benchmarks are representative of a wide range of scenarios.

Specifically, we select three carefully designed, state-of-the-art DNNs, MobileNet [38], ResNet50 [35], and ResNeXt101 [51], with increasing computation complexity (0.5 to 16 GFLOPs), parameter size (16 to 320 MB), and accuracy (68% to 79%) for *object recognition*. MobileNet is originally designed for mobile devices, whereas the other two mostly run in the cloud. For *Q&A*, the input is a question along with a context paragraph containing the answer to the question. The "accuracy" metric for this is the Exact Match (EM) score, i.e., whether the output answer exactly matches the question. We prepare two DNNs, BiDAF [68], and BERT [28]. The former is lightweight but task-specific (customized for *Q&A*) (10× MB), whereas BERT is much larger, generically supporting various downstream tasks.

Datasets. We use domain specific standard datasets to adapt network architectures, fine-tune their parameters, and validate their performance. Specifically, ImageNet [27] and Cifar100 [44] are used for *object recognition*, whereas SQuADv1.1 [61] is used for *Q&A*.

8.1 Collective architecture adaptation

Collective adaptation time. We generate 128 different adaptation configurations based on four DNNs (MobileNet, ResNet50, ResNeXt101, and BERT). Among these, the least

Table 2: Accuracy - collectively adapted models (*Mistify*) vs individually adapted models (Per-case)

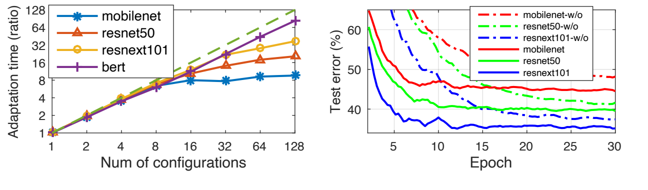
DNN	Per-case (%)	*Mistify* (%)	Relative diff (%)
MobileNet	55.8	54.7	-2.0%
	69.4	69.5	+0.1%
ResNet50	68.2	68.0	-0.3%
	72.9	72.5	-0.6%
ResNeXt101	74.0	74.3	+0.4%
	77.6	77.9	+0.3%
BERT	71.4	70.6	-1.2%
	79.1	78.8	-0.4%

and most demanding configurations respectively constrain the adapted DNNs to 2× and 0.5× the default DNN memory usage and computation complexity. Then, we select different subsets of these 128 configurations, adapt all of them with and without *Mistify*, and compare their overall time consumption to evaluate our collective adaptation approach (Section 4.3). Figure 6(a) shows the relative time needed without *Mistify* over with *Mistify*. *Mistify* accelerates the overall adaptation time almost linearly with the number of configurations when it is less than 10, consistently achieving around 10x acceleration even for DNNs as small as MobileNet. For large DNNs, such as BERT, that are structurally more amenable to adaptation (i.e., easier to prune a subset of the network without affecting validation accuracy), the acceleration scales well with over 100 configurations.

Adaptation quality. Next, we examine the quality of the DNNs collectively adapted by *Mistify* versus those adapted individually. Table 2 shows two rows for each network, corresponding to compression and expansion by a factor 4 with respect to the complexity and memory consumption of the original DNN. This spans the range from low- to high-end hardware [75]. For instance, the inference times of the compressed and expanded ResNet50, running on a Google Nexus 5 (low-end, 2013 model) and a Samsung Galaxy 10 (high-end, 2019 model), are both around 30 ms, low enough for practical usage. "Accuracy" corresponds to the EM score (exactly matching the ground-truth answer) for NLP. To avoid being affected by the parameter tuning quality, all adapted DNNs are trained with the whole datasets, and without considering any device-specific constraints. *Mistify*'s collective adaptation achieves almost the same accuracy compared to the case-by-case strategy, with less than 0.5% accuracy loss for most cases and only 1% for the worst scenario (e.g., when adaptation configurations are incompatible with total ordering, causing the overall adaptation path to detour substantially). These are within the typical range of accuracy loss in exchange for resource efficiency [64].

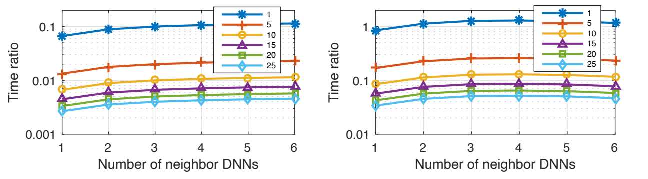
8.2 Parameter tuning

We use a more specialized dataset Cifar100 to evaluate parameter tuning on the edge. The whole dataset is partitioned into subsets, mimicking the local data of each edge device.



(a) DNN apdatation time. (b) Parameter tuning time.

Figure 6: Speed and performance improvements for architecture adaptation and parameter tuning with *Mistify*.



(a) MobileNet (b) BERT

Figure 7: The ratio of communication time over training time, reflecting the scalability of fine-tuning in *Mistify*.

Convergence speed and quality. We compare the convergence speed and test accuracy for three different networks (MobileNet, ResNet50, and ResNeXt101), with and without *Mistify*'s support for parameter tuning (Section 5.1). Figure 6(b) shows that, even without additional data, KD-enhanced parameter tuning (solid lines) already achieves over 3× faster convergence as well as better accuracy.

Scalability. We assess the scalability of the parameter tuning algorithm (Section 5.1) in terms of the ratio of the communication time over the training time given different network bandwidths. We consider two model extremes, MobileNet (very compact) and BERT (very sophisticated). In Figure 7, each line corresponds to a specific network bandwidth in MB/s. When the network bandwidth exceeds 5 MB/s, our algorithm is consistently scalable, with communication merely taking less than 15% of the time relative to training. Further, the lines almost flatten when more than three neighbors' DNNs are used, so using more peer DNNs for our tuning does not impact scalability.

Accuracy of parameter tuning. We randomly partition Cifar100 and SQuAD each into 5 subsets, each used by an edge device for local training. Then, we compare the fine-tuning accuracy using different approaches. Table 3 shows that knowledge distillation (KD) improves parameter tuning accuracy by 40% over local training alone. Compared to the ideal distillation case where an exceptionally accurate teacher network is available (a pre-trained, cloud version), the ensemble of 4 peer DNNs achieves within 10% of the optimal KD, despite using half the training data and adding differential privacy to the model parameters.

8.3 Run-time model re-adaptation overhead

The foreground path. Switching DNNs in response to the run-time dynamics (Section 6) incurs two types of overhead:

Table 3: The accuracy of parameter tuning with *Mistify*.

Scenario	DNNs (%)		
	MobileNet	ResNet50	BERT
Local training	39.7	43.9	22.5
KD	66.4	75.3	78.8
1-peer tuning	53.8	61.5	51.9
2-peer tuning	58.1	67.2	65.6
4-peer tuning	59.8	69.0	71.8

Table 4: Additional number of parameters and DNN switching time overhead.

DNN	Addi. / orig. params (M)	Time (s)
MobileNet-b3	2.67 / 3.43	2.11
MobileNet-b5	4.57 / 3.43	
ResNet50-b3	18.2 / 23.9	3.34
ResNet50-b5	31.7 / 23.9	
BERT-b3	92.4 / 110	21.84
BERT-b5	171 / 110	

i) additional memory to store alternate DNNs; and/or ii) downtime for loading the new DNN and on-demand preparation of the resource runtime. The model size corresponds to the in-memory size, not the on-disk size of the serialized form. Table 4 illustrates the trends of additional memory or time consumption for different DNNs. The suffix "-bk" means adding k branches to the adapted DNN. Holding 75% to 1.5× more parameters in memory is an affordable cost for modern hardware, but can save us 2 to 20 seconds by avoiding loading new DNNs on the critical path of inference serving.

Latency of modifying the configuration tree. We also measure the latency of generating a configuration tree (Section 4.3) given various numbers of configurations. Using 1000 configurations, each consisting of 4 constraints, the whole tree is built in 37 ms, and inserting into an existing configuration tree only takes microseconds.

8.4 End-to-end performance

Based on the device specifications in Table 1 and typical latency requirements for vision and NLP tasks [1, 63], we generate different combinations of memory, complexity, and latency constraints as the execution settings, and evaluate the quality of the DNN models tailored by *Mistify*. We further compare the manual overhead involved in *Mistify* with running MorphNet [31] and ChamNet [25] directly.

Balancing performance and resource usage. We set the memory budget to range from 0.1 GB to 10 GB, covering embedded IoT devices to edge servers. The computation complexity constraints for running inference on a DNN vary between 0.1 to 100× GFLOPs, roughly equivalent to achieving 10s of microseconds of inference latency for resource-constrained devices and powerful edge servers alike.

Figure 8 shows the three-way trade-offs between accuracy, latency, and resource consumption. The top three plots correspond to *recognition*, the lower three to *Q&A*. *Mistify* reduces the compute requirements by over 20× with less than 5% accuracy loss for the CV workloads, and could achieve 50× reduction of complexity in exchange for 12% relative quality-of-result degradation. Note that the accuracy loss is due to the adaptation algorithms, not *Mistify* itself. Similarly, *Mistify* consistently achieves a near-optimal and practically usable accuracy (comparable to existing hand-tuned on-device models in production [25, 49]) with between 0.5 to 10 GB of run-time memory usage, hence significantly decreasing the deployment complexity for state-of-the-art DNN models on the edge. Mapping resource consumption to inference time, *Mistify* consistently achieves near-optimal accuracy performance even when the latency requirements vary by 8 to 10×, corresponding to using accelerator hardware ranging from advanced, datacenter grade to low-power, lightweight devices.

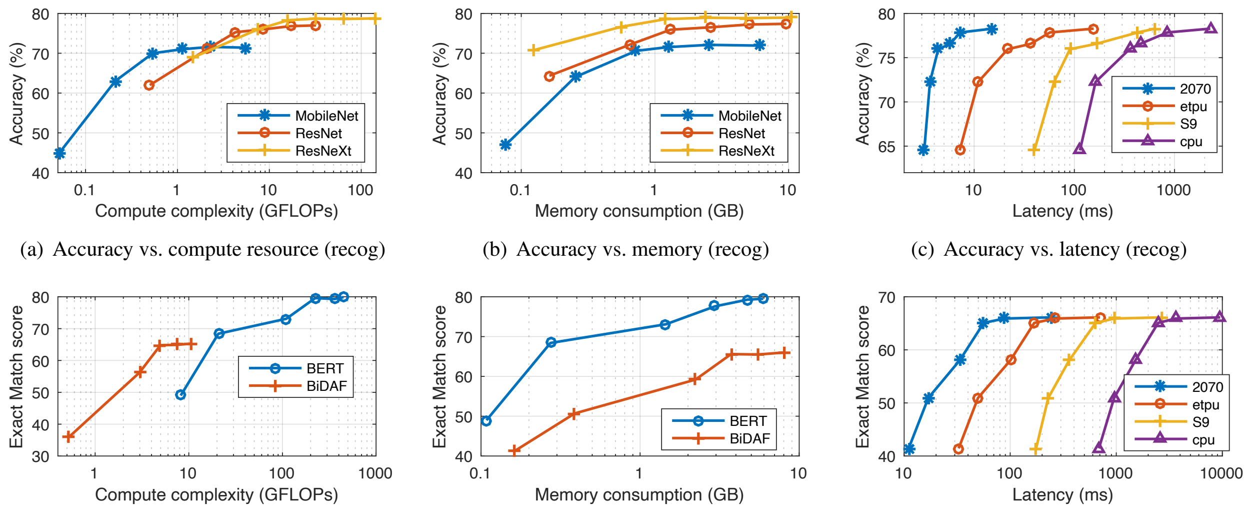
Reducing manual overhead. We further assess the end-to-end manual effort and time overhead needed to port a pre-designed DNN to different edge devices. The manual overhead is quantified with two metrics: lines of code (LoC) needed for code addition or modification, and number of files (NoF) touched. The former depicts the overall overhead, and the latter one captures the scatteredness of the modifications, which correlates with the probability of making mistakes. For NoF, we follow a typical file organization [12], i.e., model definition, training, evaluation, and other stages are separated into different files or folders.

Table 5 demonstrates that *Mistify* reduces the overall modification needed in LoC by 7 to 10×. More importantly, *Mistify* exposes high-level configuration files to users, obviating the need for source script modifications. *Mistify* only requires editing one file. Thus, it can reduce the number of files users need to access by orders of magnitude (over 100×). Finally, *Mistify* can batch-adapt to 100 execution settings using less than 3% of the time needed for the other approaches, highlighting the enormous potential of harnessing the correlation among configurations to optimize the overall porting efficiency.

9 Related work

We are not aware of any prior work that aims at providing an automatic porting *service* bridging DNN design and seamless edge deployment. The most related work revolves around model adaptation and knowledge distillation *algorithms*.

Model adaptation. Production DNN models hand-tuned by experts can run fast and accurately on mobile devices [38, 40, 49, 62]. The essential techniques include quantization, sparsification, and neural block optimization. Recently, Distiller [11], AMC [36], MorphNet [31], OFA [22], ChamNet [25], and many neural architecture search (NAS) works [17, 50, 65, 83, 84] systematically explore the search space for the optimal neural network structure, obviating the hand-tuning by experienced experts. However, none of them is directly usable like *Mistify*, because all are still *algorithms*, requiring manually annotating source code to construct the



(a) Accuracy vs. compute resource (recog) (b) Accuracy vs. memory (recog) (c) Accuracy vs. latency (recog)

(d) Accuracy vs. compute resource (Q&A) (e) Accuracy vs. memory (Q&A) (f) Accuracy vs. latency (Q&A)

Figure 8: The dynamic tradeoff between latency, accuracy, and resource consumption with *Mistify*.

Table 5: Comparison of overhead for porting DNN to edge with/without *Mistify*.

Metrics	2 configurations				10 configurations				100 configurations			
	Manual	Mor.	Chm.	*Mistify*	Manual	Mor.	Chm.	*Mistify*	Manual	Mor.	Chm.	*Mistify*
Lines of Code	>0.2k	55	97	**6**	>1k	138	159	**14**	>10k	782	511	**104**
Num of Files	6	4	5	**1**	30	12	32	**1**	300	102	302	**1**
Total time (%)	100			**54.2**	100			**12.5**	100			**2.86**

adaptation logic, hence not scalable to edge scenarios with multiple adaptation instances. None supports on-device fine-tuning or considers run-time adjustments. *Mistify* is orthogonal as an automated *system framework* and can incorporate them as pluggable algorithmic modules.

While frameworks like TF-Lite [2], PyTorch [58], and MCDNN [34] provide some model *compression* and *switching* support, *Mistify* differs in the techniques supported and the level of manual efforts needed. To generate a good model, careful model architecture design is essential, which normally requires significant expertise. *Mistify* abstracts away the model architecture searching process with the configurable APIs to make it accessible to non-experts, automating the end-to-end process and optimizing for batch model generation.

Knowledge distillation. Initially proposed as an optimization for model training, *knowledge distillation* transfers "knowledge" (i.e., parameter values) from a *teacher* network to a *student* network [37]. The idea is then extended to *mutual distillation* among peer models [15, 47, 81]. *Mistify* adopts and revises the general idea in a *selective distillation* manner to improve edge training accuracy while enhancing privacy.

Edge-centric deep learning inference engines. Emerging frameworks such as TF-Lite [2] and more [7, 29, 54] are optimized for inference serving on mobile and IoT devices, aiming to hide the deployment complexity from developers and device users. However, the interface exposed by existing engines only permits model download from the cloud (or the central server), without tailoring to edge runtime requirements and constraints, proactively or reactively. In contrast, *Mistify* provides an interface for two-way state exchange and a feedback loop between the cloud and the edge, facilitating targeted model design and efficient execution on the edge.

10 Conclusion

Deep learning models today are typically trained in the cloud and then ported to edge devices manually. Not only is manual porting unscalable, it indicates a lack of separation between model design (optimized for accuracy) and deployment (optimized for resource efficiency).

In this paper, we design and implement *Mistify*, a framework to automate this porting process, which reduces the DNN porting time needed to cater to a wide spectrum of edge deployment scenarios by over 10×, incurring orders of magnitude less manual effort. *Mistify* not only provides a useful service to complete the transition from DL workload design to deployment on the edge, but cleanly separates these two stages. We believe the system will further facilitate advanced model design and seamless model deployment.

Abstract

Resource allocation and scheduling strategies for deep learning training (DLT) jobs have a critical impact on their average job completion time (JCT). Unfortunately, traditional algorithms such as Shortest-Remaining-Time-First (SRTF) often perform poorly for DLT jobs. This is because blindly prioritizing only the short jobs is suboptimal and job-level resource preemption is too coarse-grained for effective mitigation of head-of-line blocking.

We investigate the algorithms that accelerate DLT jobs. Our analysis finds that (1) resource efficiency often matters more than short job prioritization and (2) applying greedy algorithms to existing jobs inflates average JCT due to overly optimistic views toward future resource availability. Inspired by these findings, we propose Apathetic Future Share (AFS) that balances resource efficiency and short job prioritization while curbing unrealistic optimism in resource allocation. To bring the algorithmic benefits into practice, we also build CoDDL, a DLT system framework that transparently handles automatic job parallelization and efficiently performs frequent share re-adjustments. Our evaluation shows that AFS outperforms Themis, SRTF, and Tiresias-L in terms of average JCT by up to 2.2x, 2.7x, and 3.1x, respectively.

1 Introduction

Deep learning has become a key technology that drives intelligent services based on machine learning such as face recognition [51,56,57], voice assistant [28,29,46], self-driving cars [11, 16, 40], and medical image processing [35, 43]. Practical deep learning models often require training with a large number of samples for high accuracy, so it is common practice to accelerate deep learning training (DLT) with parallel execution using multiple GPUs. Thus, today's GPU cluster for DLT accommodates running multiple distributed DLT jobs that multiplex the shared GPUs.

Minimizing the average job completion time (JCT) is often a desirable goal, but existing approaches are ill-suited for two reasons. First, existing DLT schedulers [24,34] tend to prioritize only "early-finishing" jobs, but we observe that prioritizing "late-finishing but scalable" jobs is key to average JCT reduction. Algorithms such as Shortest-Remaining-Time-First (SRTF) [44] that prioritize early-finishing jobs have been shown optimal when the throughput scales linearly with the allocated GPUs [48]. However, this does not apply to DLT jobs in general as evidenced by the fact that even a simple fairness scheme such as Max-Min [20] often achieves better average JCT than SRTF. Second, existing algorithms are typically coupled with non-elastic resource allocation [24, 55], which always allocates the requested number of resources to each job and rarely regulates it. This is inherently inefficient as it disallows share re-adjustment at runtime even when some GPUs are underutilized or idle. Also, job-level resource preemption is often too coarse-grained for effective mitigation of head-of-line (HOL) blocking.

In this work, we investigate scheduling algorithms that accelerate DLT jobs. Our rigorous analysis and experiments with real-world DLT traces reveal the following. First, it is critical to consider both resource efficiency and short job prioritization for average JCT reduction. This is because real-world DLT workloads typically include relatively short jobs whose throughput scales poorly as well as highly-scalable jobs that run longer than others. In such scenarios, it is detrimental to prioritize only short jobs as it would reduce the aggregate resource efficiency that ends up with average JCT blowup. Second, designing an optimal algorithm is infeasible as the optimal *past* decisions would highly depend on the *future* jobs. In fact, repeatedly applying a greedy algorithm leads to grossly poor behavior due to its overly optimistic view toward future resource availability.

Incorporating the above findings, we draw a rule-of-thumb of elastic resource sharing for average JCT reduction: more resources to efficient jobs if the resource contention is heavy in the future, otherwise more resources to short jobs. This indicates that the scheduler should proactively prepare for the contention in the future by utilizing current resources more efficiently (see Section 3.2 for details). However, the future is typically unknown. Thus, of other possible ways to achieve it, we propose a scheduling algorithm which assumes that the future will be similar to the past, hence the name Apathetic Future Share (AFS). By assuming that the future load still exists, and that the level of it will be similar to the past, we do not rush into overly biasing to either efficiency or shortness. Instead, we gracefully adapt to the change of contention by re-adjusting shares of all jobs at each churn event. Our evaluation shows that this heuristic is highly effective in real-world DLT traces. AFS outperforms existing algorithms like Tiresias [24] and Themis [34] by 1.9x to 3.1x and 1.2x to 2.2x in average JCT reduction.

To deliver the algorithmic benefits to the real world, we also implement CoDDL, a DLT system framework that efficiently supports elastic share adaptation. Users of CoDDL simply submit a model based on a single GPU, and the system transparently parallelizes it with an arbitrary GPU share determined by the scheduler. The system handles frequent share re-adjustments efficiently via fast cancellation of outdated in-flight re-adjustment commands, which avoids potential thrashing on a burst of reconfigurations. It also overlaps job execution and slow initialization of a newly-allocated GPU, which effectively minimizes the idle time of GPUs during reconfiguration.

Our contribution is three-fold. (1) We show the importance of considering both resource efficiency and short job prioritization for average JCT minimization. We present empirical evidence with real-world traces and an analytical model that considers both to reduce average JCT. (2) We show that handling future jobs requires proactive preparation in current share calculation. We demonstrate that a simple heuristic like AFS brings significant benefits to average JCT reduction. (3) We design and implement CoDDL, which enables efficient realization of elastic share adaptation.

2 Background and Motivation

We begin by describing the DLT job scheduling problem with our underlying assumptions. We then present the limitations of existing schemes and discuss an alternative as well as a set of new challenges it poses.

2.1 Problem and Challenges

We investigate the problem of scheduling multiple DLT jobs in a GPU cluster. A DLT job trains a deep neural network (DNN) that can utilize multiple GPUs for parallel execution. We assume that neither the arrivals of future jobs nor their lengths (training durations) are known to the GPU cluster.[1] We seek to develop efficient algorithms and systems support to enhance overall cluster performance: minimize average JCT, enhance cluster efficiency, and alleviate job starvation.

[1]For the sake of presentation, we consider the case where job lengths are available to the GPU cluster in earlier parts of the paper.

Algorithms	Prioritize short job	Prioritize efficient job	Elastic sharing
SRTF [44]	✓		
Max-Min [20]		△	✓
Optimus [38]		✓	✓
SRSF, Tiresias [24]	✓	△	
Themis [34]	✓	△	✓
AFS	✓	✓	✓

Table 1: Comparison of the algorithmic gain with existing algorithms. △ indicates that it is handled implicitly.

Our approach to improving cluster performance is to design a job scheduler that leverages *elastic resource sharing* among DLT jobs. As opposed to non-elastic sharing [24, 55], which only selects the jobs to run and allocates the requested number of resources (job-level coarse-grained scheduling), elastic sharing decides how many resources to allocate to each job and regulates it during runtime to better achieve the performance goal (resource-level fine-grained scheduling). This approach opens up the possibility of further optimization, but it is feasible only when jobs in the workload can adapt to their changing resource usage with a high degree of freedom. DLT jobs nicely fit into the category; they can scale-in/out automatically [1, 4, 45] to utilize more or fewer GPUs, as they have a common scale-out pattern for data-parallel training [12, 13]. In a greedy multi-tenant environment, this implies that DLT jobs always want more GPUs (as long as it improves training throughput), thus the scheduler should focus on better distribution of GPUs across jobs rather than sticking to a fixed (or non-elastic) amount for each job.

Even when jobs can freely change their resource usage, elastic sharing is not always effective for average JCT reduction. As regulating the resources of a running job incurs an overhead, even migrating a job to avoid resource fragmentation produces little gain unless the job's runtime is long enough. Also, the fine-grained scheduling via elastic sharing does not provide any extra benefit for average JCT reduction if the job throughput scales linearly to the given resources, where SRTF is proven to be optimal [44, 48]. However, we find that the DLT workload is one example that could benefit from elastic sharing. DLT jobs typically run for a long time in the cluster – the real-world workloads we use (see Section 5.1) show up to 2.8 *days* of average JCT, while a typical big-data job completes within 30 minutes [19, 26, 39]. Also, the DLT job throughput is known to scale *sublinearly* to the number of allocated GPUs due to inter-GPU communication overhead for parameter updates.

Putting elastic resource sharing into practice poses a new set of challenges on two fronts. On the algorithms side, we find that minimizing average JCT of sublinearly-scaling jobs requires fine-grained resource preemption that simultaneously considers job lengths and resource efficiency. Existing DLT schedulers either adopt non-elastic sharing that only conducts a coarse-grained *job-level* resource preemption [24, 55], or handles preemption in a less aggressive

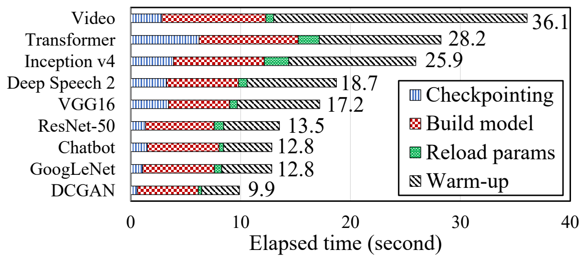

Figure 1: Breakdowns of DLT restart overhead in TensorFlow. Details of models are found in Table 4. Warm-up indicates the execution overhead seen at the first training iteration.

manner to reduce average JCT [34, 38] (see Table 1). We investigate these challenges in greater detail in Section 3.

On the systems side, we find that the overhead of existing DLT auto-scaling [1, 4, 45] and inter-GPU communication APIs [2, 3] is too large to support elastic-share schedulers because they require a complete restart of a DLT job when it updates the resource share. A full restart of a DLT job often takes tens of seconds (see Figure 1), and elastic sharing would only aggravate the situation as it tends to incur more frequent share re-adjustments. To bring the algorithmic benefit to real-world DLT jobs, we build the CoDDL system to address these challenges. We investigate these challenges in greater detail in Section 4.

2.2 Resource Efficiency Matters

Before we present our results in the following sections, let us look deeper into one central concept: resource efficiency. Cluster resource schedulers are often coupled with job preemption to curb HOL blocking that inflates average JCT. For linearly-scaling jobs, the preemption needs to prioritize short jobs (i.e. SRTF), which can be achieved with job-level resource preemption alone. In this case, resource efficiency[2] is a non-issue as all jobs have the identical efficiency gain for the same amount of extra resources. However, sublinearly-scaling jobs (e.g., DLT jobs) tend to have a different efficiency gain, so fine-grained balancing is required in prioritizing either short or efficient jobs for HOL blocking mitigation. Failing to consider both leads to suboptimal behavior.

Let us demonstrate that the existing algorithms fail to explicitly consider either efficiency or short job prioritization, thus exhibit inconsistent performance across two distinct workload scenarios. We run two non-elastic sharing algorithms (SRTF and Shortest-Remaining-Service-First (SRSF) [24]) and two elastic sharing ones (Max-Min and AFS-L) using two traces.[3] SRSF is similar to SRTF in that it performs job-level resource preemption, but differs in that it prioritizes jobs with a smaller remaining *service* time (i.e., a product of remaining time and the number of requested

[2]We refer to resource efficiency of a GPU as the marginal throughput in ratio that it contributes to its job, which drops as a job is given more GPUs.

[3]Except for Max-Min, all other algorithms require knowledge on job lengths in this particular experiment. Max-Min is at a disadvantage.

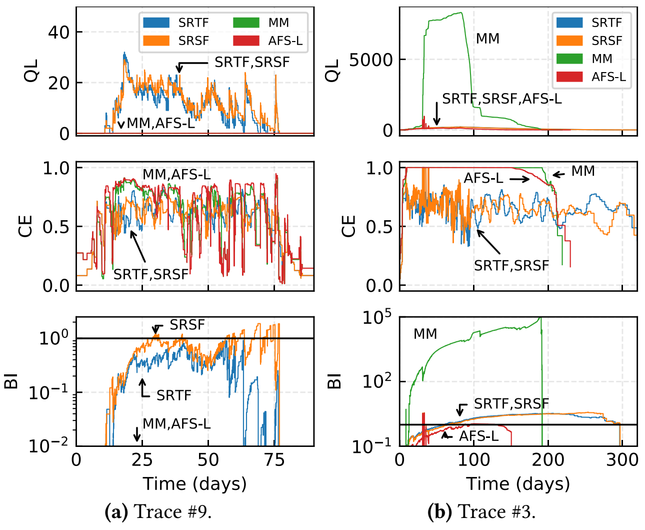

Figure 2: QL, CE, and BI (log-scale) during runtime for two traces in Table 3. MM is Max-Min. Note the different scale of Y-axis in (a) and (b). Experiment setup is in Section 5.1.

resources), in a way to penalize a job that requires many resources. Max-Min distributes available resources across all jobs in max-min fairness, hence performs finer-grained resource preemption than SRTF and SRSF. AFS-L is our algorithm whose details are deferred to Section 3. It is important to note that (1) none of the existing algorithms (except AFS-L) is the best in both traces, and more importantly, (2) Max-Min outperforms both SRTF and SRSF in some cases (5 out of 11 traces in Table 3 in Appendix).

To make our discussion clear, we define three metrics:

- *Queue Length (QL)*: number of pending jobs (yet to be allocated resources) in the cluster. This metric roughly measures the busyness of the cluster.
- *Cluster Efficiency (CE)*: aggregate resource efficiency of the cluster. A larger CE leads to a smaller makespan (elapsed time to complete all jobs). Let us denote by J_R the set of running jobs on an M-GPU cluster. Then,

$$CE := \frac{1}{M}\sum_{j\in J_R}\frac{\text{Current Throughput of } j}{\text{Throughput of } j \text{ with 1 GPU}}.$$

- *Blocking Index (BI)*: average fractional pending time to remaining time of pending jobs, i.e. it increases as pending jobs that can finish shortly pend for a long time. Let us denote by J_P as the set of pending jobs on an M-GPU cluster. Then,

$$BI := \frac{1}{|J_P|}\sum_{j\in J_P}\frac{\text{Pending Time of } j}{\text{Remaining Time of } j \text{ with 1 GPU}}.$$

Figure 2 illustrates two distinct workload scenarios with the above three metrics. Figure 2a presents moderate contention with a relatively few jobs that are submitted to the cluster, whereas Figure 2b shows heavy contention with a relatively large number of jobs.

Moderate contention. The average JCTs for SRTF, SRSF, Max-Min, and AFS-L are 31.1, 32.8, 18.3, and 15.2 hours, respectively. Note that Max-Min achieves lower JCT than SRTF and SRSF. This case is where job-level resource preemption, being too coarse-grained, results in unnecessary job blocking, and in turn poor JCT performance. To see this, let us consider Max-Min. As the number of submitted jobs is relatively small, Max-Min enables the cluster to accommodate nearly all jobs concurrently with *individual resource-level* preemption. Max-Min does not explicitly aim to deal with job blocking to reduce average JCT, but its behavior results in effective mitigation (or even elimination) of it.

On the other hand, SRTF and SRSF impose restrictions on the number of GPUs each job can utilize (either requested amount or nothing) with job-level resource preemption. Due to a small pool of jobs, SRTF and SRSF find it hard to select a good combination of jobs to utilize GPUs. In Figure 2a, Max-Min shows better QL and BI than SRTF and SRSF as it accommodates all jobs in contrast to SRTF and SRSF.

Heavy contention. The average JCTs for SRTF, SRSF, Max-Min, and AFS-L are 3.53, 3.32, 63.20, 2.40 days, respectively. SRTF and SRSF achieve lower JCT than Max-Min in this case as failing to prioritize short jobs aggravates job blocking, which in turn leads to poor JCT. To see this, let us consider SRTF and SRSF. Unlike the previous case, the number of submitted jobs is relatively large, so it is unavoidable to leave some jobs to starve. SRTF and SRSF mitigate job blocking to curb it. As the pool of jobs is diverse in terms of the requested number of GPUs due to its large size, SRTF and SRSF find it easy to select a good combination of jobs to do so.

On the other hand, Max-Min aims to maximize the fairness across submitted jobs rather than to explicitly prioritize short jobs. As a result, it leaves many (and a growing number of) short jobs under-served, causing severe job blocking. In Figure 2b, QL and BI show that Max-Min cannot deal with a large number of submitted jobs while SRTF and SRSF are good at prioritizing short jobs and thus able to keep it at bay.

3 Scheduling Algorithm

Our elastic resource sharing scheme strives to balance prioritizing between short and efficient jobs. At first glance, finding the optimal allocation strategy (possibly, by evaluating all possible allocation candidates) is an NP-complete problem [17]. Also, future job arrivals (which are unknown at the time of scheduling) can wreak havoc on previous resource allocation decisions that would have been optimal otherwise. Instead, we first gain insight through rigorous analysis on a simplified problem, and then factor in practical concerns of the original problem.

3.1 Overview

Problem. We formally define the DLT scheduling problem as follows. Let n denote the total number of jobs including all unknown future jobs. Each DLT job j_k ($1 \le k \le n$) is submitted at an arbitrary time to a cluster with a fixed number of GPUs (M) where each job trains a DL model in a bulk-synchronous-parallel (BSP) [12, 13] fashion.[4] Every job in its lifetime incurs two scheduling events (i.e., arrival and completion)[5] under which the scheduler re-adjusts the GPU shares of all jobs to minimize average JCT. Specifically, it strives to find the optimal value of n-dimensional vector $R_u = \{r_{1,u}, r_{2,u}, \cdots, r_{n,u}\}$, where $r_{k,u}$ is the number of GPUs allocated to j_k after the u-th event (either arrival or completion, $1 \le u \le 2n$).[6] For simplicity, we assume all GPUs have the identical computing/memory capacity that is accessed with the identical network latency.

Approach. As aforementioned, one cannot find the optimal R_u without knowledge on the future jobs.[7] Thus, our goal is to find a clever heuristic that helps improve overall JCT. Our high-level intuition is that repeatedly applying greedy optimization to existing jobs will be "overly optimistic" in the future when a new job arrives, as it rests on the greedy assumption that all resources released by finishing jobs will be used solely by the existing jobs. This implies that the scheduler assumes all active jobs in the cluster will have a non-decreasing number of resources at every scheduling event (i.e. $r_{k,u} \le r_{k,u+1}$), which is far from reality except when there is no more job in the future.

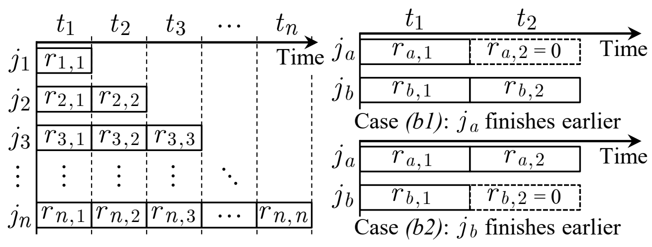
Key assumption. We propose the Apathetic Future Share (AFS) assumption, which predicts that the resource usage of each job (except the finishing one) would be the same in the future, and find the optimized shares based on that. This is not only simple but it also closely approximates the real cluster environment where the level of resource contention does not change dramatically during most of its runtime.

Organization. In what follows, we explain AFS in detail and discuss its corner cases. First, in a two-job case with the knowledge on their job length, we gain insight by presenting a greedy optimization. Next, we extend it to an n-job case without the knowledge on the job length by incorporating the AFS assumption.

3.2 Insight from Two-Job Analysis

Time slot-based analysis. Let us consider a problem with n DLT jobs submitted to an M-GPU cluster all at once in the beginning. Assume that we know the optimal algorithm to allocate the GPUs and schedule the jobs, and that Figure 3a shows the allocation result over time. The jobs are listed in the order of completion where j_1 finishes first and j_n last. t_k ($k > 1$) represents a time slot k which denotes the time interval between the completions of j_{k-1} and j_k; t_1 represents the interval from the beginning to the completion of j_1. j_k is allocated $r_{k,t}$ GPUs at time slot t. Its share is released and re-distributed to other jobs at its completion.

[4]Discussion on asynchronous training [32, 42] is found in Appendix D.
[5]We omit other kinds of events (e.g. eviction timeout) for brevity.
[6]Completed or not arrived jobs are allocated zero GPU.
[7]Several simple examples are shown in Appendix A.



t_1 t_2 t_3 $\cdots$ t_n
Time
j_1 $r_{1,1}$
j_2 $r_{2,1}$ $r_{2,2}$
j_3 $r_{3,1}$ $r_{3,2}$ $r_{3,3}$
j_n $r_{n,1}$ $r_{n,2}$ $r_{n,3}$ $\cdots$ $r_{n,n}$
j_a $r_{a,1}$ $r_{a,2}=0$
j_b $r_{b,1}$ $r_{b,2}$
Case (b1): j_a finishes earlier
j_a $r_{a,1}$ $r_{a,2}$
j_b $r_{b,1}$ $r_{b,2}=0$
Case (b2): j_b finishes earlier

(a) Time slots of n jobs. **(b)** Time slots of 2 jobs.

Figure 3: Example timelines of jobs.

Optimal allocation for two jobs. Let us consider the simplest scenario in which we have one GPU and two jobs (j_a and j_b). We need to allocate the GPU to the shorter job first. Thus, we compute the lengths of both jobs to obtain the solution, which Figure 3b illustrates: if j_a turns out to be shorter, $(r_{a,1}, r_{a,2}, r_{b,1}, r_{b,2}) = (1,0,0,1)$; otherwise, $(r_{a,1}, r_{a,2}, r_{b,1}, r_{b,2}) = (0,1,1,0)$.

To extend the case to $M > 1$, without loss of generality, let us assume j_a finishes earlier than j_b. Suppose $M-1$ GPUs have been optimally allocated for t_1 and t_2. How should one determine which job to allocate the extra M-th GPU to? More concretely, let us denote by w_k (k is either a or b) the total training iterations required for j_k to complete and by $p_{k,u}$ the throughput of j_k with $r_{k,u}$ GPUs at time slot u. One can express t_1 and t_2:

$$t_1 = \frac{w_a}{p_{a,1}}, \quad t_2 = \frac{w_b - p_{b,1}t_1}{p_{b,2}}.$$

We have two cases to consider. (a) j_a earns the GPU first. In this case, $r_{a,1}$ and $r_{b,2}$ increase by one (hence $p_{a,1}$ and $p_{b,2}$ will increase accordingly). (b) j_b earns the GPU first. In this case, two possibilities arise depending on which job finishes first as shown in Figure 3b:

Case (b1): j_a finishes earlier (i.e., $\frac{w_a}{p_{a,1}} < \frac{w_b}{p'_{b,1}}$, where $p'_{k,u}$ is the throughput of j_k with $(r_{k,u}+1)$ GPUs at time slot u). $r_{b,1}$ increases by one and $r_{b,2} = M$.

Case (b2): j_b finishes earlier (i.e., $\frac{w_a}{p_{a,1}} \geq \frac{w_b}{p'_{b,1}}$). $r_{b,1}$ increases by one and $r_{a,2} = M$.

We obtain (1) and (2) by subtracting the average JCTs for cases (b1) and (b2) from the average JCT for case (a), respectively:

$$\frac{w_a}{p'_{a,1}} - \frac{w_a}{p_{a,1}} + \frac{w_a}{2p'_{b,2}}\left(\frac{p'_{b,1}}{p_{a,1}} - \frac{p_{b,1}}{p'_{a,1}}\right), \tag{1}$$

$$\frac{w_a}{p'_{a,1}} - \frac{w_b}{p'_{b,1}} + \frac{p_{b,1}}{2p'_{b,2}}\left(\frac{w_b}{p_{b,1}} - \frac{w_a}{p'_{a,1}}\right) - \frac{p_{a,1}}{2p'_{a,2}}\left(\frac{w_a}{p_{a,1}} - \frac{w_b}{p'_{b,1}}\right). \tag{2}$$

Here, if either (1) or (2) is positive, then one can allocate the extra GPU to j_b first and further minimize average JCT. Otherwise, one should allocate it to j_a first.

For an arbitrary number of GPUs, one needs to repeat the above procedure starting with one GPU. As long as one knows the workload (w_k) and throughput ($p_{k,u}$) information in advance, she can determine the optimal resource allocation for the simple two-job case.

Notation	Description
M	Total # of GPUs in the cluster
n	# of jobs
j_k	Job k
$r_{k,u}$	# of GPUs assigned to j_k after the u-th event
R_u	$\{r_{1,u}, r_{2,u}, \cdots, r_{n,u}\}$
w_k	# of training iterations of j_k
t_u	Length of time slot u
$p_{k,u}$	Throughput of j_k using $r_{k,u}$ GPUs
$p'_{k,u}$	Throughput of j_k using $r_{k,u}+1$ GPUs

Table 2: Description of mathematical notations.

Handling future jobs. We attain valuable insight when we add a third job j_c. For the sake of presentation, let us assume j_c is submitted right after j_a finishes in case (b1).[8] With the new job present, j_b is likely to be allocated fewer GPUs and consequently achieves a lower throughput ($p'_{b,2}$). This could flip the sign of (1) from negative to positive, which would prioritize the longer job (j_b) over the shorter job (j_a). Likewise, a lower throughput of j_a ($p'_{a,2}$) could flip the sign of (2) from positive to negative in case (b2), which would also prioritize the longer job (j_a) over the shorter job (j_b). This example clearly shows that (1) the presence of a future job at time slot 2 may impact the optimal decision at time slot 1, which demonstrates the *infeasibility of an optimal resource allocation*, and (2) if future jobs increase resource contention, it is often beneficial to allocate *more GPUs to longer but efficient jobs*, which is in contrast with SRTF.[9] This implies that we can prepare for future contention by assigning more resources to efficient jobs, which would be difficult for greedy optimization to achieve as it does not consider future job arrivals.

Apathetic Future Share. We have learned that future jobs may interfere with greedy decisions in the past. We can avoid this pitfall by shifting from the optimistic view from greedy decisions to our AFS assumption that the future share of any existing job will be the same as the current share even if some jobs finish and release their shares. Thus, we set $p'_{a,2} = p_{a,1}$ and $p'_{b,2} = p'_{b,1}$ in (1) and (2).[10] Then, evaluating if either (1) or (2) is positive is translated into a simple inequality:

$$\frac{p'_{b,1} - p_{b,1}}{p'_{b,1}} > \frac{p'_{a,1} - p_{a,1}}{p_{a,1}}. \tag{3}$$

If (3) is true, j_b has priority over j_a for the extra GPU, and vice versa.

AFS implicitly prepares for future job arrivals by continuously adapting to the change of resource contention, which is done by re-evaluating (3) to re-adjust the shares of current jobs at each churn event. AFS tends to give higher priority to longer-but-efficient jobs when the contention level increases, refraining from over-committing resources to shorter-but-inefficient jobs (i.e., greedy approaches). Our evaluation in Section 5.2 shows that this assumption is highly effective in

[8]This analysis is similarly applied regardless of when j_c arrives.

[9]Appendix B provides more rigorous details.

[10]$p'_{a,2}$ is not $p'_{a,1}$ as $p'_{a,2}$ is used when j_b earns the GPU first (case (b2)).

real-world DLT workloads as AFS achieves the best average JCT reduction in all our traces.

The AFS assumption may prove ineffective in a few corner cases. One such case is when the future contention level decreases; jobs start simultaneously but no future jobs arrive until they finish. In this case, strategies acting more greedily (exploiting decreasing contention) may perform better than AFS. Although it is not uncommon in DLT workloads that a slew of jobs start at the same time, e.g. parameter sweeping [9], they typically run with other background jobs as we observe in the real cluster traces, rendering the decreasing contention assumption invalid. The other such case is when the future contention level increases; jobs start at different times and finish all at the same time. In this case, strategies acting more altruistically (exploiting increasing contention) may perform better than AFS, but we believe it is a rare case in real-world clusters. We finally note that if contention levels or their statistical characteristics are available, more sophisticated strategies than AFS can be devised to take advantage of them. For the time being, we focus on the more usual case where no such information is easily available.

3.3 AFS Algorithm for Multi-Job

Extending to n jobs. One may have noticed that extending the two-job case to the n-job case is highly non-trivial as it would be prohibitive to analyze all cases that potentially bring JCT reduction. To avoid the impasse, we directly apply our heuristic, AFS-L, to pick the job with the highest priority among n jobs for allocating each GPU. We determine the relative priority between any two jobs by evaluating (3) and apply the transitivity of priority comparison (see the proof in Appendix C) to find the job with the highest priority. We repeat this process M times, which results in $O(M \cdot n)$ steps for M GPUs with n jobs.

Algorithm 1 formally describes AFS-L, our resource allocation algorithm for n jobs under the assumption that workload size information for the jobs is known. At each churn event, Algorithm 1 determines the per-job GPU shares. The jobs with a positive share run until the next churn event. More specifically, AFS-L simply finds the job with the top priority (j^*) via TopPriority() and allocates one GPU to it, and repeats the same process M times. TopPriority() starts by picking two jobs at random. Given the current GPU shares, j_a is the shorter job and j_b is the longer one. If the current GPU share is zero, its length is considered infinite. Then it evaluates (3) to find the higher priority job and marks it as j^*. It repeats for all jobs to find the top choice.

AFS-L is a two-stage operation. In stage one, it assumes all jobs run with a single GPU and allocates one GPU in the increasing order of the job lengths. If M is smaller than the current number of jobs, the algorithm stops here. Otherwise, it moves into stage two, where it distributes the remaining GPUs by considering both job length and resource efficiency, which is achieved by evaluating (3).

Algorithm 1: AFS-L Resource Sharing

```
Function TopPriority(Jobs $J$)
    $j^* \leftarrow$ any job in $J$
    for $j \in J$ do
        $j_a \leftarrow j^*, j_b \leftarrow j$
        if $j_a.cnt = 0$ and $j_b.cnt = 0$ then
            if $j_a.len(1) < j_b.len(1)$ then $j^* \leftarrow j_a$
            else $j^* \leftarrow j_b$
        else
            if $j_a.len(j_a.cnt) \geq j_b.len(j_b.cnt)$ then
                Swap $j_a$ and $j_b$
            if (3) is true then $j^* \leftarrow j_b$
            else $j^* \leftarrow j_a$
    return $j^*$
Procedure AFS-L(Jobs $J$, Total Resources $M$)
    for $j \in J$ do
        $j.cnt \leftarrow 0$
    $m \leftarrow M$
    while $m > 0$ do
        $j^* \leftarrow$ TopPriority($J$)
        $j^*.cnt \leftarrow j^*.cnt + 1$
        $m \leftarrow m - 1$
    for $j \in J$ do
        Allocate $j.cnt$ resources for $j$
```

Handling unknown job lengths. AFS-L performs well, but it requires job length information to compare lengths of j_a and j_b in TopPriority(). As job length information is often unavailable, we modify TopPriority() to function without it by evaluating (3) for both cases: ($j_a = j^*$ and $j_b = j$) and ($j_a = j$ and $j_b = j^*$). (3) being true in either case indicates that prioritizing j_b is better for average JCT. If it evaluates to false in both cases, the real priority would depend on the finishing order of the jobs, which cannot be decided without knowing job lengths. In such a case, we give a higher priority to either one at random. Note that (3) cannot be true in both cases.

AFS-P is our job-length-unaware algorithm that modifies AFS-L by adopting the traditional *processor sharing* [31] approach to mimic the SRTF-like behavior of stage one in AFS-L. Specifically, the algorithm maintains a counter for each job that tracks the amount of time for which it is scheduled. The counter is zero at job arrival and increases by one whenever the job is executed for one unit of time.[11] If there are fewer jobs than M, the algorithm ignores the counters and uses modified TopPriority() to determine the shares. If the number of jobs exceeds M (the algorithm stays in stage one), it allocates one GPU in the increasing order of the job counters in a non-preemptive manner and evicts a job whenever it is executed for one unit of time, which triggers the scheduler to re-schedule all jobs. This policy mitigates job blocking if the current number of jobs exceeds M, but it is unnecessary otherwise as every job would run with at least one GPU. Appendix D provides more discussion on AFS.

[11] AFS-P set the unit time as 2 hours for all full-scaled traces used in this work. Like existing practices of processor sharing, we should scale the unit time if the workload is in a different scale.

4 Systems Support for Elastic Sharing

Elastic share adaptation requires every job to reconfigure to an arbitrary number of GPUs at any time. To support this efficiently, we present CoDDL, our DLT system framework that transparently handles automatic job parallelization.

4.1 CoDDL System Architecture

CoDDL is a centralized resource management system for a dedicated DLT cluster. It enables the system administrator to specify a scheduling policy and also parallelizes DLT jobs automatically. The key requirement of this system is to minimize the overhead incurred by frequent reconfiguration of DLT jobs to their elastically adapted resource shares.

CoDDL is divided into a front-end and a back-end. The front-end interacts with users (DLT job owners). It accepts a DL model to train from a user and reports its progress back periodically to the user. The current user interface is based on TensorFlow [6], although we can easily support other frameworks as well. A user specifies her model via native TensorFlow APIs and provides the batch size and her model graph (automatically extracted via native TensorFlow APIs) to a CoDDL client. The client submits these to the back-end system that initiates a DLT job.

The back-end determines resource shares for the submitted jobs and allocates them. It consists of a central controller (which includes the scheduler), per-server agents, and per-GPU workers as shown in Figure 4. To clarify, a GPU cluster consists of multiple servers, each of which consists of multiple GPUs. The controller invokes the scheduler to determine the shares and notify the agents of the updated per-job shares. The agents in turn order their local workers to reflect the changes. The agents manage the intra-server workers and the workers carry out actual DLT with their own GPU.

4.2 Automated Parallel Training

A CoDDL user does not need to write a model for multiple GPUs considering parallel execution. Rather, she writes it only for a single GPU and the system automatically parallelizes it to run with an arbitrary number of GPUs. The basic approach to the parallelization is similar to existing works [1, 4, 30, 45] while it seamlessly supports a large batch size that exceeds the physical memory size of a GPU.

Auto-parallelization. The key to job parallelization is to enable each worker to exchange gradients for model update with an arbitrary number of co-workers. To achieve this, we insert special vertices for every pair of gradient and updater vertices such that these new vertices work as a messenger between the DLT framework and our custom communication stack (see Section 4.3 for details) in Figure 4. Whenever a gradient is calculated, the newly added vertex notifies the communication stack of the availability of the gradient and registers a callback function. Then, the communication stack reduces the gradients, and triggers the callback function so that the DLT framework starts updating the parameters.

Accumulative gradient update. Per-GPU batch size of a job is determined by its total batch size and GPU share. The smaller the GPU share of the job is, the larger the per-GPU batch size gets. Hence, the memory footprint often exceeds the physical memory budget of a single GPU. To prevent memory overflows, CoDDL transparently performs accumulative gradient update by adding extra vertices to the graph. It selects the batch size small enough to fit the memory budget of one GPU and repeatedly adds up the gradient results until it reaches the originally-set per-GPU batch size.

4.3 Efficient Share Re-adjustment

Elastic resource sharing schedulers tend to perform frequent share re-adjustments. In fact, we observe that AFS-P executes 6.3x on average or up to 22x more reconfigurations than Tiresias-L for real-world traces. To address the overhead, CoDDL optimizes the reconfiguration process and avoids potential thrashing due to a burst of reconfigurations that arrive in a short time.

Custom communication stack. CoDDL implements its own communication stack so that workers can dynamically join or leave an on-going DLT job without checkpointing and restarting it. It consists of a data-plane (NCCL [2]) stack and a control-plane (sMPI) stack. The data plane is responsible for efficient reduce operations with a static set of workers. The control plane reconfigures NCCL whenever there is a GPU share re-adjustment order from the controller (①). It also communicates with co-workers to monitor the availability of intermediate data (e.g., gradients and parameters) (②), and invokes NCCL APIs to exchange it (③, ④). One of the control-plane stacks operates as a leader, which periodically polls all other followers if it is ready to join or leave the job, and shares this information with all followers.

Concurrent share expansion with job execution. CoDDL mitigates the overhead for resource share expansion by continuing job execution during the reconfiguration. This would minimize the period of inactivity caused by frequent reconfigurations. The key enabler for this is to separate the independent per-GPU operations from the rest that communicates with remote GPUs in distributed DLT. The independent operations (e.g., forward/backward propagation, gradient calculation, updating parameters) can be executed on their own regardless of the number of remote GPUs. Only the operations that gather the gradients would depend on the communication with remote GPUs. So, when a job is allocated more GPUs, the job continues the execution with the old share while newly-allocated GPUs are being prepared; the new GPUs are loaded with the graph, and receive the latest parameters from one of the existing workers in the job. When the new GPUs are ready to join, they tell other workers to update the communication stack to admit the new GPUs. We find the overhead for this operation is as small as 4 milliseconds.

Zero-cost share shrinking. The process of share shrinking is even simpler. When the GPU share of a job decreases, the job only needs to tell its communication stack to reflect the shrunk share and continues the execution with the remaining GPUs. Then, the kernels on the released GPUs are stopped and tagged as idle. Again, it takes only 4 milliseconds regardless of a model.

Handling a burst of reconfigurations. While running our system, we often observe a burst of reconfiguration orders from the controller as multiple churn events happen simultaneously. Naïvely carrying them out back to back would be inefficient as the older configuration would be readily nullified by the newer one. There are two approaches to efficiently handling them. One approach is to coalesce multiple consecutive reconfiguration orders into one while the current reconfiguration is going on. While it is simple to implement, the controller would need to synchronize with all agents and workers before initiating the next reconfiguration. Instead, we implement "cancelling" the current reconfiguration on the individual worker level. In this approach, a new reconfiguration order will be delivered to the agents as soon as it is available, but the agent can cancel the on-going reconfiguration with its workers. Unless careful, this could create a subtle deadlock as one worker may leave a job on a new reconfiguration order while the rest of the workers wait for it indefinitely in a blocking call (e.g., initializing, all-reduce, etc.). To avoid the deadlock, CoDDL allows a worker to leave the job only when all others are aware of it.

Failure handling. Efficient share re-adjustment of CoDDL makes it easy to handle failures efficiently as it is similar to handling churn events. The controller and each agent are responsible for monitoring the status of all agents and the workers of its own, respectively. If any of them stops responding or returns a fatal error, it is reported to the controller, and it simply excludes the failed entities from the available resource list and re-runs the scheduler to reconfigure all jobs. Unlike ordinary churn events, it is deadlock-free for a failed worker to exit without informing to its co-workers since it is done by agents and the controller instead.

4.4 Network Packing and Job Migration

Depending on the DL model, the placement of GPUs may affect the training performance. It is generally more beneficial to use as fewer machines as possible for the same number GPUs to minimize network communication overhead [34,55]. Also, the performance could be unpredictable if multiple jobs compete for network bandwidth on the same machine.

CoDDL adopts a simple yet effective GPU placement mechanism called *network packing*, which enforces the GPU share of each job to be a factor or a multiple of the number of GPUs per machine. For instance, in a cluster with 4 GPUs per machine, the share of a job should be one of $1/2/4n$ GPUs. This regulation can be proven to eliminate the "network sharing", which satisfies the following two conditions – (1) every job is allocated GPUs scattered on the minimum number of machines and (2) at most one job on a machine communicates with remote GPUs on other machines (while all other jobs on the machine use only local GPUs). When the GPU share is determined by the scheduling algorithm, the scheduler applies the regulation to come up with an allocation plan that minimizes the difference from the original plan. More details on the algorithm and the proof are found in Appendix E.

Despite the network packing, we still need job migration as it does not prevent resource fragmentation. Since a job can continue training without migration unless the newly allocated GPU set does not include any GPU that the job was previously using, the scheduler finds a placement decision that maximizes the number of jobs which reuse at least one GPU, and then maximizes the total number of reused GPUs as the secondary goal. It conducts migration as the final resort when it is unavoidable.

4.5 Throughput Measurement

Algorithms like Optimus [38] and AFS require the throughput (or throughput scalability for AFS-P) with an arbitrary number of GPUs for determining the GPU share. While Optimus estimates the throughput scalability with a few sampled measurements for iteration, gradient calculation, and data transmission, we find it unreliable due to the heterogeneity of computing hardware, network topology, and DL system frameworks. Instead, CoDDL takes the *"overestimate-first-and-re-adjust-later"* approach. It over-allocates the number of GPUs first but re-adjusts the share from real throughput measurements later. This exploits the fact that GPU share shrinking incurs a small overhead of only a few milliseconds.

Overestimate first and re-adjust later. When a new job arrives, the scheduler allocates an initial share to it by assuming the linear throughput scalability. We limit the initial share to be within its fair share (1/n). When the job gets its GPU share, it takes the throughput measurement with all allocatable units that are smaller than the given share. Note that this measurement is done efficiently as shrinking the share incurs little cost (Section 4.3) and all iterations used for the measurement are part of training. In most cases, it requires only two reconfigurations for a new job arrival. In a rare case where a job needs to predict the throughput beyond the currently allocated share, it assumes the linear scalability from the last allocatable unit. Then, the re-adjustment is made again when the real throughputs are reported to the controller.

5 Evaluation

We evaluate AFS if it improves average JCT on a diverse set of real-world DLT workloads against existing scheduling policies. We evaluate it on simulation as well as on real-world cluster with CoDDL.

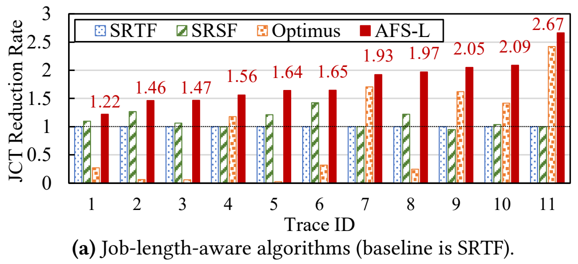
5.1 Experiment Setup

Cluster setup. We use a 64-GPU cluster for experiments. Each server is equipped with four NVIDIA GTX 1080 GPUs, two 20-core Intel Xeon E5-2630 v4 (2.20GHz), 256 GB RAM, and a dual-port 40 Gbps Mellanox ConnectX-4 NIC. Only one NIC port of each server is connected to a 40 GbE network switch and the servers communicate via RDMA (RoCEv2), leveraging NCCL 2.4.8 [2]. All DLT jobs run TensorFlow r2.1 [6] with CUDA 10.1 and cuDNN 7.6.3.

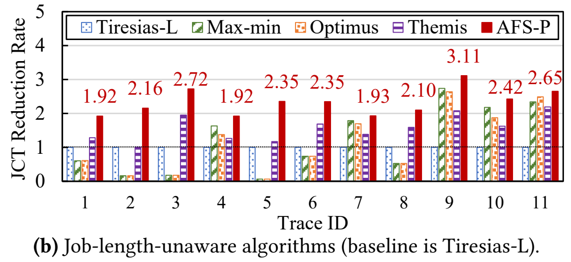
DLT workload. We use 137-day real-world traces from Microsoft [5, 27] (Table 3 in Appendix). We evaluate with *all* traces except those that have fewer than 100 jobs. From the traces, we use submission time, elapsed time, and requested (allocated) numbers of GPUs of each job. Since the traces do not carry training model information, we submit a random model chosen from a pool of nine popular DL models (Table 4 in Appendix) whose training throughput scales up to the requested number of GPUs. Each DLT job submits the chosen model for training in the BSP manner with the same batch size throughout training, even though the GPU share changes during the training. The number of training iterations of the job is calculated so that its completion time becomes equal to the total executed time from the trace, based on the use of the requested number of GPUs.

Simulator. We implement a simulator to evaluate the algorithms for large traces. All experimental results without explicit comments are from the simulator. The simulator is provided with the measured throughput of each model on our real cluster for job length calculation. We confirm that simulation results conform to those on real execution for all algorithms with scaled-down traces. Figure 15 in Appendix shows examples of our scheduler conformance tests. The error rate is low (<1%) for algorithms that do not require throughput measurements but slightly high for others (2.7~5.2%) due to the measurement overhead on real cluster.

Algorithms. Scheduling algorithms are divided into two categories: job-length-aware and job-length-unaware. The former consists of SRTF, SRSF [24], Optimus [38], and AFS-L while the latter consists of Tiresias-L [24], Optimus, Max-Min, Themis [34], and AFS-P. Optimus is counted into both as real job lengths differ from the estimated ones by Optimus. We just assume that their estimation is always correct.



(a) Job-length-aware algorithms (baseline is SRTF).



(b) Job-length-unaware algorithms (baseline is Tiresias-L).

Figure 5: Average JCT reduction rates with respect to baselines for scheduling algorithms.

Metrics. We evaluate average JCT, makespan, QL, CE, and BI, and GPU utilization during runtime for real experiments. While makespan is often used to evaluate resource efficiency of scheduling algorithms [22, 24, 38], we believe CE is a better metric as makespan would depend on the last job submission time, which is orthogonal to resource efficiency. CE does not suffer from such an issue as it reports the reduction rate of makespan per unit time instead.

5.2 JCT Evaluation on Simulation

Figure 5 compares average JCT reduction rates for each category of the algorithms. Values larger than 1 mean that their average JCT is better than the baseline algorithms (SRTF or Tiresias-L). Interestingly, we observe that Max-Min and Optimus show a similar trend on the same set of traces (1,2,3,5,6,8). These traces launch many jobs in a short interval while many of them run longer than other traces. In such cases, it is important to serve shorter jobs first to avoid HOL blocking, but neither does so. Not surprisingly, SRSF outperforms SRTF on these traces as penalizing jobs with more GPUs helps reduce HOL blocking beyond favoring short jobs. AFS-L and AFS-P consistently outperform all others in their category by 1.2x to 2.7x over SRTF or by 1.9x to 3.1x over Tiresias-L. This shows that resource efficiency-aware HOL blocking mitigation is effective in practice.

One may argue that non-elastic sharing algorithms would achieve better JCT if we allow them to use more GPUs as we do for elastic-share algorithms. However, we find that it only marginally improves average JCT or even performs

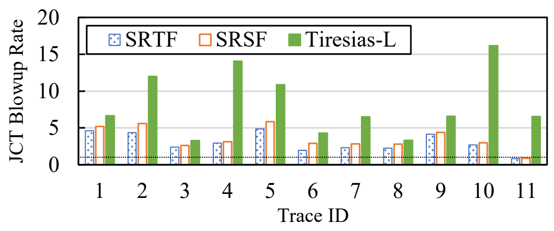


Figure 6: Average JCT blowup rates when we allow SRTF, SRSF, and Tiresias-L [24] to use the maximum number of GPUs each job can utilize. Dotted line indicates unity.

worse. For example, if we allow SRTF, SRSF, and Tiresias-L to allocate enough GPUs for peak throughput of each job, Figure 6 shows that their average JCTs rapidly grow by up to 4.85x, 5.84x, and 16.14x, respectively. Only one trace improves by 21% and 17% for SRTF and SRSF. This is because non-elastic allocation with a larger GPU share reduces the cluster efficiency as it would increase the inefficiency of individual resource. What matters more is to flexibly adjust the GPU share according to job lengths and resource efficiency, which is impossible with non-elastic allocation.

5.3 Evaluation on Real Cluster

Algorithm behavior on real cluster. Figure 7 compares job-length-unaware algorithms running on our GPU cluster. As full-scale execution would take months to finish, we scale down the job submission times and total iterations to 1% and 0.2% of the original values for traces #9 and #3, respectively.

We observe similar trends with QL, CE, and BI as those in the full-scale simulations in Figure 2. AFS-P achieves (a) 3.54x and (b) 2.93x better average JCT over Tiresias-L, (a) 1.12x and (b) 1.66x better than Optimus, and (a) 1.22x and (b) 1.30x better than Themis. Note that the CEs of Optimus and AFS-P fluctuate heavily in Figure 7a because they complete most of the jobs in the cluster rather quickly, which decreases the CE due to underutilization (see the low QL). Optimus, Themis, and AFS-P show higher GPU utilizations than that of Tiresias-L in Figure 7b as they tend to assign fewer GPUs to each job than Tiresias-L especially when there are many jobs in the cluster.

Efficient share re-adjustment. We evaluate the effectiveness of CoDDL's share re-adjustment over a baseline system without concurrent share expansion and zero-cost shrinking (ES) or without reconfiguration cancelling (RC). We monitor the training progress of a specific job (video prediction model) along with other jobs on a full-scale trace (#10) extracted from day 50 and 116. Figure 8 compares job progress, allocated GPU shares, and # of jobs submitted over time.

In Figure 8a, we observe that the job finishes 2.12x and 2.82x faster than "No RC" and "No RC/ES", respectively. On this day, 19 short jobs enter the system in a short time interval of 2 to 70 seconds for the first few minutes. During this time, the job with ES and RC is allocated a much larger GPU share than the one with full restart. This is because ES enables

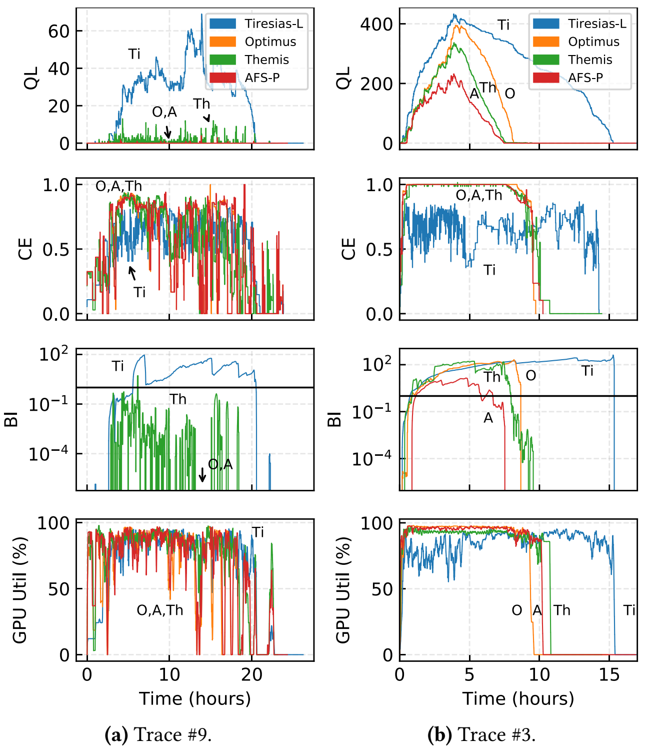

Figure 7: Real-cluster execution over CoDDL using Tiresias-L (Ti), Themis (Th), Optimus (O), and AFS-P (A) schedulers. Average JCTs are (a) 1.45, 0.50, 0.46, and 0.41 hours (b) 5.65, 2.51, 3.21, and 1.93 hours, respectively.

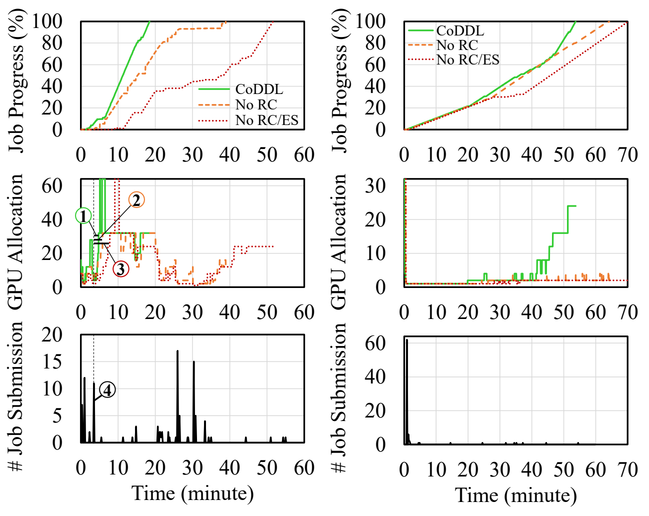
the short jobs to finish more quickly as they can continue job execution even during reconfiguration. This enables the monitored job to earn more GPUs. In addition, RC helps the job adapt to newly-assigned resources quickly even when the controller updates the resource share frequently. In the graph, we see that all short jobs that arrive at ④ finish within 1.50 minutes (①) while "No RC" and "No RC/ES" take 4.10 (②) and 5.06 minutes (③), respectively.

Figure 8b shows results on day 116 where there are a slew of job submissions (68 jobs) at start, commonly seen in DLT clusters (e.g. parameter sweeping [9]). The monitored job finishes 1.19x and 1.30x faster than "No RC" and "No RC/ES", respectively. The AFS-P scheduler performs more stably at heavy contention as each job would employ a small share (one GPU per job if the number of jobs exceeds that of GPUs). In this case, a churn would rarely affect other jobs as most of them are likely to keep their previous share. This explains the smaller benefit compared to the scenario in Figure 8a.

5.4 Evaluation of Tail JCTs

DLT jobs in a multi-tenant cluster tend to be heavy-tailed (see Appendix F), so we evaluate tail JCTs of schedulers. Unlike other systems whose tail latency directly measures the worst-case system (or scheduler) performance caused by the congestion, tail JCT in DLT clusters is a fairness metric that evaluates the trade-off between average and tail JCTs.



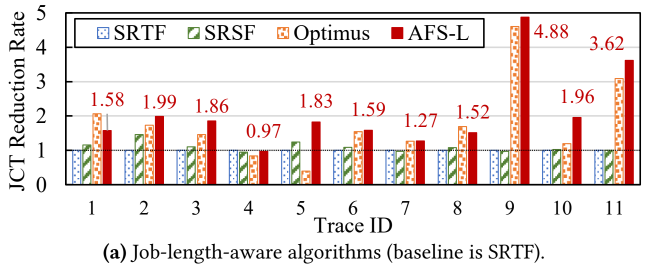
(a) Day 50. **(b)** Day 116.

Figure 8: Real-cluster execution of parts of full-scale trace #10 over CoDDL using AFS-P scheduler. X-axis indicates the elapsed time since the arrival of the monitoring job. "No RC/ES" means that we disable both RC and ES.

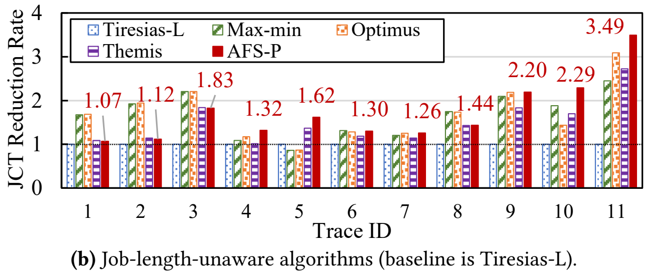
The difference arises as the intrinsic characteristic of a DLT job (i.e. how much resource it can utilize and how long it runs) often dominates the JCT rather than the congestion itself. Consequently, it is often hard to blame the system for a long tail when the major causes are (1) the user's request to run for a long time and (2) the scheduler's decision that avoids allocating more resources to those jobs that incur the average-tail trade-off (or fairness) issue.

Figure 9 shows that AFS reduces tail JCTs over existing schedulers in most cases in addition to the average JCTs, as demonstrated in Figure 5 as well. Actually, other scheduling algorithms targeting for reducing average JCT such as SRTF often suffer from severe job starvation. In contrast, it is interesting that AFS experiences little starvation (thus shows good tail JCTs) while achieving low average JCT for online jobs. As explained, AFS allocates at least one GPU for all jobs when $n < M$ (stage one), and distributes remainders when $n \geq M$ (stage two), which helps avoid job starvation. The low BI values of AFS in Figure 7 also implies that it effectively avoids starvation.

In some traces, Max-Min or Optimus shows better tail JCTs over AFS. This is an expected behavior because Max-Min and Optimus do not prioritize short jobs at all, which is relatively more beneficial to tail JCT reduction. However, this does not necessarily mean that they are fairer than AFS because the tail JCT reduction is often achieved by sacrificing the average JCT substantially, as is already shown in Figure 5. To clarify this, Figure 10 compares the JCT reduction rates over varying job lengths. The figures group all jobs into 100 bins in the increasing JCT order on the X-axis (a longer job comes more rightward) and plot the average reduction rate of each bin on the Y-axis (a more prioritized job shows up higher).

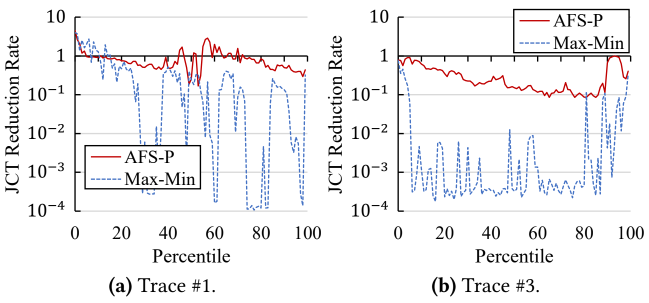


(a) Job-length-aware algorithms (baseline is SRTF).



(b) Job-length-unaware algorithms (baseline is Tiresias-L).

Figure 9: 99th%-ile JCT reduction rates with respect to baselines for scheduling algorithms.



(a) Trace #1. **(b)** Trace #3.

Figure 10: JCT reduction rates over varying job lengths. Results of other traces are omitted as they show similar results.

The result indicates that Max-Min not only performs more poorly on average but it also shows uneven performance gain compared to AFS-P. Especially when the cluster is heavily contended (trace #3), it tends to prioritize very long jobs by its algorithmic design.[12] While we do not present here, Optimus also shows the similar behavior as Max-Min. In contrast, AFS-P demonstrates relatively more even performance gain regardless of the job length.

5.5 Benefit over Altruistic Approach

One low-hanging fruit of leveraging elastic resource sharing is that it can enhance cluster efficiency by distributing idle resources to running jobs. Altruistic scheduling [22] is a straightforward approach to achieving this: it first schedules jobs to achieve the primary goal (in this case, assigning the user-requested number of GPUs) and then distributes leftover resources for the secondary goal (in this case, assigning more GPUs to achieve the largest throughput). Figure 11 shows

[12]Figure 10 shows that Max-Min also prioritizes very short jobs. This is a common feature of job-length-agnostic schedulers (including AFS-P) rather than being specific to Max-Min, because very short jobs are less affected by the algorithmic detail of the scheduler as they typically finish as soon as they are first scheduled.

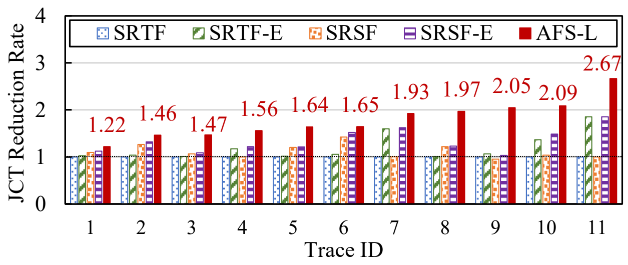


Figure 11: Benefit of altruistic approaches (SRTF-E and SRSF-E) to reduce average JCT.

the performance of this approach when applied to SRTF and SRSF to make their elastic versions, SRTF-E and SRSF-E, respectively. Even though these reduce average JCT from their non-elastic versions, AFS-L still shows a substantial benefit over these, which indicates the importance of fine-grained individual resource-level adjustment.

6 Related Work

Leveraging optimality of SRTF. SRTF, also known as Shortest-Remaining-Processing-Time discipline (SRPT) or preemptive Shortest-Job-First (SJF), has been proven to minimize average JCT in cases where a single resource is available [18,44,48]. In case of multiple resources, SRTF is optimal only when the throughput of all jobs scales linearly to the given amount of resources, which does not hold for DLT jobs due to inter-GPU communication overhead. In general, optimal scheduling of online jobs is NP-complete [17].

Even though SRTF does not perform optimally in real-world systems, many practical cluster schedulers [21–24] leverage it as a good heuristic for reducing average JCT. Among them is Tiresias [24] designed for DLT job scheduling similar to this work. It suggests a variation of SRSF that considers remaining time multiplied by requested number of GPUs instead of remaining time alone. This approach penalizes jobs that request many GPUs. Compared to SRTF, SRSF improves average JCT because such jobs typically utilize GPUs less efficiently, thus it is often better to execute jobs using fewer GPUs instead for resource efficiency. Tiresias also focuses on relaxing the constraint of both SRTF and SRSF that job lengths should be known in advance. In comparison, our algorithms handle more general cases beyond penalizing the jobs with a large share. Also, our algorithms benefit from more fine-grained resource allocation and preemption, which substantially improves both average and tail JCTs.

Elastic sharing algorithms. Optimus [38], OASiS [8], and Themis [34] are DLT job schedulers that adopt elastic sharing similar to this work. Optimus estimates finishing time of a DLT job via modeling loss degradation speed and performing online fitting of the model during training, and designs a heuristic algorithm to minimize average JCT. However, the approach raises two issues. First, it is unclear whether it is always possible to reliably estimate loss degradation speed, which is also questioned by a follow-up work [24]. Second, Optimus has no mechanism to prioritize short jobs, which would often suffer from HOL blocking that results in JCT blowup. OASiS solves an integer linear program to maximize the system throughput. As maximizing system throughput often incurs severe starvation, it does not fit the goal of our work. Themis suggests a resource auction algorithm mainly motivated for fairness, but it actually achieves the closest JCT performance to AFS-P among all existing works. This is because it leverages elastic resource sharing for its partial auction algorithm and random distribution of leftover resources, prioritizes short jobs by setting a static lease duration of assigned GPUs, and also tends to prioritize efficient jobs since it is fairness-motivated, which prevents greedy jobs (which are typically resource-inefficient) from monopolizing resources. However, its optimization target is maximizing fairness, which is not always ideal for reducing average JCT. To be specific, if a job shows its largest throughput with m GPUs and the job has been running with other $n-1$ jobs on average over time, Themis's fairness metric tries to assign GPUs to this job until it achieves at least m/n times of throughput speedup.[13] Compared to AFS, this could give much higher priority to inefficient jobs which is fairer but it could degrade overall cluster performance.

Systems for elastic sharing. While there are several works which suggest an elastic sharing algorithm for DLT job scheduling [8,34,38], none of them fully cover the necessary systems support for elastic sharing: automatic scaling, efficient scale-in/out, and efficient reconfiguration handling. A recent work [36] implement an efficient method for scaling a single job without stop-and-resume similar to the ES in Section 5.3 of our work. However, it focuses only on scaling a single job, and does not cover handling churn events efficiently in multi-job scheduling. We believe the latter is the key to evaluating an elastic resource sharing system since its overhead hugely depends on the frequency of churn events as evidenced by the different amount of gain of either ES or RC in Figure 8a and 8b.

7 Conclusion

Existing scheduling policies have been clumsy at handling the sublinear throughput scalability inherent in DLT workloads. In this work, we have presented AFS, an elastic scheduling algorithm that tames this property well into average JCT minimization. It considers both resource efficiency and job length at resource allocation while it amortizes the cost of future jobs into current share calculation. This effectively improves the average JCT by bringing 2.2x to 3.1x reduction over the start-of-the-art algorithms. We have also identified essential systems features for frequent share adaptation, and have shown the design with CoDDL. We hope that our efforts in this work will benefit the DLT systems community.

[13]This does not cover all features of Themis. Refer to [34] for details.

Appendix

A Future Dependency of Job Scheduling

At first glance, it may appear as if we could find the optimal allocation of resource shares by taking into account all factors we discussed. We would simply need to know the lengths of all jobs that vary according to their GPU usage, enumerate all possible allocation candidates, and compare the resultant average JCTs to obtain the smallest.

Not only would such an attempt be infeasible due to the exponential growth of possible candidates,[14] a fundamental challenge underlies the usage of a GPU cluster in practice: churn by future jobs. They can wreak havoc on previous resource allocation decisions that otherwise would have been optimal.

To see this, let us consider a toy example. Suppose we have two jobs, A and B, initially submitted. With 1 GPU, each job takes 2 hours to finish. With 2 GPUs, they take 1 and 1.5 hours, respectively. Let us assume that we run them on a 2-GPU cluster. The optimal strategy to achieve the minimal average JCT of 1.25 hours would be SRTF: A is scheduled first (1 hour) with 2 GPUs and then B (1.5 hours). A naïve alternative that allocates all available resource shares equally to all pending jobs (assuming for the sake of simplicity that the number of pending jobs does not exceed the total number of shares) would achieve the average JCT of 2 hours. What if an unforeseen arrival of future jobs comes into the picture?

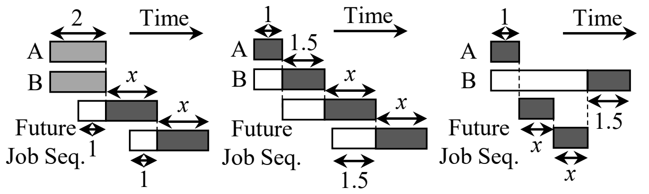
Suppose a sequence of identical future jobs were to arrive. They take 2 hours with 1 GPU and x hours ($1 < x < 2$) with 2 GPUs. Let us consider a scenario in which the first future job arrives 1 hour later since the beginning and all subsequent jobs arrive x hours later than the preceding one. Regardless of the value of x, the naïve alternative achieves smaller average JCT than SRTF (Figure 12a). SRTF would perform as in Figure 12b when $1.5 < x < 2$ and as in Figure 12c when $1 < x < 1.5$. This example demonstrates that even an optimal allocation, if it does not account for future job arrivals, can turn into a mediocre one. Thus, to design an algorithm that performs well in practice, one must incorporate the possibility of future job arrivals into her design.

B Impact of Resource Efficiency

To present how resource efficiency impacts the evaluation of (1) and (2), which decides which job (either j_a or j_b) gets the extra GPU, let us first define f_k as *fractional throughput gain* of j_k:

$$f_k = \frac{p'_{k,1}}{p_{k,1}}.$$

[14]The optimal online job scheduling is NP-complete [17]. A brute force search would require examining 10^{209} cases if we run 20 concurrent jobs on a 60-GPU cluster.



(a) Naïve. (b) SRTF, $1.5 < x < 2$. (c) SRTF, $1 < x < 1.5$.

Figure 12: Examples in which the optimal allocation of resource shares depends on the arrival pattern of future jobs. Dark gray, light gray, and white boxes indicate that the corresponding jobs use two, one, and zero GPUs, respectively.

This metric measures the marginal throughput j_k earns with respect to its current throughput when it is allocated an extra GPU. Intuitively, a larger value indicates a larger resource efficiency. This metric is constrained by $1 < f_k \leq 2$, as we consider regimes where an extra GPU increases training throughput and the throughput scales sublinearly to the allocated GPUs.

We rewrite (1) (j_b earns the extra GPU if it is positive) as follows:

$$\left(\frac{p_{b,1}}{p'_{b,2}}f_b - 2\right)f_a - \left(\frac{p_{b,1}}{p'_{b,2}} - 2\right). \qquad (4)$$

If no future job arrives, the share of an existing job would monotonically increase. Hence, $p_{b,1} \leq p'_{b,2}$ holds. Combined with $f_b \leq 2$, the terms in the parentheses are negative. This means that smaller f_a makes (4) more likely to be positive. Also, one can check that larger f_b makes (4) more likely to be positive. Put together, it concludes that j_b is more likely to get the extra GPU if its resource efficiency is relatively higher than that of j_a.

If future jobs do arrive, the share of an existing job may decrease (i.e., $p_{b,1} > p'_{b,2}$ may hold) to the point where (4) is always positive, hence j_b always gets the extra GPU. Aside from this case, similar arguments apply. Also, evaluating whether (2) is positive follows a similar line of arguments and leads to the same conclusion: resource efficiency matters.

C Transitivity of (3)

Since we use (3) as a job-to-job comparison function to select a single job j^* with the top priority in Algorithm 1, (3) should be transitive, otherwise we cannot guarantee that such j^* exists. As the transitivity of (3) looks non-trivial, we provide a simple proof here.

Problem. Given that:

$$\frac{p'_{b,1} - p_{b,1}}{p'_{b,1}} > \frac{p'_{a,1} - p_{a,1}}{p_{a,1}},$$

$$\frac{p'_{c,1} - p_{c,1}}{p'_{c,1}} > \frac{p'_{b,1} - p_{b,1}}{p_{b,1}},$$

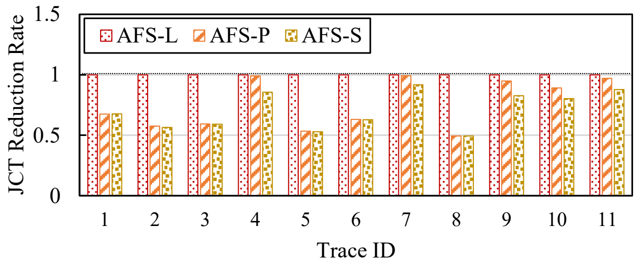


Figure 13: Rate of average JCT reduction from AFS-L with different scheduling algorithms using traces in Table 3 over a 64-GPU cluster.

prove:

$$\frac{p'_{c,1} - p_{c,1}}{p'_{c,1}} > \frac{p'_{a,1} - p_{a,1}}{p_{a,1}}.$$

Proof. As $p'_{b,1} \geq p_{b,1}$, the following holds true.

$$\frac{p'_{c,1} - p_{c,1}}{p'_{c,1}} > \frac{p'_{b,1} - p_{b,1}}{p_{b,1}} \geq \frac{p'_{b,1} - p_{b,1}}{p'_{b,1}} > \frac{p'_{a,1} - p_{a,1}}{p_{a,1}}.$$

□

D Discussion on AFS

AFS-L vs. AFS-P. Figure 13 compares the performance of AFS-L and AFS-P. We observe that AFS-P performs especially worse than AFS-L when there are many unfinished jobs in the cluster, which makes it more difficult for processor sharing of AFS-P to mimic the SRTF-like behavior of AFS-L. However, even in such cases, the average JCT blowup of AFS-P is curbed at twice the value from AFS-L in our experiments. It still outperforms other existing algorithms as demonstrated in Section 5.

Sensitivity to throughput measurement. Unlike legacy scheduling algorithms, AFS-P relies on throughput measurement to determine the resource shares. To evaluate the performance sensitivity to throughput measurement, we design AFS-S as a proof-of-concept algorithm. AFS-S is the same as AFS-P except that it only obtains the number of GPUs that lead to the maximum throughput for a job, rather than precisely estimating the throughput in relation to the number of GPUs. As it does not evaluate job throughputs, AFS-S ends up distributing the resources by the max-min fairness rather than enforcing fine-grained resource distribution of AFS-P. Figure 13 shows that AFS-S performs similarly to AFS-P in many cases. This implies that the performance of AFS-P is insensitive to detailed throughput measurement, rather contingent on figuring out the number of GPUs that gives rise to the highest performance.

Asynchronous training. As CoDDL automatically scales a DLT job instead of letting users do it manually, we need to select a default strategy for distributed training. We select bulk-synchronous-parallel (BSP) training over asynchronous training because its system throughput is equal to algorithmic training throughput. With asynchronous training, it is common that the system throughput increases linearly while the algorithmic training throughput does not, partly due to exchanging outdated parameter updates. This can be viewed as wasting GPU resources (requiring extra training iterations), similar to BSP's wasting GPU time on GPU-to-GPU communication. However, in case of asynchronous training, such a waste is difficult to be detected by the system, as it additionally requires evaluating algorithmic training performance (i.e. how fast training and/or evaluation accuracy improves, what is the final accuracy of the trained model, etc.). Optimus [38] suggests a method for measuring algorithmic performance by predicting the training loss curve, but it is unclear whether predicting the loss curve is always possible in theory, as is also questioned by a follow-up work [24].

E Removing Network Sharing

This section provides the details and the proof of the guarantee mentioned in Section 4.4 – the network packing regulation removes network sharing across the cluster, while providing a small constant bound of the difference from the originally-determined share to the regulated share for all jobs. We formulate the problem as follows. We assume a homogeneous GPU cluster where each machine is equipped with 2^k GPUs ($k \geq 0$). Given n jobs to share m machines ($n > 0$ and $m > 0$), say the scheduling algorithm originally assigns s_i GPUs to job i ($i \in \{1, \cdots, n\}$), where $\sum_{i=1}^{n} s_i = 2^k m$. Then, the controller applies the network packing regulation, adapting s_i to r_i that requires r_i to be one of zero, 2^ℓ ($0 \leq \ell < k$), or a multiple of 2^k, for all i. We prove two propositions as follow.

Proposition 1: removal of network sharing. Given r_i GPUs to job i for all i, there exists at least one GPU placement decision that the following conditions hold true. First, for all i, job i uses exactly $\lceil r_i/2^k \rceil$ machines, which is the minimum number required. Second, at most one job on any machine uses two or more machines.

Proof. We describe one of the feasible placement algorithms that makes this proposition hold true. Initially, no machines are assigned to any jobs. First of all, we discard all jobs that $r_i = 0$. For all i where r_i is a multiple of 2^k, assign $r_i/2^k$ machines to job i. Then, all those jobs and assigned machines already satisfy the two conditions of the proposition, so now we only consider the remaining jobs and machines. Since all remaining jobs are assigned less than 2^k GPUs each, to satisfy the first condition, we need to let each remaining job use only GPUs on the same machine – this is a bin-packing problem where each machine is a bin of size 2^k and each job is an item of size r_i. Fortunately, since r_i of all remaining jobs is a power of two less than 2^k, the bin size is always divisible by the item size, thus the simple first-fit-decreasing algorithm can always fit all remaining jobs to the remaining machines. This also satisfies the second condition at the same time because all remaining jobs do not use inter-machine networking and all remaining machines do not run any multi-machine jobs. □

Proposition 2: feasibility and difference bound. Regardless of the value of $\{s_1, \cdots, s_n\}$, there always exists at least one $R = \{r_1, \cdots, r_n\}$ that the following conditions hold true. First, the total number of assigned GPUs do not change due to the regulation, i.e. $\sum_{i=1}^{n} r_i = \sum_{i=1}^{n} s_i = 2^k m$.[15] Second, for all i, we guarantee the minimum value of r_i, say x_i, which is as follows:

$$r_i \geq x_i = \begin{cases} \left\lfloor \frac{s_i}{2^k} \right\rfloor 2^k, & \text{if } s_i > 2^k, \\ 2^{\lfloor \log_2 s_i \rfloor}, & \text{if } 0 < s_i \leq 2^k, \\ 0, & \text{if } s_i = 0. \end{cases}$$

Note that x_i is the maximum value that satisfies the network packing regulation while not exceeding s_i.

Proof. Say that we assign x_i GPUs to all job i, i.e. $r_i = x_i$. Then, R satisfies both the network packing regulation and the second condition of this proposition. However, since $x_i \leq s_i$, this may not satisfy the first condition of this proposition, i.e. this may remain unassigned idle GPUs and the number is $d = \sum_{i=1}^{n} s_i - \sum_{i=1}^{n} r_i$. Thus, we will prove that in any cases where $d > 0$, we can always reduce d by assigning more GPUs while always satisfying the network packing regulation and the second condition of this proposition.

If $d \geq 2^k$, we can reduce d to be lower than 2^k using two methods. First, assign 2^k more GPUs to any job i with $r_i \geq 2^k$. Since r_i is already regulated by the network packing (i.e. it is a multiple of 2^k), adding 2^k more GPUs to r_i will keep it to be a multiple of 2^k. Second, assign more GPUs to any job i with $r_i = 2^\ell$ $(0 \leq \ell < k)$ and $d \geq 2^\ell$ so that r_i increases to $2^{\ell+1}$. Note that at least one of these two methods is always usable unless d becomes less than 2^k.

If $d < 2^k$, we can only use the second method aforementioned to reduce d. Note that we cannot use the second method if $r_i > d$ for all job i. Thus, we need to prove that d becomes zero if $r_i > d$ for all job i. Actually, it is self-conflicted if we say $d > 0$ in that case. The total number of GPUs is $d + \sum_{i=1}^{n} r_i$ and it should be equal to $2^k m$, but it cannot be a multiple of 2^k if $0 < d < r_i$ for all job i because r_i itself is a multiple of 2^k or a power of 2 less than 2^k. □

F DLT Workload Details

All experiments carried out in this paper use the Philly DNN workload [5, 27], 137-day real-world DNN traces from Microsoft. It consists of 15 traces from different virtual clusters, and we use 11 of them as shown in Table 3 that contain 100 or more jobs. From the traces, we use submission time, elapsed time, and requested (allocated) numbers of GPUs of each job. Figure 14 shows that the DLT jobs in the workload tend to be heavy-tailed.

Since the traces do not carry training model information, we submit a random model chosen from a pool of nine popular DL models shown in Table 4 whose training throughput scales up to the requested number of GPUs. Each DLT job submits the chosen model for training in the BSP manner with the same batch size throughout training, even though the GPU share changes during the training. The number of training iterations of the job is calculated so that its completion time becomes equal to the total executed time from the trace, based on the use of the requested number of GPUs.

[15]This condition is needed to make sure that the regulation avoids embarrassingly inefficient adaptation that makes extra idle GPUs.

ATP: In-network Aggregation for Multi-tenant Learning

Abstract

Distributed deep neural network training (DT) systems are widely deployed in clusters where the network is shared across multiple tenants, i.e., multiple DT jobs. Each DT job computes and aggregates gradients. Recent advances in hardware accelerators have shifted the the performance bottleneck of training from computation to communication. To speed up DT jobs' communication, we propose ATP, a service for in-network aggregation aimed at modern multi-rack, multi-job DT settings. ATP uses emerging programmable switch hardware to support in-network aggregation at multiple rack switches in a cluster to speedup DT jobs. ATP performs *decentralized, dynamic, best-effort* aggregation, enables efficient and equitable sharing of limited switch resources across simultaneously running DT jobs, and gracefully accommodates heavy contention for switch resources. ATP outperforms existing systems accelerating training throughput by up to 38% - 66% in a cluster shared by multiple DT jobs.

1 Introduction

Traditional network design relied on the end-to-end principle to guide functionality placement, leaving only common needs implemented within the network, primarily routing and forwarding. However, datacenter networks and workloads have evolved, and there is a strong case to support common application functionality within the network [22, 41, 71].

Deep Neural Networks (DNN) are emerging as a critical component of more and more enterprise applications such as computer vision [33], natural language processing [26, 67], databases [65], compilers [66], systems [68], and networking [54]. These applications all require distributed DNN training (DT) to iteratively train better DNNs for improved prediction performance. Enterprises typically run DT on multi-rack clusters [12] shared by other applications. Each DT job has several workers and parameter servers (PS) spread across several machines. Workers compute gradients and send these gradients to the PS(s) over the network for aggregation. *Gradient aggregation*, which combines partial results from multiple workers and returns a single aggregated result, is commonly used in DT, and contributes substantially to overall training time [48]. Recent advances in special hardware [6, 12] have shifted the performance bottleneck of distributed training from computation to communication [48, 56]: VGG16 training can be $4X$ faster without network communication [56].

Further, datacenter networks are becoming feature-rich with the introduction of new classes of programmable network devices such as programmable switches (e.g., Intel's FlexPipe [8], Cavium's XPliant [13], Barefoot Tofino [4]) and network accelerators (e.g., Cavium's OCTEON and LiquidIO products [9], Netronome's NFP-6000 [10], and FlexNIC [43]). Together, they offer in-transit packet processing and in-network state that can be used for *application-level stateful computation* as data flows through the network.

Current DT stacks implement gradient aggregation purely in the application. However, the emergence of DT as a common application and its reliance on gradient aggregation, as well as the emergence of application-level stateful computation as a network feature, suggests an opportunity to reduce training time by moving gradient aggregation inside the network. This reduces network bandwidth consumption from workers to the PS(s). For both single DT and multiple DT jobs (i.e., multi-tenant settings) this bandwidth allows pushing more gradients through the network, and increases the total throughput of gradient flows thereby reducing training times.

Recent proposals show the initial promise of such in-network aggregation: e.g., SwitchML [56] increases training throughput for VGG16 by $2X$ via in-network aggregation on a programmable top-of-rack switch. However, the general problem of making aggregation a true in-network service to be leveraged by multiple DT tenants in a multi-rack/multi-switch cluster has not received systematic attention. Realizing such a service calls for mechanisms to share limited multi-switch aggregation resources across multiple tenants.

The key goal of our work is to speed up multiple DT jobs running simultaneously in a cluster by maximizing the benefits from in-network multi-switch aggregation, and distributing these benefits across multiple DT jobs in an equitable manner. To do so, we propose a new network service for multi-rack clusters called Aggregation Transmission Protocol, i.e., ATP. ATP supports *dynamic aggregation* at rack switches. DT jobs go through 'on' and 'off' gradient aggregation phases, and ATP uses decentralized mechanisms to ensure that switch resources used by a DT job entering its off phase can be dynamically reused by a DT job in its on phase. ATP supports *best-effort* aggregation. This enables DT jobs to gracefully fall back to end-host aggregation under heavy contention from many tenants without extra overhead.

*ChonLam Lao and Yanfang Le are co-primary authors, and Wenfei Wu is the corresponding author.

ATP chunks gradients for each DT job into fixed size fragments that we refer to as *gradient fragment packets* and partitions programmable switch resources into the same fixed size fragments called *aggregators*. As these gradient fragment packets flow through the network, ATP opportunistically aggregates them by accumulating results at the earliest available programmable switch, or in the worst-case at the PS end-host.

ATP proposes a decentralized aggregator allocation mechanism that supports aggregation at line rate for multiple jobs by dynamically allocating free aggregators when gradient fragment packets arrive at a switch. A key issue with an in-network aggregation service is that traditional end-to-end protocols do not work when gradient fragment packets are consumed in the network due to aggregation, as that may be misinterpreted as packet loss. Thus, ATP co-designs the switch logic and end host networking stack specifically to support reliability and effective congestion control.

We opensource ATP's implementation [2]. Our implementation works atop clusters using P4-programmable switches. Such switches expose a limited set of in-network packet processing primitives, place ungenerous memory limits on network state, and have a constrained memory model restricting reads/writes. We overcome these constraints, and show how ATP can support highly effective dynamic, best-effort aggregation that can achieve 60Gbps. Our implementation also has mechanisms that improve state-of-the-art floating point value quantization to support limited switch computation. ATP's implementation adopts a kernel bypass design at the end-host so that existing protocol stacks are not replaced by ATP's network stack and non-ATP applications can continue to use existing protocol stacks.

We run extensive experiments on popular DNN models to evaluate ATP in a single rack testbed with multiple jobs. Our evaluation shows that in multi-tenant scenarios, dynamic, best-effort in-network aggregation with ATP enables efficient switch resource usage. For example, the performance only decreases by $5-10\%$ when only half of the desired aggregators are available, and outperforms current state-of-the-art by 38% when there is heavy contention for on-switch resources. We simulate multi-rack cluster experiments with a typical topology and show a 66% reduction in network traffic with ATP. We benchmark loss-recovery and congestion control algorithms proposed in ATP. The loss recovery mechanism of ATP outperforms the state-of-the-art (SwitchML) by 34% and an ATP job with congestion control speeds up $3X$ compared to one without congestion control.

2 Background and Motivation

2.1 Preliminaries

PS Architecture. This design [39, 51, 62] as shown in Figure 1 enables data-parallel training, where training data is partitioned and distributed to workers. There are two phases: gradient computation, where workers locally compute gradients; and gradient aggregation, where workers' gradients are transmitted over the network to be aggregated (which involves the addition of gradients) at one or more end-hosts called parameter servers (PSs). The aggregated parameters are then sent back to the workers. Gradients are tensors, i.e., arrays of values. With multiple PSs, each PS has a distinct partition of parameters.

Programmable Switch. The recent emergence of programmable switches provides opportunities to offload application-level stateful computation [41, 47, 71]. A popular example is the Tofino switch [4], which we use. Programmable switches expose memory as stateful and stateless objects. Stateless objects, *metadata*, hold the transient state for each packet, and the switch releases this object when that packet is dropped or forwarded. Stateful objects, *registers*, hold state as long as the switch program is running. A *register* value can be read and written in the dataplane, but can only be accessed once, either for read or write or both, for each packet. A register is an array of values. In the context of in-network aggregation, each packet has a subset of gradient values and needs a set of registers to aggregate them. We call this set of registers an *aggregator*.

Programmable switches have constrained compute resources, memory($\sim$ 10MB [53]), and programmability for application-level processing. Register memory can only be allocated when the switch program launches. To change memory allocation, users have to stop the switch, modify the switch program and restart the switch program. The computation flexibility is limited by the number of stages, the payload parsing capability, and the time budget at each stage: only independent computation primitives can be placed in the same stage and the number of register accessed in the same stage is also limited. These limits lead to small packet sizes for in-network computation and storage applications: the payload size of SwitchML and NetCache is 128B [40, 41, 46, 56] [1].

In-Network Aggregation. Gradients can be seen as a sequence of fragments (each fragment has a subset of gradient values), and aggregation (addition of gradients) of all the gradients is the aggregation of each of these fragments. In-network aggregation for each fragment is done in a specific aggregator. Figure 2 exemplifies this for a DT job with two workers using one programmable switch. Workers 1 and 2 create packets having a fragment with 3 tensor values and send them to the switch. Suppose the switch first receives the packet $p1$ from worker 1. It stores the tensor values contained in $p1$ in the aggregator's registers $R1$, $R2$, $R3$. The switch then drops packet $p1$. When the switch then receives packet $p2$ from worker 2, it aggregates the tensor values contained in $p2$ with contents of $R1$, $R2$, $R3$. If there were additional workers, the switch would update the registers with the aggregation of both packets. In this example, because $p2$ is from

[1]The exact parameters of programmable switches and ATP are specific to "Tofino" programmable switches; if other programmable switches have similar limitations, ATP can be used similarly.

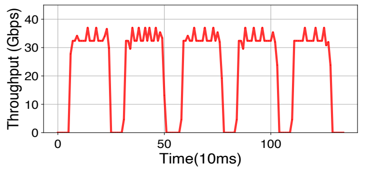

Figure 3: A DT job training VGG16 shows on-off communication pattern for a simple one worker-one PS setting.

the last worker, the switch overwrites the values in packet $p2$ with the aggregated result and multicasts $p2$ to both the workers. This architectural improvement not only reduces network traffic and eliminates the incast but also saves the CPU cycles used for aggregation operation at the end hosts. As this improvement only applies to communication, the *overall* training acceleration ratio depends specifically on the ratio of communication to computation in the DT job [28, 56].

A recent work, SwitchML [56], prototypes this idea for a single DT job in a rack-scale network. We use SwitchML as an example to illustrate the design space and underscore the key attributes of an ideal in-network aggregation service. SwitchML removes the PS by offloading gradient aggregation *entirely* to the top-of-rack switch. It allocates a static pool of aggregators in the rack switch to a DT job, and streams gradient fragment(s) from workers to the switch only after previously sent gradient fragment(s) are aggregated and have vacated aggregator(s) on the switch. We argue next that design choices in SwitchML need to be reconsidered in the multi-job and multi-rack settings, necessitating a systematic in-network service.

2.2 In-Network Aggregation as a Service

When applied to multiple DT jobs, SwitchML requires static partitioning of switch resources, where each job is statically assigned to a partition. In a multi-tenant scenario, this results in underutilization of switch resources. DT jobs go through on and off gradient aggregation phases as shown in Figure 3, and switch resources belonging to a DT job in the off phase can be shared with a DT job in the on phase in a *dynamic manner*, but static partitioning precludes this.

SwitchML offloads gradient aggregation for each DT job entirely to the rack switch. With heavy switch resource contention, DT jobs have to wait for switch resources leading to underutilization of the network link bandwidth from the workers to the PS(s). In a better design, a DT job could instead aggregate a fraction of gradients at the switch in a *best-effort manner* while aggregating the rest at the end-host.

Rack-scale solutions like SwitchML limit job scalibility and are not optimal in terms of traffic reduction for cross-rack jobs. Enabling aggregation service at every layer of the network topology complicates the service design and the network operation. ATP balances complexity and performance by enabling aggregation at the workers' and PS's ToR switches.

Thus, in the context of multi-job and multi-rack, an ideal in-network aggregation service should support *dynamic, best-effort, multi-rack* gradient aggregation for optimal efficiency and speedup. As we show in Section 3, realizing such an in-network aggregation service requires key innovations at end-hosts and in how switch resources are apportioned and dynamically (re)used. In addition, an in-network aggregation service brings to fore two other aspects of the network stack that need redesign, namely, reliability and congestion control.

Rethinking Reliability. In-network aggregation breaks end-to-end semantics as some packets are consumed inside the network during aggregation. Traditional end-host based reliability mechanisms can misinterpret in-network packet consumption as a packet loss, leading to unnecessary retransmissions and lead to incorrect gradient aggregation due to the inability of existing reliability mechanisms in dealing with these new class of packet events. Thus, we need a new *reliability algorithm* to deal with this new class of packet events.

Rethinking Congestion-Control. In the multi-tenant case, the network resources (switch aggregators and network bandwidth) available to a DT job fluctuates because (1) DT jobs exhibit on-off communication phases (Figure 3), (2) the total number of DT jobs varies, and (3) background traffic varies. Utilizing fluctuating network resources efficiently and sharing them fairly depends on congestion control. However, as end-to-end semantics are broken we cannot use traditional congestion control algorithms that rely on RTT or drops as the congestion signal. We need a new *congestion control algorithm* that identifies the right congestion signal so as to modulate the throughput of gradient fragments from workers' for each DT job to meet the requirements of efficient use and fair division of network resources across DT jobs.

3 Design

ATP is a network service that performs *dynamic, best-effort aggregation* across DT jobs. ATP's design aligns with guidelines for building robust and deployable in-network computation [53]: (1) offload reusable primitives: ATP is a network service for in-network aggregation and a common function to different DT frameworks; (2) preserve fate sharing: ATP is able to progress in the event of network device failure via fallback to aggregation at the end-host; (3) keep state out of the network: ATP's end-host reliability algorithms are able to recover lost data and deal with partial aggregation; (4) minimal interference: ATP chooses aggregation only at Top-of-Rack (ToR) switches to sidestep issues owing to probabilistic routing in the network.

3.1 ATP Overview

ATP lies in the transport layer which specifically targets in-network aggregation of gradient tensors in DT applications; it is not a general-purpose transport. Compared to general-purpose TCP: (a) ATP redesigns specific transport features, such as reliability, congestion control, and flow control for its target context. (b) ATP does not implement TCP's in-order byte-stream and multiplexing abstractions as they do not apply to the target context.

ATP performs aggregation at the granularity of fragments of a gradient that fit in a single packet, i.e., *gradient fragment packets*. ATP chunks the gradient tensor at each worker into a sequence of fixed-size fragments such that each fragment fits in a packet and assigns each a sequence number. Gradient aggregation for a DT job merges values at the same sequence number from each worker's tensor.

Upon booting, each ATP programmable switch allocates a portion of switch register memory to be shared by ATP jobs. This memory is organized as an array of fixed-size segments, which we refer to as *gradient fragment aggregators*, or just *aggregators*. Each aggregator is accessed by its index in the array, and aggregates gradient packets with a specific sequence number belonging to the same DT job.

ATP workers stream gradient fragment packets to the PS(s)[2]. ATP aggregates gradient fragment packets inside the network when in-network resources are available. If in-network resources are unavailable, gradient fragment packets are sent to the end-host PS for aggregation. ATP restricts in-network aggregation to ToR programmable switches. This means that gradients from each worker can at most be aggregated at two levels – (1) the rack switch at the worker and (2) the rack switch at the PS. This requires coordination of decisions to ensure that each gradient fragment packet is aggregated *exactly once*. We use a decentralized, dynamic, best-effort approach to determine where aggregation occurs.

Gradient fragment packets contains *direction* fields. These directions interact with the ATP switch logic at the programmable switches, to program *soft-state* in the aggregator to elicit a coordinated decision. The aggregator soft-state can be discarded at any time, leading to aggregation at the PS instead of the switch. The directions in a gradient fragment packet comprise fields that help switches decide whether to aggregate the packet, in which gradient aggregator to aggregate, and to identify completion or failure of aggregation at an aggregator. Switch logic uses these directions to program soft-state in the switch that identifies whether a gradient aggregator already exists for an incoming gradient fragment, and keeps track of intermediate aggregation results and completion of aggregation.

Soft-state in switches and directions in packets ensure that

[2]Note that two gradients from different workers that will be aggregated never meet at switches in ring all-reduce architecture [58]. To the best of our knowledge, any in-network aggregation, as well as ATP, can not apply to ring all-reduce architecture.

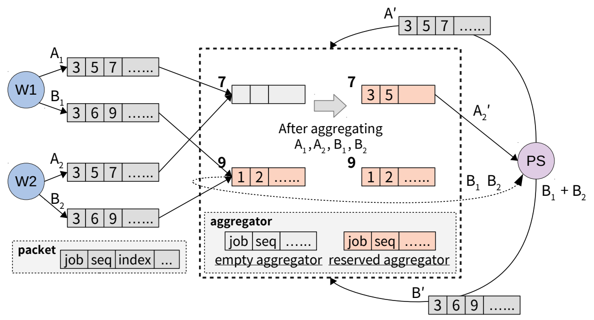

Figure 4: ATP dynamic, best-effort aggregation example. The *directions* fields are *job ID, sequence and aggregator index* in packet. *soft-state* is the values in the aggregators.

ATP does not require job-specific switch program changes (and avoids switch restarts) upon job arrival/departure.

Figure 4 exemplifies how ATP achieves dynamic, best-effort aggregation. A job with ID 3 has two workers, $w1$ and $w2$. The workers compute gradients which are subsequently broken by ATP at end hosts into two packets each - (A_1, B_1), and (A_2, B_2). ATP aggregates gradient packets A_1 with A_2, and B_1 with B_2, either at the switch or at the PS, as explained next. Packets A_1 and A_2 are routed and hashed to aggregator 7; since the aggregator is empty, it is "reserved" by packet A_1 by changing the aggregator's *soft-state* to its job ID and packet sequence. When A_2 arrives at the switch, it hashes to the same aggregator and triggers aggregation; then, the resulting packet containing the aggregation result, A_2', is sent to the PS. In contrast, packet B_1 can not reserve aggregator 9, because it is reserved by a packet with job ID 1 and sequence 2. Thus, packet B_1 is forwarded directly to the PS; the same occurs with B_2. Packets B_1 and B_2 are aggregated at the PS. For either pair of packets, the PS sends the parameter packets (A' and B') via multicast back to workers $w1$ and $w2$. When the switch receives A', aggregator 7 is deallocated and set as empty (i.e., A' is hashed to aggregator 7, and the aggregator's job ID and sequence match with those in A') to enable aggregator 7 to be used by future fragments from another job.

To detect and deal with packet losses ATP uses time-out based retransmission or out-of-sequence parameter ACK packets from the PS. When a packet is retransmitted, it sets the resend flag. This serves as a direction for the switch to deallocate and transmit any partially allocated result to the PS. Also, to deal with congestion, say if queue depth is above a certain threshold when packet A_2 is received, an ECN flag in A_2 is set and carried over to A_2'. This is copied to the parameter packet A' in PS and received by the workers who adjust their windows. The window adjustment is synchronized in both the workers as it is triggered by the same ECN bit in A'.

3.2 ATP Infrastructure Setup

ATP requires a one-time static setup involving programming and restarting switches to bring the service up. Any dynamic per-job setup is managed by inserting the appropriate job-specific directions in gradient fragment packets.

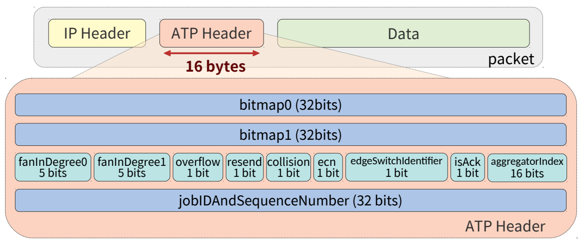

Figure 5: ATP packet format.

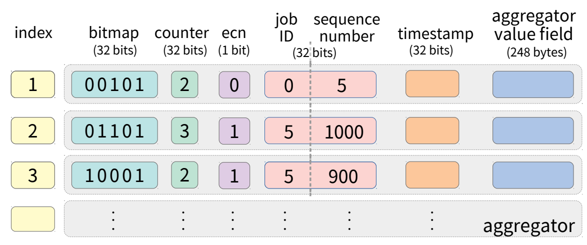

Figure 6: ATP Switch memory layout.

Static Infrastructure Setup. The infrastructure, comprising the switches and the end-host networking stack, is configured once to serve all ATP jobs. Each programmable switch installs a classifier to identify ATP traffic—gradient and parameter packets—and allocates a portion of switch resources—aggregators—to aggregate ATP traffic. The end host installs an ATP networking stack, which intercepts all the push or pull gradient calls from DT jobs. End-hosts have knowledge of the network topology—switch, end-host port connectivity, and total number of aggregators at a switch—so they can orchestrate aggregation across multiple switches.

Dynamic Per-Job Setup. Each new DT job is assigned a unique job ID. The job assigns each worker an ID from 1 to W, where W is the total number of workers. The job tracks the location of workers in the network topology to build an aggregation hierarchy. In case workers and PS are spread across racks, the job can use multiple switches for in-network aggregation. The ATP networking library computes the job's worker fan-in at each level of the aggregation hierarchy, which is used to determine when aggregation is complete (§3.5). ATP uses IGMP to build a multicast distribution tree for the PS to return parameters to workers.

3.3 Data Structures

Packet Format. Figure 5 shows the gradient fragment packet format. The ATP header fields comprise directions and contain metadata about the fragment. The `jobIDAndSequenceNumber` field is the identifier of a packet and is used to match gradient packets from different workers on the same job. The `Data` field contains tensor values (or aggregated tensor values).

One-hot encoding is used to identify the worker's position in the aggregation hierarchy (`bitmap0`), and the first-level switch's position at the second edge switch (`bitmap1`). The fan-in degree indicates the number of workers attached to the first edge switch (`fanInDegree0`) and workers or switches attached to the second edge switch (`fanInDegree1`). These four fields are used to determine when aggregation has completed (§3.5). The `edgeSwitchIdentifier` flag is set to 0 if the packet is en-route to the first edge switch in the aggregation hierarchy and 1 if the packet is en-route to the second edge switch.

Workers detect dropped packets when they receive out-of-order parameter packets, which triggers them to resend gradient packets for aggregation (§3.7). The `resend` flag is set if it is a retransmitted gradient packet. The `ECN` flag is marked by a switch when the switch's output queue length exceeds some threshold, which is used for detecting network congestion. The `collision` flag is marked by a switch when it forwards a gradient packet onward due to the aggregator not being available because it is in use by a different job. This flag helps PS choose another aggregator to avoid collision in the next round.

Parameter packets use the same packet format, but indicate the different contents by setting the `isAck` flag. They are multicast from the switches to workers when an aggregation is complete, and serve as acknowledgments (ACKs) for the gradient packets sent by the workers.

Switch Memory. Figure 6 shows the switch memory layout. Switch memory is organized as an array of fixed-size aggregators, each accessed by its index in the array. The `value` field contains aggregated data from different workers. The size of the value field is the same as that of a gradient fragment value. The `bitmap` field records which workers have already been aggregated to the aggregator's value field. The `counter` field records the number of distinct workers included in the aggregated value. The `ECN` field records congestion status and is set if any aggregated packet had the `ECN` flag set. The `timestamp` field is updated when an aggregation is performed, and is used to detect when an aggregator has been abandoned (e.g., when all workers fail) and can be deallocated (§3.7). The identifier fields <`Job ID, Sequence Number`> uniquely identify the job and the fragment that this aggregator serves.

3.4 Inter-rack Aggregation

Scaling aggregation beyond a single rack provides more flexibility w.r.t. where DT executes in a cluster. Aggregating just at a worker's local ToR switch is simple, but leads to unnecessary network traffic to the PS when workers reside in different racks. Alternatively, aggregation can be done at higher layers of the network topology. However, this approach would greatly increase protocol complexity because the system has to handle route changes in the interior of the network. For example, ECMP-based routing can change the number of gradient streams incident at a particular switch in the interior of the network. This necessitates careful coordination between network routing and the aggregator allocation mechanism. Thus, ATP only deploys in-network aggregation in ToR switches, either at the worker's rack (first-level) or at the PS's rack (second-level). This complies with a recent study which shows that programmable switches today are

usually deployed at ToR switches for near-server computation offloading [27].

To coordinate where aggregation occurs, ATP uses two groups of `bitmap` and `fanInDegree` fields in gradient packets, i.e., `bitmap0/1` and `fanInDegree0/1` as shown in Figure 5. The `edgeSwitchIdentifier` field indicates which bitmap and degree a switch should use when processing the gradient packet, the first or second level of aggregation. When a first-level aggregation switch forwards a packet, it sets the `edgeSwitchIdentifier` bit in the packet header. The bitmap size limits the total number of workers ATP can support. As our testbed switch supports only 32-bit values, our implementation can support up to 1024 (=32×32) hosts; in general if the programmable switch can support n-bit values, ATP can support up to n^2 workers.

It is worth noting that ATP's multi-rack aggregation can be extended to more levels as long as the aggregation point is the fixed waypoint in the routing. As ATP's switches in two levels behave differently when handling packet retransmission (§3.7), switches whose level is higher than two should follow the logic in the second level. More details can be found in §A.2.

3.5 Switch Logic

Switch logic implements the algorithm that supports the *dynamic, best-effort* in-network aggregation service. It provides aggregator allocation, deallocation, and gradient aggregation. The allocation policy in ATP is First-Come-First-Serve without preemption: if a gradient fragment packet can reserve an aggregator, it keeps the aggregator until it is deallocated. In the ideal case, each edge switch completes aggregation of all incident worker gradient packets and sends the aggregated result downstream. We describe how failure cases (e.g., packet loss) are handled in §3.7. A detailed flowchart outlining switch logic can be found in Figure 7.

Aggregator Allocation. The arrival of a gradient fragment packet triggers aggregator allocation. When a gradient fragment packet arrives, the switch checks the availability of the aggregator at the packet's `aggregatorIndex` field. End-hosts compute `aggregatorIndex` as HASH(<`Job ID, Sequence Number`>)%`numAggregators`, which is consistent across all workers in a job. However, hash collisions could cause `aggregatorIndex` from different fragments and different jobs to map to the same index: e.g., in Figure 4, gradient fragment packets of Jobs 1 and 3 collide at index 9.

If the identifier field <`Job ID, Sequence Number`> in the aggregator is empty, we store the packet's identifier in the aggregator, and copy the gradient packet's `data` field into the aggregators `value` field. The switch copies the bitmap field in the aggregator from the appropriate bitmap field in the packet (`bitmap0` if `edgeSwitchIdentifier` is 0, else `bitmap1`), and initializes the counter to 1.

If the aggregator's identifier field is non-empty, the switch compares it to packet's identifiers (box ① in Figure 7). If they are different, there is a hash collision and ATP pushes the gradient fragment packet downstream to be processed at the PS. To avoid aggregation on this packet at the downstream switch and propagate the collision information to the PS, ATP sets `resend` and `collision` flags. To indicate this packet came from a switch and not a worker, it flips the edge switch identifier in the packet (② in Figure 7) as well. If the aggregator and packet identifiers are equal, gradient aggregation occurs.

Gradient Aggregation. If an aggregator is available for a gradient fragment packet, ATP uses the `edgeSwitchIdentifier` to fetch the fan-in degree and the bitmap for this switch from the packet (③ in Figure 7). Then, ATP checks whether this packet has been aggregated by testing the packet's bitmap against the aggregator's bitmap (④ in Figure 7). If not, ATP aggregates (adds) the packet's gradient data to the `value` field in the aggregators and also or's the bitmap field in the gradient packet to the bitmap field in the aggregator (⑤ in Figure 7). ATP increments the aggregator's `counter` field. If the packet already been aggregated (e.g., it was resent), ATP `OR`'s the `ECN` field from the packet into the aggregator's `ECN` field and drops the packet (⑦ in Figure 7).

If the `counter` in the aggregator is less than the corresponding fan-in degree (⑥ in Figure 7), ATP drops the gradient fragment packet and `OR`'s the `ECN` — this is the step that saves bandwidth to the PS. If, however, they are equal then aggregation at this switch is complete and ready to be pushed downstream. The switch replaces the packet's data field with the aggregator's value field, and the corresponding bitmap field with the aggregator's bitmap and sends the packet downstream towards the PS.

ATP chooses to forward the complete aggregation results to the PS instead of sending them back to workers. This design makes the aggregation results stored at the PS. When a parameter packet to workers is dropped, the PS can resend the aggregation result.

Aggregator Deallocation using Parameter Packets. The switch multicasts parameter packets back to the workers when it receives parameter packets from PS. A parameter packet works as the acknowledgement (ACK) of the gradient fragment packets, and must traverse the edge switches used for aggregation. When an ATP switch processes a parameter packet, the switch checks if the aggregator at the packet's index has a matching identifier, and if so deallocates the aggregator by changing all fields to null (⑧ in Figure 7).

3.6 End Host Logic

Workers in ATP push gradient fragment packets toward the PS and receive updated parameters back. The PS accepts gradient fragment packets, as well as partially or fully aggregated packets, to compute the full aggregation and sends the updated parameters back to workers. The PS also addresses collisions over aggregator indexes by *rehashing*.

Worker Pushing Gradients. The ATP end-host network stack obtains gradients by intercepting push or pull calls from DT jobs. It chunks these gradients into a sequence of 306B packets (58B header + 248B gradient values). ATP converts floating-point numbers in gradients to 32-bit integers [56] to work with switches that do not support floating-point operations. These gradient fragment packets are small and ATP introduces optimizations for high packet I/O throughput (§4).

PS Updating Parameters. ATP allocates an area of memory for each job at the PS for collecting aggregated gradients as an array of <`bitmap, value`> indexed by sequence number. The bitmap tracks which workers' gradient fragments have been aggregated in the `value` field. PS maintains a bitmap for each value to track which worker values have been aggregated. When a gradient fragment packet arrives, the PS compares its bitmap with that of the packet for an overlap. If they do not overlap, the PS aggregates the packet's data into its stored value, and updates the stored bitmap from the packet's bitmap. For example, if the incoming gradient packet is an individual gradient packet, PS checks if a packet from that worker was already aggregated (i.e., PS bitmap for the worker is set to 1) due to a resent packet, drops duplicates and otherwise updates the value and bitmap. On completion of aggregation of a parameter fragment, the PS sends the updated parameter fragment to the switch, which multicasts back to all workers in the job.

For a single gradient fragment, it is possible that the aggregator is busy when the first few packets arrive (hash collision), but available for later packets (released). In this case, the first packets are forwarded directly to the PS, while the remaining ones are aggregated at the switch. However, without intervention the switch will never send along the aggregated values because it is waiting for *packets that have already been sent*. Workers detect this stalled aggregation when they receive parameter packets for higher-sequenced fragments, and all workers will treat the stalled fragment as *a loss*. Each worker retransmits the stalled fragment with the `resend` bit set. This ensures completion of aggregation (by piggybacking on packet loss recovery; §3.7).

To reduce the frequency of aggregator collisions, we propose a *dynamic hashing scheme*. PS checks the `collision` bit of gradient packets. If the `collision` bit is set, the PS rehashes to get a new aggregator index (as HASH(<`aggregatorIndex`>)%`numAggregators`). It sends this new `aggregatorIndex` to workers in the unused `bitmap` field of the parameter packet. Workers remap the collision-prone index to the new index, and send any subsequent gradient that would have been sent with the old index with the new index instead. This simple approach helps *evolve* the hash function in a dynamic manner over time at each worker, making it collision-resistant.

Worker Receiving Parameters. The network stack maintains a sliding window over the sequence of gradient fragment packets. After sending an initial window of packets, the worker records the first un-ACKed sequence number as the *expected sequence number* and waits for parameter packets from the PS. The worker uses the parameter packets from PS to slide the window and send new gradient packets. When a worker receives a parameter packet, it checks if the packet has the expected packet sequence number. If the parameter packet was already received (e.g., because it is lost by some other worker and retransmitted at that worker's request), it is ignored. If it has the expected number, the worker increases the expected sequence number and invokes the congestion control algorithm (§3.7) to update the current window. If the number of in-flight packets is less than the congestion window, ATP sends the remaining window (congestion window size - in-flight packets) of gradients fragment packets. If the parameter has a sequence number higher than expected, ATP may consider the expected gradient fragment as lost, triggering loss recovery (§3.7).

3.7 Reliability and Congestion Control

Reliability. Due to loss of gradient fragment or parameter packets, the PS may not send parameter packets in sequence. As noted previously, when this occurs, a worker updates the received parameters but does *not* update expected sequence number. When a worker receives three consecutive parameter packets other than the expected sequence number, it detects loss of the gradient fragment with the expected sequence number. In this case, ATP worker retransmits the missing fragment packet with the `resend` bit set; this indicates to switches that there may be a partial aggregation state in the switch.

ATP takes a simple approach and does not try to do in-network aggregation of resent gradients. This design considers the case that packet drop is due to one or more worker failures, where worker recovery can take a significant amount of time (§A.3). In this case, the remaining active workers still keep retransmitting gradient packets, but the switch cannot complete the aggregation. The aggregators are occupied but do not perform effective aggregation, which wastes the aggregator.

ATP takes different steps at the first and second levels of aggregation. At the first level, when a resent packet arrives, the switch checks for a matching aggregator. If it exists, and the aggregator bitmap does not indicate that the resent packet's fragment has already been aggregated, then the switch aggregates the value from the packet into the aggregator, merges the bitmap from the packet into the aggregator's bitmap, forwards the results (which may be partial) downstream, and *deallocates* the aggregator. When subsequent resent packets arrive, the corresponding aggregator has already been deallocated, so the switch simply forwards the resent packet downstream.

At the second level, the switch is unable to merge partial results because it has one bit rather than a bitmap to indicate the aggregation status for each of its first-level aggregation. Instead, the second-level switch discards its aggregation state and forwards any resent packet (including partial aggregations from the first level) to the PS, where the aggregation ultimately completes. This ensures that upon packet loss, all gradient fragments are (re)sent to the PS and the aggregator for the fragment is deallocated.

The memory leaks can occur when a job stops abnormally before PS sends parameter packets to deallocate aggregators. Without any mechanism, the aggregator would remain occupied because the PS never ACKs with a corresponding parameter packet. To handle this, on every parameter packet, the switch checks the `timeout` value for the register specified by the parameter packet's index. Even if its job ID and sequence number do not match the parameter packet, the switch will deallocate the aggregator if the timestamp is older than a configured value.

Congestion Control. In a multi-tenant network, multiple ATP jobs and other applications share the network. They contend for various resources including network bandwidth, receiver CPU, and switch buffers. In ATP, multiple jobs also contend for aggregators at the switches.

High contention for aggregators in the switch can lead to a situation where aggregators cannot aggregate all traffic. This causes the traffic volume to increase, which will trigger queue length buildup in switches and packet loss due to switch buffer overflow. The observable symptoms in this case are similar to network congestion. Based on this, ATP uses *congestion control* to manage *all* contended resources.

In TCP, senders detect congestion using RTT, duplicated ACKs, or ECN marks, and respond by adjusting sending windows. For ATP, we pick ECN marks as the primary congestion signal. RTT measured from a worker sending a gradient packet to it receiving a parameter ACK packet will not work because it includes synchronization delay between workers. As all the workers receive the same parameter packet, using ECN ensures that all workers see similar congestion signals. We enable the ECN marking in switches, and use both ECN and (rare) packet loss as the congestion signal. To ensure that ECN marks are not lost during aggregation, ATP merges the `ECN` bit in fragment packets into the `ECN` bit in aggregator (⑦ in Figure 7), which is later forwarded to the PS when aggregation completes. This `ECN` bit is then copied to the parameter packet and eventually reaches all the workers.

Each ATP worker applies Additive Increase Multiplicative Decrease (AIMD) to adjust its window in response to congestion signals. The window size ATP starts at 200 packets, which at 300 bytes for each packet is within the bandwidth-delay product ($\sim$ 60KB) of a 100Gbps network. ATP increases window size by one MTU (1500 bytes or 5 packets) for each received parameter packet until it reaches a threshold, which is similar to slow start in TCP. Above the slow-start threshold, ATP increases window size by one MTU per window. When a worker detects congestion via ECN marking on a parameter ACK or three out-of-order ACKs, it halves the window, and updates the slow start threshold to the updated window.

3.8 Dealing with Floating Point

Gradient values are real numbers and DNN training frameworks offer several numerical types to represent them, each type offering varying trade-offs between range, precision and computational overhead. Gradient values are typically represented using 32-bit floating point type.

The current generation of programmable switches does not support 32-bit floating point arithmetic. Like prior work [56], ATP converts gradient values at each worker from 32-bit floating point representation to 32-bit integer representation by multiplying the floating point number by a scaling factor (10^8) and rounding to the nearest integer. The switch aggregates these 32-bit integers and PS converts the aggregated value back to 32-bit floating points by dividing by the scaling factor. ATP chooses a large scaling factor, i.e., 10^8, so as to minimize loss of precision as 32-bit floating point representation provides precision of 7 decimal digits [7]. A detailed justification of ATP's choice of scaling factor can be found in §B.1.

A large scaling factor can lead to the overflow of aggregated gradients. There are two alternatives to deal with overflows: proactive and reactive. The former (described in §B.2) is cautious and wastes opportunities for in-network aggregation by sending some gradient packets directly to the PS for aggregation. We explain the pitfalls of this mechanism in §B.2. Instead, ATP uses a reactive mechanism: all gradient packets are sent with the intention of aggregation at a network switch. If a gradient packet triggers overflow at an aggregator in the switch, we utilize a switch feature (*saturation*) to set the aggregator value to the maximum value or minimum value represented with 32-bit integers. If the aggregator value is saturated, any further gradient packets destined at this aggregator only update the directions (i.e., bitmap, fanIndegrees) and the value remains saturated. When the aggregation is done, i.e., fanInDegree value is equal to the number of workers, the saturated aggregator value is written to the gradient packet and sent to the PS. If the PS finds the aggregator value is saturated, it requests the original gradient values in floating-point format from all workers. This triggers a retransmission and all the workers send packets with floating-point gradient values directly to the PS, which finally performs aggregation.

In the worst case, such a reactive overflow correction incurs the cost of retransmission of all gradient packets in an iteration. Note that the overhead incurred during overflow correction is exactly the same as that during packet loss recovery. In our evaluations, we see no deterioration in training throughput if the packet loss rate is $< 0.1\%$ (§5.2.3). This translates to overflow correction as well: if the frequency of overflow correction is $< 0.1\%$ (over packets), we will see no deterioration in training throughput. We empirically show that there is hardly any overflow for all popular models' training in §5.3. The frequency of overflow correction can be further reduced using a dynamic scaling factor (§B.3).

Because overflow correction adds little overhead, ATP's in-network aggregation yields substantial speed-up in per-epoch times. Coupled with quantization not affecting the number of epochs, ATP overall yields significant gains in time-to-target-accuracy, as we also show in §5.3.

4 Implementation

ATP's implementation consists of (i) the protocol logic on P4 switches and end host, and (ii) hardware offloads to optimize small-packet performance.

Programmable Switch. The switch implementation has processing logic for gradient aggregation and control logic to allocate, deallocate, and manage aggregators. The main challenge is that the whole packet must be parsed in a limited time budget and processed in the limited switch pipeline stages.

Aggregation. Prior work [56] processed packets in a single pass, which limited packets to 184B. ATP increases this limit by taking two passes (called **two-pass**) at the switch for each packet, which is a mixed usage of the *resubmit* [3] and *recirculate* features. The details are in §C. This raises the maximum packet size to just 306B – larger, but still small packets. This leaves 4 switch stages for control operations.

Control logic. This is responsible for checking whether an aggregator is available, processing protocol flags, and updating the aggregation state. To work within the restriction of one-time access to a register, ATP applies various techniques to handle complex operations. Consider the bitmap check process, which involves a read of the bitmap in the aggregator and then an arithmetic operation on the gradient value and bitmap value; finally, a write to the bitmap in the aggregator. We instead note that a write to bitmap is equivalent to setting a bit always. This allows us to reorder the write operation to just before the read operation. This read-followed-by-write serves as one-time register access which is permissible. Another method in ATP to address one-time access restriction for one packet is to use two packets; e.g., ATP allocates the aggregator with gradient packets but deallocates the associated aggregators using parameter packets.

[3]We leverage ‘ force_shift ingress‘ feature to drop the data part that has been aggregated before the resubmit.

End-Host Networking Stack. We implement ATP as a BytePS [69] plugin, which integrates in PyTorch [15], TensorFlow [14] and MXNet [19]. BytePS allows ATP's use without application modifications. ATP intercepts the *Push* and *Pull* function calls at workers as they communicate with ATP PS.

Small Packet Optimizations. ATP's network stack leverages Mellanox's RAW ETHERNET userspace network programming model [1]. ATP uses **TSO** [50] and Multi-Packet QP (**MP-QP**) [42] hardware acceleration features to improve small-packet processing. TSO speeds packet sending by offloading packetization to the NIC and improves PCIe bandwidth via large DMA transfers. To improve packet receiving rate, MP-QP uses buffer descriptors that specify multiple contiguous packet buffers and reduce the NIC memory footprint by at least $512X$. These features together reduce CPU cost via fewer calls to send/receive packets and fewer DMA operations to fetch packet send and receive descriptors.

ATP uses multiple threads to speed up packet processing. When ATP receives tensors to transfer, it assigns the tensor to a thread to send, which may cause load imbalance across different threads. Each worker in ATP has a centralized scheduler to receive tensors from the application layer, and maintains the total workload for each thread. Whenever the scheduler receives tensors to be sent, it extracts the size and assigns the tensor to the least loaded thread to balance the load.

Baseline Implementation. We implement a prototype of SwitchML [56], which uses the switch as the PS and provides a timeout-based packet-loss recovery mechanism. We apply TSO and MP-QP features to the SwitchML implementation at end hosts to improve small-packet operations, but do not apply the two-pass optimization at the switch to align with the public version of SwitchML. As a result, the packet size for SwitchML implementation is 180 bytes. We also open-source our SwitchML implementation [3].

5 Evaluation

We evaluate ATP via testbed experiments and software emulation to answer the following questions:

1. How does ATP perform compared to state-of-the-art approaches for a single job (§5.2.1)?
2. How does ATP's inter-rack aggregation perform compared to an alternate rack-scale service (§5.2.2)?
3. What are the overheads of ATP's loss recovery mechanisms (§5.2.3)?
4. How does conversion to integers in ATP affect time to accuracy (§5.3)?
5. How does dynamic aggregator allocation compare to a centralized static scheme under multi-tenancy (§5.4)?
6. How effective is ATP's congestion control (§5.5)?

5.1 Experimental Setup

Cluster Setup. We evaluate ATP on a testbed with 9 machines. 8 of them have one NVIDIA GeForce RTX 2080Ti GPU with NVIDIA driver version 430.34 and CUDA 10.0.

All machines have 56 cores of Intel(R) Xeon(R) Gold 5120T CPU @ 2.20GHz, 192GB RAM with Ubuntu 18.04 and Linux kernel 4.15.0-20. Each host has a Mellanox ConnectX-5 dual-port 100G NIC with Mellanox driver OFED 4.7-1.0.0.1. All the hosts are connected via a 32x100Gbps programmable switch with a Barefoot Tofino chip. We evaluate inter-rack aggregation using Tofino's software switch model [5] to emulate ATP switches in software with the same code.

Baselines. We compare ATP against BytePS [69]; both use a worker-PS architecture. BytePS supports TCP (BytePS + TCP) and RDMA over Converged Ethernet (RoCE) [36] (BytePS + RDMA) as network protocols. We turn on PFC [25] for RDMA to provide a lossless network. While ATP uses the default of N workers to 1 PS (labeled Nto1), we optimize BytePS with as many PSs as the workers (labeled NtoN) to alleviate the network bottleneck. Also, we co-locate one each of the N PSs and N workers in the same machine. We also compare ATP with our implementation of SwitchML, a state-of-the-art baseline with in-network aggregation support. We also compare ATP against Horovod [58] with RoCE (Horovod+RDMA) and with TCP (Horovod+TCP) which uses a ring all-reduce architecture [61].

Workloads. We run Pytorch on top of the above schemes to evaluate many popular real-world models: AlexNet, VGG11, VGG16, VGG19, ResNet50, ResNet101, and ResNet152 [33, 44, 60]. Each model trains on the ImageNet dataset. The DT job has 8 workers unless specified. For most experiments we use VGG16 (model size 528MB) and ResNet50 (model size 98MB), as representatives for network-intensive and compute-intensive workloads, respectively. We also run an aggregation microbenchmark where each worker repeatedly transfers 4MB tensors (maximum size BytePS supports), which are aggregated in the network (ATP) or at the PS(s) (BytePS), and are then sent back to the workers. In contrast to real jobs, this microbenchmark has equal-sized tensors and always has data to send with no "off" phase.

Metrics. We use three metrics to measure performance: (1) *training throughput* for DT jobs, which is the number of images processed per second (*image/sec*) normalized by the number of workers; (2) *time to accuracy* to show a DT job's quality, which is the training time to reach a target or maximum accuracy; and (3) *aggregation throughput* for the microbenchmark, which is the total bytes of parameters received at each worker per second (*Gbps*).

5.2 Single Job Performance

5.2.1 ATP Training Performance

We compare ATP against all baselines on single-job training throughput for all the models in our workload as shown in Figure 8. ATP achieves the best performance for all jobs with a maximum speedup of 1.5X over BytePS NtoN RDMA, 1.24X over Horovod RDMA, 2.5X over BytePS NtoN TCP, 8.7X over BytePS Nto1 TCP, 4.2X over Horovod TCP and 1.5X over SwitchML. Performance gains are larger on network-intensive workloads (VGG) than compute-intensive workloads (ResNet). PS-based ATP is comparable to, and in many cases outperforms, the state-of-the-art ring all-reduce approach (Horovod+RDMA). ATP outperforms SwitchML due to support for larger packet size made possible via our optimized two-pass implementation of switch logic.

5.2.2 Inter-rack Aggregation

ATP provides aggregation at two levels in inter-rack configurations. We pick a typical network topology as shown in Figure 9, where the PS is connected to switch $SW2$ and workers $w0$-$w5$ are connected to different switches. We compare against a rack-scale solution (*RSS*) that aggregates locally at each rack and forwards partial aggregates to the PS. In our test topology, *RSS* performs aggregation for $w0$-$w1$ at $SW0$, $w2$-$w3$ at $SW1$, $w4$-$w5$ at $SW2$, and then, aggregation from $SW0$, $SW1$ and $SW2$ at the PS. This approach simplifies the algorithm at the switch at the cost of more network traffic to the PS. We measure the amount of traffic the PS receives with ATP and *RSS* using the software simulator (so we cannot measure real throughput). PS with *RSS* receives $3X$ more traffic than PS with ATP. This is because *RSS* sends the partial aggregates from $SW0 - SW2$ to PS while ATP aggregates individual packets from $w5$ and $w4$ and partial aggregates from $SW0$ and $SW1$ at switch $SW2$ before they are sent to PS; this eliminates $^2\!/_3$ of the traffic to the PS.

5.2.3 Packet Loss Recovery Overhead

ATP handles packet loss at the end host, but guarantees aggregation correctness and prevents memory leaks in the switch. To evaluate the overhead of packet loss recovery, we configure one worker to adversarially drop packets with a packet loss rate between 0.001% and 1% (as in prior work [56]). We compare against SwitchML, which uses a timeout mechanism to detect packet loss, and turn off ATP's congestion control to avoid window back-off due to this adversarial packet loss. We use the timeout value (1ms) from SwitchML.

Figure 10 shows the training and microbenchmark throughput normalized to no loss for varying loss rates. Overall, ATP degrades gracefully when the loss rate increases, and to a lesser degree than SwitchML. This is because ATP adopts out-of-sequence ACKs as a packet loss signal, which enables ATP to detect and respond to packet losses faster than SwitchML.

5.3 ATP Time-to-Accuracy (TTA)

5.3.1 Single Job TTA

ATP changes the nature of computation of gradient aggregation via conversion of gradient values to integers to enable aggregation on the switch and has reactive mechanisms to deal with overflows. To confirm this does not affect the training quality of our workload, we evaluate ATP's accuracy over time against the baseline (BytePS NtoN RDMA). We find that ATP spends the same number of epochs to achieve the same top-5 accuracy as BytePS NtoN RDMA for all the models. Figure 11 plots the top-5 accuracy with time for ResNet50,

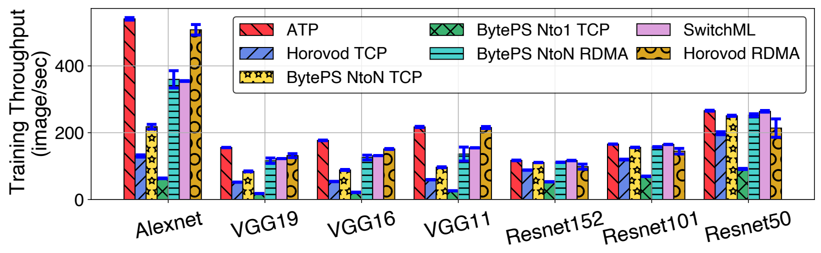

Figure 8: Single job throughput

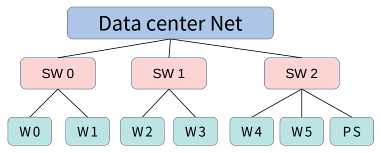

Figure 9: Multi-rack topology

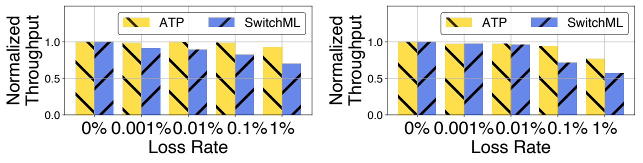


(a) VGG16 (b) Microbenchmark

Figure 10: Throughput in different packet loss rate.

VGG16 and ResNet152. With VGG16, a network-intensive workload, ATP outperforms BytePS and reaches 75% top-5 accuracy 1.25X faster than BytePS. With ResNet50, ATP and BytePS reach 93% top-5 accuracy in comparable amount of time (ATP is 1.02X faster) as shown in Figure 11a. ATP does not speed up training for ResNet50 as it is a compute-intensive workload. ResNet152 (Figure 11c) exhibits the same trend as ResNet50. We also conduct TTA experiments on VGG19, ResNet101 and AlexNet models, and observe that ATP reaches target accuracy 1.2X, 1.01X and 2.39X faster, respectively. Figures for these results are in §D.3.

Overflow Correction. Retransmissions due to ATP's overflow correction mechanism can be a source of overheads. In our results, we see overflows only with ResNet152, with 445 aggregated gradient packets (i.e., 0.00002% of all aggregated gradient packets generated in an epoch) requiring overflow correction. These happen only in the first few iterations of the first epoch when the model is initialized with random weights and the magnitude of gradient updates is large.

Worst-case Precision Loss. ATP uses a scaling factor of 10^8. Gradient values with a magnitude less than 10^{-8} are approximated as zero and experience complete loss of precision. We observe that an average of only 0.00002% of the gradients values per epoch in ResNet50 are less than 10^{-8}. As a result, ATP causes no loss of accuracy in the final trained model.

5.3.2 Multi-job Time-to-Accuracy (TTA)

We also evaluate TTA with 2 VGG16 jobs for ATP, BytePS NtoN RDMA, and Horovod with RDMA. Each job has three workers. We use one switch to emulate a dumbbell topology and separate one worker from the other two of a job at the two ends of the dumbbell. The link line rate is 100$Gbps$. A worker-to-worker (or PS) path from each job share the dumbbell link. Figure 12 shows the 75% top-5 accuracy with time for each VGG16 job. Similar as single job TTA performance, ATP outperforms BytePS and Horovod and reaches 75% top-5 accuracy 1.20X faster than the fastest BytePS job, and 1.25X faster than Horovod. Two jobs in ATP and Horovod achieve the same accuracy with the same training time, while this is not the case for BytePS. We observed PFC storms from NICs in BytePS, which we suspect is due to the heavy PCIe contention between NIC and GPU.

In summary, these results demonstrate that ATP does not compromise training quality and is able to achieve baseline training accuracy in less time than other methods owing to the acceleration provided by in-network aggregation.

5.4 Multiple Jobs

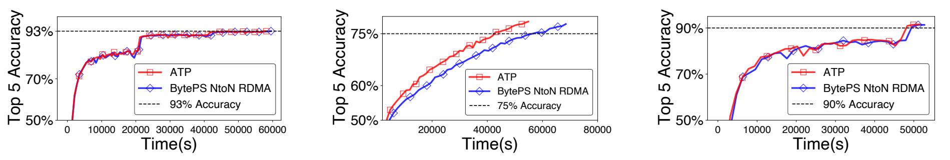
ATP does dynamic best-effort sharing of switch resources across multiple jobs. Our multi-tenant extension of SwitchML statically partitions switch resources equally across jobs.

5.4.1 Dynamic vs. Static Sharing

We compare ATP's dynamic best-effort approach against SwitchML's static approach by launching 3 identical VGG16 jobs (with identical placement for workers and PS) connected to one programmable switch. We vary the number of aggregators for the 3 jobs on the switch. The static approach allocates a fixed 1/3 fraction of the aggregators to each job, while ATP's dynamic approach shares these aggregators dynamically, so that when any job is in an off phase its aggregators are available to other jobs.

We first tune the number of aggregators reserved for the 3 jobs to find the minimum number needed to get maximal training throughput for each job with the static approach. We find that 1980 aggregators, referred to as *peak throughput aggregators* (PTA), equally divided across the three jobs maximize throughput because jobs saturate the link from the switch to the PS. To measure the impact of sharing strategy under contention, we reduce the number of available aggregators from 100% of PTA to 33% of PTA, and measure training throughput with both static and dynamic approaches.

Figure 13a shows the average training throughput (measured after warm-up, from the second epoch of training onwards) as we vary the number of aggregators available to the 3 jobs from 100% of PTA (1980 aggregators) to 33% of PTA (660 aggregators). With 100%, the dynamic approach performs similarly to static approach. This is because in both cases all aggregation happens in-network, and the switch to PS link is fully utilized. As we reduce the number of aggregators available, throughput for the dynamic approach degrades



(a) ResNet50 (b) VGG16 (c) ResNet152

Figure 11: Time to accuracy

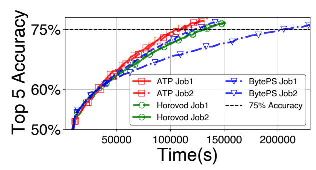


Figure 12: TTA with two VGG16 jobs

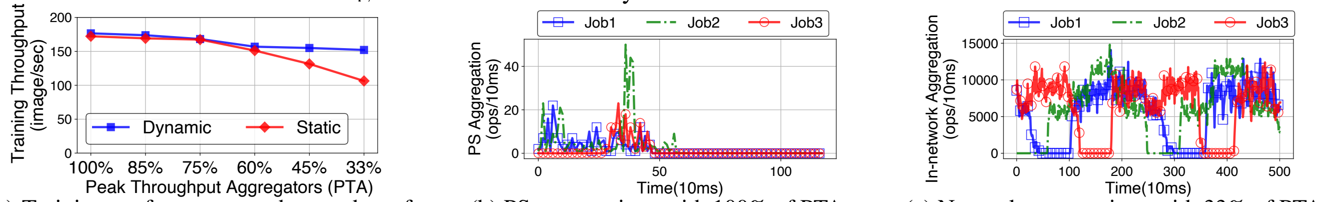

(a) Training performance as the number of PTA changes. (b) PS aggregations with 100% of PTA (c) Network aggregations with 33% of PTA

Figure 13: Dynamic v.s. static allocation with different peak throughput aggregators (PTA) ratio.

less than that with the static approach. This is because the dynamic approach allows sharing of unused aggregators across jobs and also uses available switch-to-PS link capacity for PS-based aggregation. We show this by delving into ATP's dynamic approach when using 100% and 33% of PTA.

Figure 13b shows the total number of aggregations at the PS every 10ms for each job with ATP's dynamic approach using 100% of PTA, starting at job warm-up. Initially, there are hash collisions because of jobs allocating the same aggregator index, which leads to aggregation at the PS. After 500ms, ATP's hash-collision avoidance kicks in and the dynamic approach converges to complete in-network aggregation.

Figure 13c shows how ATP's dynamic approach responds when jobs enter an off phase. The figure shows the number of aggregations performed at the switch every 10ms when only 33% of PTA are available. The trace shows that when one job enters an off phase (zero in-network aggregations), the number of in-network aggregations for the remaining jobs increases. For example, at sample 120, job 3 (red) enters an off phase, and the in-network aggregations for jobs 1 and 2 increase until job 3 resumes at sample 180.

5.4.2 Effectiveness of ATP's Hashing Scheme

In §5.4.1, we show ATP's hashing scheme works with 100% of PTA for 3 jobs. To evaluate at larger scale, we launch 8 microbenchmark jobs with 100% of PTA with ATP's hashing enabled (**Hash-based dynamic**) and without hashing enabled (**Linear-based dynamic** which allocates aggregator indexes in sequence, i.e., index = seq_num % N), and compare against the baseline scheme (static allocation with 100% of PTA).

Figure 14 plots the aggregation throughput for the three schemes as the number of jobs increases. ATP's hash-based scheme matches the baseline static scheme and greatly outperforms the linear-based scheme, as without hashing, a continuous sequence of gradients from multiple jobs collide, introducing a significant amount of retransmission. Overall, these experiments indicate that the dynamic hash function can effectively distribute aggregators to each job. It can achieve

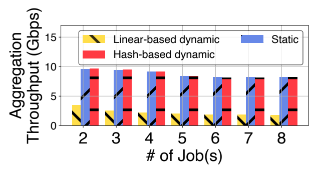

Figure 14: Large scales

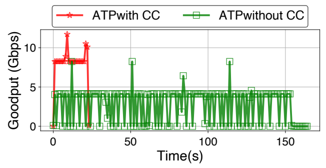

Figure 15: ATP job with and without congestion control

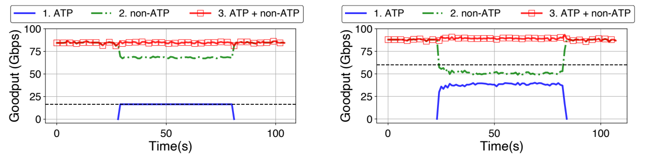

(a) ATP: VGG16 (b) ATP microbenchmark

Figure 16: Aggregation goodput with non-ATP traffic.

comparable performance to the static approach when there is no contention for switch aggregators, and outperform the static approach under contention.

5.5 Effectiveness of Congestion Control

ATP's congestion control mechanism aims to minimize packet loss while maximizing the link utilization. Network congestion happens (1) when ATP traffic is co-located with bandwidth-hungry normal traffic, such as TCP or RDMA transfers; (2) when ATP does not perform in-network aggregation due to a shortage of switch resources from other contending ATP jobs, causing an incast to the PS. We evaluate ATP's congestion control mechanism in both cases.

With non-ATP traffic. It is common to co-locate multiple systems and applications in a multi-tenant multi-rack cluster, such as storage and data pre-processing systems. We validate ATP's congestion control effectiveness when co-locating with such traffic. We launch a training job with 6 workers and 1 PS for ATP. We add background flows competing for bandwidth on a link to a worker, which individually can achieve line rate. The experiment starts with background traffic, and then starts a training job at $t = 25$s. We stop the training job after 50s.

We perform this experiment both with VGG16 and with our microbenchmark to emulate large models on ATP.

Figure 16a reports the aggregation goodput (total size of parameters aggregated in a second) from the worker that experiences network congestion for VGG16 (ATP), the goodput from the non-ATP traffic (non-ATP), and the aggregate goodput (ATP + non-ATP) over time. The dashed black line shows the peak goodput VGG16 job can achieve without background traffic; this link bandwidth demand is less than fair share. We see that the VGG16 job with ATP is able to achieve peak goodput (as demand is less than fair share) and that the sum of goodputs is close to line rate on the uplink from this worker. This indicates that ATP's CC is able to co-exist with non-ATP background traffic with max-min fair allocation in this setting.

Figure 16b plots the same scenario instead with the microbenchmark job. The dashed black line shows the peak goodput this job can achieve without background traffic, which is indicative of a link bandwidth demand greater than fair share of the network uplink rate at the worker. We see that ATP is able to achieve near the fair share of the bottleneck link (the uplink from this worker) and that the sum of goodput from both traffic types is close to link rate. This showcases near equitable sharing of link bandwidth. Figure 16a and Figure 16b show that the congestion control of ATP is able to respond quickly to changes in congestion, and converge to a new bandwidth which is very stable.

With other ATP traffic. We launch a single VGG16 job (8 workers) using ATP for 10 iterations. We reserve only 50% of the switch aggregators needed to achieve peak training throughput with complete in-network aggregation (to emulate contention from background ATP jobs). Figure 15 shows the aggregation goodput averaged per second from a single worker against time with and without congestion control (CC). We see that the congestion control of ATP kicks in, and the aggregation goodput stabilizes around 7.5Gbps for the worker. Note that this goodput is lower than the peak goodput ($\sim$20Gbps) from the previous experiment because here we have an 8-to-1 (8 workers to 1 PS) incast, only 50% of traffic is reduced in the network, and the PS in our implementation saturates at 60Gbps (§D.1).

Without CC, the goodput fluctuates dramatically between 4Gbps and 0; this is because incast causes frequent packet loss without congestion control, and introduces high packet loss recovery overhead. The training goodput of ATP with congestion control is 66.8 img/s while that without congestion control is 23.2 img/s, a decrease of 65%. These results show that the congestion control for ATP can effectively maintain high goodput and is effective in avoiding packet loss.

In summary, ATP's congestion control helps it co-exist with other tenants (both ATP and non-ATP).

6 Other Related Work

We discuss prior works that propose advances in hardware, software, offloads, and algorithms to accelerate DNN training.

Speedup Network Transmission. Prior efforts propose to improve gradient aggregation time by (1) smarter network scheduling – increasing the overlap between GPU/CPU computation and network transmission via fine-grained tensors transmission scheduling (per layer instead of the whole gradient or parameter) [32, 37, 52, 70]; combining model- and data-parallelism via pipelining [31, 35]; using asynchronous IO [20, 24]. (2) reducing network traffic – using large batch size to reduce the communication frequency [11, 29, 38]; using quantization [57] or reducing redundancy in SGD [45] to reduce bytes sent over the network; optimizing mixture of local-global aggregation to adapt to network change at runtime [21, 64]. ATP can incorporate these optimizations to further improve its performance.

In-network Aggregation. The idea of in-network aggregation has been explored in wireless networks [18, 59]; in big-data systems and distributed training systems using end-hosts [23], a specialized host [48], high performance middleboxes [49] or overlay networks [17,63]. DAIET [55] proposed a simple proof-of-concept design of in-network aggregation without a testbed prototype. ShArP [30], supported by special Mellanox Infiniband switches, builds an overlay reduction tree to aggregate data going through it, but it does not apply the aggregation until the switch receives all the data. ATP is the first to provide a *dynamic, best-effort* in-network aggregation service for multi-tenant multi-switch clusters.

7 Conclusion

We build an in-network aggregation service, ATP, to accelerate DT jobs in multi-tenant multi-rack networks. ATP provides a *best effort in-network aggregation* primitive via careful co-design of switch logic (for aggregation) and the end-host networking stack (for reliability and congestion control). Testbed experiments show that ATP is able to outperform existing systems by up to $8.7X$ for a single job, and it is even slightly better than the current state-of-the-art ring all-reduce with RDMA. In a multi-tenant scenario, best-effort in-network aggregation with ATP enables efficient switch resource usage, and outperforms current state-of-the-art static allocation techniques by up to 38% in terms of training time when there is heavy contention for on-switch resources.

A Additional Design Details

This section is a supplement to ATP's design description from §3. We first provide additional design details for clearer exposition and then outline design extensions to make ATP more general and robust.

A.1 Switch Algorithm for Reliability

Figure 17 explains the details on how the switch handles the three issues discussed in Section 3.7. If the retransmitted gradient fragment packets have an aggregator at switch (① in Figure 17), ATP uses the bitmap in the gradient fragment packet header to check if bitmap field in the aggregator is set (⑤). If unset, the data field element is aggregated to the value field of the aggregator and the bitmap field in the aggregator is set (⑥). After aggregation or if the retransmitted gradient has already been seen, ATP copies the value field and the bitmap field from the aggregator to the data field and the bitmap field of the packet, deallocates the aggregator, and sends the packet downstream (⑦). Given that only the first retransmitted gradient packet triggers aggregator deallocation, the retransmitted packets with the same sequence number from other workers do not hit the aggregators or reserve a new aggregator and thus, they will be directly forwarded to upstream devices. Note that at the second level of aggregation, ATP directly forwards a retransmitted gradient packet for simplicity (③). In all the cases, ATP deallocates the aggregator and sets all fields to null (③ and ⑦).

The parameter packet, whether it is retransmitted or not, always triggers the deallocation of the aggregator with the same <Job ID, Sequence Number>.

A.2 Aggregation at Multiple Hierarchy Levels

ATP can be extended to support aggregation at multiple hierarchy levels, i.e., beyond ToR switches to also enable aggregation at aggregation layer switches and core layer switches. The only pre-requisite is that packet routes for all gradient packets have to be deterministic (e.g., as in ECMP) and known ahead of time so that ATP knows the exact switch in the network at which gradient packets (or partially aggregated gradient packets) for a particular sequence number converge. This helps to precisely determine the fan-in degree at each intermediate switch from workers to the PS. This helps higher-level switches to aggregate partially aggregated results from lower-level switches and determine when aggregation at higher-level switches is complete. To enable multi-level aggregation, we need to add more `bitmap` and `fanInDegree` fields to ATP packet header (one for each additional in-network gradient aggregating switch) to track the progress of aggregation at all the switches involved in gradient aggregation enroute from the workers to the PS.

Notably, for non-deterministic route load balancing schemes, such as Presto [34] and CONGA [16], ATP packets only deterministically route through TOR switches with non-deterministic routing at higher levels of the datacenter network hierarchy. Thus, to support such cases, ATP does aggregation only at the TOR-layer.

A.3 Recovering from Worker Failures

PS-based architectures deal with worker failures by re-spawning a worker process, perhaps on a different machine connected to a different ToR switch. This requires invalidating stale aggregators having incomplete aggregation results that are waiting on gradient packets from the failed worker. Such stale entries are invalidated as ATP has checks and balances to overcome switch memory leaks (described in §3.7). Also, the re-spawned worker might be on a different machine and connected to a different TOR switch. This might require changes to the `fanInDegree` field in ATP packet headers. ATP re-triggers dynamic job-setup phase (described in §3.2) after any such failure event and the PS re-initiates gradient aggregation by sending an ACK on the new multicast tree that includes the re-spawned worker for the earliest sequence number that is yet to be aggregated.

A.4 Dealing with Stragglers

A slow worker or a slow link can slow down the whole training process. However, this is an artifact of synchronous training and not an issue with ATP. Note that because ATP alleviates network bottlenecks as it aggregates gradients in the network, it reduces the likelihood of network-induced stragglers.

A.5 Comparison to Ring All-reduce Approach

Ring all-reduce uses one-to-one communication in each training iteration/round. With this communication pattern, ATP does not have any opportunity to assist. A drawback of ring all-reduce is that the amount of data that each worker sends and receives is higher and is $4(n-1)\frac{|U|}{n}$, where n is the number of workers, $|U|$ is the total number of bytes to be aggregated. With ATP the amount of data that each worker sends and receives is $2|U|$; the amount of data that each PS sends and receives is $2|U|/m$ where m is the number of PSs. Quantitatively, this indicates that ring all-reduce generates more network traffic than ATP, which may congest the network for other running applications in the cluster. We compare ATP against the ring all-reduce approach (**Horovod RDMA** and **Horovod TCP**) in Figure 8, demonstrating that ATP is better than ring all-reduce for training popular models.

B Addtional details on dealing with floating point

ATP converts floating point values to integers by multiplying with a scaling factor to enable gradient aggregation on programmable switches.

B.1 ATP's Choice of Scaling Factor

The choice of the scaling factor is crucial. A smaller scaling factor can lead to rounding-off a lot of digits after the decimal point and a greater loss in precision. Theoretically, the precision loss due to this conversion is bounded by $\frac{n}{s}$ (Theorem 1 in [56]), where n is the number of workers and s is the scaling factor. A large scaling factor can lead to aggregation of large integers and may cause overflow at the switches. Theoretically, there is no overflow if gradient values are less than an upper bound $B = \frac{2^{31}-n}{ns}$ (Theorem 2 in [56]).

Prior work [56] relies on empirical measurements to find this upper bound B for gradient values of a popular suite of ML training jobs and chooses a scaling factor $s = \frac{2^{31}-n}{nB}$. The precision loss with this choice of scaling factor is bounded by $\frac{n^2B}{2^{31}-n}$.

There are two drawbacks with this approach. First, the guarantee of no overflows with this approach strictly relies on obtaining an accurate estimate of the upper bound B on gradient values. This makes the approach expensive to accommodate jobs that train new and unseen models as empirically determining the value of B for a new model requires an end-to-end training run. Second, the scaling factor decreases as the value of B and the number of workers n increase, which leads to an increasing loss of precision. With 100 workers and $B = 200$, the value of the scaling factor is $\sim 10^5$ and the maximum loss of precision is $\sim 10^{-5}$ per gradient value. We sample gradient values below 10^{-5} in some epochs across models and find that there are 18% such gradient values for ResNet50, 42.8% for VGG16 and 39.8% for AlexNet. These values will experience completed loss of precision, hurting model accuracy upon training.

With ATP, we choose a high scaling factor so as to minimize loss of precision. We note that 32-bit floating point representation provides the precision of 7 decimal digits [7]. Thus, to provide an equivalent precision, ATP chooses the scaling factor of 10^8. The decoupling of the scaling factor from B completely eliminates the first drawback and partially eliminates the second drawback described above. However, a large scaling factor can lead to an overflow of aggregated gradients.

There are broadly two mechanisms to overcome overflows: proactive and reactive. ATP chooses a reactive mechanism (§3.8) because there are drawbacks to using a proactive mechanism that we discuss next.

B.2 Pitfalls of Proactive Overflow Mechanism

The proactive mechanism prevents overflows from ever occurring at the switch. It determines a maximum gradient value threshold B such that, as long as gradient values aggregated in the switch are less than B, any overflow is avoided. The value of B ($= \frac{2^{31}-n}{ns}$) is computed at each worker during job initialization. Packets with gradient values $\leq B$ are aggregated in the switch, while workers flag packets with gradient values $> B$. Packets with this flag are not aggregated in the switch and are eventually aggregated at the PS. It is worth noting that this mechanism naturally fits with the best-effort aggregation service provided by ATP and cannot be implemented in the prior SwitchML work.

Job	False Positive Packets
ResNet50 - 8 Workers	37,002
ResNet50 - 16 Workers	231,528
ResNet50 - 32 Workers	1,156,126
ResNet50 - 64 Workers	14,602,998

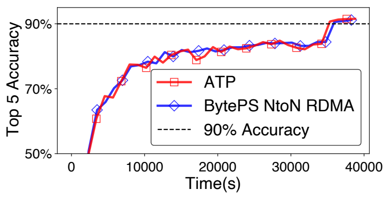
Table 1: Average false positive packets per epoch increase as workers increase.

Unfortunately, a proactive mechanism severely limits the opportunities for in-network aggregation. With 100 workers and a scaling factor of 10^8, the value of B is 0.2. To highlight this, in Table 1, we measure the number of false positives in a single epoch when training a ResNet50 model. We classify a gradient packet with a particular sequence number as a false positive if the gradient value in that packet is $> B$ but the aggregated gradient value for that sequence number from all the workers does not overflow the integer bound (2^{31}). Each false positive packet could have been aggregated in the switch and consumed in the network, but instead with the proactive approach ends up traversing the network from the worker all the way to the PS. As seen in Table 1, the number of false positive packets gets worse as we increase the number of workers in a ResNet50 job. This trend applies to all models, although the magnitude of false positive packets might change. This is not desirable because a higher number of false positive packets means that we lose out on in-network aggregation opportunities and that the number of packets traversing the link to the PS increases. Thus, increasing false positive packets leads to an increased likelihood of incast which only snowballs as the number of workers in the job increases.

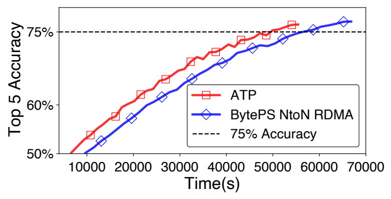
For these reasons, in ATP, we avoid using a proactive mechanism and use a reactive mechanism for overflow correction (§3.8).

B.3 Dynamic Scaling Factor

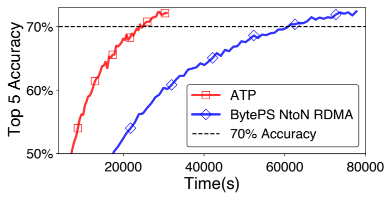
A static scaling factor can, in the worst case, lead to a very high overflow correction frequency when the magnitude of gradient values from all workers is large. In such a case, reducing the value of the scaling factor will reduce the overflow correction frequency and will also not lead to a loss of precision (as the gradient values are large). Thus, a possible optimization would be to make dynamic adjustments to the scaling factor in reaction to the current range of gradient values in recent iterations, especially for the case when the number of workers n is large. In our evaluations with popular models and the scale at which these distributed models are trained today, we do not see the need for such dynamic



(a) ResNet101



(b) VGG19



(c) AlexNet

Figure 18: Time to accuracy

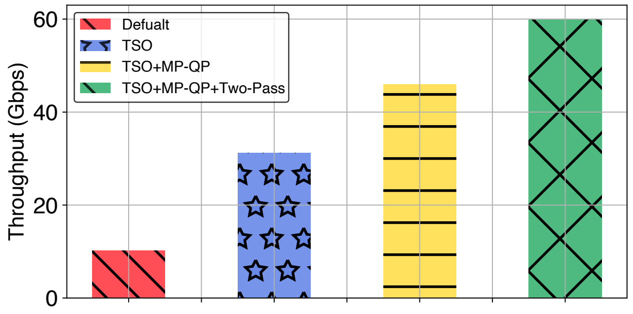


Figure 19: Throughput with different hardware acceleration.

scaling.

However, dynamic scaling adjustments may be beneficial in the future as new large models emerge and training jobs scale-out even further. Inspired by SwitchML [56], workers compute the scaling factor for each gradient in the next window with $s = \frac{2^{31}-n}{nb}$ (Theorem 2 in [56]), where b is the gradient value. Workers pick the minimal scaling factor in a packet, which guarantees there is not any overflow within a packet. When a tensor aggregation starts, a gradient packet piggybacks this value of the subsequent packet, which is sent after receiving the current packet's corresponding parameter packet. The switch computes the minimal scaling factor among workers, which will be carried to the PS. PS can instruct workers to use this scaling factor only when the overflow happens frequently. Note that the first gradient packet aggregation for each tensor can overflow with this approach. SwitchML sends an empty packet only containing the scaling factor at the beginning of the aggregation for each tensor, which causes one RTT waste and the finishing time of a tensor can be doubled if the tensor is small. ATP chooses the reactive approach, where the cost is one RTT in the worst case that all the gradient aggregations in the first window overflow. We leave this as future work.

C Additional Implementation Details

This section supplements the description of ATP's implementation in §4.

To increase the packet size processed by the switch, ATP programs the switch to process each ATP packet twice, which we refer to as **two-pass**. The first half of the gradients in the packet are aggregated in the first pass and the second half are aggregated in the second pass. Instead of using two end-to-end (all the way from ingress on a port to egress to a port) pipelines, which requires two ports to recirculate the packets, ATP uses the *resubmit* and *recirculate* features together, which allows to re-process the same packet (except the last packet that completes gradient aggregation) only in the ingress pipeline of the switch. This avoids using an additional port at the egress pipeline.

Recall that ATP drops the first $n-1$ packets (where, n is number of workers) after aggregation at the switch, and writes the aggregated results from the aggregator to the n-th worker's gradient packet, where n is the number of workers. ATP uses *resubmit* for the first $n-1$ gradient packets after the first pass. As the name suggests, this takes the packet from the end of the ingress pipeline after the first processing pass, left shifts the packet using the 'force_shift ingress' feature on the parser to drop the data part that has been aggregated in the first pass, and immediately resubmits this packet to the ingress pipeline for a second pass to process the second half of the packet. However, we can not apply the resubmit feature to the last gradient packet because ATP writes the first half of the aggregated results to the last packet during the first pass and a resubmit with left shift will lead to a loss of this aggregated result. To deal with this, ATP avoids using the resubmit feature for the last packet. Instead, we use 'recirculate' to enable a second end-to-end pass for the second half of the last packet. This approach requires only one additional port to recirculate the last packet. If the next generation of programmable switches is able to process larger packet sizes or the NIC supports higher packet processing rate, ATP will not require a two-pass implementation at the switch.

D Additional Evaluation Details

This section provides additional evaluation results (§D.1, §D.3) and supplements some existing results (§D.2).

D.1 Small Packets Optimizations

ATP applies multiple hardware acceleration techniques to boost throughput with small-packets as mentioned in Section 4. We demonstrate the effectiveness of each optimization by measuring the throughput of the microbenchmark using configurations that incrementally add more optimizations. We launch two hosts attached to a single switch, one as a worker, and the other as PS. The switch logic of ATP is forwarding packets from the worker to the PS. The PS copies the received data from the receiver memory region to the sender memory

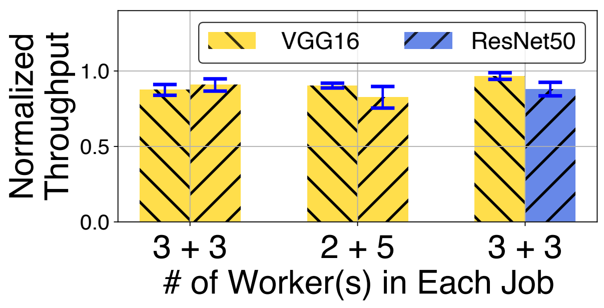

Figure 20: Multiple jobs.

region and then sends the data back to the worker.

Figure 19 shows the network throughput gains as we progressively add optimizations. TSO provides the biggest benefit, and increases performance by $3X$. Incorporating MP-QP (§4) at the end hosts further increases performance $1.47X$. Finally, adding aggregation based on two-pass implementation at the switches increases the throughput by a final $1.3X$. Overall, ATP's **TSO+MP-QP+Two-Pass** optimizations provide a $6X$ throughput improvement over no hardware acceleration (**Default**). We also notice that throughput does not double between **TSO+MP-QP** and **TSO+MP-QP+Two-Pass** when packet size doubles. This occurs because throughput is bottlenecked by the memory copy at the PS and workers [4].

In summary, ATP is able to achieve high throughput with small packets by utilizing recent advances in hardware acceleration.

D.2 Switch Resource Sharing

In this section, we study ATP's dynamic aggregator allocation approach and observe the impact of the number of workers and the model size on the performance of contending jobs. We launch two DT jobs on ATP under various settings.

First, we launch two VGG16 jobs each with 3 workers. Figure 20 shows the training throughput normalized against the job in isolation. We see equal throughput, across identical jobs (same model and number of workers), indicating equal sharing of switch resources. Also, the throughput reduction for each of the two jobs is only 10%.

Second, we launch two VGG16 jobs with 5 and 2 workers each. The job with more workers performs slightly worse than that with fewer workers (145.6 image/s for 5 v.s. 159.3 image/s for 2 workers).

Third, we launch a VGG16 and a ResNet50 job and observe only 5% and 10% throughput reduction respectively; reduction for the large model (5% in VGG16) is less than that for the small model (10% in ResNet50).

In summary, ATP's switch resource sharing is equitable for similar workloads. In the case of different workloads it tends to favor jobs using fewer workers and larger models.

[4]The memory copy overhead can be eliminated by proper memory alignment. We leave this improvement for future work.

D.3 Time To Accuracy

Figure 18 illustrates the TTA training curve for ResNet101, VGG19 and AlexNet with the same setting from §5.3. ResNet101 (Figure 18a) does not see a noticeable speed up ($1.01X$ in ATP) as it is a compute-intensive model similar to our measurements in §5.3 (ResNet50 and ResNet152). The results for VGG19 (Figure 18b) and AlexNet (Figure 18c) reflect $1.2X$ and $2.39X$ speed up, which is consistent with the training throughput presented in §5.2.1 for communication-intensive models.

On the Use of ML for Blackbox System Performance Prediction

Abstract

There is a growing body of work that reports positive results from applying ML-based performance prediction to a particular application or use-case (*e.g.,* server configuration, capacity planning). Yet, a critical question remains unanswered: does ML make prediction simpler (*i.e.,* allowing us to treat systems as blackboxes) and general (*i.e.,* across a range of applications and use-cases)? After all, the potential for simplicity and generality is a key part of what makes ML-based prediction so attractive compared to the traditional approach of relying on handcrafted and specialized performance models. In this paper, we attempt to answer this broader question. We develop a methodology for systematically diagnosing whether, when, and why ML does (not) work for performance prediction, and identify steps to improve predictability.

We apply our methodology to test 6 ML models in predicting the performance of 13 real-world applications. We find that 12 out of our 13 applications exhibit inherent variability in performance that fundamentally limits prediction accuracy. Our findings motivate the need for system-level modifications and/or ML-level extensions that can improve predictability, showing how ML fails to be an easy-to-use predictor. On implementing and evaluating these changes, we find that while they do improve the overall prediction accuracy, prediction error remains high for multiple realistic scenarios, showing how ML fails as a general predictor. Hence our answer is clear: ML is not a general and easy-to-use hammer for system performance prediction.

1 Introduction

Performance prediction has long been a difficult problem, traditionally tackled using handcrafted performance models tailored to a specific application [26,27,43,44,53,56,61,62] or use-case[1] [23,30,55,58]. However, this approach is tedious, doesn't generalize, and is increasingly difficult given the growing complexity of modern systems. Ideally, one would want a predictor that is **accurate, general, and easy to use**. By *general*, we mean an approach that applies to a broad range of applications and a broad range of use-cases; by *easy to use*, we mean an approach that can be applied without requiring detailed knowledge of the application internals or use-case.

[1]Throughout this paper, we use the term *use-case* to refer to an application of prediction such as scheduling (*e.g.,* where/when to run jobs), configuration (*e.g.,*, how many workers or how much memory to use), or capacity planning (*e.g.,* determining what server configurations to purchase).

Given the success of machine learning (ML) in many domains, it is natural to think that ML might offer a solution to this challenge: *i.e.,* that an ML model can learn the relationship between a system's externally observable features and its resultant performance *while treating the application as a black-box*. The ability to treat the application as a black-box and remain agnostic to the prediction's use-case would enable a predictor that meets our goals of generality and ease-of-use.

But does ML deliver on this promise? Several recent efforts have applied ML to predict or optimize performance [22, 37, 47, 57, 60]; these report positive results and hence one might assume that the answer to our question is "yes." However, as we discuss in §9, these effort focus on specific applications, models, or use-cases and hence do not shed light on our question of broad generality and ease-of-use. In this paper, we take a first step towards filling this gap, empirically evaluating whether ML-based prediction can simultaneously offer high accuracy, generality, and ease-of-use.

The first step in such an undertaking is to define a methodology for evaluation. As we shall show, evaluating the accuracy of a model's prediction is subtle particularly when prediction fails because in such cases we need to understand the cause of failure: was it a poor choice of model? was the model poorly tuned? or was the application's performance somehow fundamentally not predictable? In other words, we need a methodology that allows us to both, evaluate the accuracy of a predictor and *attribute* errors in prediction.

This observation led us to define a methodology for systematic evaluation and analysis of ML-based predictors that, as we detail in §2, provides us with two bounds: a lower bound on the prediction error that *any* model can hope to achieve, and a more realistic bound that is based on the best prediction made by the ML models that we consider. We apply our methodology to evaluate 6 different ML models (*e.g.,* k-nearest neighbors, random forest, neural networks) in predicting performance for 13 real-world applications (*e.g.,* Tensorflow, Spark, nginx) under a range of test scenarios (*e.g.,* predicting the impact of dataset size).

Our first key finding is that *irreducible* prediction errors are common (§4). In particular, we find that the majority of our applications exhibit a high degree of performance variability that cannot be captured by any black-box parameters and that manifests even in best-case scenarios (*e.g.,* running an identical configuration of the application, on identical hardware, with no contention for resources). E.g., we show that, even across identical runs, the performance of the JVM Garbage Collector (GC) varies between two modes depending on the precise timing of GC events (§5). Because of this variability, our lower bound on prediction error is non-trivial: we show that no application consistently achieves a lower bound on prediction error that is <10% and many applications fare far worse; *e.g.,* the lower bound on prediction error in memcached is >40% in ∼20% of our prediction scenarios. Borrowing the terminology of the ML community [34], we say that the prediction error that results from this variability is "irreducible" as it stems from behavior that cannot be modeled or controlled, and hence cannot be learned. Irreducible error fundamentally limits the accuracy that *any* ML model can achieve.

We further find that, while the root cause of irreducible error varies across applications, a common theme is that they stem from design decisions that were made to optimize performance, efficiency or resilience but in the process led to a fundamental trade-off between predictability and these other design goals (§5).

These findings suggest a clear negative result for our goal of an ML-based predictor that is both accurate and general. So, where do we go from here? A natural follow-on is to ask whether we can usefully relax our goals of generality and ease-of-use - *i.e.,* make some assumptions about application design or prediction use-cases that would improve predictability.

The second part of our paper explores this question. We do so from two different vantage points: that of the application developer and that of the operator who is using predictions for some operational task.

Our *developer-centric* exploration asks: if developers expose knobs that give operators the *option* to disable design features that lead to irreducible errors, how much would this improve the accuracy of ML predictors?

Our *operator-centric* exploration asks: if we assume operators can accommodate some notion of uncertainty in how they use the predictions, then could ML meet our goals for a useful predictor?

We note that both of the above represent a non-trivial compromise on our original goal and, perhaps more importantly, in neither case do we address the question of *how* developers/-operators would make such changes nor the impact that such changes might have on other design goals such as efficiency, resilience, etc. Instead we are merely asking whether making these changes would improve predictability.

Our findings on this front are mixed. We find that, in both cases, our relaxed assumptions do significantly improve predictability in our best-case scenarios, but we continue to see prediction fail in a non-trivial fraction of our more realistic tests. E.g., in our best-case setup, the lower bound on prediction error is now <6% in >90% of our test cases but, in our more realistic tests, 3 (out of 13) applications see error rates >30% in ∼10% of test cases.

While not the clean result that one might have hoped for, they reinforce that ML-based performance prediction is best applied with a scalpel rather than a hatchet. In this sense, our study mirrors the extensive literature in applied machine learning that explores the trade offs between black- *vs.* gray-box learning. While this trade off has been studied (and debated!) in many other domains [35, 38, 54], to our knowledge we are the first to do so for performance prediction in systems.

Thus unlike many NSDI papers, our contribution lies not in the design and implementation of a particular system but instead in triaging and critically examining the role of ML for managing system performance. Specifically:

• We provide the first broad evaluation of the generality of ML-based prediction, showing that blackbox prediction is often fundamentally limited and expose why this is the case.
• In light of these limitations, we propose and empirically evaluate two complementary approaches aimed at broadening the applicability of ML-based prediction and show that these approaches alleviate but don't eliminate the above limitations.

We view our study as a first step and recognize that it must be extended to more applications and models before we can draw final conclusions on the generality of ML-based performance predictors. We hope that our methodology and results provide the foundation for such future work.

2 Methodology

Our methodology is based on two tests and two predictors: the Best-Case (BC) and Beyond Best-Case (BBC) tests, plus the Oracle and Best-of-Models predictor. In what follows, we first define our metrics and parameters followed by these tests and predictors.

2.1 Metrics and Parameters

We test prediction accuracy by comparing an ML model's prediction to the true performance measured in our experiments. We measure quality of predictions using the root mean square relative error (rMSRE) which is computed as:

$$rMSRE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(\frac{Y_i - f(X_i)}{Y_i}\right)^2}, \quad (1)$$

where n is the number of points in the test set for a given prediction scenario and (X_i, Y_i) is a test sample where Y_i is the true measured performance and f is the function learned by the ML model that, given a test feature of value X_i, predicts the performance as $f(X_i)$. rMSRE is a common metric used in regression analysis [34] and in prior work on performance prediction [60]. Note that rMSRE measures the true error in predicted performance - *i.e.,* comparing predicted to actual performance. It is possible that a predictor with high rMSRE is still "good enough" for a particular use-case[2] and, indeed, it is common in papers that focus on specific use-cases to evaluate prediction in terms of the benefit to their use-case. However, given our goal of generality and remaining agnostic

[2]For example: say that a predictor must pick between two configurations c_1 and c_2 where c_1 leads to a JCT of 10s and c_2 to 100s, then even a predictor with an rMSRE of 50% would successfully pick the right configuration.

to the specifics of a use-case, we believe rMSRE is the correct metric for a *predictor* and one can separately study what prediction accuracy is required for a target *use-case*.

We consider the following three classes of parameters that impact an application's performance[3]:

(i) **Application-level input** parameters capture inputs that the application acts on; *e.g.,* the records being sorted, or the images being classified. We consider both the size of these inputs and (when noted) the actual values of these inputs.

(ii) **Application-level configuration** parameters capture the knobs that the application exposes to tune its behavior – *e.g.,* the degree of parallelism, buffer sizes, etc.

(iii) **Infrastructure** parameters capture the computational resources on which the application runs – *e.g.,* CPU speed, memory size, whether resources are shared vs. dedicated.

These parameters correspond to what-if questions that are likely to be of practical relevance: *e.g.,* predicting how performance scales with input data size, under increasing parallelism (executors), or with more infrastructure resources. We note that the above parameters, when used as features for our ML models, capture the application as a black-box, together with the infrastructure it runs on. We also note that these are static parameters known prior to running the application, in contrast to runtime metrics and counters such as a task's CPU or cache utilization. While runtime counters are widely used for monitoring performance, relying on them for prediction limits our potential use-cases to scenarios where prediction is invoked after the application is *already running* rather than at the time of planning, placement, or scheduling. Moreover, it is unclear how one might *use* a predictor based on runtime counters to manage performance: *e.g.,* even if an operator can predict that a CPU utilization value of C leads to a desired performance target, she must still know how to set system parameters in order to achieve the desired CPU utilization. In other words, runtime counters are *measures* not parameters.[4] Hence, in this paper, we assume the ML models cannot use runtime counters as features for prediction.

2.2 The Best-Case (BC) Test

Our BC test is designed to give a predictor the "best chance" at making accurate predictions. It does so by making very strong assumptions on both the systems and ML front, as we describe below.

(1) ML front: simplifying the predictive task. The BC test makes two assumptions that greatly simplify the prediction task. First, in all the data given to the model (training and test), only a single parameter is being varied and that parameter is the *only* feature on which the model is trained. In other words: say we ask an ML model M to predict an application's performance for a particular configuration c_i that is defined by k parameters: i.e., $c_i =< p_1 = X_1, p_2 = X_2, p_3 = X_3, \ldots, p_k = X_k>$, where the p_i are parameters and X_i are parameter values. In the BC test, we give M a training data set in which only one parameter - say p_2 – is varied and all other parameters are set to the test value; *i.e.,* all training data will come from runs where p_2 is varied while $p_1 = X_1, p_3 = X_3, \ldots, p_k = X_k$. We call this our **one-feature-at-a-time** assumption.

Second, the model's training data always includes datapoints from the scenario it is being asked to predict. I.e., continuing with the above example, when predicting the application's performance for an input configuration $<p_1 = X_1, p_2 = X_2, p_3 = X_3, \ldots, p_k = X_k>$, not only do we enforce the one-feature-at-a-time assumption, we also require that the training set for the task include datapoints with $p_2 = X2$. Hence, the training set contains data points from an identical configuration to the one the model is being asked to predict! For example, if we ask the model to predict the time it takes to sort a dataset of size 5GB, the training set already includes times for sorting the same 5GB dataset. We call this the **seen-configuration** assumption since it ensures that, during training, the ML model has already "seen" the configuration it is being asked to predict.

We emphasize the extreme simplification due to the above assumptions: the complexity of prediction has been reduced from understanding the impact of k features to just one feature (*e.g.,* p_2), the training data is deliberately selected to cleanly highlight the impact of this feature, *and* the training set includes data from test configurations that are *identical* to what the model is being asked to predict!

(2) Systems front: best-case assumptions. Given our assumptions so far, the only reason prediction might be non-trivial is if we see variable performance across repeated runs of the application even with a fixed configuration of parameters. That software systems may exhibit variable performance is well recognized in the systems community with two commonly cited reasons for this: (i) contention for resources that an application might experience when it shares physical infrastructure with other applications/tenants [33,40,49,52] and (ii) variability that arises when the processing time depends on the values of data inputs [29] Our assumptions on the systems side aim to remove the likelihood of such variability. To avoid variability due to contention, we run our workloads on *dedicated* EC2 instances [1], and only run a single experiment at a time on a given server. We call this our **no-contention** requirement. We are still left with the possibility of contention within the datacenter network.Our workloads are not network-heavy and, with one exception (nginx, discussed later) none of our workloads appear to be impacted by contention with other apps over network bandwidth and hence we optimistically conclude that network contention is unlikely to have affected predictability for our workloads. We still cannot *entirely* avoid contention, however – *e.g.,* some of our apps use shared cloud

[3]We define these precisely in the context of each application in §3.

[4]I.e., one would need to predict how a parameter impacts the runtime metric in addition to how the runtime metric impacts performance. This might be appropriate for certain use-cases that include long-running jobs, *e.g.,* [61], and where we cannot directly predict how parameters impact performance but, for now, we focus on understanding whether the more general and direct/simple approach works.

services such as the S3 and DNS. Nonetheless, we believe the scenario we construct is far more conservative than what is commonly used in production and hence we view it as a pragmatic approximation of the best case while still running on real-world deployment environments like EC2.

Our second assumption is that, for a given input dataset size, the application's input data is identical across all experiments. I.e., repeated runs of a test configuration act on the same input data. E.g., all training/test data for an application that sorts N records, will involve exactly the same N records. We call this our **identical-inputs** assumption.

The sheer simplicity of our prediction tasks should be immediately apparent:we're essentially asking a model to predict performance for a test configuration that is identical to that seen in training. Our expectation was that, under these conditions, a model should be able to predict performance with a very high level of accuracy - *e.g.,* with error rates well under 5-10% – and if a model cannot accurately predict performance under the above conditions then it is unlikely to be a useful predictor under more realistic conditions.

2.3 The Beyond Best-Case (BBC) Test

In the BBC test, we systematically relax each of the constraints/assumptions imposed in the BC test to study prediction accuracy under more realistic scenarios:

(i) Relaxing the seen-configuration assumption. For this, we perform a leave-one-out analysis in which all data samples corresponding to the configuration on which a model is tested are withheld from the training set. More precisely, for a performance dataset with N configurations $\{c_1, c_2, \dots, c_N\}$, when testing a datapoint with configuration c_i, we use a model trained on a dataset that consists of the $N-1$ configurations *other* than c_i; *i.e.,* our training set excludes all training datapoints for configuration c_i. We perform this N-fold leave-one-out analysis for each of our prediction scenarios.

Note that predictions are now harder as models must learn the *trend* in performance as a function of the parameter being varied. Such predictions are useful in answering *what-if* questions of the form: *"what performance can we expect if we increase the number of workers to 10?"*

(ii) Relaxing the one-feature-at-a-time assumption. We relax our constraint of varying only one parameter at a time and instead enumerate the configuration space generated by simultaneously varying all the features in question and then sample from this space to collect training and test data on which we rerun our predictions. We describe the details of our approach inline when presenting our results.

(iii) Relaxing the no-contention assumption. For this, we repeat the experiments used to collect training and test data but this time do not run our experiments on dedicated EC2 instances. We present additional detail on our experimental setup in the following section.

(iv) Relaxing the identical-inputs assumption. For this, we generate a different input dataset for each datapoint in the training and test set. Section 3 provides additional detail on our input datasets in the context of each test application.

We studied the impact of relaxing each of the above assumptions individually and then all together. In this paper, we present a subset of our results as relevant.

2.4 Predictors

As mentioned, our evaluation considers two predictors.

The Best-of-Models (BoM) predictor. Recall that in order to obtain a broad view of ML-based performance prediction, we consider a range of ML models (§3). For any given prediction test, we compute the rMSRE for each ML model, and define the *best-of-models error (BoM-err)* as the minimum rMSRE across all the models we consider. Thus BoM-err tells us how well *some* ML model can predict system performance. However, if BoM-err is high, we still cannot tell whether this is because of a poor choice or tuning of ML models, or whether performance prediction was inherently hard. For this, what we would like to have is a lower bound on the error rate we can expect from *any* ML model. We achieve this through our *Oracle Predictor*.

The Oracle predictor looks at all the data points in the *test* set that share *the same feature values* as the prediction task, and returns a prediction that will minimize the metric in Eqn. 1 for all these data points. We obtain this by differentiating the expression for the metric in Eqn. 1 with respect to the prediction and finding the global optima for each *unique feature value*, , as below.

$$f_{\text{oracle}}(X) = \left(\sum_{i=1}^{n} \frac{\delta(X_i,X)}{Y_i}\right) \Big/ \left(\sum_{i=1}^{n} \frac{\delta(X_i,X)}{Y_i^2}\right), \tag{2}$$

$$\delta(a,b) = 1 \text{ if } a \text{ is equal to } b\text{, and 0 otherwise.} \tag{3}$$

Note that our features are discrete entities (number of workers, size of dataset, type of instance) and thus the oracle is well-defined. We use O-err to denote the error rate obtained by this Oracle. If there is no variance at all in these data points, the Oracle will achieve zero error. Simply put, O-err quantifies the impact of variance in performance – across multiple runs of the same application and under *identical* configurations – on prediction accuracy.

Clearly, our Oracle predictor is not usable in practice since it is allowed to "peek" at both the test data and the error function; nonetheless O-err is helpful in attribution. Specifically, it gives us a lower bound on the prediction error that *any* ML model could achieve and, in this sense, sheds light on whether performance prediction is at all feasible, *i.e.,* a high O-err perhaps suggests that predicting system performance is "impossible." In addition, a small gap between O-err and BoM-err confirms that our model is well tuned (§3).

3 Test Setup

Our experimental setup comprises two main stages: application profiling and model training. In the profiling stage, an application is run under different configurations to generate a raw dataset. In the training stage, the dataset first undergoes pre-processing (featurization, normalization, and outlier removal), and is then randomly split into two disjoint datasets: the *training* set is used to train models and the *test* set is reserved for model evaluation. The training set is also used for hyper-parameter tuning of ML models. In what follows, we discuss key aspects of each stage. This is not an exhaustive description of our experimental setup – all datasets [6] and tooling [20] from our experiments are publicly available.

3.1 Application Profiling

Applications. Table 1 enumerates the applications used in our study. Our selection reflects multiple considerations including the application's relevance in production environments, diversity (spanning web services, timeseries database, microservices, data analytics, and model serving), and ease of instrumentation. See Appendix A for additional details.

Parameter Values and Performance Metrics. We select values for our three broad classes of parameters as follows:

(i) *application-level input parameters.* We experiment with varying the size of these inputs on a scale of 1 to 10, with scale 1 being the default input size in the workload generator;

(ii) *app-level configuration parameters.* We experiment with varying the number of worker nodes between 1 and 10.

(iii) *infrastructure parameters.* We experiment with 13 different EC2 instance types: from the 150+ instance types offered on EC2 we select the latest generation of the three common instance families (c5, m5 and r5) with four different scales (large, xlarge, 2xlarge, 4xlarge) plus a c4.4xlarge instance for a total of 13 instance types (see [2] for details). This selection matches the instances used in prior work [57, 60].

As listed in Table 1, we use different performance metrics (*e.g.,* job completion time, request throughput) depending on the application. We run each parameter setting 10 times recording the resulting performance. This constitutes our raw dataset. Appendix A and our code repository [20] include additional details on the setup.

3.2 Model Training

We select six ML algorithms: k-nearest neighbors, random forest regression, linear regression, linear support vector machine (SVM) regression, kernelized SVM regression, and neural networks. We select these as they are commonly used in practice and, taken together, represent well the various families of ML techniques: parametric and non-parametric models, linear and non-linear models, discrete and continuous [34]. This diversity is in contrast to prior work that focuses on a single ML technique [22, 37, 47, 57, 60].We follow the standard machine learning practice of k-fold cross-validation (k=3) for setting hyper-parameters. Folds were carefully picked such that they represented the data well and included points for each feature value present in the training set. We searched for regularization parameters (all models); kernels (RBF, polynomial, and sigmoid) and their parameters for SVMs; number and depth of trees for random forests; number of neighbors for nearest neighbors; and number of hidden layers (varying from zero to four), size of layers, activation functions (ReLU, tanh), and learning rates for neural networks. The neural networks we used, MLPs with different non-linearity, are the standard models for treating data of the form in this paper (as opposed to RNN/LSTM/CNNs).

As is standard in machine learning, we pre-process our dataset before training our models. We convert numeric features to have zero mean and unit standard deviation (by subtracting the mean and dividing by the standard deviation, computed per feature channel across the entire training set). We map all categorical features to their numerical index. We also throw out outlier data-points (that have any feature value or performance metric beyond the 99th percentile) from the training set. We use `scikit-learn`, a widely used machine learning tool-set for data preparation and model training [46].

We then train each model to predict the impact of a particular parameter p on performance for a given app A. For this, we select data points corresponding to runs of A in which *all* parameters other than p are fixed. We do a 50:50 random split of the resultant dataset into a training and test set.

4 Results: Existing Applications and Models

We start with the results from our BC test. Recall that each prediction task involves predicting the performance of a given application for a given configuration of: (i) application input size, (ii) number of workers, and (iii) instance types, while subject to the constraints and assumptions presented in §2.2.

We start by looking at the results for our BC test. Fig.1a plots the cumulative distribution function (CDF) of the O-err for each application across all predictions tasks while Fig.1b shows the same for the BoM-err.[5] Recall that O-err captures the irreducible error inherent to an application (i.e., no ML model could achieve an error rate lower than the O-err) while the BoM-err captures the lowest error rate achieved by some ML model. Given the extreme simplicity of our best-case prediction task, we expected a very high degree of accuracy with an O-err of (say) well under 5% error. To our surprise, our results did not match this expectation. For example: in 5 of our 13 applications, O-err is $>$15% for at least 20% of prediction tasks; for LR1 O-err is $>$30% for 10% of the prediction tasks; for memcached O-err exceeds 40% for approximately 20% of prediction tasks; in fact, no application enjoys an O-err of $<$10% in all prediction scenarios.

The high O-err that we see in our (extremely generous) best-case scenario tells us that many applications suffer from non-trivial irreducible error which fundamentally limits our ability to achieve high prediction accuracy under the general black-box conditions that we desired. Given that we fail even at the BC test, we focus next on understanding the sources of this irreducible error. But first, a few additional observations:

[5]We show a detailed breakdown of error based on the feature being predicted in Appendix C.

Framework	Application/Description	Input Workload	Input Parameter	App. Config. Parameter	Infra. Parameter	Metric

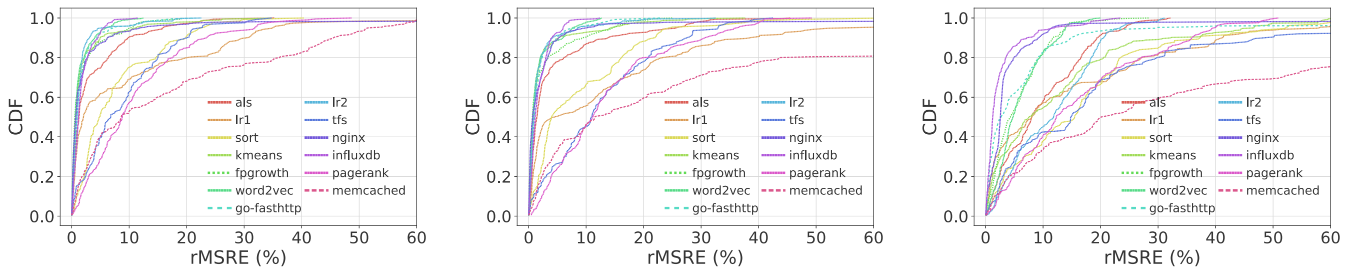
Table 1: Applications, input workload, parameters, and metrics used in our study.



(a) CDF of O-err in the BC test

(b) CDF of BoM-err in the BC test

(c) CDF of BoM-err in the BBC test

Figure 1: O-err and BoM-err for existing applications and ML models.

(i) As one might expect, prediction accuracy deteriorates as we move from the BC to the BBC test. As a sample result, Figure 1c shows the CDF of the BoM-err for our BBC test when relaxing our seen-configuration assumption: for 6 of our 13 applications (*vs.* 3 in the BC test), the 80%ile BoM-err exceeds 20% (for 1 app, it exceeds 60% error!)
(ii) As the CDFs suggest (and as we validated on individual data points), BoM-err on our BC test tracks O-err very closely, confirming that the higher-than-expected errors arise from irreducible causes, as opposed to poor ML engineering.
(iii) The error rates vary across applications even when they use the same framework (*e.g.,* Spark-based sort vs. LR2). This reinforces the importance of considering a range of applications when evaluating ML for performance prediction.

5 Tackling Irreducible Error

The high irreducible errors that we saw in the previous section tells us that, even for a fixed configuration of parameters, there are times when an application's performance was so variable that *no* predictor could predict performance with high accuracy. While it is well recognized that software systems can experience variable performance due to various runtime factors, we were surprised to see the extent of this variability even in our best-case scenario. Recall that, in our best-case scenario, we are essentially just repeatedly running an identical software stack, on identical hardware, with identical data inputs, and without contention on our servers. What can cause performance to vary significantly across runs? In particular, we were interested in understanding whether the sources of variability could be captured by features that are known prior to runtime. If so, we could hope to achieve higher prediction accuracy by simply adding more features to our ML models.

Unfortunately, we find that this variability stems from design choices – often optimizations – the effect of which could *not* have been captured by system parameters known prior to running the application. In this section, we briefly summarize our findings (§5.1) and then discuss their implications (§5.2).

5.1 Root-Cause Analysis

Table 2 summarizes the findings from our root cause analysis. Each entry summarizes the root cause we discovered, the applications it impacted, the trade-off that eliminating this root cause would impose, the manner in which we modified applications to eliminate/mask their impact, and the burden associated with undertaking such analysis. We stress that the modifications we make are ad-hoc hacks intended only to verify that we correctly identified our root-causes; as we discuss later, we do *not* view them as the desirable long-term fix.

Finally, we report the person hours it took to identify and validate these root causes. We recognize that any such estimate depends on many nebulous factors such as our familiarity with the codebase and experience in performance analysis. We present it merely as anecdotal evidence that analyzing performance in modern systems is non-trivial and would benefit from better developer support as we discuss in §8.

To give the reader a tangible sense of these root causes, we first present a longer description of the first two root causes, followed by a very brief summary of the remaining ones. A detailed description – with experimental validation – is in Appendix B, while the following section (§6) evaluates the impact of eliminating these root causes on O-err and BoM-err.

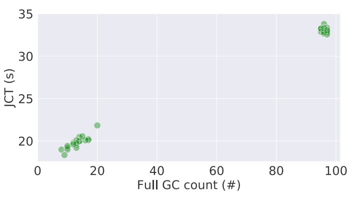
5.1.1 Spark's "Worker Readiness" Optimization

We found that the relatively high O-err in Spark's Terasort application stems from a dynamic sizing optimization in Spark. By default, Spark launches an application once at least 80% of its target worker nodes are ready, and the application partitions the input dataset based on the number of workers ready at this time. This optimization ensures resilience to failure and stragglers, but leads to variable parallelism and hence JCTs. This variability leads to irreducible errors and cannot be captured by any input parameters/features as the exact degree of parallelism is affected by small differences in worker launch times which cannot be predicted prior to runtime.

Disabling this optimization lowered Terasort's average O-err from 12.6% to 2.6% in our predictions that involve varying the instance type. While this optimization also affected other Spark apps (*e.g.,* PageRank), its impact there was small.

5.1.2 Adaptive Garbage Collection in the JVM

Our analysis showed that LR1's error stems from an optimization in the Java Virtual Machine's (JVM) garbage collector (GC). Specifically, we found a positive correlation between the number of "full" GC events (explained below) and JCT, leading to the bimodal behavior in the figure above.



As a performance optimization, the JVM GC divides the memory heap into two regions – young and old – and typically tries to constrain garbage collection to just the young region. However, in situations where the memory heap is consistently low on free space, the JVM GC runs a "full" collection that operates over the entire heap space (young and old regions). To determine whether a full GC is needed, the JVM maintains a *promotion estimate* metric. Our analysis revealed that due to minor differences in the timing of memory allocation and GC events, the promotion estimate ends up just above the threshold (triggering a full GC) in some runs and just below it in others, leading to the bimodal behavior (see Appendix B.2). Once again, since the exact mode being triggered depends on the detailed timing of runtime events, this effect could not have been captured by any input parameters/features known prior to actually running the job.

We verify our analysis by rerunning our experiments with an extra 50MB of memory which ensures that the promotion estimate remains below the threshold in all runs. This eliminates the high-mode runs, reducing average O-err by 9× from 18.2% to 2.1% in our predictions that involve varying the number of workers.

5.1.3 Other Root Causes

We briefly mention the remaining entries in Table 2; detailed tracing for each is in Appendix 9.

HTTP Redirection and DNS Caching in S3. We found that multiple applications built on Amazon's S3 storage service suffered variable performance that arose from the DNS-based resolution of S3 object names; some name resolution requests experienced HTTP redirects while others didn't depending on the detailed timing of when DNS updates were propagated.

Imperfect Load-Balancing. We observed high irreducible errors when predicting the request throughput of a Tensorflow Serving (TFS) cluster. We run TFS within a Kubernetes cluster and found that this error stems from the randomized load-balancing policy that Kubernetes employs, which leads to an inherent imbalance in the load at each server; when running the cluster at high utilization this imbalance led to some servers being overloaded and the *variability in this imbalance* leads to variations in the overall request throughput.

Non-deterministic Scheduling. We found that independent Spark tasks were being scheduled in different orders across different runs leading to different JCTs. This variability arose because the data structure used to track runnable tasks (Scala's `HashSet`) offers no guarantees on the order of iteration through the set members. Switching to a different data structure eliminated this variability.

Variability in Cloud APIs. Our last two cases of high O-err stemmed from variability across repeated invocations of cloud APIs: memcached was affected by variability in how worker instances were placed (which affects node-to-node latency) while nginx suffered from variability in the default network bandwidth associated with particular instances types. Again, with little visibility into (or control over) cloud API implementations, the impact of this variability could not be predicted by input parameters/features prior to runtime.

5.2 Implications and Next Steps

At a high level, many of the irreducible errors we encountered may be attributed to two common design techniques: the use of randomization (*e.g.,* in load-balancing, scheduling) and the use of system optimizations in which a new mode of behavior is triggered by a threshold parameter (*e.g.,* a promotion estimate, timeouts, a threshold on available workers). Some of these design choices can be altered with little loss to design goals such as performance or resilience (*e.g.,* remov-

Root Cause	**Applications Impacted**	**Trade-off**	**Modification**	**Effort to diagnose**
Spark's "start when 80% of workers are ready" optimization	Terasort	Decreased resilience to stragglers and worker failure	Disable optimization	5 person days
Multi-mode optimization in JVM Garbage Collector	LR1	Slower garbage collection	Avoid triggering, or disable, optimization	39 person days
Non-determinism in Spark sched.	PageRank	None	Use deterministic data structure	14 person days
HTTP redirects and DNS caching in S3's name resolution	KMeans, LR2, FPGrowth, ALS	Decreased flexibility[6] (OR slower name resolutions)	Client-side caching of HTTP redirects (OR always redirect)	10 person days
Imperfect load-balancing at high load	TensorFlow serving	Load imbalance when each server has different numbers of workers	Modified load-balancing policy to always favor local workers	7 person days
Variability in implementations of Cloud APIs (EC2)	memcached, Nginx	Cloud APIs expose more information (less flexibility)	Use AWS placement APIs / include inter-node RTTs as ML feature	5 person days

Table 2: Root causes of the irreducible errors we observed in our test applications. Person hours were calculated using the timestamps in our debugging logs and covers the entire process of reproducing observed behavior, adding instrumentation, processing logs, modifying the system to eliminate suspected causes, running tests for validation, etc.

ing the non-determinism in Spark's scheduler). However, for many others, eliminating them would come at some loss in performance/efficiency (*e.g.,* DNS caching improves scalability, partitioning regions offers faster GC). Moreover, because of the recent emphasis on extracting performance, modern systems now make extensive use of such optimizations.

Given the lower bound set by the O-err (as discussed in §2.4) and the underlying root causes, no amount of model modifications or feature engineering would have resulted in significantly better prediction accuracy. So, where do we go from here? We set out to test an ambitious hypothesis: that ML could serve as a general and easy-to-use predictor of system performance. Unfortunately, we found that most of the applications we studied suffered poor prediction accuracy on a non-trivial number of test cases even under extremely favorable test conditions. Moreover, the design choices that led to low accuracy cannot be easily forsaken without impacting other goals such as performance.

Thus a natural follow-on is to ask whether we can usefully relax our goal of generality - *i.e.,* make some assumptions about application design or prediction use-cases that would still allow us to leverage ML-based prediction in a (mostly) general and easy-to-use manner. As mentioned in §1, the remainder of this paper explores this question from the vantage point of application developers (§6) vs. operators (§7).

6 Results: Modified Applications

We now examine the impact of removing the above root-causes on performance predictability. If doing so improves prediction accuracy, then we can envision a workflow where the application developer identifies the root causes of irreducible errors and makes them configurable. For example, the JVM garbage collector (GC) designer can expose a knob to turn off the optimization for reducing full GCs. This, in turn, would enable system operators to disable such techniques depending on their desired trade-off between predictability and other design goals such as performance.

We emphasize that our goal here is not to provide a mechanism for identifying and eliminating sources of irreducible errors. Developing a systematic approach for this is an interesting problem but beyond the scope of this paper. Instead, we focus on the consequences of doing so: *if* these sources are identified and eliminated, to what extent would it improve performance predictability? Further note that, in line with this objective, we focus on evaluating the resultant impact on performance *predictability*, and not on performance itself.[7]

We now (re)evaluate predictability for our BC (§6.1) and BBC (§6.2) tests after applying the "fixes" to remove the root causes of irreducible errors as discussed in §5.

6.1 BC test results

Fig. 2a shows the CDF of the O-err for our modified applications across all prediction tasks. As expected, removing the sources of irreducible errors results in a dramatic reduction in O-err. All applications now have O-err well within 10% for at least 90% of their prediction tasks. In other words, 90%ile O-err is $< 10\%$ for all 13 applications, and in fact, only two applications have O-err $> 6\%$.

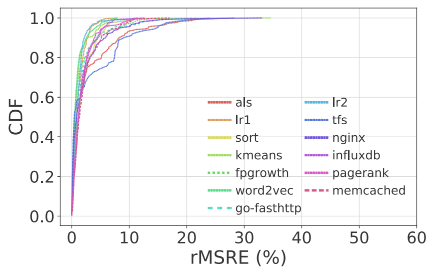
Fig. 2b shows the corresponding CDF for BoM-err. Again, only two applications have 90%ile BoM-err $> 6\%$, of which only one (TFS) has 90%ile BoM-err $> 10\%$. Further observe that the trends for BoM-err closely track those of O-err above, highlighting that ML comes close to achieving the lower bound on prediction errors for our simple BC predictions.

6.2 BBC test results

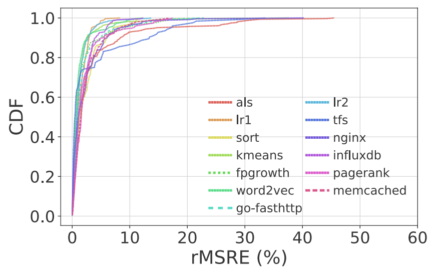
With the promising BC test results, we next turned our attention to BBC tests after application modifications. We systematically relaxed the assumptions of our BC test (as described in §2), and present a subset of results for brevity.

Fig. 2c presents the CDF for BoM-err after we relax the seen-configuration assumption by performing a leave-one-out test as described in §2. Note that, since the test dataset remains unchanged, O-err is the same as in our BC prediction above. Comparing Figures 2b and 2c, we see that the BoM-

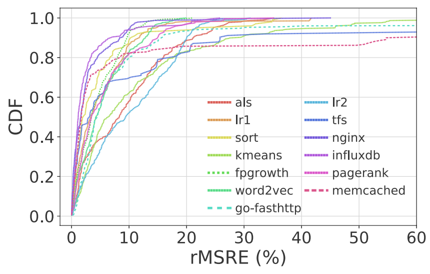
[7]In fact, many of our "fixes" would actually improve performance (*e.g.,* allocating more memory, caching the correct server address) and hence including such results would be misleading!



(a) CDF of O-err in the BC test



(b) CDF of BoM-err in the BC test



(c) CDF of BoM-err in the BBC test

Figure 2: O-err and BoM-err in the BC and BBC test after modifying applications to remove sources of irreducible errors. Note the sharp drop in performance prediction errors, as compared to unmodified applications in Fig. 1.

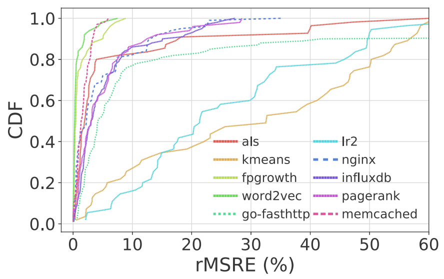


Figure 3: CDF of BoM-err in the BBC leave-one-out test where input data content is not identical, for predictions across varying input data scale. Relaxing the identical-inputs assumption reduces the prediction accuracy for multiple applications.

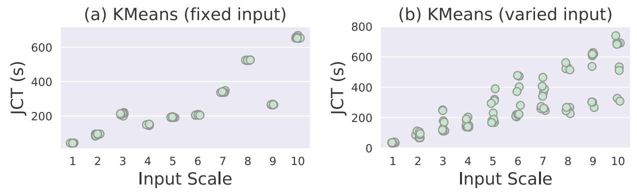

Figure 4: JCTs for KMeans with fixed vs. varied inputs for each value of input scale. KMeans JCT is sensitive to the input dataset.

err is significantly higher for the BBC leave-one-out test than for the BC test. 10 out of the 13 applications exhibit 90%ile BoM-err $>$ 10%. Some degradation in prediction accuracy is expected due to the increased difficulty of the prediction tasks, which now require the ML models to learn the *trend* in performance. What is surprising is that multiple applications experience exceptionally high BoM-err for a significant fraction of prediction tasks. For example, the 90%ile BoM-err of memcached exceeds 60%, while that of KMeans and TFS exceeds 25%. As can be seen, the corresponding 95%ile BoM-err is even higher. We dig deeper into the reasons behind these high errors in §6.3.

While we observe these high prediction errors for only a subset of applications and prediction scenarios, these results emphasize that we cannot simply rely on ML as a general predictor that works across all apps and prediction scenarios.

We next present results from tests in which we relaxed the identical-inputs assumption in addition to relaxing the seen-configuration assumption. In other words, we perform a leave-one-out analysis, but now generate a different input dataset for each datapoint in the training and test set. We do so for 10 applications by varying the random seed in the workload generator, keeping the distribution underlying the input data unchanged. Fig. 3 shows the corresponding CDF for BoM-err across prediction tasks where we vary input scale. We observe that, in general, relaxing the identical-inputs assumption further reduces the prediction accuracy for multiple applications.[8] The applications that are most notably impacted are KMeans and LR2. This is because the performance of these applications is sensitive to the input data. For example, as we show in §6.3, the number of iterations for KMeans, and therefore its JCT, depends on the actual values/content of the input data. This results in a multi-modal behaviour for a given input scale, and thus, high prediction errors. As expected, the corresponding O-err (not shown for brevity) is also high.

Finally, we relaxed our no-contention assumption by repeating the above experiments on non-dedicated (or "shared") instances and found that doing so did not produce statistically meaningful differences in our results. In particular, moving to shared instances resulted in $<$3% degradation in BoM-err across all scenarios (detailed results in Appendix D.2).

6.3 Deep Dive on high BBC prediction errors

Our BBC leave-one-out tests required the ML models to learn the underlying *trend* in performance as a function of the parameter being varied. We observed that in many cases (with high BoM-err), this trend is inherently hard to predict because it changes too fast (i.e. the underlying function has a high Lipschitz constant). This causes our ML models to generalize poorly [24, 42]. We highlight this phenomena for three applications here, and discuss some of the others in Appendix D.4.

(i) KMeans has a high average BoM-err of 40.4% and 30.4% for prediction across varying input-scale with identical inputs and non-identical inputs respectively. We observed that the

[8]Note that Fig. 3 captures a subset of prediction scenarios (i.e. across varied input scale). This is in contrast to Fig. 2c that captures a wider range of prediction scenarios, which explains any observed deviation from this general trend. Appendix D.3 shows the results for our leave-one-out test with only the predictions across varied input scale, for a more direct comparison.

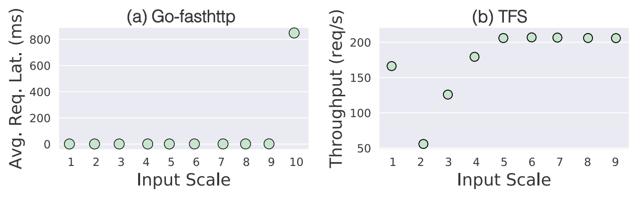

Figure 5: Average request latency of go-fasthttp and TFS at varying input scales. These functions vary too fast, and are hence inherently hard to predict.

performance of KMeans is sensitive to the content of its input dataset. At larger input sizes, Kmeans exhibits multi-modal behavior; specifically, the number of iterations to converge (and hence, the JCT) depends on the input data content (this effect is shown in Fig. 4(b)). This multi-modality impacts O-err and BoM-err in prediction tasks where input content is varied. With identical inputs, this multi-modality impacts the underlying trend as the input scale is varied, making it (surprisingly, even more) difficult to learn. The JCT for an input scale factor of 9 in Fig. 4(a) is an example of this behavior.

*(ii) Go-fasthttp has an exceptionally high average BoM-err of 128.6% for predictions across varying input-scale.*The mean query latency increases dramatically at the highest input scale because the system behavior changes under such high load due to queuing (Fig. 5(a)). This sudden change makes prediction on that value inherently difficult. The BoM-err for go-fasthttp reduces to 4.9% if the test datapoints for the highest input scale are removed from consideration.

(iii) TFS has a higher BoM-err of 52.7% for prediction across varying input-scale. This is again due to the underlying function being difficult to learn, as shown in Fig. 5(b). We are still investigating the root-cause behind this.

6.4 Summary

Application modifications to eliminate sources of irreducible errors do produce a notable increase in prediction accuracy, suggesting that a workflow where application developers provide knobs that give operators the option of disabling these error sources could be a promising direction moving forward. However, there are important concerns that cannot be neglected: (1) From the viewpoint of predictability, as we move to more realistic BBC scenarios, prediction errors do remain high for certain applications due to the underlying trend being difficult to learn (as illustrated in §6.3). Eliminating irreducible errors via application modification is not sufficient in these scenarios. (2) From the viewpoint of generality and ease-of-use, identifying the root causes of errors and making them configurable imposes a non-trivial burden on application developers; the same is true of asking system operators to reason about the trade-offs between predictability and other goals such as performance. In other words, such changes do weaken the black-box nature of performance prediction that we originally hoped ML-based predictors could provide.

7 Probabilistic Predictions

It may not always be possible to identify and eliminate sources of irreducible errors as required by the previous section. For instance, it might be too time-consuming to do so, or the system may be closed-source and not amenable to modifications. Or, operators may not want to compromise on the benefits of the relevant system optimizations (*e.g.,* experiencing slower garbage collection by disabling the GC optimization). Therefore, we now explore an approach that allows operators to *embrace*, rather than eliminate, performance variability.

Our empirical observations in §5 reveal that the optimizations causing irreducible error often lead to bimodal/multimodal performance distributions. This is the key insight that drives our approach, leading us to hypothesize that a way forward could be to extend ML models to predict not just one performance value, but a probability distribution from which we derive k possible values, with the goal that the true value is one of the k predictions, for a low k.

This immediately raises the question of whether such top-k probabilistic predictions would even be useful to an operator? We believe they can be, depending on the use case. For instance, the operator can use the worst among the k predictions when provisioning to meet SLOs; or they can use the average expectations across the k predictions to pick an initial number of workers in a system that anyway dynamically adapts this number over time; or they can use the probability distribution to compare which system configuration will perform better in expectation when purchasing new servers. Note that, as in §6, this approach also comes with a trade-off – using the worst of k predictions may lead to over-provisioning, or using the expected average may lead to sub-optimal choices.

Our goal here is not to design such use cases of probabilistic predictions, or reason about these trade-offs. We instead focus on the following questions: *assuming* operators could make use of top-k probabilistic predictions: (i) how do we extend ML models to enable top-k predictions, and (ii) is there a small enough value of k that results in accurate top-k predictions? If not, exploring use cases of top-k predictions would be moot.

We thus proceed with discussing how we extended two of our models to predict probabilistic outputs (§7.1), and our prediction results (§7.2).

7.1 Extending ML models

We extend random forest and neural network to predict performance as a probability distribution across k possible outputs. We chose these models as they were most natural to extend.

Probabilistic Random Forests (Prob. RF). Instead of using the average JCT of the training points at the leaf node as the prediction (as is done in conventional decision trees), we use the *distribution* of the JCT data points at the leaf node, modeled using a Gaussian Mixture Model (GMM) [34] with k components. We train this Prob. RF as before, still picking splits that minimize the variance of JCT in child nodes.

Mixture Density Networks (MDNs). We adopt MDNs [25],

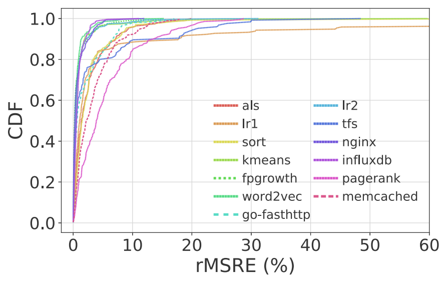

Figure 6: CDF of BoM-err in the BC test where models with prob. outputs are used (k=3). Compare to Fig. 1b.

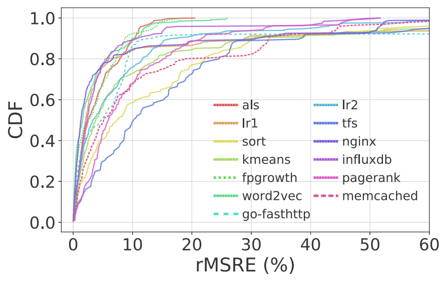

Figure 7: CDF of BoM-err in the BBC leave-one-out test where the models with probabilistic outputs are used (k=3). Compare to Fig 1c.

and modify our neural network to predict parameters for a Gaussian Mixture Model with k components (mean and variance for each component and mixing coefficients). We use negative log-likelihood of the data under the predicted GMM, as the loss function to train the MDN.

We implement Prob. RF based on random forest module in `scikit-learn`, and MDN in TensorFlow [21].

7.2 Top-k Prediction Results

To evaluate predictability with the probabilistic models above, we obtain k predictions from the models as the k different means of the k component GMM, and report the *top-k rMSRE* score, i.e. the rMSRE score of the best prediction among the k predictions made by the model. Such a top-k rMSRE shares the same interpretation as the rMSRE score – in fact, rMSRE scores reported so far can be thought of as top-1 rMSRE scores. In our evaluation, we observed a sharp drop in error rates as we move from a top-1 to top-2 measure and that further improvement plateaus off for $k > 3$. For brevity, we present a subset of our results for $k = 3$.

BC Test Fig.6 shows the top-3 BoM-err under the BC predictions. We see a significant decrease in BoM-err compared to our top-1 prediction presented earlier in Fig.1b. The 90%ile BoM-err is less than 10% for all but two applications. Note that the test data set remains unchanged by our use of probabilistic models, and hence O-err remains as high as in Fig.1a. The reduced BoM-err with top-k predictions shows the promise of this approach in embracing inherent variability.

BBC Test Fig.7 presents the top-3 BoM-err under the BBC test, where we relax the seen-configuration assumption by conducting leave-one-out predictions. While there is an improvement over models that make a single prediction (as in Fig 1c), we note that our multi-modal predictions don't improve performance in cases where the underlying trend is hard to predict for a reason other than multi-modality (*e.g.*, TFS and go-fasthttp).

7.3 Summary

Our findings along this direction are similar to those in §6. While it is possible to reduce prediction errors by extending our ML models to predict top-k performance values, two concerns with regard to generality and ease-of-use remain: (1) Even with top-k predictors, we continue to see scenarios with high error rates when we consider our more realistic BBC tests because the underlying performance trend is difficult to learn. Thus achieving a fully general predictor remains out of reach. (2) The use of top-k predictors complicates the process of applying performance prediction (which compromises ease-of-use) and may lead to sub-optimal decisions; in fact, how to best use such predictions and reason about the resulting trade-offs remains an open question.

8 Takeaways and Next Steps

We set out to evaluate whether ML offers a simpler, more general approach to performance prediction. We showed that: **(1)** Taken "out of the box", many of the applications we studied exhibit a surprisingly high degree of irreducible error, which fundamentally limits the accuracy that *any* ML-based predictor can achieve, and **(2)** We *can* significantly improve accuracy if we relax our goals (accepting the trade offs) and modify applications and/or modify how we use predictions. But even with these relaxations we still see a non-trivial number of predictions with high error rates! E.g., apps where $\sim$10% of the BBC tests have BoM-err $>$ 30-40%.

While ML fails to meet our goal of generality, we did find several scenarios where ML-based prediction *was* effective, showing that we must apply ML in a more nuanced manner by first identifying whether/when ML-based prediction is effective. Our methodology provides a **blueprint** for this, as summarized in Figure 8. Concretely, say that operators want to assess and improve the predictability of a target application. The first step is to run our BC test with the target workloads. If O-err is low, they can continue to the BBC test and check BoM-err. Otherwise, they have two options. The first is to disable any root-causes of variability if possible, rebuild the application, and re-run the BC test. If disabling root-causes is not possible or not desirable, operators can choose to use the top-k predictions. They can also combine both options, reconfiguring the application and using probabilistic predictions.

Even for this more nuanced approach, many open questions remain: (i) do our findings hold beyond the 13 apps and 6 models studied? (ii) how do we design systems to more easily identify sources of irreducible error? (iii) how can developers and operators more easily reason about trade offs between predictability and other design goals? Etc.

Our work provides empirical evidence motivating the above

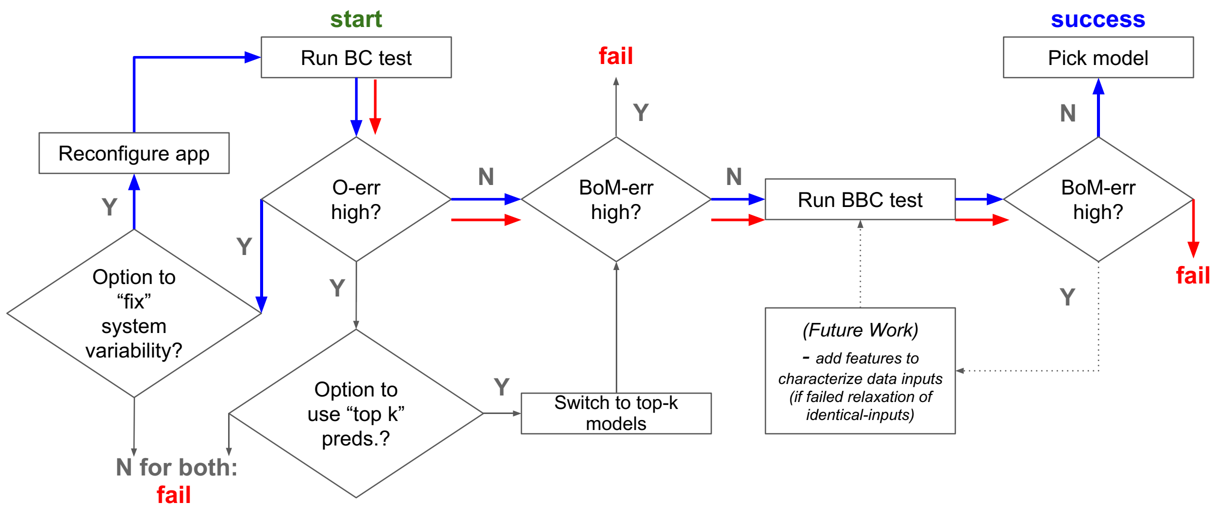

Figure 8: Methodology blueprint. As examples from our findings: Terasort's path (shown in blue) started out with only 73% of prediction tests having an O-err <10% in our BC test but once we eliminated its root-cause of irreducible error (the worker-readiness optimization), 99+% of test cases saw an O-err <10% and the BoM-err even in our BBC test was <10% for ~90% of test cases leading to what we would deem a successful outcome. By contrast, KMeans (shown by the red path) started with a good O-err in our BC test (>90% of test cases had O-err <10%) but ultimately failed when we relaxed our identical-inputs assumption where point >60% of prediction tests had O-err >20%!

questions and a blueprint for how to approach and evaluate them. Overall, we remain cautiously skeptical about the role of ML in predicting system performance. We note that a common thread in the above questions is the need to evaluate predictors in a manner that is systematic and *consistent across studies*. We call on the community to adopt and extend our methodology as the foundation for such evaluation.

9 Related Work

Prior work has explored using ML based performance prediction for tuning and optimizing system configuration. Ernest [57] uses domain expert knowledge to build an analytical model for Spark performance, that is based on transformations and combinations of different features (such as number of cloud instances and input dataset scale), and trains the parameters of this model using ML.

Similar data-driven, gray-box modeling approaches have been applied to predicting and tuning performance for deep learning workloads and scientific computing [47, 48]. Paris [60] is a black-box performance modeling tool for selecting the best instance type by training a Random Forest model for each instance, and profiling unseen test applications on a small subset of instances to feed as input to the model.

Selecta [37] makes innovative use of collaborative filtering to predict performance and select the best-performing storage configuration for data analytics applications. CherryPick [22] explores black-box optimization (Bayesian Optimization) for a guided search towards the optimal cloud configurations without accurately predicting performance. Google's Vizier [31] leverages similar black-box optimization and makes it an internal application service for various workloads. Each of the above focus on answering a specific question with a specific ML technique. Our goal is to understand how ML can be more broadly applied to predicting performance across a range of systems and predictive tasks. We hope that our results, particularly as they relate to our methodology and irreducible error, can be applied to many of the contexts explored in prior work. Monotasks [44] proposes a radically new design for Spark aiming at assisting performance diagnostics and prediction; it does not explore the role of ML for performance prediction.

Similar to our proposal in §7.1, several recent papers recognize that performance is perhaps better represented as a probability distribution. [51] proposes modeling the performance of individual functions/methods as probability distributions and presents automatic instrumentation to capture such distributions. [45] shows how to design cluster schedulers that take as input, distributions derived from historical performance. Our proposal adds a new dimension to this general approach: we show how to extend ML models to generate probabilistic performance predictions.

Google Wide Profiler [36, 50] explores the use of performance counter information collected on an always-on profiling infrastructure in datacenters to provide performance insights and drive job scheduling decisions. As mentioned in §2, our work differs in that we focus on static parameters to enable use-cases where predictions happen before runtime.

Performance variability has been widely reported in contexts from hardware-induced variability [41], to stragglers in batch analytics [59], variability in VM network performance [52], and tail request latencies in microservices [29]. Our work can be thought as complementary: we studied a wide range of applications, report variability even under best-case scenarios, focus on the impact of variability to ML-based performance prediction, and propose systematic approaches to cope with variability.

Appendix

A Test Applications: Additional Detail

We include **Memcached**, a popular in-memory key-value store. We use the mutilate [13, 39] memcached load generator which generates realistic memcached request streams and records fine-grained latency measurements. We vary the key size (corresponding to the varying input scale prediction), number of memcached servers (varying number of servers), and the server instance type, while keeping the other workload parameters in mutilate as fixed values[9]. We report results on predicting the average query latency.

We include **Influxdb**, a widely used timeseries database. We use its official benchmarking tool Inch as the client. Inch sends write queries to Influxdb and reports the time it takes to complete each write query. We vary the number of points per timeseries written per query (varying input scale prediction), the number of Influxdb servers, and the server instance type. We report results on predicting the query latency.

We include **nginx**. We use wrk2, an http benchmarking tool used by nginx's official benchmark reports [19]. It sends http requests and reports fine-grain latency and throughput measurements. We vary the per-client request rate, number of worker processes (each worker process is a single-threaded process; the maximum number of worker processes we vary to is equal to the number of cores of the instance), and the server instance type. We report results on predicting the median request latency.

We include **go-fasthttp**, a high-performance HTTP package for building REST services. We use the wrk2 tool to generate HTTP loads again. We vary the request rate, number of server instances, and the server instance type. We report results on predicting the median request latency.

We include multiple **Spark-based applications** spanning diverse forms of computation: sorting, graph computation, classification (two different implementations), data mining, recommendation etc.

We include **Tensorflow Serving (TFS)**, a high performance model serving system, which we orchestrate using Kubernetes (k8s). Our TFS setup resembles that of other (e.g., Web) serving systems in which a front-end load balancer (we use EC2 ELB) spreads client requests across a backend of (model) serving instances.

B Understanding Irreducible Errors – Details

B.1 Spark's "Worker-readiness" Optimization

Details included in the main text.

B.2 Multi-mode Optimization in JVM GC

We elaborate on the details of how the JVM adapative GC leads to variable application performance in the context of our Spark Logistic Regression (LR1) workload.

[9]See https://github.com/perfd/perfd/blob/master/apps/memcached/manifests/perf_predict/suite_1/keySize.yaml for an example setup.

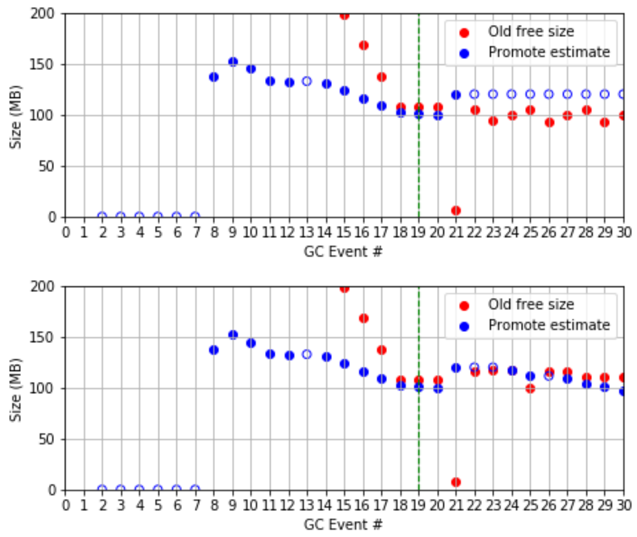

Figure 9: High-mode (top) and Low-mode (bottom) trajectories for promotion estimate and free space in old region during the first 30 garbage collections. Hollow blue dots depict major/full GCs and solid blue dots depict minor GCs.

§5.1.2 revealed a positive correlation between the number of *full* GCs (explained below) and JCT with a distinct bimodal behaviour. We now describe how this bimodality arises. For this, we first explain relevant aspects of the GC mechanism in Java Virtual Machine (JVM) that Spark uses.

JVM divides the Java memory heap into two regions – a *young* region to allocate new objects, and an *old* region to accommodate 'old' objects that have survived multiple GC rounds. It supports three different types of GCs over these regions: (i) *minor GC* on the young region, (ii) *major GC* on the old region, and (iii) *full GC* over the entire heap space (both young and old regions), with the surviving objects residing in the old region.

In the face of heap space shortage, JVM first runs a minor GC on the young region, deleting the unused objects and promoting the old objects (that have survived multiple GC rounds) to the old region. A minor GC triggers a major GC if the old region has too little free space to hold the promoted objects. If a minor GC constantly triggers a major GC, the garbage collector can save time by skipping the minor GC (and the ensuing major GC), and directly running full GC over the entire space. JVM implements this adaptive skipping of minor GC as a performance optimization. To estimate whether a minor GC would trigger a major GC, it maintains a *promotion estimate*, calculated as the moving average of the number of promoted objects after each round of minor GC. If the promotion estimate is higher than the amount of free space in the old region, JVM GC skips the minor GC and runs a full GC directly.

We now show how this adaptive skipping behavior impacts performance predictability. We randomly pick one sample each from the slower "high-mode" runs (whose JCTs sit at the top-right corner of the figure in §5.1.2) and the faster "low-mode" runs (whose JCTs sits in the bottom-left corner of the figure in §5.1.2). The top and bottom plots in Fig.9 show the promotion estimate values and the amount of free space in the old region observed for the first 30 GC events in the two sample runs respectively.

Fig.9(top) reveals that beyond GC event #21, the promotion estimate in the high-mode run remains greater than the amount of free space in the old region (even after event 30, beyond what the plot shows). This results in consecutive full GCs (shown as hollow blue dots). Note that since no objects get promoted in a full GC, the JVM does not update the promotion estimate.

Fig.9(bottom) shows how the low-mode run escapes from such a fate: the promotion estimate is higher than the amount of free old space only for a few GC events, and stays lower than that beyond GC event #26. Consequently, the low mode run sees more minor GCs than full GCs (shown as solid blue dots). Since a full GC, which scans objects across a larger memory space, is significantly more time consuming than a minor GC, the perpetuation of full GCs has a large impact JCT (witnessed in the scatter-plot in §5.1.2).

Fig.10 shows the corresponding time-series of GC events along with events that mark the start and finish of individual tasks (for clarity, we only show the time range of 20-26s, which captures the regime where the two runs start deviating from one another). Careful observation of Fig.10 reveals that the GC behaviour of the two runs begins to diverge around time 24s, when two of tasks finish slightly earlier in the high mode run than in the low mode run. We checked that around this time, the two modes see a difference of about 10MB in the amount of free old space (which is rather small compared to the total heap size of 1GB).

Such subtle differences cannot be determined without knowing the runtime state of the garbage collection and the Spark application.

B.3 Non-determinism in the Spark Scheduler

Our analysis revealed that PageRank's high O-err stems from non-determinism in the Spark scheduler. Specifically, in a job with multiple stages, a stage A may be *independent* of stage B in the sense that A's tasks can be scheduled to run whether or not B's tasks have completed. Our traces showed that independent stages were being scheduled in different orders in different runs leading to different JCTs. This arises because of how the Spark scheduler tracks dependencies between stages. Spark's scheduler maintains a graph that captures the dependencies between stages; a stage v's parents in the graph are those stages that can only be scheduled after v is complete. Spark's scheduler uses the Scala `HashSet` data structure to track the parents of a stage. When the search propagates to the parents, the order of visiting these parents can be inconsistent across runs because `HashSet` makes no guarantees on the order of iteration through the set members.

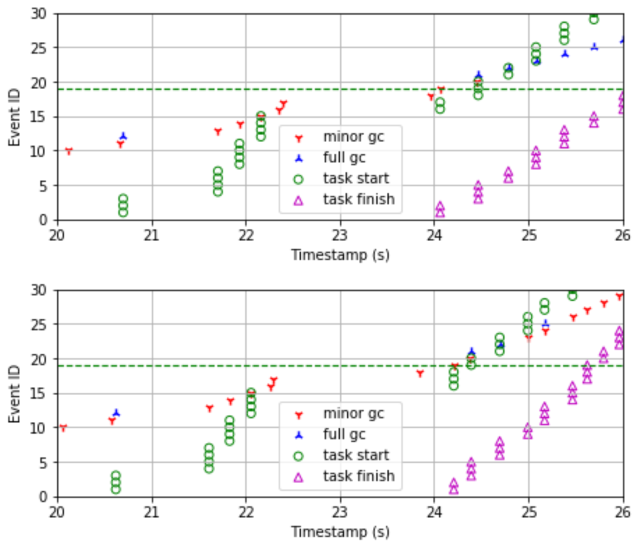

Figure 10: High-mode (top) and Low-mode (bottom) trajectories for the run-time events. Note that unlike Fig.9, the x-axis unit here is the wall time.

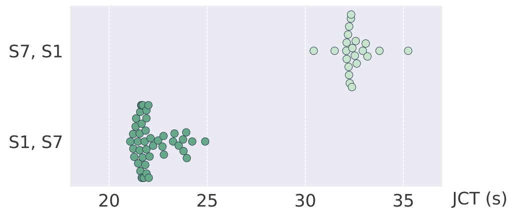

Figure 11: Bimodal performance that results from scheduling independent stages in different orders.

Fig.11 shows the effect of this non-determinism. Stages 1 and 7 are two independent stages and the figure plots the JCT for runs where stage 7 is scheduled before stage 1 (dots on the bottom-left) and vice versa (dots on the top-right). We see that the difference in scheduling order corresponds to bimodality in the JCTs. We emphasize that this bimodality could not be predicted prior to runtime as it depends on the runtime state of the HashSet structure rather than any static input parameters.

Setup	Naive-err	BoM-err	O-err
Baseline	44.7%	19.2%	18.2%
+Sched. mod.	40.7%	5.7%	3.2%

Table 3: Prediction error before vs. after.

To verify our analysis, we modify the Spark scheduler such that the order of scheduled stages is consistent across runs with identical configurations (replacing HashSet with a LinkedHashSet). Table 3 shows that our modification (the "+Sched. mod." row) reduces the O-err by more than 5.7x bringing the error to under 4%.

B.4 HTTP Redirection and DNS Caching in S3

Multiple applications in our study – KMeans, LR2, FPGrowth, and ALS – experienced irreducible errors due to name resolution in Amazon's S3 storage service. We explain this effect in the context of the KMeans application.

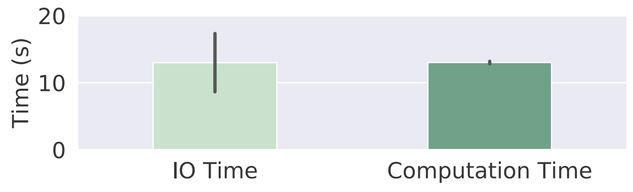

Figure 12: Breakdowns of Spark KMeans job completion time as time spent on cloud storage IO (writing the results to S3) and on computation for 100 experiment runs.

When triaging the overall JCT, we often found that, on average, the computation time was on par with the S3 IO time but that the standard deviation for the latter was 24× times higher than the former (Fig.12). Analysis of the application's runtime logs for KMeans revealed that the *variance* in performance stems from I/O to Amazon's S3 storage service. This is shown in Fig.12 which breaks down the overall JCT into computation time and S3 IO time. We see that the computation time has little variance while the S3 IO time has substantial variance (between 17.5s and 9s).

Further instrumentation revealed a correlation between the time spent on S3 IO and the number of HTTP redirection events, and that the latter varied across multiple runs of identical test configurations.

S3 is a distributed storage service in which objects are spread across multiple datacenters. When a new object "bucket" is created, its DNS entry points to a default datacenter location. If a user creates a bucket in a datacenter other than the default one, then a request to that bucket is first sent to the default server, which responds with an HTTP redirect containing a new URL that resolves to the datacenter where the bucket is located.

Such redirection continues until the DNS entry for the bucket is correctly updated.[10] The S3 buckets in our experiments were created in a different datacenter from the default one, leading to such HTTP redirects.

Fig.13 illustrates the above behavior during one of our experiments. We plot two values over time: (a) the number of distinct S3 servers that our application connected to, and, (b) the time spent on S3 IO. We observe three distinct phases to S3 performance, demarcated by green lines in Fig.13.

Interestingly, we observe a significant intermediate period where the two values oscillate. We found that this oscillation arises because AWS load-balances DNS requests across a pool of DNS servers and the servers in this pool converge to the new DNS entry at different times. In summary, we see

[10]AWS states that DNS entries can take up to 24 hours to be fully propagated; we observed average delays of approx 4 hours. AWS also recommends that clients not cache the redirect URL as its validity is only temporary.

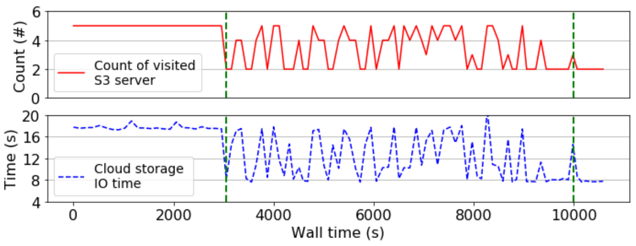

Figure 13: The number of S3 servers visited during the cloud storage IO (top) and the total IO time (bottom). This is plotted over wall-clock time during multiple rounds of experiments.

variable performance even for identical test configurations due to the distributed and eventually-consistent nature of object name resolution in S3. To validate our analysis, we repeated our experiments after modifying the KMeans application to cache the correct bucket location after the first redirection event (yes, ignoring AWS' recommendation). Table 4 shows that this modification dramatically reduces prediction error to an O-err of 1.0% and a BoM-err of 1.1%.

Setup	Naive-err	BoM-err	O-err
Baseline	22.7%	16.0%	15.2%
Correct bucket loc.	5.6%	1.1%	1.0%

Table 4: Prediction error before vs. after.

One might ask whether it is possible to predict the impact of AWS's DNS service on applications. An in-depth exploration of this question is beyond the scope of this paper. However, we note that doing so appears impractical, if not infeasible, since we would have to know how an application's lifetime overlaps with the DNS timers not just for a single server but for an entire pool of servers, as well as precisely knowing how DNS requests are load-balanced across this pool.

B.5 Imperfect load-balancing at high load

We observed high irreducible errors when predicting the request throughput provided by a TFS cluster under increasing numbers of workers (servers). Our analysis revealed that this high error stems from how client requests are load-balanced across TFS servers. We run TFS servers within a Kubernetes cluster and hence incoming client requests undergo two levels of load balancing. First, the AWS Elastic Load Balancer round-robins incoming client connections across the k8s nodes. Next, each k8s node load balances incoming RPCs across the TFS instances.

We found that the irreducible errors in TFS stem from the second stage of load-balancing. The load-balancing within k8s is based on selecting a TFS server at random, leading to some inherent imbalance in the load at each server. When running the TFS cluster at high utilization (as our experiments do), this imbalance means that some servers are already running at capacity while others are running below the maximum request rate they can sustain. The *variability in this imbalance* leads to variations in the overall request throughput; e.g., in repeated runs of one identical test setup, we saw aggregate throughput vary between 80-140 req/sec.

Setup	Naive-err	BoM-err	O-err
Baseline tput.	123.5%	26.7%	11.8%
-Rnd LB tput.	163.2%	7.6%	6.7%

Table 5: Prediction error before vs. after.

To verify this effect, we reconfigure the k8s load-balancer to always direct client RPCs to the local TFS server instance. In effect, this disables the k8s load-balancer which is acceptable for our test purposes. Table 5 shows that this modification substantially reduces the prediction error. We found a similar effect when predicting request latency and also found that incorporating heavy-hitter clients exacerbated the error due to randomized load-balancing.

B.6 Variability in Implementations of Cloud APIs

We observed high O-err in the memcached and ngnix applications, both stemming from variability in how the cluster is configured and the limited control/visibility that default cloud APIs provide for this process.

In the case of memcached, the variability stemmed from how our worker instances were being placed within the cloud infrastructure. Our experiments used EC2's default VM placement which offers no guarantee on the proximity between our allocated instances and hence our node-to-node latency varied across runs. This in turn led to variable memcached read latencies, as we found memcached read times are dominated by the network latency between the client and server in our setup. We found that switching to an API that consistently places a set of instances close together reduced the O-err from 36.9% to 2.4% (varying input scale) [14].

For nginx, the high O-err stemmed from variability in the default network bandwidth associated with smaller instance types. Specifically, with EC2's "c5" instances types, those smaller than c5.9xlarge are by default assigned "up to" 10Gbps network bandwidth while c5.9xlarge instances are assigned exactly 10Gbps. For smaller instance types we found that EC2 *occasionally* throttles network bandwidth and the degree of throttling varies across runs (see Appendix B.6). The response time in nginx is also dominated by the network latency between client and server and hence this variability in throttling leads to unpredictable request latencies. Repeating our scale-out and input-scaling tests with a c5.9xlarge instance (instead of our previous default of c5.xlarge for the client and c5.4xlarge for the server) reduced the O-err from 15.6% to 2.0% under varying number of workers.

Fig.20 depicts the varying available bandwidth across different runs of the same configuration (specifically, the number of worker processes in varying number of worker process scenario). We measured the node-to-node bandwidth using iperf between the instance running the client (wrk2) and the instance running the nginx right before the experiments were run. The results show that despite the configurations (instance types, number of worker processes) remaining the same, the available bandwidth can vary. We conjecture this is a result of the bandwidth allocation mechanism AWS employs, which throttles bandwidth usage based on an estimation of the average network utilization of the instances [4].

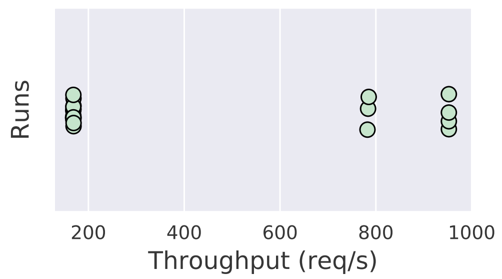

Figure 14: Available bandwidth (measured with `iperf`) between client and server nodes across different runs of the same configuration.

Note that it is arguable whether the above sources of error are "irreducible". On the one hand, it might be possible to augment cloud APIs or incorporate the parameters of cloud APIs as a feature in our ML models, however, doing so is likely to come at a loss in flexibility and efficiency for cloud operators. E.g., one might envisage placement APIs that guarantee *consistent* proximity between instances, but the achievable proximity is likely to vary depending on the number and type of instances (we will see an example of this in §**??**). Similarly, if the AWS throttling that we observed is determined by current network load,[11] then it is not clear how one might capture the impact of throttling prior to runtime. We leave the question of how cloud providers might augment their APIs to aid performance predictability as a topic for future work.

C Best-Case Analysis - More Details

Fig.15 and Fig.16 describe the per-app average prediction error rates for best-case experiments.

D Beyond Best-Case Analysis - More Details

D.1 Leave-one-out - More Details

Fig.17 and Fig.18 describe the per-app average prediction error rates for leave-one-out experiments.

D.2 Dedicated Instance vs. Shared Instance

Fig.20 shows the impact of changing dedicated instance type to shared instance type for the Memcached and Spark sorting applications. We see that overall the relaxation does not have a statistically meaningful impact on the predictability of these two applications.

[11] AWS documentation does not elaborate on the exact conditions under which they implement throttling [4]

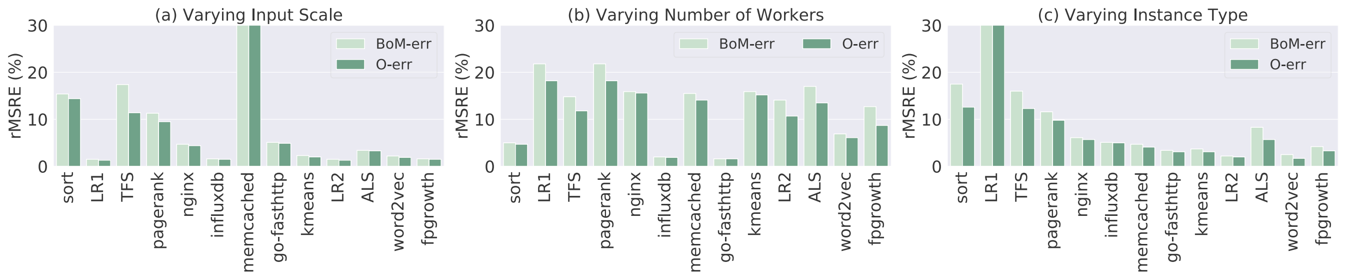

Figure 15: Best-case prediction errors for different applications under (a) changing input-scale, (b) scaling-out the number of workers, and (c) scaling-up the instances; before system modifications.

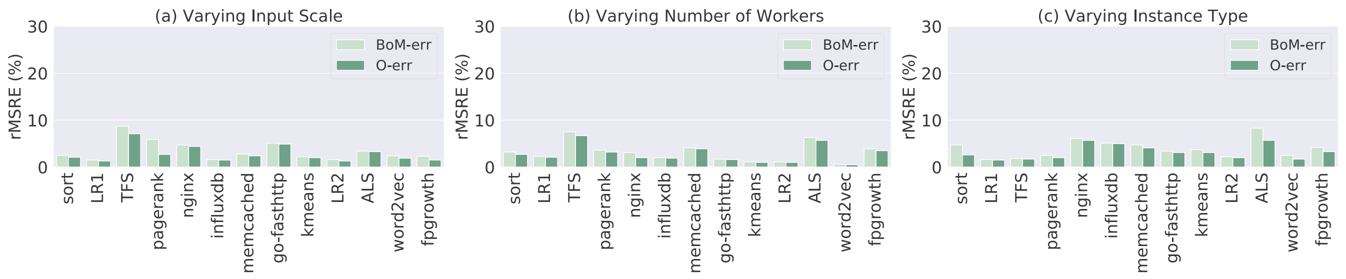

Figure 16: Best-case prediction errors for different applications under (a) changing input-scale, (b) scaling-out the number of workers, and (c) scaling-up the instances; after system modifications.

D.3 Leave-one-out Test with only Varied Input Scale

Fig.21 shows the CDFs of BoM-err in the BBC leave-one-out test, for only the predicitons across varying input data scale.

D.4 High BoM-err in BBC after App. Modifications - Other Applications

(i) TFS has a higher BoM-err of 52.7% for prediction across varying input-scale. This proved to be because the trend in TFS throughput under varying input scale is inherently hard to predict. The underlying function – shown in Fig.5(a) – has a high Lipschitz constant (*i.e.,* it changes too fast), which causes the trained model to have poor generalization [24, 42]. We have not yet been able to determine the root cause for this odd trend in TFS.

(ii) Memcached has a high BoM-err of 50.9% for prediction across scaling up instance types. Recall from §5 that memcached performance is sensitive to the node-to-node latency and hence we modified our experiments to use AWS's cluster placement group API that ensures nodes in a cluster are consistently placed close to each other. This avoids variability in placement across multiple runs of an identical test configuration. However, what we discovered is that while AWS's placement API is consistent in the proximity at which it places instances of a particular type, this proximity may vary across *different* instance types, making it hard for our ML models to learn a trend across instance types (as is needed for our leave-one-out analysis).

E Comparing ML Models

So far, we focused on the error of the best-performing ML model for a given task. We now compare across our six ML models. We do so in the context of our leave-one-out analysis since it is both more challenging and realistic. Table 6(top) reports the error rate that each model achieves for each of the three prediction scenarios, averaged across all applications. We normalize each of these error rates by the lowest average error for the corresponding prediction scenario. Therefore, a normalized value of 1.0 indicates that the corresponding model performed the best (on average) for the corresponding prediction scenario. Table 6(bottom) similarly reports the normalized error rates for each model and each application, but now averaged across all prediction tasks.

It is important to note that our analysis uses only out-of-the-box versions of each ML model and applies the same hyperparameter tuning approach to each of them. This is in contrast to many prior studies (in systems contexts and beyond) in which a particular model is often specialized and carefully tuned to achieve high accuracy for a given prediction task [28, 32, 60]. In this sense, our results can be viewed as a "fair" comparison of models while at the same time we acknowledge that the performance of any individual model/prediction could probably be improved through careful tuning. We view our approach as establishing a useful baseline and conjecture that there is value to a low-effort ML predictor, especially given the rapid pace of evolution in modern software services.

We draw the following conclusions from our results:

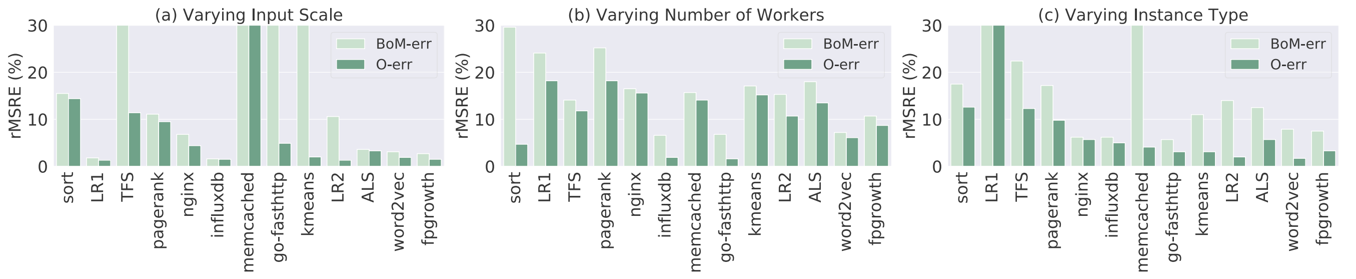

Figure 17: Leave-one-out prediction errors for different applications under (a) changing input-scale, (b) scaling-out the number of workers, and (c) scaling-up the instances; before system modifications.

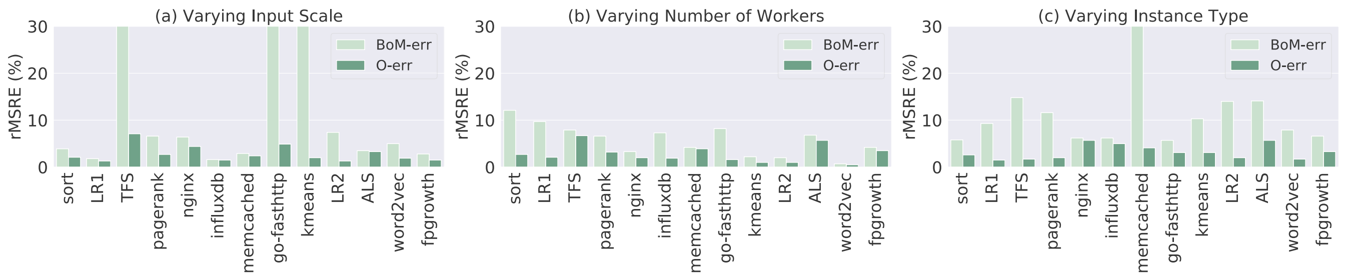

Figure 18: Leave-one-out prediction errors for different applications under (a) changing input-scale, (b) scaling-out the number of workers, and (c) scaling-up the instances; after system modifications.

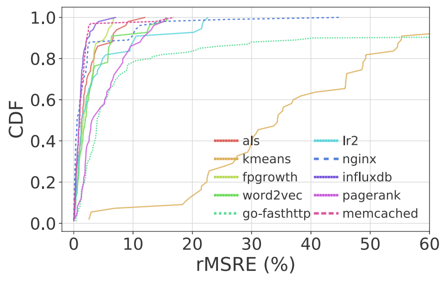

Figure 19: CDF of BoM-err in the BBC leave-one-out test where input data content is identical, for predictions across varying input data scale

(i) The key takeaway from our results is that there is no clear winner: no ML model performs the best across all prediction scenarios and across all applications. This validates the merits of studying a range of ML models and applications so that we can understand how to best apply or combine various models.

(ii) There is no clear loser either: each model performs the best for at least one prediction scenario or application.

(iii) Even though there is no clear winner, neural network often results in the best performance or has error rates close to the best performing model. There were a few exceptions where neural network resulted in 2× higher error rates than the lowest error. We found that using a different hyper-parameter tuning methodology reduced the neural network error in these cases. This confirms the common wisdom that neural net-

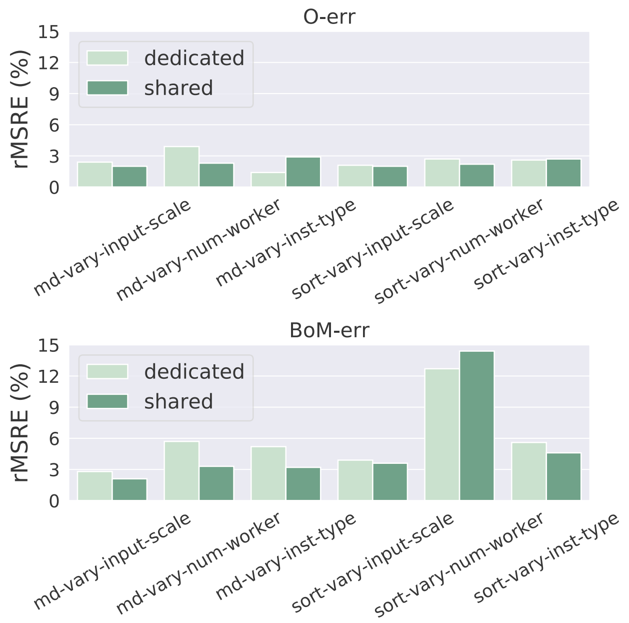

Figure 20: Memcached (md) and Spark sorting (sort) prediction accuracy in the three prediction scenarios with dedicated instances and shared instances.

works, while powerful, can be difficult to train and tune.
(iv) For cases where neural network performed the best, there was often at least one other simpler model performed as well.

Abstract

Training machine learning models in parallel is an increasingly important workload. We accelerate distributed parallel training by designing a communication primitive that uses a programmable switch dataplane to execute a key step of the training process. Our approach, SwitchML, reduces the volume of exchanged data by aggregating the model updates from multiple workers in the network. We co-design the switch processing with the end-host protocols and ML frameworks to provide an efficient solution that speeds up training by up to 5.5× for a number of real-world benchmark models.

1 Introduction

Today's machine learning (ML) solutions' remarkable success derives from the ability to build increasingly sophisticated models on increasingly large data sets. To cope with the resulting increase in training time, ML practitioners use distributed training [1, 22]. Large-scale clusters use hundreds of nodes, each equipped with multiple GPUs or other hardware accelerators (e.g., TPUs [48]), to run training jobs on tens of workers that take many hours or days.

Distributed training is increasingly a *network-bound* workload. To be clear, it remains computationally intensive. But the last seven years have brought a 62× improvement in compute performance [64, 78], thanks to GPUs [74] and other hardware accelerators [11, 34, 35, 48]). Cloud network deployments have found this pace hard to match, skewing the ratio of computation to communication towards the latter. Since parallelization techniques like mini-batch stochastic gradient descent (SGD) training [37, 43] alternate computation with synchronous model updates among workers, network performance now has a substantial impact on training time.

Can a new type of accelerator *in the network* alleviate the network bottleneck? We demonstrate that an *in-network aggregation* primitive can accelerate distributed ML workloads, and can be implemented using programmable switch hardware [5, 10]. Aggregation reduces the amount of data transmitted during synchronization phases, which increases throughput, diminishes latency, and speeds up training time.

Building an in-network aggregation primitive using programmable switches presents many challenges. First, the per-packet processing capabilities are limited, and so is on-chip memory. We must limit our resource usage so that the switch can perform its primary function of conveying packets. Second, the computing units inside a programmable switch operate on integer values, whereas ML frameworks and models operate on floating-point values. Finally, the in-network aggregation primitive is an all-to-all primitive, unlike traditional unicast or multicast communication patterns. As a result, in-network aggregation requires mechanisms for synchronizing workers and detecting and recovering from packet loss.

We address these challenges in SwitchML, showing that it is indeed possible for a programmable network device to perform in-network aggregation at line rate. SwitchML is a co-design of in-switch processing with an end-host transport layer and ML frameworks. It leverages the following insights. First, aggregation involves a simple arithmetic operation, making it amenable to parallelization and pipelined execution on programmable network devices. We decompose the parameter updates into appropriately-sized chunks that can be individually processed by the switch pipeline. Second, aggregation for SGD can be applied separately on different portions of the input data, disregarding order, without affecting the correctness of the final result. We tolerate packet loss through the use of a light-weight switch scoreboard mechanism and a retransmission mechanism driven solely by end hosts, which together ensure that workers operate in lock-step without any decrease in switch aggregation throughput. Third, ML training is robust to modest approximations in its compute operations. We address the lack of floating-point support in switch dataplanes by having the workers scale and convert floating-point values to fixed-point using an adaptive scaling factor with negligible approximation loss.

*Equal contribution. Amedeo Sapio is affiliated with Barefoot Networks, but was at KAUST during much of this work.

SwitchML integrates with distributed ML frameworks, such as PyTorch and TensorFlow, to accelerate their communication, and enable efficient training of deep neural networks (DNNs). Our initial prototype targets a *rack-scale architecture*, where a single switch centrally aggregates parameter updates from serviced workers. Though the single switch limits scalability, we note that commercially-available programmable switches can service up to 64 nodes at 100 Gbps or 256 at 25 Gbps. As each worker is typically equipped with multiple GPUs, this scale is sufficiently large to push the statistical limits of SGD [32, 43, 50, 98].

We show that SwitchML's in-network aggregation yields end-to-end improvements in training performance of up to 5.5× for popular DNN models. Focusing on a communication microbenchmark, compared to the best-in-class collective library NCCL [77], SwitchML is up to 2.9× faster than NCCL with RDMA and 9.1× than NCCL with TCP. While the magnitude of the performance improvements is dependent on the neural network architecture and the underlying physical network speed, it is greater for models with smaller compute-to-communication ratios – good news for future, faster DNN training accelerators.

Our approach is not tied to any particular ML framework; we have integrated SwitchML with Horovod [89] and NCCL [77], which support several popular toolkits like TensorFlow and PyTorch. SwitchML is openly available at https://github.com/p4lang/p4app-switchML.

2 Network bottlenecks in ML training

In the distributed setting, ML training yields a high-performance networking problem, which we highlight below after reviewing the traditional ML training process.

2.1 Training and all to all communication

Supervised ML problems, including logistic regression, support vector machines and deep learning, are typically solved by iterative algorithms such as stochastic gradient descent (SGD) or one of its many variants (e.g., using momentum, mini-batching, importance sampling, preconditioning, variance reduction) [72, 73, 83, 90]. A common approach to scaling to large models and datasets is data-parallelism, where the input data is partitioned across workers.[1] Training in a data-parallel, synchronized fashion on n workers can be seen as learning a model $x \in \mathbb{R}^d$ over input/training data D by performing iterations of the form $x^{t+1} = x^t + \sum_{i=1}^{n} \Delta(x^t, D_i^t)$, where x^t is a vector of model parameters[2] at iteration t, $\Delta(\cdot,\cdot)$ is the model update function[3] and D_i^t is the data subset used at worker i during that iteration.

The key to data parallelism is that each worker i, in parallel, locally computes the update $\Delta(x^t, D_i^t)$ to the model parameters based on the current model x^t and a mini-batch, i.e., a subset of the local data D_i^t. Typically, a model update contributed by worker i is a multiple of the stochastic gradient of the loss function with respect to the current model parameters x^t computed across a mini-batch of training data, D_i^t. Subsequently, workers communicate their updates, which are aggregated ($\sum$) and added to x^t to form the model parameters of the next iteration. Importantly, each iteration acts only on a mini-batch of the training data. It requires many iterations to progress through the entire dataset, which constitutes a training epoch. A typical training job requires multiple epochs, reprocessing the full training data set, until the model achieves acceptable error on a validation set.

From a networking perspective, the challenge is that data-parallel SGD requires computing the sum of model updates across all workers after every iteration. Each model update has as many parameters as the model itself, so they are often in 100s-of-MB or GB range. And their size is growing exponentially: today's largest models exceed 32 GB [84]. These aggregations need to be performed frequently, as increasing the mini-batch size hurts convergence [66]. Today's ML toolkits implement this communication phase in one of two ways:

The parameter server (PS) approach. In this approach, workers compute model updates and send them to *parameter servers* [45, 56, 64]. These servers, usually dedicated machines, aggregate updates to compute and distribute the new model parameters. To prevent the PS from becoming a bottleneck, the model is sharded over multiple PS nodes.

The all-reduce approach. An alternate approach uses the workers to run an all-reduce algorithm – a collective communication technique common in high-performance computing – to combine model updates. The workers communicate over an overlay network. A *ring* topology [6], where each worker communicates to the next neighboring worker on the ring, is common because it is bandwidth-optimal (though its latency grows with the number of workers) [79]. *Halving and doubling* uses a binary tree topology [93] instead.

2.2 The network bottleneck

Fundamentally, training alternates compute-intensive phases with communication-intensive model update synchronization. Workers produce intense bursts of traffic to communicate their model updates, whether it is done through a parameter server or all-reduce, and training stalls until it is complete.

Recent studies have shown that performance bottleneck in distributed training is increasingly shifting from compute to communication [64]. This shift comes from two sources. The first is a result of advances in GPUs and other compute accelerators. For example, the recently released NVIDIA A100 offers 10× and 20× performance improvements for floating-point

[1]In this paper, we do not consider model-parallel training [28, 82], although that approach also requires efficient networking. Further, we focus exclusively on widely-used distributed synchronous SGD [1, 37].

[2]In applications, x is typically a 1, 2, or 3 dimensional tensor. To simplify notation, we assume its entries are vectorized into one d dimensional vector.

[3]We abstract learning rate (step size) and model averaging inside Δ.

and mixed-precision calculations, respectively [74] compared to its predecessor, the V100 – released just 2.5 years previously. This pace far exceeds advances in network bandwidth: a 10× improvement in Ethernet speeds (from 10 Gbps to 100 Gbps) required 8 years to standardize.

Second, the ratio of communication to computation in the workload itself has shifted. The current trend towards ever-larger DNNs generally exacerbates this issue. However, this effect is highly application-dependent. In popular ML toolkits, communication and computation phases can partially overlap. Since back-prop proceeds incrementally, communication can start as soon as the earliest partial results of back-prop are available. The effectiveness of this technique depends on the structure of the DNN. For DNNs with large initial layers, its effectiveness is marginal, because there is little to no opportunity to overlap communication with computation.

When is the network a bottleneck? To answer this quantitatively, we profile the training of 8 common DNNs on a cluster with 8 workers using NVIDIA P100 GPUs. To precisely factor out the contribution of communication to the processing time of a mini-batch, we emulate communication time at 10 Gbps or 100 Gbps Ethernet assuming transmission at line rate. We record the network-level events, which allows us to report the fraction of time spent in communication as well as how much can overlap with computation (Table 1). At 10 Gbps, all but three workloads spend more than 50% of their time in communication, usually with little computation-phase overlap. These workloads benefit greatly from 100 Gbps networking, but even so communication remains a significant share (at least 17%) of batch processing time for half of the workloads.

What happens when GPUs become faster? Our profile uses P100 GPUs, now two generations old. Faster GPUs would reduce the computation time, increasing the relative communication fraction. Our measurement of non-overlappable communication time allows us to determine the scaling factor α applied to GPU computation time at which point the network is saturated. There is still some speedup beyond an $\alpha\times$ faster GPU, but it is limited to the initial phase, before communication begins. Note $\alpha < 4$ for half the workloads (Table 1), suggesting that network performance will be a serious issue when using the latest GPUs with a 100 Gbps network.

3 In-network aggregation

We propose an alternative approach to model update exchange for ML workloads: *in-network aggregation*. In this approach, workers send their model updates over the network, where an aggregation primitive in the network sums the updates and distributes only the resulting value. Variations on this primitive have been proposed, over the years, for specialized supercomputer networks [2, 26] and InfiniBand [33]. We demonstrate

Model	Size	Batch	10 Gbps		100 Gbps		
	[MB]	size	Batch [ms]	Comm [%]	Batch [ms]	Comm [%]	α
DeepLight	2319	2^{13}	2101 ± 1.4	97% (2%)	258 ± 0.4	79% (20%)	1.0
LSTM	1627	64	1534 ± 8.3	94% (10%)	312 ± 6.8	46% (56%)	1.5
BERT	1274	4	1677 ± 7.1	67% (3%)	668 ± 3.1	17% (35%)	3.5
VGG19	548	64	661 ± 1.9	73% (67%)	499 ± 1.1	10% (99%)	6.7
UGATIT	511	2	1612 ± 2.5	28% (84%)	1212 ± 3.5	4% (99%)	17.6
NCF	121	2^{17}	149 ± 0.6	72% (4%)	46 ± 0.1	23% (27%)	1.2
SSD	98	16	293 ± 0.6	26% (99%)	293 ± 1.6	3% (99%)	15.2
ResNet-50	87	64	299 ± 10.9	29% (67%)	270 ± 1.2	3% (94%)	19.8

Table 1: Profile of benchmark DNNs. "Batch [ms]" reports the average batch processing time and its standard deviation. "Comm" reports the proportion of communication activity as % of batch time. The figure in parentheses is the percentage of *that* time that overlaps with computation. For example, DeepLight at 10 Gbps spends 97% of its batch time in communication; only 2% of this 97% communication overlaps with computation. The table lists a scaling factor for an hypothetical $\alpha\times$ faster GPU that implies communication is contiguous and saturates the 100 Gbps bandwidth once communication begins.

that it is possible to realize in-network aggregation in an Ethernet network and benefit ML applications.

In-network aggregation offers a fundamental advantage over both all-reduce and PS. It achieves the minimum possible latency and the minimum communication cost, quantified in data volume each worker sends and receives: $2|U|$ bytes, where $|U|$ is the total number of bytes to be aggregated. This is a significant improvement over the equivalent cost for bandwidth-optimal all-reduce, which is $4|U|\frac{n-1}{n}$ [79]. The PS approach can match this communication cost of $2|U|$ bytes, at the expense of more resource cost; in the limit, it doubles the number of required machines and network bandwidth.[4] Regardless of resource costs, in-network aggregation avoids end-host processing required to perform aggregation and, therefore, provides "sub-RTT" latency [46], which the contrasted approaches cannot achieve.

Illustrating the advantages of in-network aggregation. To characterize the extent to which communication is a bottleneck for training performance, we use our profile of eight DNN models from §2.2. We evaluate the impact of communication performance using a trace of network-level events recorded during training. This trace captures real compute times and memory access latency, including the latency for barrier events that precede each synchronization, but allows us to emulate different network speeds and computation patterns. In particular, our trace records the detailed timing of individual all-reduce invocations, so it faithfully accounts for potential overlap between communication and computation.[5]

We compare the performance of in-network aggregation (INA) with the current best practice, ring all-reduce (RAR). Table 2 summarizes the batch processing speedup over the

[4]If the PS nodes are co-located with the worker nodes, then the effective bandwidth per node is halved, doubling latency.

[5]The ML toolkit adopts an optimization known as *tensor fusion* or *bucketing* that coalesces multiple all-reduce invocations to amortize setup overhead. Our traces reflect the effect of this optimization.

Figure 1: Example of in-network aggregation of model updates. U_i is the model update computed by worker i. Workers stream pieces of model updates in a coordinated fashion. In the example, each workers can have at most 4 outstanding packets at any time to match the slots in the switch. The switch aggregates updates and multicasts back the values, which are collected into the aggregated model update A_i, then used to form the model parameters of the next iteration.

ring all-reduce performance. INA is consistently superior to RAR. For communication-bound models (the four models in the 100 Gbps case), INA is up to 80% and up to 67% faster at 10 and 100 Gbps, respectively. Note that this analysis reflects a *theoretically optimal* implementation of RAR. The measured speedups (§6) of our real INA implementation are higher, because real RAR implementations do not achieve optimal performance; it is difficult to fully exploit all available bandwidth and avoid system overheads.

We also note that our profiling environment uses NVIDIA P100 devices. These are currently two-generation old GPU accelerators. We investigate with real benchmarks in §6 the impact of faster GPUs, which increases the relative impact of communication overheads.

Alternative: gradient compression. Another way to reduce communication costs is to reduce the data volume of model updates using lossy compression. Proposed approaches include reducing the bit-width of gradient elements (quantization) or transmitting only a subset of elements (sparsification). These approaches come with tradeoffs: too much compression loss can impact the resulting model accuracy.

We adopt the results of a recent survey of gradient compression methods [96] to emulate the behavior of Top-*k* [3] and QSGD [4] as two representative sparsification and quantization compressors, respectively. We use data from that study to identify the compression overhead and data reduction achieved. Our synthetic communication time, then, includes both the computational cost of compression and the communication cost of the all-gather operation used to exchange model

Model	INA	QSGD		Top-*k*	
		64	256	1%	10%
			10 Gbps

† The BERT task is fine-tuning from a pre-trained model, for which compression does not have a noticeable impact. The impact during pretraining is analyzed in Appendix E.

Table 2: Analysis of batch processing speedup relative to ring all-reduce based on synthetic communication. For Top-*k* compression, impact on model quality is shown in parentheses. Accuracy penalties greater than 1% are shaded in gray; red indicates failure to converge. At 100 Gbps, only the models that are network bottlenecked are shown. ↗ indicates 100 Gbps cases where SwitchML achieves a higher batch processing speedup due to practical system overheads.

updates (following their implementation [96]).

We observe (Table 2) that, although gradient compression decreases data volume, it is not necessarily superior to INA. In general, the computational cost of compression and decompression is non-negligible [58,96]; in some cases, it outweighs the communication-reduction benefits. In particular, INA outperforms QSGD on all workloads for both the 64 and 256 levels (6 and 8 bits). Similarly, Top-*k* underperforms INA at the 10% compression level, and even *reduces* performance relative to RAR in the 100 Gbps setting. These observations agree with recent work [58, 96]. In particular, Li et al. [58] proposed additional hardware offloading, using an FPGA at every worker, to mitigate compression costs. As this requires additional hardware, our analysis does not consider it.

Gradient compression *does* outperform INA when it can achieve high compression ratios, as with Top-*k* at 1%. However, in many cases, this level of compression either requires more training iterations to converge, or hurts the accuracy of the resulting model [96]. For example, the NCF model achieves 95.8% hit rate without compression after 20 epochs of training, while with Top-*k* compression at 10% it achieves 93.6%. It fails to converge at 1% compression. We report convergence comparisons for various models in Appendix D.

4 Design

Our system, SwitchML, implements the aggregation primitive in a programmable dataplane switch. Such switches are now commercially available, with only a small cost premium compared to fixed-function switches [5]. In-network aggregation is conceptually straightforward, but implementing it inside a programmable switch, however, is challenging. Although programmable switches allow placing computation into the network path, their limited computation and storage capabilities impose constraints on implementing gradient aggregation. The system must also tolerate packet loss, which, although uncommon in the rack-scale cluster environment, is nevertheless possible for long-running DNN training jobs. SwitchML addresses these challenges by appropriately dividing the functionality between the hosts and the switches, resulting in an efficient and reliable streaming aggregation protocol.

4.1 Challenges

Limited computation. Mathematically, gradient aggregation is the average over a set of floating-point vectors. While a seemingly simple operation, it exceeds the capabilities of today's programmable switches. As they must maintain line rate processing, the number of operations they can perform on each packet is limited. Further, the operations themselves can only be simple integer arithmetic/logic operations; neither floating-point nor integer division operations are possible.

Limited storage. Model updates are large. In each iteration, each worker may supply hundreds of megabytes of gradient values. This volume far exceeds the on-switch storage capacity, which is limited to a few tens of MB and must be shared with forwarding tables and other core switch functions. This limitation is unlikely to change in the future [10], given that speed considerations require dataplane-accessible storage to be implemented using on-die SRAM.

Packet loss. SwitchML must be resilient to packet loss, without impact on efficiency or correctness (e.g., discarding part of an update or applying it twice because of retransmission).

4.2 SwitchML overview

SwitchML aims to alleviate communication bottlenecks for distributed ML training applications using in-network aggregation, in a practical cluster setting.[6] SwitchML uses the following techniques to reduce communication costs while meeting the above challenges.

Combined switch-host architecture. SwitchML carefully partitions computation between end-hosts and switches to circumvent the restrictions of the limited computational power at switches. The switch performs integer aggregation, while end-hosts are responsible for managing reliability and performing more complex computations.

[6]For simplicity, we assume dedicated bandwidth for the training jobs. We also assume that worker, link or switch failures are handled by the ML framework, as it is common in practice [1,56].

Algorithm 1 Switch logic.

```
1:  Initialize State:
2:      n = number of workers
3:      pool[s], count[s] := {0}
4:  upon receive p(idx, off, vector)
5:      pool[p.idx] ← pool[p.idx] + p.vector        {+ is the vector addition}
6:      count[p.idx]++
7:      if count[p.idx] = n then
8:          p.vector ← pool[p.idx]
9:          pool[p.idx] ← 0; count[p.idx] ← 0
10:         multicast p
11:     else
12:         drop p
```

Pool-based streaming aggregation. A complete model update far exceeds the storage capacity of a switch, so it cannot aggregate entire vectors at once. SwitchML instead *streams* aggregation through the switch: it processes the aggregation function on a limited number of vector elements at once. The abstraction that makes this possible is a pool of integer aggregators. In SwitchML, end hosts handle the management of aggregators in a pool – determining when they can be used, reused, or need more complex failure handling – leaving the switch dataplane with a simple design.

Fault tolerant protocols. We develop lightweight schemes to recover from packet loss with minimal overheads and adopt traditional mechanisms to solve worker or network failures.

Quantized integer-based aggregation. Floating-point operations exceed the computational power of today's switches. We instead convert floating-point values to 32-bit integers using a block floating-point-like approach [25], which is done efficiently at end hosts without impacting training accuracy.

We now describe each of these components in turn. To ease the presentation, we describe a version of the system in which packet losses do not occur. We remove this restriction later.

4.3 Switch-side aggregation protocol

We begin by describing the core network primitive provided by SwitchML: in-switch integer aggregation. A SwitchML switch provides a pool of s integer aggregators, addressable by index. Each slot in the pool aggregates a vector of k integers, which are delivered all at the same time in one update packet. The aggregation function is the addition operator, which is commutative and associative – meaning that the result does not depend on the order of packet arrivals. Note that addition is a simpler form of aggregation than ultimately desired: model updates need to be *averaged*. As with the all-reduce approach, we leave the final division step to the end hosts, as the switch cannot efficiently perform this.

Algorithm 1 illustrates the behavior of the aggregation primitive. A packet p carries a pool index, identifying the particular aggregator to be used, and contains a vector of k integers to be aggregated. Upon receiving a packet, the switch aggregates the packet's vector ($p.vector$) into the slot addressed by the packet's pool index ($p.idx$). Once the slot has aggregated vectors from each worker,[7] the switch outputs the result – by rewriting the packet's vector with the aggregated value from that particular slot, and sending a copy of the packet to each worker. It then resets the slot's aggregated value and counter, releasing it immediately for reuse.

The pool-based design is optimized for the common scenario where model updates are larger than the memory capacity of a switch. It addresses two major limitations of programmable switch architectures. First, because switch memory is limited, it precludes the need to store an entire model update on a switch at once; instead, it aggregates pieces of the model in a streaming fashion. Second, it allows processing to be done at the packet level by performing the aggregation in small pieces, at most k integers at a time. This is a more significant constraint than it may appear; to maintain a very high forwarding rate, today's programmable switches parse only up to a certain amount of bytes in each packet and allow computation over the parsed portion. Thus, the model-update vector and all other packet headers must fit within this limited budget, which is today on the order of a few hundred bytes; ASIC design constraints make it unlikely that this will increase dramatically in the future [10, 16, 92]. In our deployment, k is 64 or 256.

4.4 Worker-side aggregation protocol

The switch-side logic above does not impose any constraints on which aggregator in the pool to use and when. Workers must carefully control which vectors they send to which pool index and, since pool size s is limited, how they reuse slots.

There are two considerations in managing the pool of aggregators appropriately. For correctness, every worker must use the same slot for the same piece of the model update, and no slot can be simultaneously used for two different pieces. For performance, every worker must work on the same slot at roughly the same time to avoid long synchronization delays. To address these issues, we design a custom aggregation protocol running at the end hosts of ML workers.

For now, let us consider the non-failure case, where there is no packet loss. The aggregation procedure, illustrated in Algorithm 2, starts once every worker is ready to exchange its model update. Without loss of generality, we suppose that the model update's size is a multiple of k and is larger than $k \cdot s$, where k is the size of the vector aggregated in each slot and s denotes the pool size. Each worker initially sends s packets containing the first s pieces of the model update – each piece being a contiguous array of k values from offset *off* in that worker's model update U. Each of these initial packets is assigned sequentially to one of the s aggregation slots.

After the initial batch of packets is sent, each worker awaits the aggregated results from the switch. Each packet received indicates that the switch has completed the aggregation of a particular slot. The worker consumes the result carried in the packet, copying that packet's vector into the aggregated model update A at the offset carried in the packet ($p.off$). The worker then sends a new packet with the *next* piece of update to be aggregated. This reuses the same pool slot as the one just received, but contains a new set of k parameters, determined by advancing the previous offset by $k \cdot s$.

Algorithm 2 Worker logic.

```
1: for i in 0 : s do
2:     p.idx ← i
3:     p.off ← k · i
4:     p.vector ← U[p.off : p.off + k]
5:     send p
6: repeat
7:     receive p(idx, off, vector)
8:     A[p.off : p.off+k] ← p.vector
9:     p.off ← p.off + k · s
10:    if p.off < size(U) then
11:        p.vector ← U[p.off : p.off + k]
12:        send p
13: until A is incomplete
```

A key advantage of this scheme is that it does not require any explicit coordination among workers and yet achieves agreement among them on which slots to use for which parameters. The coordination is implicit because the mapping between model updates, slots, and packets is deterministic. Also, since each packet carries the pool index and offset, the scheme is not influenced by reorderings. A simple checksum can be used to detect corruption and discard corrupted packets.

This communication scheme is self-clocked after the initial s packets. This is because a slot cannot be reused until all workers have sent their contribution for the parameter update for the slot. When a slot is completed, the packets from the switch to the workers serve as flow-control acknowledgments that the switch is ready to reuse the slot, and the workers are free to send another packet. Workers are synchronized based on the rate at which the system aggregates model updates. The pool size s determines the number of concurrent in-flight aggregations; as we elaborate in Appendix §C, the system achieves peak bandwidth utilization when $k \cdot s$ (more precisely, $b \cdot s$ where b is the packet size – 1100 bytes in our setting) matches the bandwidth-delay product of the inter-server links.

4.5 Dealing with packet loss

Thus far, we have assumed packets are never lost. Of course, packet loss can happen due to either corruption or network congestion. With the previous algorithm, even a single packet loss would halt the system. A packet loss on the "upward" path from workers to the switch prevents the switch from completing the corresponding parameter aggregations. The loss of one of the result packets that are multicast on the "downward" paths not only prevents a worker from learning the result but also prevents it from ever completing A.

We tolerate packet loss by retransmitting lost packets. In

[7]For simplicity, we show a simple counter to detect this condition. Later, we use a bitmap to track which workers have sent updates.

Algorithm 3 Switch logic with packet loss recovery.

```
1:  Initialize State:
2:      n = number of workers
3:      pool[2, s], count[2, s], seen[2, s, n] := {0}
4:  upon receive p(wid, ver, idx, off, vector)
5:      if seen[p.ver, p.idx, p.wid] = 0 then
6:          seen[p.ver, p.idx, p.wid] ← 1
7:          seen[(p.ver+1)%2, p.idx, p.wid] ← 0
8:          count[p.ver, p.idx] ← (count[p.ver, p.idx]+1)%n
9:          if count[p.ver, p.idx] = 1 then
10:             pool[p.ver, p.idx] ← p.vector
11:         else
12:             pool[p.ver, p.idx] ← pool[p.ver, p.idx] + p.vector
13:         if count[p.ver, p.idx] = 0 then
14:             p.vector ← pool[p.ver, p.idx]
15:             multicast p
16:         else
17:             drop p
18:     else
19:         if count[p.ver, p.idx] = 0 then
20:             p.vector ← pool[p.ver, p.idx]
21:             forward p to p.wid
22:         else
23:             drop p
```

Algorithm 4 Worker logic with packet loss recovery.

```
1:  for i in 0 : s do
2:      p.wid ← Worker ID
3:      p.ver ← 0
4:      p.idx ← i
5:      p.off ← k · i
6:      p.vector ← U[p.off : p.off + k]
7:      send p
8:      start_timer(p)
9:  repeat
10:     receive p(wid, ver, idx, off, vector)
11:     cancel_timer(p)
12:     A[p.off : p.off+k] ← p.vector
13:     p.off ← p.off + k · s
14:     if p.off < size(U) then
15:         p.ver ← (p.ver+1)%2
16:         p.vector ← U[p.off : p.off + k]
17:         send p
18:         start_timer(p)
19: until A is incomplete

20: upon timeout p /* Timeout Handler */
21:     send p
22:     start_timer(p)
```

order to keep switch dataplane complexity low, packet loss detection is done by the workers if they do not receive a response packet from the switch in a timely manner. However, naïve retransmission creates its own problems. If a worker retransmits a packet that was actually delivered to the switch, it can cause a model update to be applied twice to the aggregator. On the other hand, if a worker retransmits a packet for a slot that was actually already fully aggregated (e.g., because the response was lost), the model update can be applied to the wrong data because the slot could have already been reused by other workers who received the response correctly. Thus, the challenges are (1) to be able to differentiate packets that are lost on the upward paths versus the downward ones; and (2) to be able to retransmit an aggregated response that is lost on the way back to a worker.

We modify the algorithms to address these issues by keeping two additional pieces of switch state. First, we explicitly maintain information as to which workers have already contributed updates to a given slot. This makes it possible to ignore duplicate transmissions. Second, we maintain a *shadow copy* of the *previous* result for each slot. That is, we have two copies or versions of each slot, organized in two pools; workers alternate between these two copies to aggregate successive chunks that are assigned to the same slot. The shadow copy allows the switch to retransmit a dropped result packet for a slot even when the switch has started reusing the slot for the next chunk.

The key insight behind this approach's correctness is that, even in the presence of packet losses, our self-clocking strategy ensures that no worker node can ever lag *more than one chunk* behind any of the others for a particular slot. This invariant is because the switch will not release a slot to be reused, by sending a response, until it has received an update packet from *every* worker for that slot. Furthermore, a worker will not send the next chunk for a slot until it has received the response packet for the slot's previous chunk, preventing the system from moving ahead further. As a result, it is sufficient to keep only one shadow copy.

Besides obviating the need for more than one shadow copy, this has a secondary benefit: the switch does not need to track full phase numbers (or offsets); a single bit is enough to distinguish the two active phases for any slot.

In keeping with our principle of leaving protocol complexity to end hosts, the shadow copies are kept in the switch but managed entirely by the workers. The switch simply exposes the two pools to the workers, and the packets specify which slot acts as the active copy and which as the shadow copy by indicating a single-bit pool version (*ver*) field in each update packet. The pool version starts at 0 and alternates each time a slot with the same *idx* is reused.

Algorithms 3 and 4 show the details of how this is done. An example illustration is in Appendix A. In the common case, when no losses occur, the switch receives updates for slot *idx*, pool *ver* from all workers. When workers receive the response packet from the switch, they change the pool by flipping the *ver* field – making the old copy the shadow copy – and send the next phase updates to the other pool.

A timeout detects packet loss at each worker. When this occurs, the worker does not know whether the switch received its previous packet or not. Regardless, it retransmits its earlier update with the same slot *idx* and *ver* as before. This slot is guaranteed to contain the state for the same aggregation in the switch. The *seen* bitmask indicates whether the update has already been applied to the slot. If the aggregation is already complete for a slot, and the switch yet receives an update packet for the slot, the switch recognizes the packet as a retransmitted packet and replies with a unicast packet containing the result. The result in one slot is overwritten for reuse only when there is the certainty that all the workers have received the slot's aggregated result. Slot reuse happens when all the workers have sent their updates to the same slot of the other pool, signaling that they have all moved forward. Note this scheme works because the completion of aggregation for a slot *idx* in one pool *safely and unambiguously* confirms that the previous aggregation result in the shadow copy of slot *idx* has indeed been received by every worker.

This mechanism's main cost is switch memory usage: keeping a shadow copy doubles the memory requirement, and tracking the *seen* bitmask adds additional cost. This may appear problematic, as on-switch memory is a scarce resource. In practice, however, the total number of slots needed – tuned based on the network bandwidth-delay product (Appendix C) – is much smaller than the switch's memory capacity.

4.6 Dealing with floating-point numbers

DNN training commonly uses floating-point numbers, but current programmable switches do not natively support them. We explored two approaches to bridging this gap.

Floating-point numbers are already an approximation. SGD and similar algorithms are defined over real numbers. Floating-point numbers approximate real numbers by trading off range, precision, and computational overhead to provide a numerical representation that can be broadly applied to applications with widely different properties. However, many other approximations are possible. An approximation designed for a specific application can obtain acceptable accuracy with lower overhead than standard floating-point offers.

In recent years, the community has explored many specialized numerical representations for DNNs. These representations exploit the properties of the DNN application domain to reduce the cost of communication and computation. For instance, NVIDIA Volta and Ampere GPUs [17, 74] include mixed-precision (16-/32-bit) TPUs that can train with accuracy matching full-precision approaches. Other work has focused on gradient exchange for SGD, using fixed-point quantization, dithering, or sparsification to reduce both the number of bits and the gradient elements transmitted [7, 8, 60, 69, 88, 95, 99]. Further, others have explored block floating-point representations [25, 53], where a single exponent is shared by multiple tensor elements, reducing the amount of computation required to perform tensor operations. This innovation will continue (as work [40, 70] that builds upon our architecture demonstrates); our goal is not to propose new representations but to demonstrate that techniques like those in the literature are practical with programmable switches.

We use a numeric representation, inspired by block floating-point, that combines 32-bit fixed-point addition in the switch with adaptive scaling on the workers. This representation is used only when aggregating gradients; all other data (weights, activations) remain in 32-bit floating-point representation.

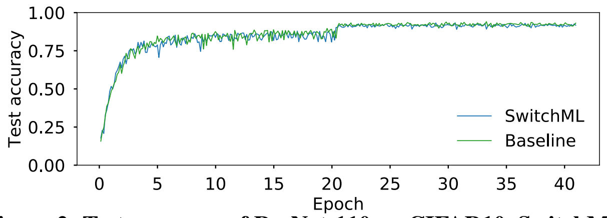

Figure 2: Test accuracy of ResNet-110 on CIFAR10. SwitchML achieves similar accuracy to the baseline.

To implement our representation, we scale gradient values using a per-packet scaling factor f, which is automatically determined for each use of an aggregator slot in the switch. The scaling factor is set so that the maximum aggregated floating point value within a block of k gradients is still representable as a 32-bit fixed point value. Namely, let h be the largest absolute value of a block of gradients; f is set to $(2^{31}-1)/(n \cdot 2^m)$, where m is the exponent of h rounded up to a power of 2 and n is the number of workers. Appendix E formally analyzes the precision of this representation.

To realize this quantization of floating-point values, workers need to agree on a global value of m prior to sending the corresponding block of gradients. We devise a simple look-ahead strategy: when workers send the j-th block to slot i, they include their local block $j+1$'s maximum gradient (rounded up to a power of 2). The switch identifies the global maximum m and piggy-backs that value when sending the aggregated gradients of the j-th block.

We verify experimentally that this communication quantization allows training to similar accuracy in a similar number of iterations as an unquantized network. We illustrate the convergence behavior by training a ResNet-110 model on CIFAR10 dataset for 64,000 steps (about 41 epochs) using 8 workers. Figure 2 shows the test accuracy over time. The accuracy obtained by SwitchML (about 91-93% in the last 5 points) is similar to that obtained by training with TensorFlow on the same worker setup, and it matches prior results [38] with the same hyperparameter settings. The training loss curves (not shown) show the same similarity. In Appendix E, we further give a detailed convergence analysis for the aforementioned representation on models in Table 1.

While the above representation is used in the remainder of the paper, we also explored the implementation of a restricted form of 16-bit floating-point. In this version, the switch converts each 16-bit floating-point value in the incoming packets into a fixed-point value and then performs aggregation. When generating responses, the switch converts fixed-point values back into floating-point values. Due to resource limitations in the switch, we were only able to support half the dynamic range of the 16-bit floating-point format; we expect this to lead to poor convergence during training. Conversely, our 32-bit integer format uses minimal switch resources, provides good dynamic range, and has a minimal overhead on workers. A 16-bit format would provide a bandwidth benefit (§6.3).

5 Implementation

We build SwitchML as a collective library which we integrate in PyTorch's DistributedDataParallel module and in TersorFlow via Horovod [89]. SwitchML is implemented as a worker component written as $\sim$3,100 LoCs in C++ and a switch component realized in P4 [9] with $\sim$3,700 LoCs. The worker is built atop Intel DPDK. We have also built a RDMA-capable implementation, but it is not yet integrated with the training frameworks. Here, we highlight a few salient aspects of our implementation. Appendix B describes more details.

Our P4 program distributes aggregation across multiple stages of the ingress pipeline, and also implements flow control, retransmission, and exponent-calculation logic. It uses the traffic manager subsystem to send multiple copies of result packets. It can process 64 elements per packet using one switch pipeline, and 256-element (1024-byte) packets using all four switch pipelines. On the worker side, we process each packet in a run-to-completion fashion and scale to multiple CPU cores using DPDK and Flow Director. We use up to 8 cores per worker. This scales well because we shard slots and chunks of tensors across cores without any shared state. The ML framework invokes our synchronous API whenever model updates are ready. In practice, model updates consist of a set of tensors that are aggregated independently but sequentially.

Supporting large packets. Good bandwidth efficiency requires processing enough integer elements in each packet to offset the network framing overhead. Our P4 program can parse and aggregate 64 $\times$ 4-byte elements per packet, but can only read 32 elements per packet when aggregation is complete. With framing overheads, a 32-element payload would limit goodput to 63% of line rate. Our P4 program supports larger packets in two additional configurations for better efficiency: a 64-element configuration with 77% goodput, and a 256-element one with 93% goodput.

We support larger packets through *recirculation*: sending packets through the switch pipelines multiple times. Our 64-element design uses a single pipeline. It makes one additional pass through the pipeline *only* when an output packet is broadcast in order to read the results: this separation of reads and writes allows us to write 64 elements in a single pass. The internal recirculation ports provided by the chip provide sufficient bandwidth. To support 256 elements, we recirculate packets through all four switch pipelines. This requires placing switch ports into loopback mode for more recirculation bandwidth, leaving 16 $\times$ 100 Gbps bandwidth available for workers. When a slot is complete, we recirculate again through all the pipelines to read the results. Tofino has sufficient bandwidth to do this recirculation at 1.6 Tbps, and the latency scales deterministically with the number of pipeline passes: we measure an additional 520 ns per pass.

Supporting RDMA. Our host-side framework, even using DPDK and multiple cores, has difficulty achieving 100 Gbps throughput due to packet processing costs. We address this by implementing a subset of RDMA in the switch. This allows workers to offload packet processing: the RDMA NIC breaks large messages into individual packets. Specifically, we use RoCE v2 [42] in Unreliable Connected (UC) mode [67]. This mode, which does not require any of RoCE's link-level flow control mechanisms, supports multi-packet messages and detects packet drops, but does not implement retransmission. SwitchML continues to rely on its existing reliability mechanism. Timeouts and duplicate packets are handled as before, except that a timeout forces a client to retransmit the entire multi-packet message. To balance the benefit of offload with the cost of retransmission, we use small, multi-packet messages (generally 16 packets per message). Although retransmissions are more expensive, the common case is much faster, even though we use a single CPU core.

RDMA Write Immediate messages are used for all communication, allowing data to move directly between the switch and GPUs, with client CPUs handling protocol operations. SwitchML metadata is encoded in RDMA headers. Concurrent messages are sent on separate queue pairs to allow packets to interleave; queue pair IDs and access keys are negotiated with the switch control plane during job setup. The switch sends aggregated results by generating RDMA Write messages to the destination buffer.

6 Evaluation

We analyze the performance benefits of SwitchML by using standard benchmarks on popular models in TensorFlow and PyTorch and by using microbenchmarks to compare it to state-of-the-art collective communications libraries and PS scenarios.

Testbed. We conduct most of our experiments on a testbed of 8 machines, each with 1 NVIDIA P100 16 GB GPU, dual 10-core CPU Intel Xeon E5-2630v4 at 2.20 GHz, 128 GB of RAM, and 3 $\times$ 1 TB disks for storage (as single RAID). To demonstrate scalability with 16 nodes, we further use 8 machines with dual 8-core CPU Intel Xeon Silver 4108 at 1.80 GHz. Moreover, we use a Wedge100BF-65X programmable switch with Barefoot Networks' Tofino chip [5]. Every node is networked at both 10 and 100 Gbps.

Performance metrics. We mostly focus on two performance metrics. We define *tensor aggregation time* (TAT) as the time to aggregate a tensor starting from the time a worker is ready to send it till the time that worker receives the aggregated tensor; lower is better. We also report *aggregated tensor elements* (ATE) per unit of time, for presentation clarity; higher is better. For these metrics, we collect measurements at each worker for aggregating 100 tensors of the same size, after 10 warmups. We measure *training throughput* defined in terms of the numbers of training samples processed per second. We measure throughput for 100 iterations that follow 100 warmups. A variant of training throughput is the batch processing throughput,

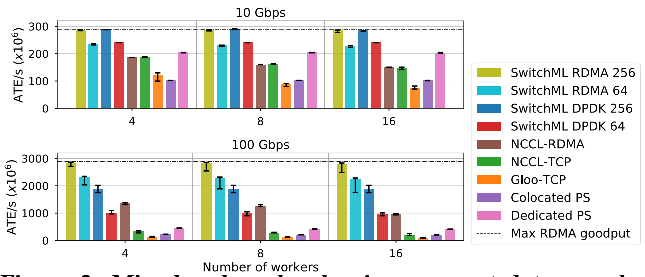

Figure 3: Microbenchmarks showing aggregated tensor elements per second on a 10 (top) and 100 (bottom) Gbps network as workers increase.

which we use to analyze performance by replaying profile traces. This throughput metric includes communication and computation costs, but excludes the time to load data.

Benchmarks. We evaluate SwitchML by training with 8 DNNs introduced in Table 1. The detailed configuration of the benchmarks is in Table 3 in Appendix B. Half of the benchmarks execute on PyTorch and half on TensorFlow.

Setup. As a baseline, we run both PyTorch with native distributed data-parallel module and TensorFlow with Horovod. By default, we use NCCL as the communication library, and use both TCP and RDMA as the transport protocol. Our default setup is to run experiments on 8 workers.

6.1 Tensor aggregation microbenchmarks

To illustrate SwitchML's efficiency in comparison to other communication strategies, we devise a communication-only microbenchmark that performs continuous tensor aggregations, without any gradient computation on the GPU. We verify that the tensors – initially, all ones – are aggregated correctly. We test with various tensor sizes from 50 MB to 1.5 GB. We observe that the number of aggregated tensor elements per time unit (ATE/s) is not very sensitive to the tensor size. Thus, we report results for 100 MB tensors only.

For these experiments, we benchmark SwitchML against the popular all-reduce communication libraries (Gloo [31] and NCCL [77]). We further compare against a parameter server-like scenario, i.e., a set of worker-based processes that assist with the aggregation. To this end, we build a DPDK-based program that implements streaming aggregation as in Algorithm 1. To capture the range of possible PS performance, we consider two scenarios: (1) when the PS processes run on dedicated machines, effectively doubling the cluster size, and (2) when a PS process is co-located with every worker. We choose to run as many PS processes (each using 8 cores) as workers so that the tensor aggregation workload is equally spread among all machines (uniformly sharded) and avoids introducing an obvious performance bottleneck due to over-subscribed bandwidth, which is the case when the ratio of workers to PS nodes is greater than one.

Figure 3 shows the results at 10 and 100 Gbps on three cluster sizes. The results demonstrate the efficiency of SwitchML:

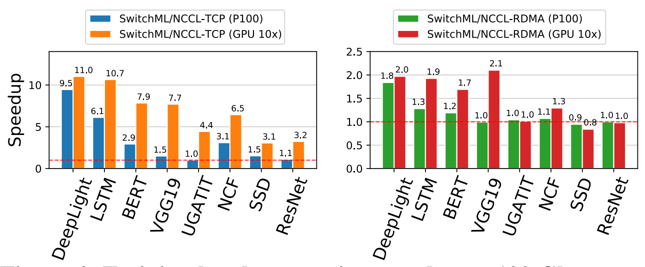

Figure 4: Training batch processing speedup at 100 Gbps considering a P100 GPU and a 10× faster GPU.

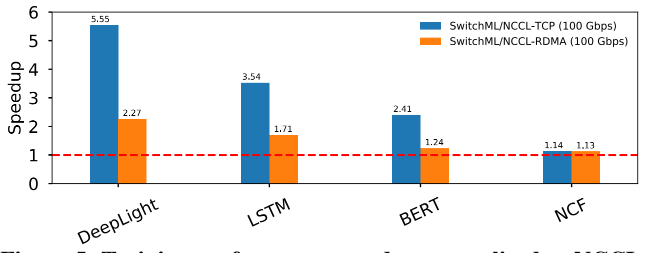

Figure 5: Training performance speedup normalized to NCCL with TCP and RDMA transport protocols.

its highest-performing variant, which uses RDMA with 256-value (1024-byte payload) packets, is within 2% of the maximum achievable goodput. Using smaller packets ($k = 64$ instead of 256) has a noticeable performance impact, underscoring the importance of our multi-pipeline design. The DPDK implementation has additional host-side overhead that prevents it from achieving full link utilization at 100 Gbps. In spite of this, SwitchML can still outperform the best current all-reduce system, NCCL, even when it uses RDMA and SwitchML does not. Moreover, SwitchML always maintains a predictable rate of ATE/s regardless of the number of workers. This trend should continue with larger clusters.

The Dedicated PS approach (with 256 values per packet) – while using *twice* the number of machines *and* network capacity – falls short of matching SwitchML DPDK performance. Unsurprisingly, using the same number of machines as SwitchML, the Colocated PS approach reaches only half of Dedicated PS performance. Our PS implementation is simpler than (and should outperform) a traditional PS, as we do not store the entire model in memory. It demonstrates that, in principle, our aggregation protocol could be run entirely in software on a middlebox, but with lower performance: in-network aggregation inherently requires fewer resources than host-based aggregation.

6.2 SwitchML improves training speed

We analyze training performance on eight DNN benchmarks. We normalize results to NCCL as the underlying communication backend of PyTorch and TensorFlow.

Figure 4 reports the speedup for processing a training batch for SwitchML compared to NCCL at 100 Gbps. SwitchML uses the DPDK implementation with 256-value packets. These results replay the profile traces collected on our cluster

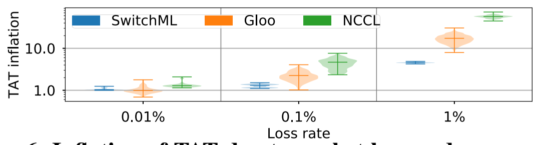

Figure 6: Inflation of TAT due to packet loss and recovery. Results are normalized to a baseline scenario where no loss occurs and the worker implementation does not incur any timer-management overhead.

(§2.2), allowing us to report both the speedup on our testbed GPUs (P100s, which are two generations old) and hypothetical GPUs that are 10× faster (by uniformly scaling the traces by this factor). This emulation lets us evaluate the setting where a fast network is paired with fast GPUs. While it is hard to predict future evolution of GPU speed vs. network bandwidth, we reason that this scaling factor currently corresponds to the span of two to three GPU generations (the A100 benchmarks at 4.2× the V100 [75], which in turn is 1.4-2.2× faster than our P100 [97]) and represents a likely bound on the real-world speedups achievable, which are anyway dependent on the model (e.g., the ResNet50 model sees a nearly 10× speedup from an NVIDIA V100 GPU compared to a K80 GPU [71]) and the other infrastructure specifics.

As expected, SwitchML accelerates batch processing especially for the larger DNNs. The speedup over NCCL-RDMA is at most 2.1×, which is in line with the fundamental 2× advantage of INA over RAR (§3). In most cases, the measured speedup is higher than the emulated communication results (Table 2) predict, because NCCL's RAR implementation does not achieve the theoretical maximum efficiency. The speedup relative to NCCL-TCP is larger (up to one order of magnitude), which is attributable primarily to DPDK's kernel-bypass advantage.

SwitchML provides significant benefits for many, but not all, real-world DNNs, even with 100 Gbps networks. For example, DeepLight and LSTM enjoy major improvements. BERT sees a somewhat lower speedup, in part because its gradient consists of many relatively small (∼60 MB) tensors. Similarly, NCF, a relatively small model, has a modest speedup. Other models, like UGATIT, SSD, and ResNet are simply not network-bound at 100 Gbps. SSD is a particularly challenging case: not only is it a small model that would require an $\alpha = 15.2\times$ faster GPU to become network-bound (Table 1), it also makes many aggregation invocations for small gradients. The overheads of starting an aggregation are not well amortized, especially in the 10× scaled scenario.

Finally, we consider the end-to-end speedup on a complete training run with 16 workers. We focus on the four models that are network-bottlenecked at 100 Gbps. Figure 5 shows the training performance speedup compared to NCCL using RDMA and TCP. These measurements use SwitchML's DPDK implementation, with 256-value packets; we expect a larger speedup once SwitchML's RDMA implementation is integrated with the training framework. Even so, SwitchML's speedups range between 1.13-2.27× over NCCL-RDMA and

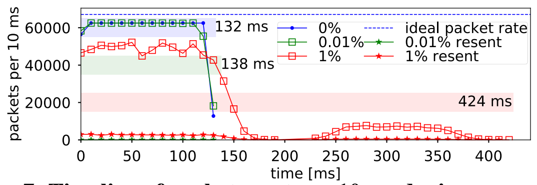

Figure 7: Timeline of packets sent per 10 ms during an aggregation with 0%, 0.01% and 1% packet loss probability. Horizontal bars denote the TAT in each case.

2.05-5.55× over NCCL-TCP. The results are not directly comparable to Figure 4, because (1) they use a larger 16-node cluster, and (2) they report total end-to-end iteration time, which also includes data loading time. Our deployment does not use any optimized techniques for data loading, an orthogonal problem being addressed by other work (e.g., DALI [76]).

6.3 Overheads

Packet loss recovery. We study how packet loss affects TAT. To quantify the change in TAT due to packet loss, we experiment with a uniform random loss probability between 0.01% and 1% applied on every link. The retransmission timeout is set to 1 ms. We run microbenchmark experiments in similar scenarios as §6.1. We report a few representative runs.

Figure 6 measures the inflation in TAT with different loss probabilities. SwitchML completes tensor aggregation significantly faster than Gloo or NCCL when the loss is 0.1% or higher. A loss probability of 0.01% minimally affects TAT in either case. To better illustrate the behavior of SwitchML, we show in Figure 7 the evolution of packets sent per 10 ms at a representative worker for 0.01% and 1% loss. We observe that SwitchML generally maintains a high sending rate – relatively close to the ideal rate – and quickly recovers by retransmitting dropped packets. The slowdown past the 150 ms mark with 1% loss occurs because some slots are unevenly affected by random losses and SwitchML does not apply any form of work-stealing to rebalance the load among aggregators. This presents a further opportunity for optimization.

Tensor scaling and type conversion. We analyze whether any performance overheads arise due to the tensor scaling operations (i.e., multiply updates by f and divide aggregates by f) and the necessary data type conversions: float32-to-int32 → htonl → ntohl → int32-to-float32.

To quantify overheads, we use int32 as the native data type while running the microbenchmarks. This emulates a native float32 scenario with no scaling and conversion operations. We also illustrate the potential improvement of quantization to single-precision (float16) tensors, which halves the volume of data to be sent to the network. (We include a conversion from/to float32.) This setting is enabled by the ability to perform at line rate, in-switch type conversion (float16 ↔ int32), which we verified with the switch chip vendor. However, for this experiment, we emulate this by halving the tensor size.

We find that these overheads are negligible at 10 Gbps.

This is due to our use of x86 SSE/AVX instructions. When we use float16, performance doubles, as expected. However, these overheads become more relevant as data rates increase, requiring to offload type conversion operations to the GPU at 100 Gbps and scaling up the number of cores; RDMA alleviates the pressure for CPU cycles used for I/O (see the gap between DPDK- and RDMA-based performance in Figure 3).

Switch resources. We comment on SwitchML's usage of switch resources in relation to network bandwidth and number of workers. As discussed in Appendix B, our implementation only makes use of the switch ingress pipeline in maximizing the number of vector elements that is processed at line rate. Aggregation bandwidth affects the required pool size. We verified that the memory requirement is less than 10% of switch resources. The number of workers does not influence the resource requirements to perform aggregation at line rate. That said, the number of switch ports and pipelines obviously pose a cap on how many directly-attached workers are supported. A single pipeline in our testbed supports 16-64 workers depending on network speed. We describe how to move beyond a single rack scale in the next section.

7 Extensions

Scaling beyond a rack. We described SwitchML in the context of a rack. However, large scale ML jobs could span beyond a single rack. SwitchML's design can support multiple racks by hierarchically composing several instances of our switch logic, although we do not have a testbed large enough to test (or require) such a design. Each worker is connected to a top-of-rack switch, which aggregates updates from the workers in the rack. Rather than broadcast the result packet to the workers, it instead sends it to a tier-1 aggregation switch, which aggregates updates from multiple racks. This can continue with as many levels as are needed to support the desired network topology. Ultimately, a root switch completes the aggregation of partial aggregates and multicasts a result packet downstream. At each level, the switches further multicast the packet, ultimately reaching the workers.

The hierarchical approach also allows us to support switches with multiple processing pipelines. Suppose a switch has pipelines that can aggregate up to p ports (for the switches we use, $p = 16$). In this setting, each switch aggregates tensors from d downstream ports and forwards partial aggregates via $u = \lceil \frac{d}{p} \rceil$ upstream ports. In other words, the switch operates as u virtual switches, one for each pipeline in the switch.

This hierarchical composition is bandwidth-optimal, as it allows n workers to fully utilize their bandwidth while supporting all-to-all communication with a bandwidth cost proportional to u instead of n. That is, every switch aggregates data in a $p:1$ ratio. As a result, the system naturally supports oversubscription of up to this ratio at the aggregation or core layers. This allows it to support large clusters with relatively shallow hierarchies; using the current generation of 64-port, 4-pipeline 100 Gbps switches, a two-layer hierarchy can support up to 240 workers and a three-layer one manages up to 3,600.

Importantly (and by design), the packet loss recovery algorithm described in §4.5 works in the multi-rack scenario. Thanks to the use of bitmaps and shadow copies, a retransmission originated from a worker will be recognized as a retransmission on all switches that have already processed that packet. This triggers the retransmission of the aggregated packet toward the upper layer switch, ensuring that the switch affected by the packet loss is always ultimately reached.

Congestion control. We have not implemented an explicit congestion control algorithm; the self-clocking streaming protocol is a flow control mechanism to control access to the switch's aggregator slots. It also serves as a rudimentary congestion control mechanism, in that if one worker's link is congested and it cannot process aggregation results at full speed, the self-clocking mechanism will reduce the sending rate of all workers. This is sufficient for dedicated networks (which is common for ML clusters in practice). For more general use, a congestion control scheme may be needed; concurrent work has been developing such protocols [29].

Deployment model. Thus far, we presented SwitchML as an in-network computing approach, focusing on the mechanisms to enable efficient aggregation of model updates at line rate on programmable switching chips with very limited memory. While that might be a viable deployment model in some scenarios, we highlight that our design may have more ample applicability. In fact, one could use a similar design to create a dedicated "parameter aggregator," i.e., a server unit that combines a programmable switching chip with a typical server board, CPU and OS. Essentially a standard server with an advanced network attachment, or in the limit, an array of programmable Smart NICs, each hosting a shard of aggregator slots. The switch component of SwitchML would run on said network attachment. Then, racks could be equipped with such a parameter aggregator, attached for example to the legacy ToR using several 100 Gbps or 400 Gbps ports, or via a dedicated secondary network within the rack directly linking worker servers with it. We expect this would provide similar performance improvements while giving more options for deployment configurations; concurrent work has been exploring a similar approach atop an FPGA board [62].

Multi-job (tenancy). In multi-job or multi-tenant scenarios, the question arises as to how to support concurrent reductions with SwitchML. The solution is conceptually simple. Every job requires a separate pool of aggregators to ensure correctness. As discussed, the resources used for one reduction are much less than 10% of switch capabilities. Moreover, modern switch chips comprise multiple independent pipelines, each with its own resources. Thus, an admission mechanism would be needed to control the assignment of jobs to pools. Alternatively, ATP [54] – a follow up work to ours – explores the idea of partitioning aggregation functionality between a switch (for performance) and a server (for capacity) so as to seamlessly support multi-job scenarios.

Encrypted traffic. Given the cluster setting and workloads we consider, we do not consider it necessary to accommodate for encrypted traffic. Appendix F expands on this issue.

8 Related work

In-network computation trends. The trend towards programmable data planes has sparked a surge of proposals [20, 21, 46, 47, 55, 61] to offload, when appropriate [80], application-specific primitives into network devices.

In-network aggregation. We are not the first to propose aggregating data in the network. Targeting partition-aggregate and big data (MapReduce) applications, NetAgg [65] and CamDoop [18] demonstrated significant performance advantages, by performing application-specific data aggregation at switch-attached high-performance middleboxes or at servers in a direct-connect network topology, respectively. Parameter Hub [64] does the same with a rack-scale parameter server. Historically, some specialized supercomputer networks [2, 26] offloaded MPI collective operators (e.g., all-reduce) to the network. SwitchML differs from all of these approaches in that it performs in-network data reduction using a streaming aggregation protocol.

The closest work to ours is DAIET [86], which was our initial but incomplete proposal of in-network aggregation for minimizing the overhead of exchanging ML model updates.

Mellanox's Scalable Hierarchical Aggregation Protocol (SHARP) is a proprietary in-network aggregation scheme available in certain InfiniBand switches [33]. SHARP uses dedicated on-chip FPUs for collective offloading. The most recent version, SHARPv2 [68] uses streaming aggregation analogous to ours. A key difference is that SHARP builds on InfiniBand where it can leverage link-layer flow control and lossless guarantees, whereas SwitchML runs on standard Ethernet[8] with an unmodified network architecture, necessitating a new packet recovery protocol. More fundamentally, SwitchML builds on programmable network hardware rather than SHARP's fixed-function FPUs, which offers two benefits. First, operators can deploy a single switch model either for SwitchML or traditional networking without waste: the ALUs used for aggregation can be repurposed for other tasks. Second, it allows the system design to evolve to support new ML training approaches. For example, we are currently experimenting with new floating-point representations and protocols for sparse vector aggregations [27]. With a fixed-function approach, these would require new hardware, just as moving from single HPC reductions (SHARPv1) to streaming ML reductions (SHARPv2) required a new ASIC generation.

[8]Although SwitchML uses RDMA, it uses only unreliable connections, and so does *not* require any of the "lossless Ethernet" features of RoCE.

Concurrently, Li et al. [57] explored the idea of in-switch acceleration for Reinforcement Learning (RL). Their design (iSwitch) differs from ours in two fundamental ways. First, while their FPGA-based implementation supports more complex computation (e.g., native floating point), it operates at much lower bandwidth (4×10 Gbps). Second, it stores an entire gradient vector during aggregation; for RL workloads with small models, this works, but it does not scale for large DNN models. Our work targets both large models and high throughput – a challenging combination given the limited on-chip memory in high-speed networking ASICs. SwitchML's software/hardware co-design approach, using a self-clocking streaming protocol, provides $40\times$ higher throughput than iSwitch, while supporting arbitrarily large models.

Finally, targeting NVIDIA's intra-GPU NVLink network, Klenk et al. [52] proposed in-network aggregation in the context of a distributed shared-memory fabric supporting multi-GPU systems where accelerators are directly attached to the fabric. While this work is orthogonal to ours, their push reduction design resembles the SwitchML protocol, suggesting that streaming in-network aggregation has broader applicability than discussed in this paper.

Accelerating DNN training. A large body of work has proposed improvements to hardware and software systems, as well as algorithmic advances for faster DNN training. We only discuss a few relevant prior approaches. Improving training performance via data or model parallelism has been explored by numerous deep learning systems [1, 13, 15, 22, 56, 64, 94]. While data parallelism is most common, it can be advantageous to combine the two approaches. Recent work even shows how to automatically find a fast parallelization strategy for a specific parallel machine [44]. Underpinning any distributed training strategy, lies parameter synchronization. Gibiansky was among the first to research [30] using fast collective algorithms in lieu of the traditional parameter server approach. Many platforms have now adopted this approach [30, 37, 41, 87, 89]. We view SwitchML as a further advancement on this line of work – one that pushes the boundary by co-designing networking functions with ML applications.

9 Conclusion

SwitchML speeds up DNN training by minimizing communication overheads at single-rack scale. SwitchML uses in-network aggregation to efficiently synchronize model updates at each training iteration among distributed workers executing in parallel. We evaluated SwitchML with eight real-world DNN benchmarks on a GPU cluster with 10 Gbps and 100 Gbps networks; we showed that SwitchML achieves training throughput speedups up to $5.5\times$ and is generally better than state-of-the-art collective communications libraries. We are in the process of integrating SwitchML-RDMA in various ML frameworks.

Acknowledgments

We are grateful to Ibrahim Abdelaziz for his work on an initial proof-of-concept of SwitchML and to Omar Alama for contributing with performance improvements and with the code release. We thank Tom Barbette and Georgios Katsikas for their help with DPDK issues. This work benefited from feedback and comments by Steven Hand, Petros Maniatis, KyoungSoo Park, and Amin Vahdat. We thank our shepherd, Sujata Banerjee, and the anonymous reviewers for their helpful feedback. For computer time, this research used the resources of the Supercomputing Laboratory at KAUST.

A Example execution

We illustrate through an example how Algorithms 3 and 4 behave in a system with three workers: w1, w2, and w3. We focus on the events that occur for a particular slot (x) starting from a particular offset (*off*).

- **t0:** Worker w1 sends its model update for slot x with offset = *off*.
- **t1:** Worker w2 sends its model update for slot x with offset = *off*.
- **t2:** Worker w3 sends its model update for slot x with offset = *off*. This update packet is lost on the upstream path at time **t3**, and hence the switch does not receive it.
- **t4:** w1's timeout kicks in for the model update sent at **t0**, leading to a retransmission of the same model update for slot x with offset = *off*. The switch receives the packet, but it ignores the update because it already received and aggregated an update from w1 for the given slot and offset.
- **t5:** w2's timeout kicks in for the model update sent at **t0**, leading to a retransmission of the same model update for slot x with offset = *off*. The switch receives the packet, but it ignores the update because it already received and aggregated an update from w2 for the given slot and offset.
- **t6:** w3's timeout kicks in for the model update sent at **t0**, leading to a retransmission of the same model update for slot x with offset = *off*. The switch receives the packet and aggregates the update properly. Since this update is the last one for slot x and offset *off*, the switch completes aggregation for the slot and offset, turns the slot into a shadow copy, and produces three response packets (shown as blue arrows).
- **t7:** The first response packet for w1 is lost on the downstream path, and w1 does not receive it.
- **t8:** Not having received the result packet for the update packets sent out earlier (at **t0** and **t4**), w1 retransmits its model update the second time. This retransmission reaches the switch correctly, and the switch responds by sending a unicast response packet for w1.
- **t9** and **t10:** w2 and w3 respectively receives the response packet. Hence, w2 and w3 respectively decides to reuse slot x for the next offset ($\mathit{off} + k \cdot s$) and sends their new updates at **t12** and **t13**.
- **t11:** The unicast response packet triggered by the second model-update retransmission (sent at **t8**) arrives at w1.
- **t14:** Now that w1 has received its response, it decides to reuse slot x for the next offset ($\mathit{off} + k \cdot s$) and sends its new updates. This update arrives at the switch at **t15**, upon which the switch realizes that the slot for offset ($\mathit{off} + k \cdot s$) is complete. This confirms that the result in the shadow-copy slot (the slot in pool 0) is safely received by every worker. Thus, the switch flips the roles of the slots again.

B Implementation details

Switch component. The main challenge we faced was to find a design that best utilizes the available resources (SRAM, TCAMs, hashing machinery, etc.) to perform as much computation per packet as possible. Data plane programs are typically constrained by either available execution resources or available storage; for SwitchML, execution resources are the tighter constraint. For example, a data plane program is constrained by the number of stages per pipeline [92], which limits the dependencies within the code. In fact, every action whose execution is contingent on the result of a previous operation has to be performed on a subsequent stage. A program with too many dependencies cannot find a suitable allocation

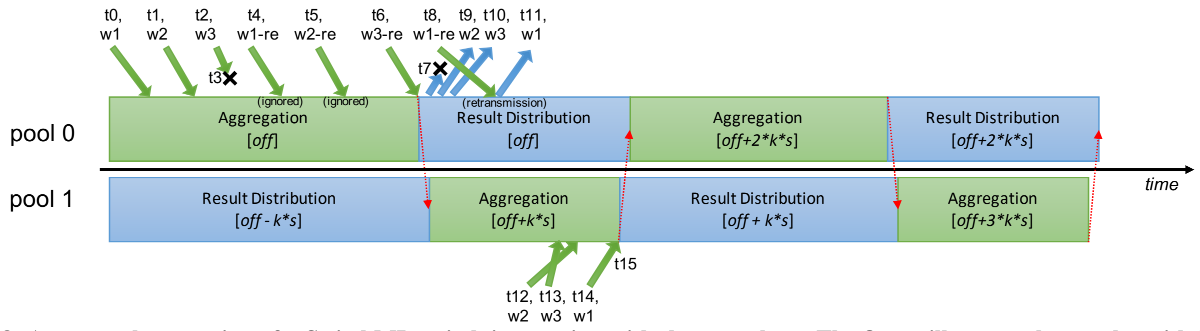

Figure 8: An example execution of a SwitchML switch interacting with three workers. The figure illustrates how a slot with index *x* is used during the different phases (shown in different colors) that alternate between the two pools.

on the hardware pipeline and will be rejected by the compiler. Moreover, the number of memory accesses per-stage is inherently limited by the maximum per-packet latency; a switch may be able to parse more data from a packet than it is able to store into the switch memory during that packet's time in the switch.

We make a number of design trade-offs to fit within the switch constraints. First, our P4 program makes the most use of the limited memory operations by performing the widest register accesses possible (64 bits). We then use the upper and lower part of each register for alternate pools. These parts can execute different operations simultaneously; for example, when used for the received work bitmap, we can set a bit for one pool and clear a bit for the alternate pool in one operation. Second, we minimize dependencies (e.g., branches) in our Algorithm 3 in order to process 64 elements per packet within a single ingress pipeline. We confine all processing to the ingress pipeline; when the aggregation is complete, the traffic manager duplicates the packet containing the aggregated result and performs a multicast. In a first version of our program, we used both ingress and egress pipelines for the aggregation, but that required packet recirculation to duplicate the packets. This caused additional dependencies that required more stages, preventing the processing of more than 64 elements per packets. Moreover, this design experienced unaccounted packet losses between the two pipelines and during recirculation, which led us to search for a better, single pipeline, program.

Worker component. Our goal for implementing the worker component is to achieve high I/O performance for aggregating model updates. At the same time, we want to support existing ML frameworks without modifications.

In existing ML frameworks, a DNN model update U comprises of a set of tensors T, each carrying a subset of the gradients. This is because the model consists of many layers; most existing frameworks emit a gradient tensor per layer and reduce each layer's tensors independently. Back-propagation produces the gradients starting from the output layer and moving towards the input layer. Thus, communication can start on the output layer's gradients while the other gradients are still being computed, partially overlapping communication with computation. This implies that for each iteration, there are as many aggregation tasks as the number of tensors (e.g., 152 for ResNet50).

Our implementation exposes the same synchronous all-reduce interface as Gloo. However, rather than treating each tensor as an independent reduction and resetting switch state for each one, our implementation is efficient in that it treats the set of tensors virtually as a single, continuous stream of data across iterations. Upon invocation, our API passes the input tensor to a virtual stream buffer manager which streams the tensor to the switch, breaking it into the small chunks the switch expects. Multiple threads may call SwitchML's all-reduce, with the requirement that each worker machine's tensor reduction calls must occur in the same order; the stream buffer manager then performs the reductions and steers results to the correct requesting thread.

One CPU core is sufficient to do reduction at line rate on a 10 Gbps network. However, to be able to scale beyond 10 Gbps, we use multiple CPU cores at each worker and use the Flow Director technology (implemented in hardware on modern NICs) to uniformly distribute incoming traffic across the NIC RX queues, one for each core. Every CPU core runs an I/O loop that processes every batch of packets in a run-to-completion fashion and uses a disjoint set of aggregation slots. Packets are batched in groups of 32 to reduce per-packet transmission overhead. We use x86 SSE/AVX instructions to scale the model updates and convert between types. We are careful to ensure all processing is NUMA aware.

RDMA implementation details. We found that the cost of processing individual SwitchML packets, even using DPDK with 256-element packets and multiple cores, was too high to achieve line rate. Other aggregation libraries use RDMA to offload packet processing to the NIC. In RDMA-based systems NICs implement packetization, flow control, congestion control, and reliable delivery. In normal usage, clients use RDMA to send and receive messages of up to a gigabyte; the NIC turns them into packets and ensures they are delivered reliably. Furthermore, clients may register memory regions with the NIC, allowing other clients to remotely read and write them without CPU involvement. This reduces or eliminates work done on the clients' CPUs to complete the transfer.

Turning a Tofino switch into a fully-featured RDMA endpoint is not the solution. Implementing timeouts and retransmission in a way that is compatible with existing poorly-documented existing RDMA NICs would be complex. Furthermore, such an implementation would not be an good fit for SwitchML: the RDMA protocols are largely designed for point-to-point communication, whereas SwitchML's protocol is designed for collective communication.

Fortunately, RDMA NICs implement multiple protocols with different properties. The standard Reliable Connected (RC) mode ensures reliable delivery and supports CPU-bypassing remote reads and writes (as well as sends and receives) of up to 1 GB. The UDP-like Unreliable Datagram (UD) mode supports just sends and receives of up the network MTU. Finally, the Unreliable Connected (UC) mode fits somewhere in between. It supports packetization, allowing for sends, receives, and writes of up to 1 GB. It also generates and checks sequence numbers, allowing it to detect packet drops, but it does not retransmit: instead, if a gap in sequence numbers is detected, incoming packets are silently dropped until the first packet of a new message arrives. Then, the sequence number counter is reset to the sequence number of that packet, and normal reception continues.

We use RDMA UC to implement a RDMA-capable variant of SwitchML using a subset of the RoCE v2 protocol [42]. Its operation is very similar to what is described in Section 4, with three main differences.

First, where base SwitchML sends and receives slot-sized packets, SwitchML RDMA sends multi-slot messages. Each packet of a message is treated largely as it is in the base protocol by the switch, but the pool index for each packet is computed as an offset from the base index provided with the first packet of the message. Timeouts are tracked just as they are in the base protocol, but when a packet drop is detected, the client retransmits the entire message rather than just the dropped packet. This makes retransmissions more expensive, but it also drastically lowers the cost incurred sending packets in the common case of no packet drops; since packet drops are rare within a datacenter, the benefit is large.

Second, SwitchML consumes and generates sequence numbers on the switch. In order to allow messages with multiple packets to aggregate concurrently, each in-flight message is allocated its own queue pair, with its own sequence number register. This allows clients to to be notified when a write message from the switch has arrived with no drops; it also allows the switch to ignore packets in messages received out of sequence. However, the same per-slot bitmap used in the base protocol is still used to ensure that duplicate packets from a retransmission of a partially-received messages are not re-applied. Packets are transmitted as individual slots addressed by a message complete. This means that the packets from multiple messages may interleave on the wire, but since each is on a separate queue pair with its own sequence number

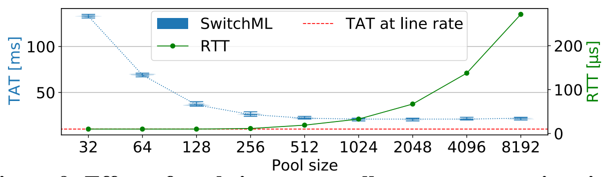

Figure 9: Effect of pool size on overall tensor aggregation time (TAT) and per-packet RTT (right y-axis) at 100 Gbps.

space, the NIC will reassemble them successfully.

Third, SwitchML RDMA uses RDMA Write Immediate messages for all communication. This allows clients to send data directly from GPU memory, and the switch to write directly into GPU memory (if the host is GPU Direct-capable). Byte order conversion and scaling are done on the GPU; the CPU is responsible only for issuing writes when data from the GPU is ready, detecting completions and timeouts, and issuing retransmissions when necessary. Necessary metadata for the SwitchML protocol is encoded in fields of the RDMA header; the RDMA RKey and Address fields are used to encode the destination slot and the address to write the response to. The Immediate field is used to carry up to four scaling factors. At job setup time, the clients communicate with the switch and give it their queue pair numbers, initial sequence numbers, and an RKey for its switch-writable memory region. The switch uses these to form RDMA Write Immediate messages with appropriate sequence numbers, destination addresses, and immediate values, of the same size as the messages sent from the clients to the switch.

Finally, it is important to note that SwitchML RDMA does not require lossless Ethernet to be configured, as is common in RoCE deployments. Enabling lossless Ethernet would reduce the probability of packet drops, but would add complexity to the network deployment. SwitchML's reliability protocol makes this unnecessary.

DNN workloads. Table 3 details the models, datasets and ML toolkits used in the experiments.

C Tuning the pool size

As mentioned, the pool size s affects performance and reliability. We now analyze how to tune this parameter.

Two factors affect s. First, because s defines the number of in-flight packets in the system that originate from a worker, to avoid wasting each worker's network bandwidth, s should be no less than the bandwidth-delay product (BDP) of each worker. Note that the delay here refers to the end-to-end delay, including the end-host processing time, which can be easily measured in a given deployment. Let b be the packet size, which is constant in our setting. To sustain line rate transmission, the stream of response packets must arrive at line rate, and this is possible when $s \cdot b$ matches the BDP. A significantly higher value of s, when used as the initial window size, will unnecessarily increase queuing time within the workers.

Model	Task	Dataset	Sys
DeepLight [23]	Click-through Rate Prediction	Criteo 1TB [19]	PyT

VGG19 [91]	Image Classification	ImageNet-1K [85]	PyT
UGATIT [51]	Image-to-Image Translation	Selfie2Anime [51]	TF
ResNet50 [38]	Image Classification	ImageNet-1K [85]	TF
SSD [63]	Object Detection	COCO 2017 [59]	PyT

Table 3: DDL benchmarks. Models, task, dataset used for training and ML toolkit (PyT=PyTorch; TF=TensorFlow).

Model	Metric	No compression	Top-10%	Top-1%
DeepLight	AUC	0.9539	0.9451	0.9427
LSTM	Perplexity	32.74	86.26	82.55
NCF	Hit rate	0.9586	0.9369	-
BERT	F1 score	91.60	91.47	91.52
VGG19	Top-1 accuracy	68.12	64.85	57.70
UGATIT	-	-	-	-
ResNet50	Top-1 accuracy	74.34	74.59	72.63
SSD	Accuracy	0.2549	0.2487	0.2309

Table 4: Test metrics comparison. NCF at Top-1% did not converge. BERT result is the median of 6 runs of fine-tuning from a pre-trained model. BERT pre-training results are shown in Figure 13. UGATIT fails to execute with the compressor implementation in [96]. See Figure 10 for the convergence behavior during training.

Second, a correctness requirement for our communication scheme is that no two in-flight packets from the same worker use the same slot (as no worker node can ever lag behind by more than one phase). To sustain line rate and preserve correctness, the lower bound on s is such that $s \cdot b$ matches the BDP. Therefore, the optimal s is for $\lceil BDP/b \rceil$.

In practice, we select s as the next power of two of the above formula because the DPDK library – which we use to implement SwitchML – performs batched send and receive operations to amortize system overheads. Based on our measurements (Figure 9), we use 128 and 512 as the pool size for 10 and 100 Gbps, respectively. This occupies 256 KB and 1 MB of register space in the switch, respectively. We note that the switch can support one order of magnitude more slots, and SwitchML uses much less than 10% of that available.

D Compression affects convergence

Table 4 reports the model quality obtained without gradient compression and with Top-k compression using $k = 1\%, 10\%$. Model quality is assessed using per-model accuracy metrics.

Results are shown in Figure 10. We observe that loss and accuracy do not necessary correlate well. For example, in the case of SSD all methods have similar loss trace, but obvious accuracy gap. For NCF, Top-k at 1% does not converge, but the accuracy can still go up.

E Model quantization

To the best of our knowledge, no Ethernet switching chip offers floating-point operations in the dataplane for packet processing. Some InfiniBand switching chips have limited support for floating-point operations for scientific computing [33]. We also confirmed that the state-of-the-art programmable Ethernet switching chips do not support native floating-point operations either. These observations lead us to two main questions.

Where should the type conversion occur? In theory either workers or the switch can perform type conversion. In the former case, packets carry a vector of integer types while in the latter case the switch internally performs the type conversions. It turns out to be possible to implement a restricted form of 16-bit floating point on a Tofino chip by using lookup tables and ALUs to do the conversion. This means there is no type conversion overhead at end hosts. However, this approach still requires to scale the gradient values due to the limited range of floating point conversion the switch can perform. Besides, unless half-precision training is used, the worker must still convert from 32-bit to 16-bit floating points. At the same time, an efficient implementation that uses modern x86 vector instructions (SSE/AVX) to implement type conversion sees only a negligible overhead (see Figure 11).

What are the implications in terms of accuracy? Recently, several update compression (e.g., quantization, dithering or sparsification) strategies were proposed (see [96] for a survey) to be used with standard training methods, such as SGD, and bounds were obtained on how these strategies influence the number of iterations until a sufficient convergence criterion is satisfied (e.g., being sufficiently close to minimizing the empirical loss over the data set). These include aggressive 1-bit compression of SGD for DNNs [88], signSGD [7, 8], QSGD [4], which uses just the sign of the stochastic gradients to inform the update, Terngrad [95], which uses ternary quantization, and the DIANA framework [69], which allows for a wide array of compression strategies applied to gradient differences. All the approaches above use lossy randomized compression strategies that preserve unbiasedness of the stochastic gradients at the cost of increasing the variance of gradient estimators, which leads to worse iteration complexity bounds. Thus, there is a trade-off between savings in communication and the need to perform more training rounds. In contrast, our mechanism is not randomized, and for a suitable selection of a scaling parameter f, is essentially lossless or suffers negligible loss only.

We shall now briefly describe our quantization mechanism. Model updates are divided into packet-sized blocks. With a small abuse of notation, in the following all equations refer to per-block operations. Each worker multiplies its block model update $\Delta_i^t = \Delta(x^t, D_i^t)$ by a vector of scaling factors $f > 0$, obtaining $f\Delta_i^t$. The elements of f are chosen per block, and are chosen such that that all k entries of the scaled update can be rounded to a number representable as an integer without overflow. We then perform this rounding, obtaining vectors $Q_i^t = \rho(f\Delta_i^t) \in \mathbb{Z}^k$ for $i = 1, 2, \ldots, n$, where ρ is the rounding operator, which are sent to the switch and aggregated,

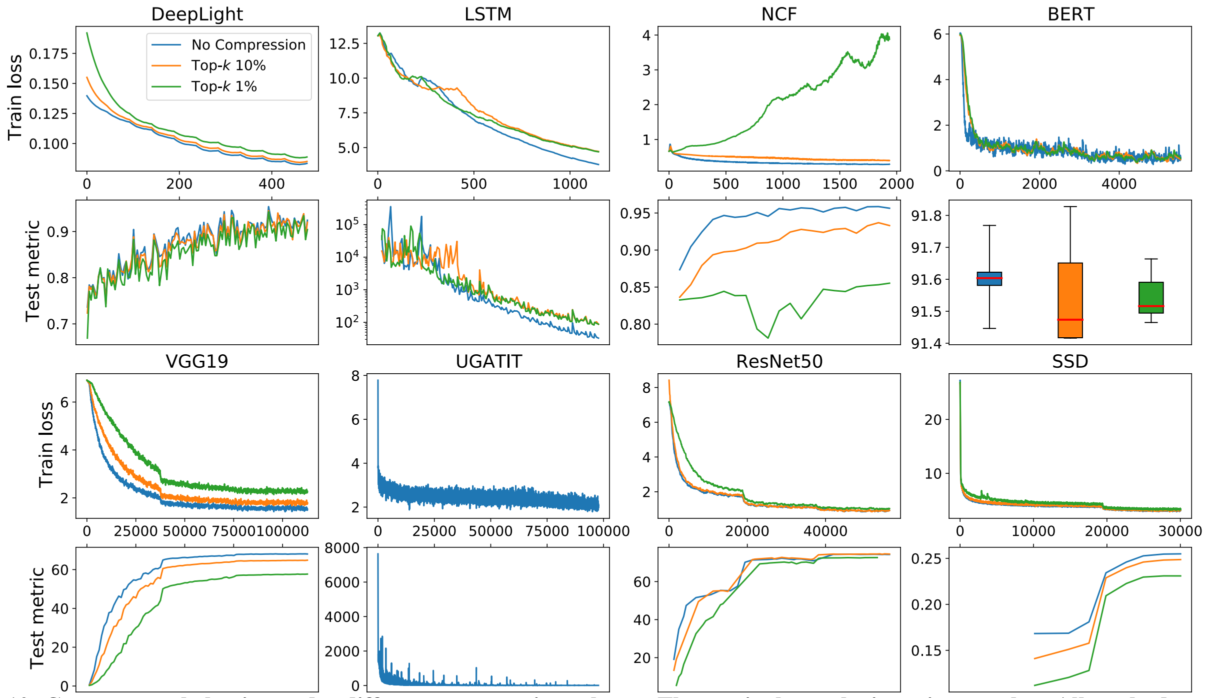

Figure 10: Convergence behavior under different compression scheme. The x axis shows the iteration number. All methods execute a fixed number of steps and hyperparameters are kept the same. Refer to Table 4 for test metrics of each task. We plot generator loss as the metric for UGATIT because there is no objective metric available for GAN workloads. Note that for the perplexity metric of LSTM, lower is better.

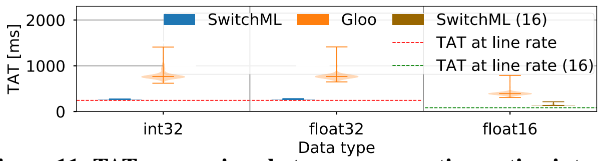

Figure 11: TAT comparison between aggregating native-integer tensors, scaling and converting from single-precision (float32) tensors, and scaling and converting from half-precision (float16) tensors.

resulting in

$$A^t = \sum_{i=1}^{n} Q_i^t.$$

Again, we need to make sure f is not too large so that A^t can be represented as an integer without overflow. The aggregated update A^t is then scaled back on the workers, obtaining A^t/f, and the model gets updated as follows:

$$x^{t+1} = x^t + \frac{1}{f} A^t.$$

Let us illustrate this on a simple example with $n = 2$ and $d = 1$. Say $\Delta_1^t = 1.56$ and $\Delta_2^t = 4.23$. We set $f = 100$ and get

$$Q_1^t = \rho(f\Delta_1^t) = \rho(156) = 156$$

and

$$Q_2^t = \rho(f\Delta_2^t) = \rho(423) = 423.$$

The switch will add these two integers, which results in $A^t = 579$. The model then gets updated as:

$$x^{t+1} = x^t + \frac{1}{100} 579 = x^t + 5.79.$$

Notice that while the aggregation was done using integers only (which is necessitated by the limitations of the switch), the resulting model update is identical to the one that would be applied without any conversion in place. Let us consider the same example, but with $f = 10$ instead. This leads to

$$Q_1^t = \rho(f\Delta_1^t) = \rho(15.6) = 16$$

and

$$Q_2^t = \rho(f\Delta_2^t) = \rho(42.3) = 42.$$

The switch will add these two integers, which results in $A^t = 58$. The model then gets updated as:

$$x^{t+1} = x^t + \frac{1}{10} 58 = x^t + 5.8.$$

Note that this second approach leads to a small error. Indeed, while the true update is 5.79, we have applied the update 5.8 instead, incurring the error 0.01.

Our strategy is to apply the above trick, but take special care about how we choose the scaling factor f so that the trick works throughout the entire iterative process with as little information loss as possible.

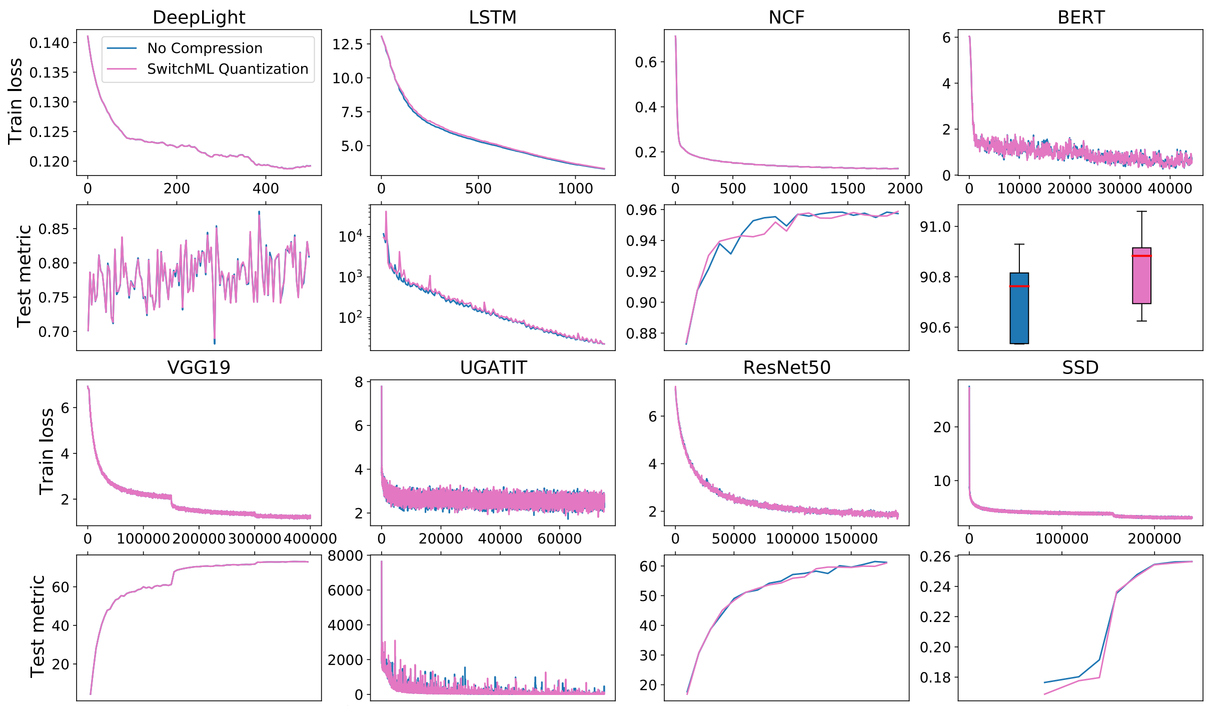

Figure 12: Convergence analysis of SwitchML quantization method on a single GPU. The x axis shows the iteration number.

A formal model. Let us now formalize the above process. We first assume that we have a scalar $f > 0$ for which the following holds:

Assumption 1. $|\rho(f\Delta_i^t)| \leq 2^{31}$ *for all* $i = 1, 2, \ldots, n$ *and all iterations* t.

Assumption 2. $|\sum_{i=1}^n \rho(f\Delta_i^t)| \leq 2^{31}$ *for all iterations* t.

The above assumptions postulate that all numbers which we obtain by scaling and rounding on the nodes (Assumption 1), and by aggregation on the switch (Assumption 2), can be represented as integers without overflow.

We will now establish a formal statement which characterizes the error incurred by our aggregation procedure.

Theorem 1 (Bounded aggregation error). The difference between the exact aggregation value $\sum_{i=1}^n \Delta_i^t$ *(obtained in case of perfect arithmetic without any scaling and rounding, and with a switch that can aggregate floats) and the value* $\frac{1}{f}A^t = \frac{1}{f}\sum_{i=1}^n \rho(f\Delta_i^t)$ *obtained by our procedure is bounded by* $\frac{n}{f}$.

Proof. To prove the above result, notice that

$$\begin{aligned}\frac{1}{f}\sum_{i=1}^n \rho(f\Delta_i^t) &\leq \frac{1}{f}\sum_{i=1}^n \lceil f\Delta_i^t \rceil \\ &\leq \frac{1}{f}\sum_{i=1}^n (f\Delta_i^t + 1) \\ &= \left(\sum_{i=1}^n \Delta_i^t\right) + \frac{n}{f}.\end{aligned}$$

Using the same argument, we get a similar lower bound

$$\begin{aligned}\frac{1}{f}\sum_{i=1}^n \rho(f\Delta_i^t) &\geq \frac{1}{f}\sum_{i=1}^n \lfloor f\Delta_i^t \rfloor \\ &\geq \frac{1}{f}\sum_{i=1}^n (f\Delta_i^t - 1) \\ &= \left(\sum_{i=1}^n \Delta_i^t\right) - \frac{n}{f}.\end{aligned}$$

□

Note that the error bound postulated in Theorem 1 improves as f increases, and n decreases. In practice, the number of nodes is constant $n = O(1)$. Hence, it makes sense to choose f as large as possible while making sure Assumptions 1 and 2 are satisfied. Let us give one example for when these assumptions are satisfied. In many practical situations it is known that the model parameters remain bounded:[9]

Assumption 3. There exists $B > 0$ *such that* $|\Delta_i^t| \leq B$ *for all* i *and* t.

As we shall show next, if Assumption 3 is satisfied, then so is Assumption 1 and 2.

Theorem 2 (No overflow). Let Assumption 3 be satisfied. Then Assumptions 1 and 2 are satisfied (i.e., there is no overflow) as long as $0 < f \leq \frac{2^{31}-n}{nB}$.

Proof. We have $\rho(f\Delta_i^t) \leq f\Delta_i^t + 1 \leq f|\Delta_i^t| + 1 \leq fB + 1$. Likewise, $\rho(f\Delta_i^t) \geq f\Delta_i^t - 1 \geq -f|\Delta_i^t| - 1 = -(fB + 1)$. So,

[9]If desirable, this can be enforced explicitly by the inclusion of a suitable hard regularizer, and by using projected SGD instead of plain SGD.

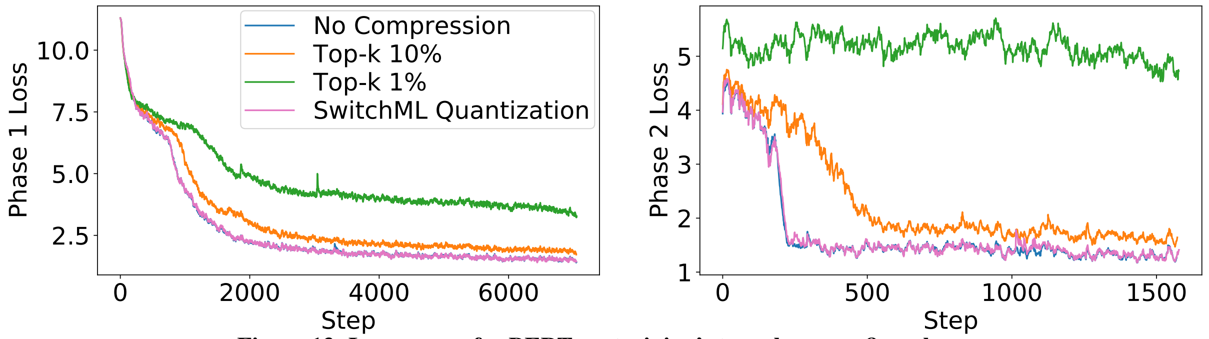

Figure 13: Loss curves for BERT pretraining's two phases on 8 workers.

$|\rho(f\Delta_i^t)| \leq fB+1$. Hence, as soon as $0 < f \leq \frac{2^{31}-1}{B}$, Assumption 1 is satisfied. This inequality is less restrictive as the one we assume. Similarly, $|\sum_i \rho(f\delta_i^t)| \leq \sum_i |\rho(f\Delta_i^t)| \leq \sum_i (fB+1) = n(fB+1)$. So, Assumption 2 is satisfied as long as $n(fB+1) \leq 2^{31}$, i.e., as long as $0 < f \leq \frac{2^{31}-n}{nB}$. $\square$

We now put all of the above together. By combining Theorem 1 (bounded aggregation error) and Theorem 2 (no overflow), and if we choose $f = \frac{2^{31}-n}{nB}$, then the difference between the exact update $\sum_i \Delta_i^t$ and our update $\frac{1}{f}\sum_i \rho(f\Delta_i^t)$ is bounded by $\frac{n^2B}{2^{31}-n}$. In typical applications, $n^2B \ll 2^{31}$, which means that the error we introduce is negligible.

Empirical study. We name the above method "SwitchML quantization" and run end-to-end experiments to study its convergence behavior. Figure 12 shows that SwitchML quantization achieves similar training loss and does not incur test metric decrease in all models detailed in Table 4. We further show in Figure 13 that SwitchML quantization has little to no difference in the training loss curve of BERT [24] pretraining compared to the no compression baseline, while Top-k compression with $k = 1\%, 10\%$ has a big impact on model convergence.

F Encrypted traffic

A recent trend, especially at cloud providers, is to encrypt all datacenter traffic. In fact, data encryption is generally performed at the NIC level itself. While addressing this setting is out of scope, we wish to comment on this aspect. We believe that given our substantial performance improvements, one might simply forego encryption for ML training traffic.

We envision a few alternatives for when that is not possible. One could imagine using HW accelerators to enable in-line decryption/re-encryption at switches. However, that is likely costly. Thus, one may wonder if computing over encrypted data at switches is possible. While arbitrary computations over encrypted data are beyond current switches' capabilities, we note that the operation performed at switches to aggregate updates is simple integer summation. The appealing property of several partially homomorphic cryptosystems (e.g., Paillier) is that the relation $E(x) \cdot E(y) = E(x+y)$ holds for any two values x, y (where E denotes encryption). For instance, recent work by Cheon et al. [14] developed a homomorphic encryption scheme for approximate arithmetic. By customizing the end-host encryption process, the worker could encrypt all the vector elements using such a cryptosystem, knowing that the aggregated model update can be obtained by decrypting the data aggregated at the switches. We leave it to future work to validate this concept.

Efficient Wideband Spectrum Sensing Using MEMS Acoustic Resonators

Junfeng Guan, Jitian Zhang, Ruochen Lu, Hyungjoo Seo,
Jin Zhou, Songbin Gong, Haitham Hassanieh
Univeristy of Illinois at Urbana-Champaign

Abstract – This paper presents S^3, an efficient wideband spectrum sensing system that can detect the real-time occupancy of bands in large spectrum. S^3 samples the wireless spectrum below the Nyquist rate using cheap, commodity, low power analog-to-digital converters (ADCs). In contrast to existing sub-Nyquist sampling techniques, which can only work for sparsely occupied spectrum, S^3 can operate correctly even in dense spectrum. This makes it ideal for practical environments with dense spectrum occupancy, which is where spectrum sensing is most useful. To do so, S^3 leverages MEMS acoustic resonators that enable spike-train like filters in the RF frequency domain. These filters sparsify the spectrum while at the same time allow S^3 to monitor a small fraction of bandwidth in every band.

We introduce a new structured sparse recovery algorithm that enables S^3 to accurately detect the occupancy of multiple bands across a wide spectrum. We use our fabricated chip-scale MEMS spike-train filter to build a prototype of an S^3 spectrum sensor using low power off-the-shelf components. Results from a testbed of 19 radios show that S^3 can accurately detect the channel occupancies over a 418 MHz spectrum while sampling 8.5× below the Nyquist rate even if the spectrum is densely occupied.

1 Introduction

The past decade has witnessed significant changes in the wireless spectrum as the FCC (Federal Communications Committee) has repurposed many frequency bands for dynamic spectrum sharing. This includes the 6 GHz band, released in April 2020, to be shared between Wi-Fi 6E and the incumbent users in this band like microwave backhaul [14]. Another example is the 3.5 GHz Citizens Broadband Radio Service (CBRS) band, which was recently approved for commercial deployments in September 2019. To leverage the CBRS band, unlicensed devices must sense a 200 MHz spectrum and avoid causing interference to primary and licensed users like military radars [13]. Of course, an earlier and more well-known example of spectrum sharing is the TV White Spaces which were released in 2010 [15]. Moreover, there are lots of opportunities for spectrum sharing in the millimeter-wave frequencies. In particular, the FCC released 14 GHz of unlicensed spectrum in the 60 GHz band that can be shared among Wi-Fi and IoT technologies [16]. These changes have been driven by the ever-increasing demand for wireless connectivity and aim to exploit previously underutilized frequency bands to accommodate new unlicensed applications and achieve highly efficient usage of the spectrum.

Efficient and truly dynamic spectrum sharing, however, requires unlicensed devices to sense wideband spectrum (hundreds of MHz to GHz) in real-time to spot and access momentarily idle channels. Unfortunately, real-time wideband spectrum sensing is challenging since it requires high-speed analog-to-digital converters (ADCs) that can sample the signal at the Nyquist sampling rate. Such high-speed ADCs are expensive, have low bit resolution, and can consume several watts of power [4, 12, 19, 34, 58].[1] To avoid using high-speed ADCs, today's systems sequentially scan the spectrum, monitoring each narrow band for a short period of time [11,47]. As a result, they cannot continuously sense all bands in real-time and can easily miss highly dynamic and fleeting signals such as radar waveforms in the CBRS band [53].

Past work has proposed using compressive sensing or sparse Fourier transforms to sense wideband spectrum without sampling at the Nyquist rate [21, 27, 31, 41]. However, these approaches inherently rely on the assumption that the frequency spectrum is sparsely occupied. Hence, they only work in the case of underutilized spectrum where at most 5% to 10% of the frequency bands are occupied [21,58]. The goal of dynamic spectrum sharing, however, is to efficiently utilize the spectrum. Hence, wideband spectrum sensing must work even in a densely occupied spectrum in order to scale usage to many users and achieve high utilization.

In this paper, we introduce S^3 (Spectrum Sensing Spike-train), an efficient low power spectrum sensing system that can monitor the real-time occupancy of multiple frequency bands in a wide spectrum. S^3 samples the wireless spectrum below the Nyquist sampling rate using cheap, commodity, low power ADCs but does not assume that the spectrum is sparsely occupied. A key enabler of S^3 is the use of MEMS (mirco-electro-mechanical-system) acoustic resonators that can create a spike-train like filter in frequency as shown in Fig 1. The MEMS filter processes the signal in the acoustic domain using carefully designed piezoelectric resonators with an assortment of equally spaced resonance frequencies. The resonators will pass the signals in these resonance frequencies and filter out the rest before converting the signal back to the RF domain. This creates an RF filter with very narrow, sharp, and periodic passbands across a wideband spectrum.

The spike-train filter enables S^3 to sample the spectrum in

[1] In fact, the power consumption of spectrum sensors is dictated by the ADC sampling rate as shown in [58]. Hence, we can significantly improve the energy efficiency by reducing the sampling rate.

the frequency domain and monitor a small fraction of bandwidth in every band. S^3 can then tell if a band is occupied or idle by examining the sampled bandwidth in it, without the need to recover the entire band. This is like finding an available spot in a parking lot; We can tell if a spot is taken by peeking at some part of the car in it and we don't need to get close to every spot and see the entire car. Moreover, even if the wideband spectrum is densely occupied, the filter makes the spectrum significantly sparser as shown in Fig. 1. This enables S^3 to sample the signal below the Nyquist sampling rate and still recover the channel occupancies.

Translating S^3 into a practical system, however, requires addressing two key challenges. First, we need an algorithm that can accurately and efficiently reconstruct the spectrum occupancy. To address this, S^3 builds on past work in sparse recovery theory but differs from it in key aspects. In particular, compressive sensing algorithms require randomly sampling the time signal and cannot simply be implemented using low-speed ADCs [27,59]. Sparse Fourier transform algorithms, on the other hand, can be implemented using low-speed ADCs, but they assume that the sparsely occupied bands are randomly distributed in the frequency spectrum [17,21]. The MEMS filter creates a sparse spectrum that is highly periodic and far from random. For such sparsity patterns, sparse Fourier transform algorithms are highly sub-optimal.

S^3 aims to achieve the best of both worlds, i.e. no random sampling in time and no assumption of random distribution of occupied frequencies. To this end, S^3 leverages the uniquely structured sparsity pattern created by the filter to overcome the above challenges. The filter restricts the occupied frequencies to known locations in the spectrum, which significantly reduces the search space. It also allows us to optimize the sub-Nyquist sampling rate. In particular, optimal recovery can be achieved by choosing a sub-sampling factor that is co-prime to the number of spikes in the filter, as we show in section 5.

The second challenge is that in practice the MEMS resonators do not create an ideal spike-train. The spikes are not extremely narrow and have a small passband bandwidth which reduces the sparsity. Moreover, the separation between the spikes is not perfectly equal, and the spikes themselves are not identical. To address this, S^3 leverages the fact that different filters that are manufactured using the same process exhibit a very similar non-ideal spike-train, as we show in Sec. 6. Hence, the filter frequency response can be measured once and incorporated into the design of S^3. Specifically, we co-design the hardware and recovery algorithm of S^3 to account for the filter non-idealities and optimize its performance.

Evaluation: We had fabricated a chip-scale MEMS filter, shown in Fig. 1, which we leveraged to build a working prototype of S^3. The prototype can sense channel occupancies over a 418 MHz spectrum in real-time while sampling $8.5\times$ below the Nyquist rate. The prototype uses two cheap, low power, off-the-shelf ADCs that sample around 50 MS/s ($\approx 1/17$ of the Nyquist rate). We extensively evaluate the performance of S^3 using a wireless testbed with 20 software defined radios that can occupy the entire 418 MHz spectrum at various power levels. Our results show that S^3 can accurately detect occupied channels. Even when the spectrum is as crowded as 90% occupied, S^3 achieves a false positive rate of 0.02 and a false negative rate of 0.0047. We also compare S^3 to state-of-the-art prior work like BigBand [21] and SweepSense [20] and demonstrate $5-10\times$ lower error rate for non-sparse spectrum. Furthermore, we show that S^3 can recover the wireless spectrum by performing outdoor and indoor measurements at various frequencies using a spectrum analyzer as the ground truth. Finally, we extend S^3 to not only detect the occupancy of the bands but also capture the power spectral density of the spectrum by quickly sweeping the center frequency for 22 MHz to cover the separation between the spikes.

Contributions: This paper has the following contributions:

- The paper bridges the latest advances in overtone MEMS acoustic resonators to RF spectrum sensing by leveraging spike-train filters to enable cheap and low power real-time wideband sensing of a densely occupied spectrum.
- The paper presents a novel sparse recovery algorithm that leverages the uniquely structured spectrum sparsity to efficiently recover a spectrum sampled significantly below the Nyquist sampling rate.
- The paper builds a prototype using commodity low-power components and evaluates its performance in a real testbed.

2 Background

In this section, we provide a brief background on wideband spectrum sensing using sub-Nyquist sampling. Further related work and background on spectrum sensing can be found in section 9.

This paper builds on past work that senses wideband spectrum without sampling at the Nyquist rate using compressive sensing [27, 31, 32, 39, 51, 58–60] or sparse Fourier transform algorithms [21, 43]. However, these approaches only work when the spectrum is underutilized and sparsely occupied which defeats the purpose of efficiently utilizing the spectrum. Furthermore, compressive sensing needs random

Figure 2: Spike-Train filter using MEMS acoustic resonators.

sampling [27, 58, 59], and as a result, requires custom hardware designs that can consume as much power as an ADC that samples at the Nyquist rate [1, 2]. Sparse Fourier transform algorithms do not necessarily require random sampling but must assume that the sparsely occupied bands are randomly distributed in the frequency spectrum to accurately recover the frequencies [17, 21].

BigBand [21] leverages sparse Fourier transform and uses co-prime sampling to acquire a sparse bandwidth while sampling 6× below the Nyquist rate. However, it only works up to 10% spectrum occupancy at which point it cannot recover the status of more than 14% of the spectrum. An extension, D-BigBand [43] can sense dense spectrum by considering the differential changes in occupancy. However, it assumes that the spectrum occupancy is mostly static with very few changes over time. Hence, it would not work for dynamic spectrum sharing where users sense and opportunistically transmit whenever they find an idle channel. [30] also attempts to extend BigBand to dense spectrum but requires sampling the signal first at the Nyquist rate in order to permute the samples and filter the signal before further sub-sampling it below Nyquist. S^3, on the other hand, can sense dense spectrum without the need for Nyquist sampling or random sampling. It also makes no assumptions on the changes in occupancy or the distribution of occupied bands across the spectrum.

3 Spike-Train MEMS Filter

Our work builds on recent advances in overtone MEMS RF filters [18, 40]. The MEMS filters convert RF signals into acoustic vibrations through the piezoelectric effect, then filter and process the signal in the acoustic domain before converting it back to the RF domain. Such filters can be further integrated with ICs to form an RF front-end solution, operating between a few MHz and 30 GHz for mobile and IoT devices. To this end, past work on MEMS RF filters optimize for a filter with a single passband [45, 64]. In contrast, the MEMS filter used by S^3 leverages overtone resonators that have an assortment of equally spaced resonance frequencies resulting in a spike train in the frequency domain. S^3 uses some of the very first spike-train MEMS filters which we had designed and fabricated [28, 29] to enable low power real-time wideband spectrum sensing of densely occupied spectrum.

To better understand how the MEMS filter works, consider the diagram of a MEMS acoustic resonator shown in Fig. 2(a). This resonator is commonly referred to as a LOBAR (Lateral Overtone Bulk Acoustic Resonator). The device consists of three electrodes on the top of a thin film made of the piezoelectric material $LiNbO_3$. RF signals come through the middle electrode and can be efficiently converted into acoustic waves through the piezoelectric effect, as long as their frequencies match the resonances of the film and are supported by the electrode design. Otherwise, the signals are reflected back and the frequencies are filtered out.

The resonance frequencies are determined by:[2]

(1) The width of the film: the film supports resonance frequencies for which acoustic wave vanishes at the edges of the film [8] i.e., the sine wave crosses zero at the edges as shown in Fig. 2(a). This condition is satisfied when the width of the film W is an integer (k) multiple of half a wavelength ($W = k\lambda/2$). Since $f = v/\lambda$, where v is the acoustic velocity in the piezoelectric material, the MEMS resonator will resonate at frequencies: $f_k = kv/2W$.

(2) The placement of electrodes: the filter will operate at center frequency f_c determined by the distance D between the electrodes: $f_c = v/2D$. Furthermore, for an odd number of electrodes, only acoustic waves that cross zero at the middle electrode, as shown in Fig. 2(a), will resonate.

Thus, the resonance frequencies will be the f_ks around f_c where k is even. This leads to a filter with center frequency f_c and a spike train where the spacing between the spikes is $\Delta f = v/W$. By modifying the width of the film and the position of the electrodes, we can modify Δf and f_c to control the frequency of the spikes in the filter.

The bandwidth or frequency span of the filter around f_c is determined by the electrodes where their RF-to-acoustic conversion efficiency degrades for resonance frequencies far from f_c, resulting in higher loss in spikes far from f_c. Adding more electrodes reduces the loss in spikes near f_c but narrows down the frequency span. We found that a three electrodes give the widest span with minimal loss of at most 2 dB.

Finally, to further enable a filter with very sharp and narrow

[2]The filter design actually involves a 4-way trade-off between (1) the frequency span, (2) the spacing between adjacent spikes, (3) the insertion loss in the spikes, and (4) the out-of-band rejection. For simplicity, we focus on the resonance frequencies design, and the trade-off between the frequency span and insertion loss. More details on the MEMS filter design trade-offs are discussed in [29].

spikes, we combine 7 of these MEMS resonators in a ladder filter topology [24]. Fig 2(b) shows an image of the filter under the Microscope. The frequency response of the filter is shown in Fig. 2(c). It has 19 periodic spikes with lowest loss between 161 and 579 MHz spanning a wide bandwidth of 418 MHz. The spacing between spikes is $\Delta f = 22$ MHz and the width of each spike is around $1 \sim 1.5$ MHz. Such an RF spike-train filter is the first of its kind. It presents a unique opportunity for processing wideband spectrum, which S^3 leverages towards efficient low power wideband spectrum sensing. It is also worth noting that the filter is passive and do not consume any power.

4 S^3 Overview

S^3 leverages the MEMS spike-train filters to sense wideband spectrum while sampling below the Nyquist rate. Fig. 3 illustrates an overview of the system pipeline. The received wideband spectrum is passed through the MEMS spike-train filter which samples the bands in the spectrum along the frequency axis. Specifically, the filter passes signals in frequencies aligned with the spikes and suppresses all the rest of the frequency components in the spectrum as shown in Fig. 3. The output of the filter is a sparse spectrum that preserves a small fraction of each band which we can use to monitor the occupancy of the band. Since the output spectrum is sparse, we can sample it below the Nyquist rate and still recover the occupancy information efficiently.

S^3 uses low-speed ADCs to sub-sample the signal. However, sampling below the Nyquist rate results in *"aliasing"* in the frequency domain i.e., multiple frequencies across the wide spectrum will alias (map) to the same frequency. Aliasing can lead to ambiguity and collisions, which prevent us from distinguishing frequencies that are occupied from those that are not. S^3 leverages the uniquely structured sparsity at the output of the spike-train filter to resolve such ambiguity and collisions and recover the spectrum occupancy. Ideally, one ADC is sufficient as we prove in section 5. However, due to practical limitations and imperfections in the spike-train filter, S^3 must use two ADCs sampling at different rates to accurately resolve ambiguity and collisions. We co-design the hardware and recovery algorithm to optimize the ADC sampling rates while accounting for the non-idealities of the spike-train filter as we describe in detail in section 6.

5 S^3 Recovery Algorithm

In this section, we describe S^3 recovery algorithm assuming an ideal spike-train filter. In later sections, we extend S^3 to deal with practical limitations.

Ideally, the spike-train filter will have equally spaced, very narrow and sharp spikes that can be approximated as an impulse train.[3] The frequency response of such a filter can be modeled as:

$$G(f) = \sum_{k}^{K} \delta(f - k\Delta f - f_0) \tag{1}$$

where K is the number of spikes, Δf is the spacing between spikes, and f_0 is the frequency of the first spike as shown in Fig. 3. Hence, the filter covers a spectrum bandwidth of $BW = \Delta f \times K$.

Let $x(t)$ be the input wideband signal in time domain and $X(f)$ be its non-sparse frequency representation whose bandwidth is also BW. After passing $x(t)$ through the spike-train filter, we get the signal $\tilde{x}(t)$ whose frequency spectrum is:

$$\tilde{X}(f) = X(f)G(f) = \sum_{k}^{K} A_k \delta(f - k\Delta f - f_0) \tag{2}$$

where $A_k = X(k\Delta f + f_0)$. $\tilde{X}(f)$ is at most K sparse i.e., it has at most K large frequency coefficients. Our goal is to recover these K coefficients A_k and estimate their power to detect the occupancy of the band around the frequency $f_0 + k\Delta f$.

S^3 samples the signal $\tilde{x}(t)$ using a low-speed ADC that samples at a rate $R = BW/P$ where P is an integer corresponding to the subsampling factor.[4] The sampling rate R is chosen such that $K \leq R \ll BW$. Let $y(t)$ be the sampled signal i.e., $y(t) = \tilde{x}(P \times t)$, and let $Y(f)$ be the Fourier transform of $y(t)$. Then, $Y(f)$ is an aliased version of $\tilde{X}(f)$:

$$Y(f) = \sum_{i=0}^{P-1} \tilde{X}(f + iR) \tag{3}$$

$Y(f)$ will cover a narrow bandwidth equal to R where frequencies in $\tilde{X}(f)$ that are equally spaced by R alias and sum together in the same frequency bin in $Y(f)$. Hence, once S^3 detects power in a frequency bin $Y(f)$, it knows that this power

[3] We can approximate the spikes as impulses if the width of the spike $\ll 1/T$ where T is the time window over which we sample the signal.

[4] Note that for simplicity, we have assumed that the ADC takes complex samples of the signal i.e., there are two ADCs sampling the I and Q of the wireless signal. We will relax this assumption in the following section.

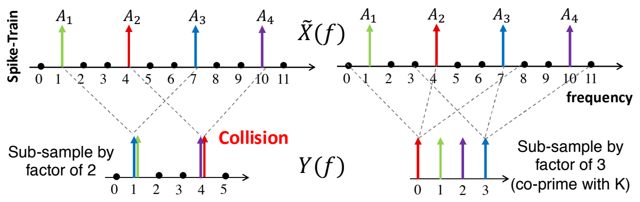

Figure 4: Co-prime sub-sampling factor avoids frequency collisions: Sub-sampling the spike train by 2 results in collisions between the spikes, but sub-sampling by 3 can avoid collisions because it is co-prime with K=4.

could have come from P different candidate frequencies in $\tilde{X}(f)$. Fig. 4 shows an example where if we sub-sample the signal by a factor $P = 2$, then every two equally spaced frequencies in $\tilde{X}(f)$ map to one value in $Y(f)$. Since $\tilde{X}(f)$ only has power in K coefficients A_k corresponding to the spikes of the filter, S^3 can easily eliminate a lot of candidates. Ideally, we want these coefficients to map to different bins. In this case, the bin value will be the same as the coefficient A_k which we can immediately estimate. However, if two coefficients A_{k_1} and A_{k_2} collide in the same bin as shown in Fig. 4, it will not be possible for S^3 to distinguish and estimate them.

S^3 can choose the sampling rate R in a manner that guarantees that no two coefficients collide. In particular, if the sub-sampling factor P and the number of spikes K are co-prime, then we can guarantee that none of K coefficients collide in the same bin and become indistinguishable. To see this, consider the example shown in Fig 4 where we have $K = 4$ spikes with coefficients A_1 to A_4 in the filtered spectrum $\tilde{X}(f)$. When we sub-sample by a factor of 2 below Nyquist, there will be collisions between A_1 and A_3, as well as A_2 and A_4. However, when we sub-sample by a factor of 3 below Nyquist, none of the coefficients collide, because the sub-sampling factor $P = 3$ and the number of spikes $K = 4$ are co-prime.

It is worth noting here that even though $P = 3$ uses a lower sampling rate than $P = 2$, increasing the sampling rate in this case results in more collisions. This is in contrast to past work on sub-Nyquist sampling [17,21] where higher sampling rates reduce collisions as the coefficients are assumed to be randomly distributed in the spectrum. Unlike past work, the structured sparsity of our spectrum requires carefully selecting the sampling rate to ensure that all coefficients can easily and immediately be recovered.

The below lemma, theoretically proves that if P and K are co-prime, then none of the coefficients will collide.

Lemma 5.1. *Given K, P are co-prime integers, let f_i and f_j be the frequencies of any two spikes in the spike train filter i.e. $f_i = k_i\Delta f + f_0$ and $f_j = k_j\Delta f + f_0$ such that $0 \le k_i, k_j < K$. Then, for all $f_i \neq f_j$, we have $f_i \neq f_j$ mod R.*

Proof. Assume there exist an $f_i \neq f_j$ such that the coefficients collide i.e., $f_i = f_j \bmod R$. Note that by definition of the spike train, we also have $f_i = f_j \bmod \Delta f$. Consequently, f_i and f_j are equal modulo the least common multiple: $\text{LCM}(R, \Delta f) = \text{LCM}(BW/P, BW/K) = BW$, since K and P are co-prime.

Algorithm 1 S^3 Sensing with an Ideal Spike-Train Filter

```
Input: $x(t)$
$B_k \leftarrow$ Band around frequency $f = k\Delta f + f_0$
$\tilde{x}(t) = g(t) \circledast x(t)$          ▷ Filter $\tilde{X}(f) = X(f)G(f)$
$y(t) = \tilde{x}(P \times t)$                  ▷ Sub-Nyquist Sample
$Y(f) = \text{FFT}(y(t))$
$A_k = Y\left((k\Delta f + f_0) \bmod R\right)$
if $E\left[|A_k|^2\right] > \sigma^2$ then
    $B_k$ is occupied
else
    $B_k$ is empty
```

Thus, $f_i = f_j \bmod BW$ which is a contradiction since BW is the entire bandwidth and we are given that $f_i \neq f_j$. Hence, by contradiction, for all $f_i \neq f_j$, we have $f_i \neq f_j \bmod R$ and none of the K coefficients collide. □

Given that we can choose a sampling rate that results in no collisions, we can easily recover the coefficients A_k as follows. We can compute $Y(f)$ by taking an FFT of $y(t)$ and for $0 \le k < K$, we directly set $A_k = Y((k\Delta f + f_0) \bmod R)$. We then apply an energy detector on A_k to obtain the occupancy of the band around the frequency $k\Delta f + f_0$. If $|A_k|^2$ is above the noise floor, then the band is occupied, otherwise, it is empty. A pseudocode for the overall sensing of S^3 with an ideal spike-train filter is shown in Alg. 1.

Next, we prove the below theorem about the correctness and the computational complexity of the algorithm.

Theorem 5.2. *Assuming a signal SNR > 0 dB for each occupied band, the system correctly recovers the occupancy of the bands using $O(K)$ samples and $O(K \log K)$ computations which is optimal.*

Proof. We will prove the above statement for the case where the entire spectrum is occupied. We can compute the the signal power of the filtered and sub-sampled signal as:

$$E\left[\|\tilde{Y}(f)\|_2^2\right] = E\left[\sum_{f=0}^{R-1} |Y(f)|^2\right] = E\left[\sum_{f=0}^{R-1}\sum_{i=0}^{P-1} |\tilde{X}(f+iR)|^2\right]$$
$$= E\left[\sum_{k=1}^{K} |\tilde{X}(k\Delta f + f_0)|^2\right] = E\left[\sum_{k=1}^{K} |A_k|^2\right] \ge KE\left[\min_k |A_k|^2\right] \tag{4}$$

Let σ^2 be the noise power per frequency. Since the spike-train filter suppresses the noise outside the spikes, the remaining noise in the signal is $K\sigma^2$. Hence, the SNR of the filtered and sub-sampled signal is:

$$SNR = \frac{E\left[\|\tilde{Y}(f)\|_2^2\right]}{K\sigma^2} \ge \frac{E\left[\min_k |A_k|^2\right]}{\sigma^2} > 1 \tag{5}$$

Thus, as long as the received signal is above the noise floor i.e. $SNR > 1$ (0 dB), filtering and sub-sampling will not increase the noise floor and the occupancy of the band can be detected

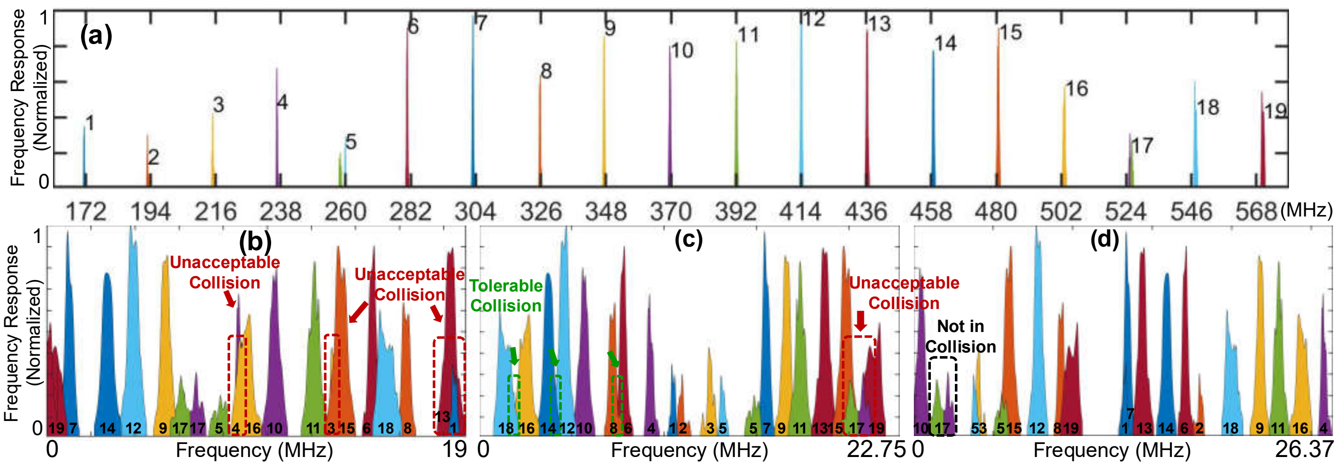

Figure 5: Aliasing of the spike-train filter at different sub-Nyquist sampling rates: (a) Locations of the 19 spikes on the frequency axis (b)Aliasing of the spikes at 38 MS/s (c) Aliasing of the spikes at 45.5 MS/s (b) Aliasing of the spikes at 52.74 MS/s.

correctly. Now, the algorithm samples at rate $R = O(K)$, takes an FFT of size $O(R)$ and then performs $O(R)$ computations. Hence, it requires $O(K \log K)$ computations and $O(K)$ sample, which is optimal. The algorithm is also deterministic, unlike compressive sensing and sparse Fourier transform algorithms which are randomized. □

6 S^3 with Practical Limitations

As mentioned earlier, the MEMS spike-train filter is non-ideal i.e., the spikes have some width as can be seen from Fig. 6. Although the ~ 1.5 MHz bandwidth is narrow compared to the channel bandwidth, it is still significant. Moreover, the spikes are neither identical nor perfectly equally spaced. In fact, they differ in magnitudes, bandwidths, and shapes. As a result, if we simply pick a sub-sampling factor P that is co-prime to the number of spikes K, there could be many collisions among the wide spikes. Figure 5 shows how the 19 spikes of our spike-train filter alias after sub-sampling. Figure 5(a) shows the spikes in the original wideband spectrum, while Fig. 5(b-d) show the aliasing of the spikes when sub-sampled at three different sampling rates. First, we choose the sampling rate to be 38 MS/s, because the resulting sub-sampling factor $P = 11$ is co-prime to $K = 19$. However, the aliased spectrum ends up with many collisions, as shown in Fig. 5(b). This suggests that the derived optimum no longer holds due to the practical limitations of the filter.

Fortunately, different filters that are manufactured through the same process exhibit a very similar spike train. Figure 6 compares the measured frequency responses of three spike-train filters we fabricated. We zoom into two spikes, otherwise the differences are very hard to spot. As one can see, the filters are almost identical. Hence, we can measure the frequency response of one spike-train filter and use it for the others.

Knowing the filter frequency response, we run an optimiza-

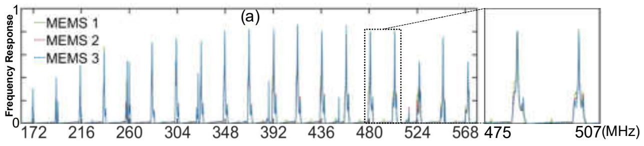

Figure 6: Measured frequency responses of three fabricated MEMS spike-train filters using the same process.

tion problem to find a sampling rate that has as little collisions as possible. Ideally, this sampling rate should separate all the wide spikes after aliasing and prevent them from overlapping with one another. If a collision is unavoidable, we want it to only occur at the boundaries of the spikes, rather than having two wide spikes fully overlap. For example, as shown in Fig. 5(b), the collisions marked in red are unacceptable, because most of a spike's frequencies experience collision. In contrast, the collisions marked in green in Fig. 5(c) are tolerable, because only the boundaries of two spikes collide. Because we can simulate and compare the aliasing at different sampling rates offline, the optimization problem, in fact, can exhaustively search for all possible sampling rates.

Another practical aspect is that in the real system, we only sample real signals and not complex in order to reduce complexity. Since the signal is real, the frequency representation is symmetric around the y-axis. Hence, with a sampling rate of $R = 38$ MS/s, the wideband spectrum actually aliases to a bandwidth of $R/2 = 19\ MHz$. Formally, if the original frequency of a spike is $f_{spike} = k\frac{R}{2} + b$, where $b < R/2$, then the aliasing frequency f_{alias} of the spike can be found through the following equation:

$$f_{alias} = \begin{cases} b & \text{if k is even} \\ \frac{R}{2} - b & \text{if k is odd} \end{cases} \tag{6}$$

In our specific case, we find 45.5 MS/s to be a really good sampling rate. As can be seen from Fig. 5(c), it spreads out the aliased frequencies of the wide spikes to 1.5, 2.6, 3.8, 4.6,

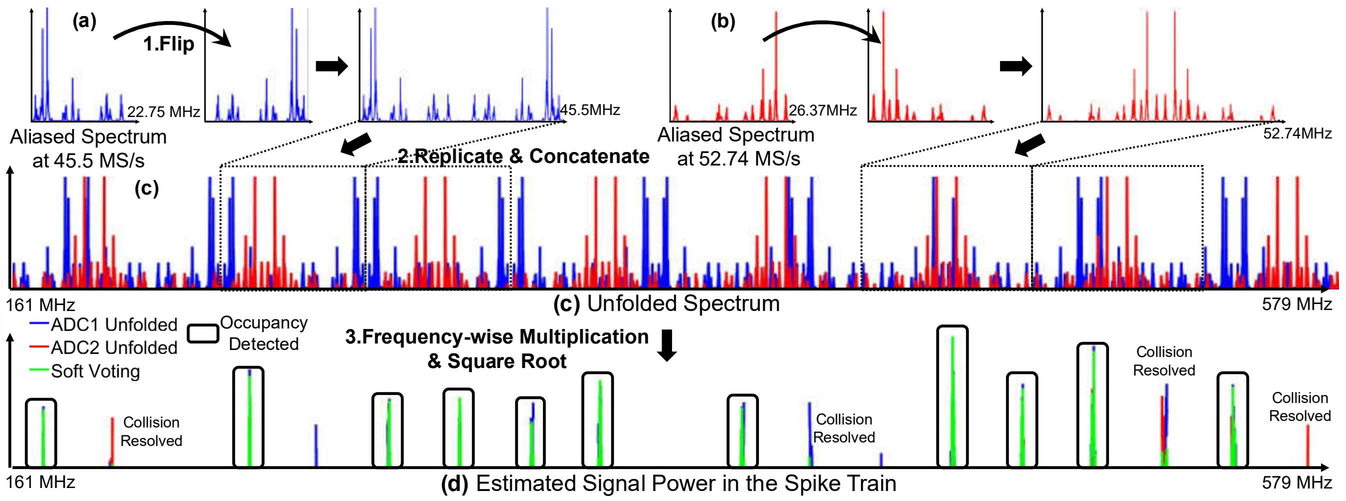

Figure 7: Practical S^3 recovery algorithm through voting: S^3 unfolds two aliased versions of the filtered spectrum to get a vote for the frequency components in the spike train. It then combines votes from the two different sampling rates to estimate the signal power in the spikes and the spectrum occupancy.

5.7, 7.3 MHz, etc. Therefore, most collisions only occur at the boundaries of the wide spikes. However, it still cannot avoid all unacceptable collisions. In fact, it's likely that no sampling rate can. For example, our spike-train filter has a unique 17th spike that is composed of two very close spikes. When sampling at 45.5 MS/s, these two small spikes completely overlap with the 15th and 19th spikes respectively. Therefore, when spike 15 and 19 are both occupied, we might falsely classify the spike 17 as occupied.

To resolve such unavoidable collisions, we leverage another sampling rate that provides us with a different set of aliasing frequencies for the spikes. We pick the second sampling rate in a way that any two spikes colliding at 45.5 MS/s do not collide again. To this end, we find a good sampling rate of 52.74 MS/s, and the resulting aliased frequencies of the spike train is shown in Fig. 5(d). One can see that the two parts of spike 17 do not collide with any other spikes at 52.74 MS/s. Thus, as long as we observe no power on frequencies corresponding to spike 17 at 52.74 MS/s, we will classify spike 17 as empty. Hence, by leveraging such incoherence between the two sampling rates, we can further resolve unavoidable frequency collisions and correctly identify the empty bands.

Using the two sub-Nyquist sampled spectra, S^3 recovers signal power in each spike, and then identifies the occupancy of the corresponding band. We leverage the two sampling rates through a soft voting scheme. The idea is that given an aliased spectrum and the sampling rate, we know all the possible original frequencies that correspond to the aliased frequencies. Hence, each aliased spectrum provides a vote for the source frequencies of the non-empty spectral components. Moreover, the non-empty frequencies on the original spectrum are also constrained to the spike-train frequencies. Therefore, when the two sampling rates vote for the same frequency that also falls in a spike, the frequency is very likely to be the true source frequency on the wideband spectrum.

Consider the two aliased versions shown in Fig. 7(a,b), where 11 out of the 19 bands are occupied and the other 8 bands are empty. Now we use them to vote where the non-empty frequency components come from. According to Eqn. 6, aliasing folds the wideband spectrum on to the bandwidth of $\frac{R}{2}$. Therefore, we can vote on all the possible source frequencies by unfolding the aliased spectrum. We accomplish this goal in the following three steps:

- **1. Unfold - Flip**: First, we flip the aliased spectrum $Y(f)$ with a bandwidth of $\frac{R}{2}$ to get the bandwidth between $\frac{R}{2}$ and R, as it equals to $Y(\frac{R}{2}-f)$ according to Eqn. 6.
- **2. Unfold - Replicate**: Then we replicate and concatenate the resulting spectrum from 0 Hz to R, and we get a vote for all frequencies in the frequency range of the spike train as shown in Fig. 7(c).
- **3. Soft Voting**: Finally, we combine the votes of the two sampling rates, where we only consider the frequencies within the spikes. This is done by multiplying the two votes on every frequency and taking a square-root. As a result, the non-empty frequencies that are voted by both sampling rates are amplified. In contrast, the frequencies where the two sampling rates vote differently will be attenuated as shown in Fig. 7(d).

After unfolding the aliased spectra and recovering the filtered spectrum through voting, we calculate the average signal power in each spike by summing up the voting results and divide it by the spike width. Additionally, we also estimate the average signal power in the spikes using the unfolded spectrum at each sampling rate separately. We classify a band as occupied if all three power estimations in the corresponding spike exceed a pre-selected power threshold. This power threshold is selected based on the noise floor, which is measured when all bands are empty. By using all three estimates, we add hard voting on top of the soft voting which adds more robustness to the occupancy detection.

7 Implementation

A. Basic Prototype: We have built a basic prototype of an S^3 spectrum sensor by combining our MEMS spike-train filter with commodity, off-the-shelf, low-power components. Figure 8(a) shows the circuit diagram of this basic prototype, and the actual prototype is demonstrated in Fig. 8(b). The signal is received through a broadband receiver. It is bandpass filtered and amplified before down-conversion to an intermediate frequency (IF) between 150 and 600 MHz. The IF signal is bandpass filtered and passed through the spike-train filter. It is then split and sampled by the two synchronized ADCs.

We wire-bond the MEMS spike-train filter onto a gold-plated PCB (printed circuit board) as shown in Fig. 8(b). We use K&S 4523A Wedge Bonder and 25 μm Aluminum wire. We use two Anolog Devices LTC2261-14 14-bit ADCs to sample the output of the spike-train filter. This ADC features an 800 MHz wideband input analog bandwidth and low power consumption of 89 mW. The ADC sampling is timed through an external square-wave clock signal. We use the DC1370A ADC evaluation board and the DC890 data acquisition controller to control the ADC sampling through the open-sourced LinearLab Tools Python API. We bypass the input low pass anti-aliasing filter on the ADC evaluation board to maintain the wide analog bandwidth.

B. Extending the Prototype: The above basic prototype using only one spike-train filter can be extended to sense spectra with different center frequency, bandwidth, and channel allocation. Moreover, system level parallelism introduces another degree of freedom and allow us to break the fixed design trade-offs at the filter level.

- **Different Spectrum:** By changing the LO frequency as well as the RF bandpass filter and LNA, we can sense different frequency ranges. In our evaluation, we test at center frequencies of 2.1, 2.4, 4.9, and 5.7 GHz.
- **Larger Bandwidth:** The current spike-train filter supports a bandwidth of 418 MHz. We can extend S^3 to larger bandwidth by either using two sensors and configuring them to sense adjacent spectra or by using two MEMS filters in parallel channels before combining the signals and sampling it as we describe in more detail in appendix A.
- **Narrower Bands:** The spikes in the spike-train filter are separated by 22 MHz. Hence, narrowband signals (< 20 MHz) that are not aligned with the spikes might be filtered out. To address this, we can combine frequency domain sampling with LO frequency sweeping over 22 MHz to capture and sense all the frequencies in the spectrum as shown in our results in section 8. Alternatively, we can design a MEMS filter with narrower spacing as explained in section 3 or use two MEMS filters and set the center frequency to be slightly different as we describe in more detail in appendix A.

C. Testbed: We evaluate the performance on S^3 both through controlled experiments in an indoor wireless testbed as well as through measurements of ambient transmissions outdoors and indoors. The wireless testbed allows us to control the spectrum sparsity, how fast the occupancy changes for different bands, the type of signals transmitted, and the power of various transmissions. It also allows us to know the groundtruth band occupancy in order to evaluate the performance of S^3.

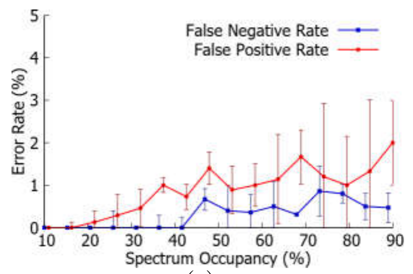
The testbed, shown in Fig. 8(c), can create a 418 MHz spectrum with various occupancy status at different frequencies. It consists of 19 N210 USRP software-defined radios, each transmitting on a 25 MHz bandwidth. While the USRPs are not very far from each other, we vary their transmission power randomly by up to 10 dB and observe received signal SNR that varies by up to 20 dB between different USRP transmitters. To avoid interference from ambient 2.4 and 5 GHz ISM band signals, we conducted experiments in two 418 MHz-wide spectra: 4.73 to 5.15 GHz and 1.93 to 2.35 GHz, each divided into nineteen 22 MHz bands. We vary the spectrum occupancy from 10% to 90%. We also vary the type of modulation being used. We test with single carrier BPSK and QAM as well as OFDM signals. Note that single carrier modulation has a non-flat power spectral density and significantly more leakage, so it results in higher false positive rates as we show in section 8. We also leverage the testbed to compare S^3 with state-of-the-art sensing systems as our baselines. We ran over 5000 experiments with different configuration of occupancy, power, modulation, etc.

8 Results

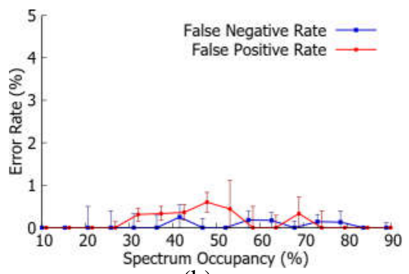
In this section, we present our main evaluation results along with a few microbenchmarks that provide insights into the performance of S^3 in various spectra.

Evaluation Metrics: We evaluate S^3 using following metrics:

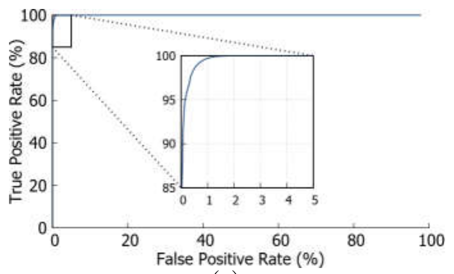
- *False Positive Rate (FPR)*: Percentage of empty bands that S^3 incorrectly reports as occupied.



(a)



(b)



(c)

Figure 9: False positives and negatives as a function of spectrum occupancy: The figure shows the false positive rate (FPR) and false negative rate (FNR) of S^3 as the spectrum occupancy increases when: (a) Modulation schemes are randomly picked by transmitters. (b) Transmitters only use OFDM modulation. (c) shows the receiver operating characteristic (ROC) curve of S^3 when the modulation schemes are randomly picked.

- *False Negative Rate (FNR)*: Percentage of occupied bands that S^3 incorrectly reports as empty.
- *True Positive Rate (TNR)*: Percentage of occupied bands that S^3 correctly reports as occupied.

A. Sensing Densely Occupied Spectrum:

Fig. 9 shows S^3's error rate in detecting occupied bands as we vary the total occupancy of the spectrum between 10% and 90%. Fig. 9(a) shows the results when the transmitters randomly pick a modulation scheme (e.g. single carrier BPSK, QAM, or OFDM). In this case, when the total occupancy of the spectrum is less than 30%, S^3 achieves a median false positive rate (FPR) less than 0.5% and a median false negative rate (FNR) of 0%. As the total occupancy increases and the spectrum becomes more crowded, the FPR and FNR gradually increase. However, even when the spectrum is extremely crowded ($\sim$ 90% occupied), S^3 can still achieve 2% median FPR and 0.47% median FNR.

Fig. 9(b) shows the same results when the transmitters only use OFDM modulation. In this case, the FPR and FNR become even smaller at all levels of occupancy with a maximum median FPR of 0.6% and a maximum median FNR of 0.25%. This result can be attributed to two factors: (1) OFDM signals have flat power spectral densities. Therefore, signal power detected in the spike train can more accurately reflect the signal presence in the corresponding channels. (2) Single carrier modulation schemes have lower spectral efficiency and leak power outside their bands, which leads to a higher FPR as can be seen from Fig. 9(a). Finally, Fig. 9(c) shows the receiver operating characteristic (ROC) curve, which demonstrates the trade-off between false positives and false negatives as we vary the threshold for detecting occupied band.

B. Comparison with State-of-the-Art:

We compare S^3 with three baselines from prior work:
