Message from the NSDI ’21 Program Co-Chairs

Welcome to NSDI ’21!

It is an understatement to say that the past year has been a stressful and difficult time for us all. The pandemic, the associated economic disruption, and the large-scale social movements for racial equality have given us reasons for both hope and grief during the last 12 months. Placed in this context, our academic work as computer scientists can feel small. Many of us struggled with our health (mental, physical, or otherwise) in the past year, as we grappled with the era in which we live. The fact that NSDI is still happening this year is a testament to the graciousness with which our community has treated each other during these hard times. As paper submitters, paper reviewers, PC members, and conference organizers, we helped each other with our kindness and our flexibility; by showing compassion in the face of last-minute schedule disruptions and requests for a little extra time, we made it possible for a huge undertaking like NSDI to move forward in uncertain circumstances.

NSDI ’21 received 369 papers in total: 114 in the spring deadline, and 255 in the fall deadline. 59 papers were accepted, for an acceptance rate of 16%. Papers were reviewed by a group of 70 experts from both academia and industry. We sincerely thank those reviewers, who provided thoughtful feedback during an enormously disruptive time. We also thank the paper authors; your submissions are what make NSDI such a great venue, and we hope that you will enjoy the conference program.

We’d like to thank all of the USENIX staff who helped us to organize this year’s conference amidst such extraordinarily challenging circumstances. At every step in the process, from configuring the HotCRP server to dealing with camera-ready production, the USENIX staff provided invaluable advice and implementation. So, we send a heartfelt thanks to Casey Henderson, Olivia Vernetti, Camille Mulligan, Arnold Gatilao, Jasmine Murcia, Jessica Kim, Julia Hendrickson, and the rest of the USENIX team. Our community is lucky to have support from such dedicated USENIX staff.

We are excited that NSDI ’21 will be held, even if the conference presentations will be virtual. We thank the efforts of everyone who made this possible, whether you submitted papers, reviewed papers, helped with the organization of the conference, or will just be attending the conference. We hope that you are safe and healthy, and that the next year will be easier and more joyful than the last.

Abstract

The last decade has witnessed a rapid growth of public clouds. More and more enterprises are deploying their applications on the cloud platform. As one of the largest public cloud providers, Tencent cloud serves tens of Tbps inbound-/outbound traffic via cloud gateways for customers with diverse cloud access requirements. Traditionally, cloud gateways were built with proprietary routers. From years of experience operating cloud network, we found that commodity router based cloud gateways are hard to scale, lack of extensibility and are difficult to inter-operate with the SDN-based cloud networks. To this end, we build our own Disaggregated Software-defined Router (DSR) to serve cloud access traffic. We architecturally split cloud router functionalities into several disjoint modules: 1) an access module built out of off-the-shelf commodity switches; 2) a software-based fast and scalable forwarding module; 3) a robust and scalable routing module built with commodity servers; 4) an SDN control module for traffic management and devices configuration. All the components can be independently scaled and maintained. DSR can deliver new network features at high velocity and has sustained the rapid growth of the cloud access traffic. In this paper, we present the design, implementation and our years of operational experiences of DSR.

1 Introduction

With customers increasingly deploying their computation and storage services in the cloud, public cloud services have achieved rapid growth in recent years [11, 16, 18, 35, 37]. As one of the largest cloud providers, Tencent cloud has provided a wide range of services including computing, storage and CDN to support a diverse set of customizable solutions across multiple industries such as e-commerce, online education and mobile games. To satisfy the cloud access requirements of worldwide customers and their end-users, it is critical for the cloud provider to set up fast, secure, stable and low-latency

*Joint first authors

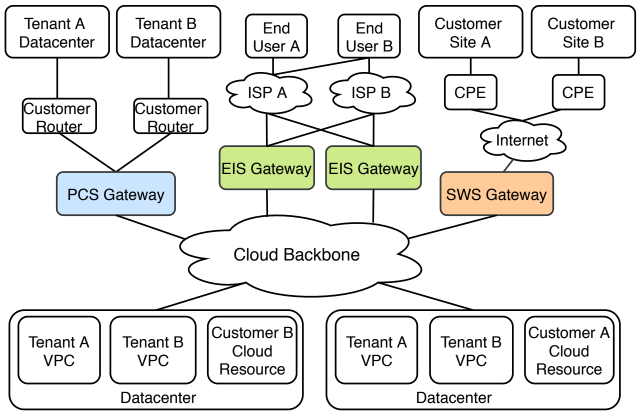

Figure 1: Various types of cloud access scenarios

connection among cloud customer's on-premise datacenters, distributed sites, Internet end-users and the cloud resources.

Tencent cloud supports various types of solutions to facilitate customers' cloud access requirements, namely Private Connect Service (PCS), Elastic Internet Service (EIS) and Software Defined WAN (*i.e.* SD-WAN) Service (SWS).

Private Connect Service. PCS establishes a direct connection between customers' on-premise datacenters and public cloud. It bypasses the Internet and offers higher reliability, faster speed and lower latency than public Internet connections. As demonstrated in Figure 1, customers access to their virtual private clouds (VPCs) hosted in the public cloud through PCS gateways. In our network, each PCS gateway supports $\sim$10K tenants, one of which has up to 20K routes. PCS provides guaranteed network quality, like consistent network performance on latency and bandwidth with low cost.

Elastic Internet Service. Many customers, *e.g.* content providers and online education institutes, run their computing and storage services in our cloud datacenters. EIS allows global end users to access these online services. As shown in Figure 1, EIS gateways are widely deployed at the Points of Presence (PoPs), interconnecting with multiple Autonomous Systems (AS). EIS gateway needs to fulfill several important tasks, *e.g.* BGP peering with different ISPs, management for inbound/outbound traffic across optimized network routes and forming demilitarized zone (DMZ). As the main entrance of a cloud region, EIS gateway needs to support a large forwarding table. In our settings, EIS gateway needs to support up to 10M longest prefix match (LPM) entries.

SD-WAN Service. Software-defined WAN Service (SWS) allows enterprise's branch offices to access their resources on the cloud through encrypted connections over any mixed transport services, such as LTE, Internet broadband, and MPLS, as illustrated in Figure 1. By leveraging IPSec VPN, WAN optimization (*e.g.* application-aware QoS, robust redundant packet transmission and data compression) and software-defined management/orchestration technologies, SWS simplifies IT infrastructure deployment and network management to connect users at distributed sites to applications on the cloud securely.

Cloud gateway is the main component in the access sites to meet these access requirements. Traditionally, the cloud gateway applies proprietary commodity routers to provide large-scale port extension, high speed traffic routing and forwarding, as well as access control against illegal connections or DDoS attack. However, with the rapid increase of customers, the traditional solution can not sustain anymore. First, we can not deploy millions of forwarding table entries in the commodity routers to meet our customers' requirements. Second, the lack of programmability of the proprietary devices slows down the feature roll-out velocity. We have to count on vendors' development plan which can be months or even years. Third, it is hard to inter-operate between the cloud SDN network and the edge BGP network. To meet these operational challenges, we provide ingenious solution for diverse types of customers to access the cloud (see § 2.2 for more details).

We set out to build a Disaggregated Software-defined Router (DSR) to address the above challenges. It enables cost-effective scaling to keep up with the fast growth of traffic volume. It leverages software feature velocity to provide fast response to user requirements. To be specific, DSR consists of a high performance data plane forwarding module, which is responsible for operations like routing table lookup, tunnel traffic encapsulation/decapsulation, IPSec encryption/decryption and packets forwarding. A standalone BGP routing module is built to exchange routing information between cloud network and external peers. SDN controllers are used to realize configuration, state management and orchestration of different components. Last but not the least, it performs routing decisions in a centralized fashion, thus yields better traffic steering. We leverage a disaggregated architecture, *i.e.* each component can be scaled independently and released on demand.

DSR serves tens of Tbps traffic, which has been deployed in Tencent cloud for over 3 years. In this paper, we introduce the design and implementation of the scalable and flexible system to access the cloud. We first use an example of the PCS connection to demonstrate the limitation of commodity routers based gateways (§ 2). Referring to the structure of commodity devices, we explain the architecture of DSR (§ 3). We present the system design details (§ 4, § 5, § 6) and share our operational experiences to the community (§ 8).

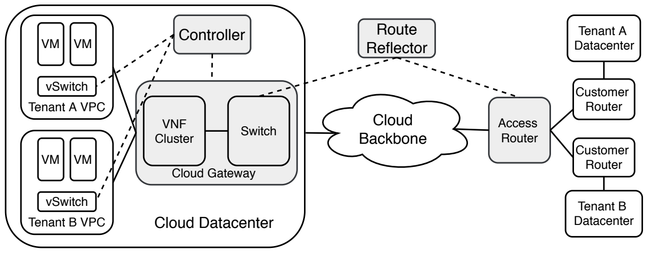

Figure 2: Commodity router based PCS

2 Background and Motivation

For ease of understanding, we first demonstrate the original solution of PCS using commodity devices. Then, we introduce the limitation of commodity router-based architecture which motivates the design of DSR.

2.1 Commodity Routers based PCS

Previously, PCS service is built by leveraging the MPLS VPN technique [7]. Figure 2 shows the architecture of the original version of PCS, which consists of the following components:

- **Access Router (AR):** It is a commodity router supporting various types of electrical or optical interfaces with different rates, *e.g.* 1Gbps/10Gbps/100Gbps. AR sets up BGP sessions for routing between customers' on-premise datacenters and public cloud. Tenants are isolated based on Virtual Routing and Forwarding (VRF) tables. AR works as an MPLS provider edge (PE) router of the cloud MPLS backbone network.

- **Cloud Gateway (CG):** CG is deployed in cloud datacenters as another MPLS PE node of the backbone network. It is built by leveraging a commodity switch and a server-based Virtual Network Function (VNF) cluster. The commodity switch is the gateway between datacenter network and MPLS backbone network. Tenants are isolated through the switch build-in VRF. Due to the limitation of routing entries in switch, the routing table from the on-premise datacenters to tenant Virtual Machines (VMs) are stored in the VNF cluster.

- **Route Reflector (RR):** RR is a commodity router. RR establishes MP-BGP sessions with AR and CG respectively. It conveys customer's on-premise IP routes to the cloud switch and vice versa.

- **Controller:** Controller is introduced to manage and configure network components. For example, controller installs a default route to CG at virtual switch (vSwitch) of each server for traffic destined for on-premise datacenters.

Now we explain how a packet is forwarded from a tenant virtual machine to its on-premise datacenter. For the outbound traffic, the vSwitch first encapsulates packets with GRE [13] header (The VPC id assigned to the tenant is encoded in the GRE header) and forwards the packet to VNF deployed in a server cluster. The VNF decapsulates the GRE tunnel and encapsulates the packet with a VLAN header which embeds a certain VLAN id according to the VPC id. Then the packet is forwarded to the cloud switch, which forwards the packet to the MPLS backbone based on the forwarding table. Whenever AR receives the packet, it forwards the packet to the destination.

For the inbound traffic, the main difference is at the cloud gateway. The cloud switch is configured with a default route to forward all traffic to the VNF cluster, which stores all the routing information for VMs in the cloud datacenter. The gateway supports the access control through firewall and safeguards applications through Distributed Denial of Service (DDoS) protection service running on dedicated servers. Finally, the VNF cluster encapsulates the packet with GRE tunnels and forwards it to certain physical machines according to its routing decision.

2.2 Motivation

Based on production experiences of operating the network, we found many limitations of the commodity router to meet the rapidly growing customers and their rising demands.

For AR, though the commodity devices can forward a large volume of traffic, *e.g.* Cisco ASR 9000 series routers [5] support tens of Tbps throughput, it cannot scale to support a large number of tenants, *i.e.*, the number of VRFs and LPM table entries are rather limited. The commodity access router only supports less than 1K of VRF elements and 1M FIB entries which cannot satisfy the requirements of PCS which needs to support $\sim$10K tenants and EIS which requires $\sim$10M forwarding tables. We have to expand network by using additional routers. It is not cost-effective and substantially increases the management and control complexity.

We usually need to roll out new network features in few weeks to meet our customers' requirements, *e.g.*, supporting jumbo frames or 4B-length AS-path attribute. In addition, the cloud providers usually deploy new functions to improve operation and maintenance capabilities, *e.g.* measurement of top-N largest flows. However, due to the lack of programmability and limited device management API of proprietary commodity routers, it can take several months or years if we need vendors to make change to device software or hardware [35, 41]. The slow feature velocity significantly affects the user experiences and the reputation of the cloud provider.

BGP protocol is widely used to interconnect autonomous networks in the Internet [35, 41]. For instance, MPBGP protocol is used to exchange routing information between access router and cloud switch. On the other hand, the cloud networks have increasingly adopted the SDN technique for efficient traffic steering and fast network failure convergence. We found many problems for inter-operation between the cloud SDN network and the external BGP network. For example, in commodity router based PCS, the controller should update the state of the direct connection in real time, such that if the direct connection fails, vSwitch can carry out corresponding routing updates and quickly switch to the backup path. To achieve that, the controller has to periodically pull the routing tables from CG. However, due to the slow NETCONF messages processing, the long pulling interval leads to slow routing convergence.

3 Design

We target at building a general platform, *i.e.* a disaggregated software-defined router (DSR), to meet various types of cloud access requirements.

3.1 Design Rationale

DSR should meet the following requirements:

- **Simplicity**. The commodity router needs to support all kinds of network standards and a variety of customized protocols for cloud network, enterprise network or campus network, etc. In cloud access scenarios, many features integrated in the commodity routers are not required. We can simplify the design by supporting a minimum set of functionalities, *e.g.*, BGP and static routing for inter-operation with external network, Bidirectional Forwarding Detection (BFD) [23], Internet Protocol Service Level Agreement (IPSLA) [10] for fast convergence, and VXLAN [27] and GRE [19] for tunneling.

- **Scalability**. To meet various cloud access requirements of Internet users, customer on-premise datacenters and enterprise branch-sites, the key components of the cloud gateway, *i.e.* data plane, routing and control plane should be able to scale independently without affecting each other.

- **Reliability**. All the key components are built in the cluster with redundancy such that no single point failure can cause performance degradation. Specifically, the key components can be deployed cross available zones for remote disaster recovery.

- **Elasticity**. The system should support high feature velocity and realize efficient inter-operation between the external

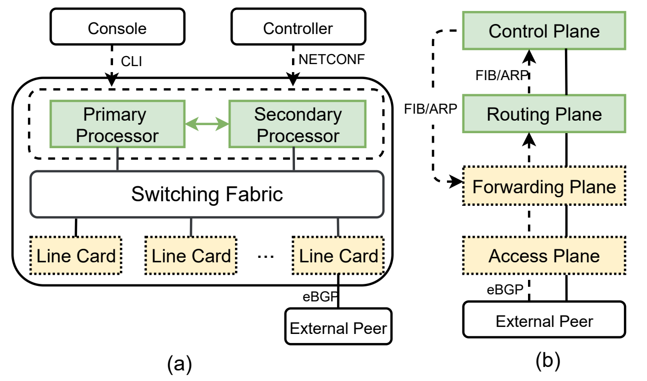

Figure 3: Sketch of (a) a typical commodity router and (b) the disaggregated software-defined router architecture

BGP network and the internal software defined cloud network in real time.

3.2 System Overview

3.2.1 The disaggregated design

We review the architecture of a typical commodity router. As shown in Figure 3 (a), it consists of three major components:

- **Processor**: Processor acts as the control plane, which runs network protocols like BGP, OSPF and BFD. Usually, there is a secondary processor for high availability.
- **Switching Fabric**: Switching fabric is responsible for high speed internal inter-connection.
- **Line Card**: Line card is intended to connect many users with different types of interfaces. It forwards and filters packets based on routing tables and access control lists (ACLs) respectively.

The three components are tightly coupled in the commodity router. The processor capability, routing table sizes and bandwidth are configured with a fixed ratio. We can not independently scale any component on demand.

Consequently, we turn the router into a disaggregated architecture, as illustrated in Figure 3 (b):

(i) The functions of line card are divided into two components: the access plane and the forwarding plane. The access plane provides various types of interfaces and supports layer 2 forwarding. Based on the operational experiences, the access plane is stable, *i.e.* we do not need to frequently update the access plane. As a result, we build the access system with a group of small-scale commodity switches. The forwarding plane deals with layer 3 packets processing with large scale forwarding tables (FIB, IPSec, QoS, etc). We introduce the software-defined forwarding module to achieve high feature velocity and scalability.

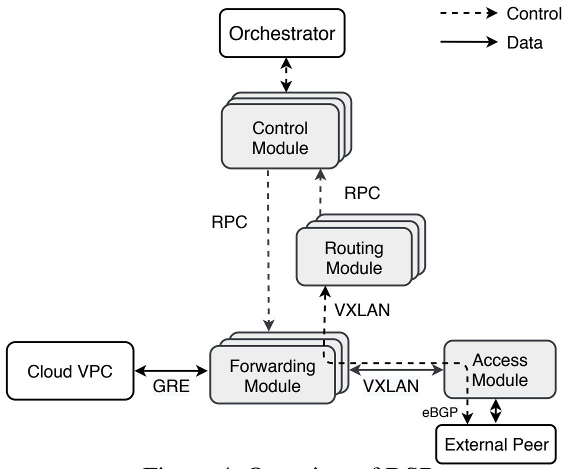

Figure 4: Overview of DSR

(ii) The functions of the processors are divided into two components: the routing plane and the control plane. They are implemented with software over common servers. The routing plane takes charge of the protocol and routing management, like BGP, BFD, IP-SLA and static routing protocols. The routing information is delivered to the control plane through RPC messaging. The control plane stores the routes, generates the forwarding tables, and then installs the FIB/ARP tables to the forwarding plane. This design is based on the observation that the routing plane and control plane require different resource settings. For example, the routing plane requires high computational capacity for complex protocol processing. Meanwhile, the control plane deals with performant management and ensures consistent forwarding processing during upgrade. We use different software suites (DPDK, ONOS&ODL) there. As a result, the development and release cycles are different for these two planes.

(iii) We use the standard VXLAN protocol for the interconnection of different planes. Tenants are isolated based on VXLAN VNI. All the components are decoupled and deployed in different fault domains which allows independent scaling. Generally, the access plane is deployed at the access sites, *e.g.* PoPs or remote user sites. The others are deployed in the cloud datacenter.

(iv) The forwarding, routing and control planes are built using multiple servers in a cluster. No single server failure can cause the break down of the entire system.

3.2.2 System architecture

The architecture of DSR is shown in Figure 4. It includes the following components.

Access module. We apply commodity off-the-shelf switches for the inter-connection between the internal cloud network and the external peers. It supports protocols of BG-

P/OSPF/BFD/LACP (Link Aggregation Control Protocol) at underlay network. It provides various types of physical ports with different rates, *e.g.* 1GE/10GE/100GE. For the overlay network, it realizes layer 2 isolation for tenants using the switch built-in VLAN functionality. VXLAN tunnels are established for communication between the access module and the forwarding module.

Forwarding module. The forwarding module is responsible for high performance packet processing and routing with large forwarding tables. It sends BGP/BFD messages to the routing module via layer 2 VXLAN tunnel and forwards data path traffic VPCs via self-defined GRE tunnel in the cloud datacenter. We build the forwarding module using a group of servers. With the server built-in large memory, it can support a large number of VRFs and large LPM tables for tenant isolation and packet forwarding. Forwarding module also supports IPSec processing and WAN optimization functionalities.

Routing module. The key purposes of the routing module are: (i) inter-connecting with the external peers (commodity devices) through dynamic routing using BGP; (ii) supporting a large amount of customers and maintaining the neighbors information; (iii) realizing fast convergence and failover when routing information updates and network failure happens. The core of the routing module is a high performance home-made BGP speaker. We optimize the BGP speaker performance and customize it for different scenarios. For example, in PCS, we embed the bandwidth allocation ratio for customers' traffic in the BGP header. While, in ISP peering scenario, we select the routing path based on the network state through SDN controller. It supports Non-Stop Routing & Forwarding (NSR& NSF) for high availability. We optimize its ability to handle a large number of BGP updates. For outbound traffic, the control module feeds VPC routes into the routing module, which in turn conveys the routes to the external peer. As the BGP messages are carried over VXLAN tunnels, they are able to establish BGP sessions directly between the external peer and routing module.

Control module. Control module acts as a local controller. It stores the routing information and is responsible for optimal traffic steering computation. Apart from that, control module provides distributed message queues in order to efficiently synchronize dynamic forwarding rules among forwarding module clusters and routing module clusters.

Orchestrator. The orchestrator acts as a global controller. It is responsible for distributing operator's configuration requests to corresponding control modules. The Orchestrator collects particular traffic scheduling requests from external management system and synchronizes them to the control module. It is a centralized routing computation platform by taking into consideration of various kinds of metrics, *e.g.* network latency, bandwidth capacity and monetary costs, to achieve consistent performance while reduce costs for customers [35, 41].

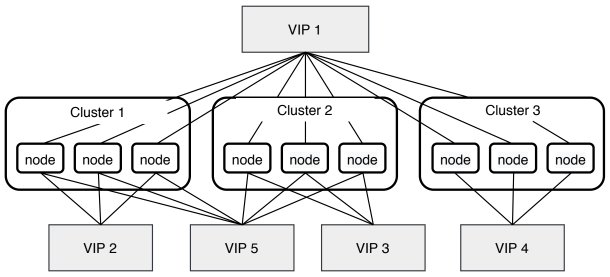

Figure 5: Scaling out forwarding plane through multiple VIPs

3.2.3 Challenges

Since DSR components are loosely coupled with each other, we can easily add or remove one instance in any component independently for scaling or upgrading purposes without affecting the whole system. For the design and implementation of each specific module, we meet the following challenges:

- We need to ensure high forwarding and routing capacity in software given a large number of tenants and highly frequent routing updates. To be specific, DSR serves 10Ks of tenants and maintains 10M entries routing tables at line rate. We have optimized the forwarding module and the BGP speaker of the routing module to address this challenge. Meanwhile, we provide low latency packet forwarding by minimizing the impact of system call, CPU scheduling and packet losses.
- Originally, the commodity router is a single device to serve the arrival traffic. However, the DSR is a distributed architecture consisting of multiple components. The instances of each components are deployed in the cluster, which are connected through multiple-path Clos network. The disaggregated design makes the management more complex than managing an individual commodity router. We need to carefully schedule and route the arrival traffic and control messaging inside DSR, which can easily affect the performance and stability of the whole system.

4 Scalability

We explain the optimization on forwarding module and the routing module to address the scalability issues.

4.1 Scalable Forwarding Plane

In order to provide a scalable forwarding module to meet the packet processing requirements, our efforts go along two directions: (i) Scaling out the packet processing components by adding new cluster of servers; (ii) Optimizing the program of packet processing and LPM lookup to ensure fast forwarding at large scale.

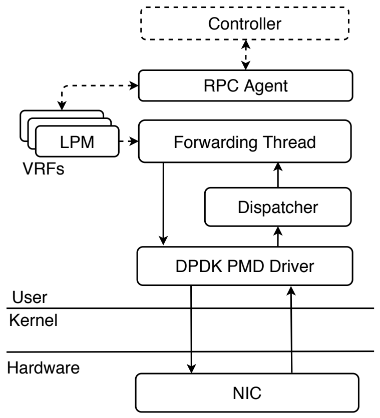

Figure 6: Architecture of the dataplane forwarding module

4.1.1 Scale out with multi-VIP

For building a scalable forwarding module based on common servers, a straightforward approach is to expose a single virtual IP (VIP) for all servers in the cluster. We announce the VIP to all tenants. All servers are then configured with the same forwarding tables. By doing so, arrival traffic are balanced to servers using ECMP hashing at a per flow basis. With this stateless load balancing, the system's processing ability can be easily scaled out/in by adding/removing servers. However, with more and more VRFs are configured, the forwarding capability of the cluster is limited since each server has to support the entire routing tables of VPCs in the region.

In fact, in our production network, the tenants' requirements on bandwidth are diverse. Most tenants require traffic bandwidth less than 10Gbps. Only a few tenants have traffic around 100Gbps. We seldom see tenants have traffic more than 500Gbps or over the forwarding capability of a single cluster. To this end, we introduce a flexible multi-VIP structure. As shown in Figure 5, each cluster is configured with multiple VIPs shared by tenants. For example, VIP 2 belongs to cluster 1, which serves multiple tenants with little traffic. Meanwhile, VIP 5 is applied to cluster 1 and cluster 2, which are assigned to users with large amount of traffic, *i.e.*, these users can deploy forwarding tables in both cluster 1 and cluster 2. Similarly, a tenant with an extremely large amount of traffic can be fulfilled by using VIP 1. Consequently, there is no needs for a single server to store routing tables of all tenants. We can improve the scalability of the system while retaining the benefits of the stateless load balance.

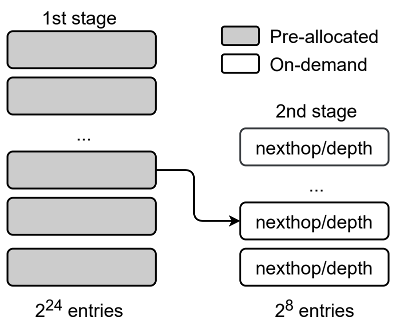
4.1.2 Fast datapath route lookup

We have leveraged the DPDK suites [12] to develop the high performance dataplane forwarding module. As illustrated in Figure 6, the arrival packets are forwarded directly from the NIC to user space bypassing kernel overhead. To efficiently utilize the modern multi-core CPU architecture, traffic need to be balanced to multiple cores, we apply the NIC built-in RSS functionality to uniformly distribute the traffic to different dispatchers which run on dedicated CPU cores. To avoid packet out-of-order, packets belong to the same overlay flow should be processed on the same core. To achieve that, the dispatchers decapsulate packets' outer tunnels and distribute packets to different forwarding threads based on the overlay 5-tuple. The forwarding threads encapsulate packets with another tunnel according to packets' destination. Packets are then forwarded to external WAN network. We plan to accelerate this procedure with advanced NICs which support overlay packet header hashing.

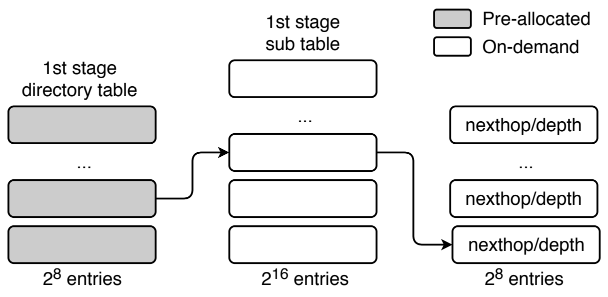
Short packet processing pipeline. In high performance packet processing, a long pipeline will likely lead to more cache misses and causes performance degradation. The packet processing cost mainly stems from the LPM lookups. Generally, a packet would require two LPM lookups, *i.e.* the packet first does LPM lookup for underlay encapsulation header based on the overlay IP, then the encapsulated packet does LPM look up for the output physical port based on the underlay IP. We have shortened this pipeline by saving the second LPM lookup. To achieve that, we combine the second LPM lookup results *i.e.* the output physical port and the the first LPM lookup results *i.e.* the encapsulation header into one unified action. The action is pre-programmed into the action field of the first LPM lookup entry. After the first LPM lookup, the packet is encapsulated and forwarded to the corresponding physical port following the pre-programmed rules. With the shorter pipeline, the packet processing performance is largely improved.

Fast route lookup at large scale. When dealing with 10M routing entries, we need to take care of the storage and the lookup speed. At first, we leverage the LPM library in DPDK suites [1] to implement the forwarding function. Unfortunately, the original DPDK LPM library is not efficient to store routing entries. We encountered performance issues with the increasing amount of tenants.

To illustrate the problem, we first briefly introduce how the DPDK LPM library works. The library uses a classic trie-tree structure to store the routing entries. As shown in Figure 7(a), for IPv4 lookup, it uses two stages. The first stage is an array with 2^{24} entries. The higher 24-bit of an IPv4 address is used as the array index. Each entry stores the base address of a secondary stage array. The lower 8-bit of an IPv4 address acts as the index into the secondary stage array. Based on the address in the first array, a routing result can be identified. Each IPv4 lookup requires at most two memory lookups in this design. However, to achieve this, DPDK LPM library needs to pre-allocate a large memory to store the entire 2^{24} entries no matter whether there exists an IP route or not. This leads to severe memory waste and limits the ability to support a large number of VRFs. For example, to store 64K IPv4 routes, the first stage would require $2^{24} \cdot 4B = 64MB$ memory for each VRF. In the worst case, to store 64K routes in the second stage, it requires $64K \cdot 2^8 \cdot 4B = 64MB$, *i.e.* 128MB



(a) DPDK LPM table design



(b) Optimized LPM table design

Figure 7: LPM table data structure

memory in total. To support 10K VRFs, 1.28TB memory is required. Moreover, the first stage requires a large continuous memory, the memory fragmentation makes it hard to fulfill the need especially when the system has been up for a long time.

The root cause of this problem is the static memory allocation mechanism. In fact, only few tenants would require a large routing table. Most of our customers has a small routing table. Based on this observation, we design a dynamic memory allocation mechanism for LPM tables (Figure 7(b)).

First, we turn the DPDK LPM first stage array into one directory table (2^8 entries) and many sub-tables (each with 2^{16} entries). Only the directory table is pre-allocated. Thus the minimum memory required for a VRF is only $2^8 \cdot 8B = 2KB$. With the same amount of memory, the number of VRFs we can support increases by 3 orders of magnitude. Furthermore, with the same amount of memory, the maximum table size that can be used by a VRF is also enlarged.

Second, in the original DPDK LPM design, the memory of both the first and the second stages are pre-allocated. In contrast, in our design, the first stage sub-tables and the seconds stage tables are both allocated on demand. This significantly improves the memory efficiency. However, this design leads to problem when considering the route modification and deletion. When a route is deleted, we can not free the memory taken by this route because there may be arrival packets at the same time. A lock mechanism can help solve the problem but with a large overhead. Instead, we have designed an user-space RCU (Read-Copy Update) mechanism to solve this problem without using any lock. To be specific, when updating a forwarding entry, we first do a copy of the original data and make changes on the new copy. Then we modify the corresponding pointer to point at the new copy. The old entry is deleted only when there is no other threads accessing it. We implemented the RCU as a Quiescent-State-Based Reclamation (QSBR) flavor one [20]. Our evaluation shows that we can provide high performance packet processing and high route updates speed at 64K entries/s simultaneously.

Hardware acceleration With the rapid growth of traffic and slowing down of Moore's law, the CPU becomes the bottleneck for packet processing in software-based routing modules. To address this problem, prior studies have applied the cost-efficient hardware acceleration technique [16,21,28,29]. With regard to the limited forwarding table, *e.g.* Barefoot Tofino chips have ∼60MB on-chip memory [6, 16, 28, 32], which can only support 100K of LPM entries according to our evaluation, we have designed a large flow offloading scheme for the forwarding module. Based on the historical information of the cloud traffic, we found that the top 1% largest flows contribute 70% of overall traffic. We maintain a small group of prefixes in switch hardware for those large flows and forwards them with the hardware. By pushing the flexible and complex logic to software while leveraging the stable hardware offloading features, this approach saves more than 50% CPUs and greatly reduces the cost[1].

4.2 Highly Scalable Routing Module

Traditionally, in commodity router based PCS, standard MPLS-VPN technique [42] is used (§ 2). To differentiate BGP routes of different tenants, BGP messages from each tenant is configured to export m distinct BGP Routing Target (RT) attributes. At the cloud side, different tenants are separated via VRFs, say n VRFs. A tenant VRF only learns BGP routes from the corresponding remote on-premise datacenter, which is achieved by importing certain RTs. The process of route insertion is rather slow for traditional routers. Once receiving a BGP route update, the corresponding VRF is located by comparing each RT attribute with all VRF's RT values. m RTs (m is around 10) and n VRFs (n is around 10K) result in an insertion complexity of $O(mn)$. The performance can not sustain highly frequent BGP routes insertion.

In DSR, with the help of the connect module switch, BGP import/export RT features are no longer required. Specifically, DSR leverages the connect module switch to tag routes from different tenants based on VXLAN tunnels. The VNI in the VXLAN tunnel is pre-determined for each tenant. Then the BGP module can insert the route to the corresponding VRF using the VNI number. This design reduces the route insertion complexity to $O(n)$.

Some PCS customers have multiple datacenters. The newly built datacenters use the latest DSR based PCS while others

[1]The detail of the implementation is beyond the scope of this paper.

may still use commodity router based PCS. For availability purpose, the routing module of DSR needs to learn the routes to certain datacenters from commodity routers. This induces a requirement of inserting BGP routes into VRFs based on the RT attributes. As aforementioned, this would take $O(mn)$ time complexity for m RT attributes and n VRFs, leading to scalability issue.

To optimize the BGP insertion performance in this scenario, we use a hash function based solution to speed up the process of VRFs lookup. The key idea is that we store the RT-to-VRF information in a hash table where the RT value serves as the key. The value of each item is organized as a linked list of VRFs based on the RT. With this optimization, the capability of route insertion is significantly improved.

The routing plane needs to exchange keep-alive messages with a huge number of BGP neighbors, *e.g.* 10K. Traditionally, the keep-alive function is implemented in the same thread with the routing message processing function. When the thread is heavily loaded with routing updates, the keep-alive messages can not be processed in real time, leading to BGP timeout at remote side. We separate the keep-alive message handling and BGP message processing into different threads to solve the problem. As a result, we can maintain stable BGP neighbor relations even under the most heavy BGP message processing workload.

In summary, with all the above optimizations, DSR can improve the routing module BGP performance by ~20 times. The BGP module can perform 500K routes insertions per second and support 10Ks of VRFs (see § 7.2 for more details).

5 Reliability

We have deliberately designed several techniques to enhance the system reliability.

5.1 Forwarding Path Failure Detection

Conventionally, when peering with commodity routers, we enable BFD protocol [23] to provide fast and consistent forwarding path failure detection. However, with the disaggregated design, components of DSR are deployed in different availability zones. There are multiple paths available between the peering devices and the routing module. The BFD messages will transmit along only one single path. If one link of the path failed, the BFD message will be lost. Then the BGP module would regard that the remote peer is not reachable and delete the corresponding routes for fast convergence. In fact, because there are many paths available from the access module to the routing module, the data path is not disconnected.

To address this problem, we should distribute the BFD messages into multiple paths. We have modified the hash function of ECMP in the access module. In detail, for an arriving BFD packet, instead of using the fixed five-tuple of the message to generate the source UDP port value in the VXLAN header, we apply the IP ID field to compute the ECMP hashing. The hash key is then encoded into the UDP source port of the VXLAN header. As a result, BFD packets will traverse different paths along the network. We apply the similar idea at the forwarding module and routing module for BFD ECHO packets in the reverse route. When a link fails, there are still enough BFD packets available to report the healthy state of the remote peer.

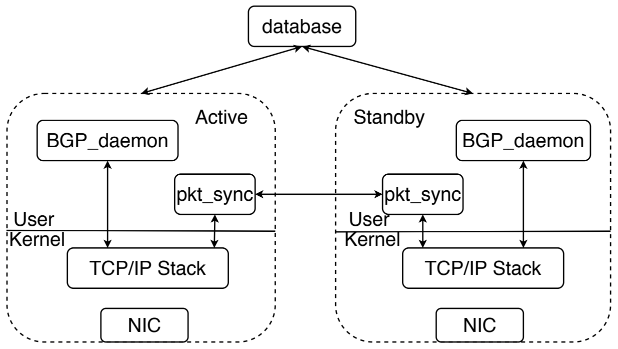


Figure 8: The NSR mechanism of the BGP module

5.2 BGP Non-Stop Routing

We developed a Non-Stop Routing (NSR) [42] mechanism against single BGP module failure. NSR mechanism requires that the failure of the BGP speaker to be transparent to the peering devices. This allows the failed BGP speaker immediately switch-over to a backup BGP speaker, and the backup device have all the information required to take over.

Traditionally, the commodity routers use a backup processor to implement the NSR functionality, as shown in Figure 3. They customize the protocol processors in the Linux kernel stack to enable this feature. However, in our case, the cloud resource manager requires that the kernel software should be homogeneous for all cloud servers to avoid operational issues.

We come up with a solution without kernel modification. As shown in Figure 8, the key idea behind our NSR design is to make the active BGP module synchronise its TCP states, *e.g.* sequence number and window size, with the standby BGP module before the active BGP speaker sends acknowledgements to the remote peer. We introduce a reliable database in the control plane to synchronize the neighbors information. Once the backup BGP speaker receives the TCP states, it initiates a socket system-call with TCP repair option, which keeps the TCP states in correct accordance without sending or receiving any TCP packet. Thus the standby module can have the same TCP states with its active counterpart.

Moreover, during BGP software upgrade, we need to make sure the data path traffic is not affected. This is accomplished by employing the NSR mechanism to proactively stop the active one and hand over BGP processing to the standby module. When the software upgrade is done, the active module is restored. It is notable that this process allows us to scale out/in the routing module easily.

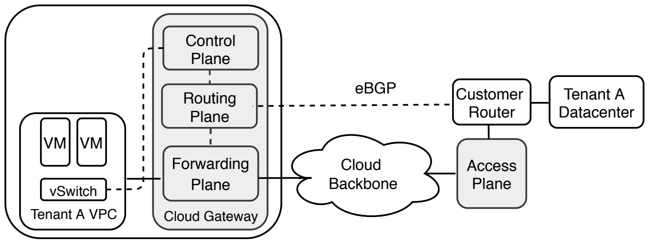

Figure 9: DSR based private line service

6 Fast Development of New Features

Public cloud users mainly rely on their providers to provide an elastic, reliable, scalable and safe networking environment. Customers have diverse requirements in terms of latency, bandwidth, self-defined protocol, etc. DSR is proposed to achieve fast feature velocity to satisfy customers' requirements. Through a few examples we demonstrate the benefits of using DSR for the operation of cloud network.

DSR based PCS gateway. We revisit the example introduced in § 2.1 and show that a more scalable and elastic PCS can be built with DSR compared with previous commodity router based design. As shown in Figure 9, once the tenant network is connected to the cloud network via PCS, the customer router can directly set up BGP sessions with the routing module of the cloud gateway. The routing module announces the routes of tenant on-premise datacenters to its VPC network through the control module. Similarly through the BGP sessions, the tenant on-premise datacenter can learn the VPC routes and VM routes from the routing module. We are able to provide real-time routing updates between the cloud SDN network and the external BGP network.

Customizing egress routing. A PCS customer may set up multiple PCS channels with the cloud through multiple DSR instances deployed at different sites. We can provide network quality aware traffic steering for our customers in this scenario. In detail, beside propagating the peering routes to the control module, DSR measures and informs the control module the quality of each path, including bandwidth, delay and packet loss rate. With both the routing information and network quality information, the control module can choose the optimal egress route for the traffic. Moreover, customers can customize their own routing policy to choose a specific path for certain traffic.

Fast failure recovery. Beside a PCS channel, the on-premise datacenter can configure another IPSec VPN channel over Internet as a backup. By default, traffic are forwarded through the PCS channel. When network failure is detected, *e.g.* a broken cable, the BGP module quickly reports the failure to the control module and withdraws the route. The control module then modifies the next hop of the routing on the forwarding module to the IPSec channel. The whole procedure can be done within 10ms, which is two orders of magnitude lower than traditional solution with commodity routers which requires periodically checking the routing updates from the commodity routers through the slow NETCONF interface.

On-premise to on-premise datacenters traffic acceleration. Through PCS, customers can transfer data among multiple on-premise datacenters via a hub-spoke model, where the cloud gateway acts as the hub. Previously, this is enabled by the route reflector, which reflects BGP routes among multiple cloud access routers. The scalability to support a large amount of customers are limited by the route reflector's BGP processing ability. With the home-made BGP module, the constraint is relaxed as the routing module can be horizontally scaled.

Protection against DDoS attack. DDoS traffic are short-bursts with high volume. When DDoS traffic are identified by the DDoS detection engine, those traffic need to be redirected to a DDoS traffic cleaning center. Notice that DSR is built on commodity servers, it can be potentially affected by DDoS traffic. We aim to redirect the suspicious DDoS traffic at the access module before they come to the software-based forwarding module. Unfortunately, the attack traffic are identified based on layer 3 routing information, but the current access switch works as a layer 2 switch for simplicity. To enable layer 3 packets forwarding for the DDoS traffic only, we introduce an ARP-spoofing scheme. To be specific, we first install the suspicious DDoS traffic routes as advertised by the DDoS detection engine in the access switch. And whenever an ARP request message of the DDoS traffic arrives, DSR can send an ARP reply with the MAC of the access module instead of the MAC of the DSR routing module. By so doing, all the inbound DDoS traffic will be encoded with the MAC of the access module as the destination MAC. Then the access switch can work as a layer 3 switch, and forwards suspicious DDoS traffic based on layer 3 routing table. Notice that as we only do ARP spoofing for DDoS traffic, the normal inbound traffic and outbound traffic are still directly forwarded to the forwarding module of DSR.

7 Evaluation

We demonstrate the capability of packet processing and BGP convergence time of DSR. The servers we used for evaluation are Dell PowerEdge R740 with 192GB memory and 80 cores (Intel(R) Xeon(R) Gold 6133 CPU@2.50GHz with hyper threading enabled). Each server is equipped with a dual 40Gbps port NIC.

7.1 Forwarding Module Evaluation

The host-based DSR forwarding module is able to process packets at line rate with low latency. In the experiment, we generate VXLAN packets and the forwarding module decapsulates a total of 68B from the header of the arrival packet.

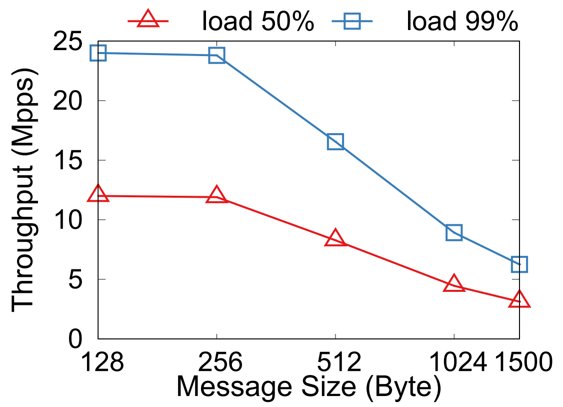

Figure 10: Dataplane throughput under different loads

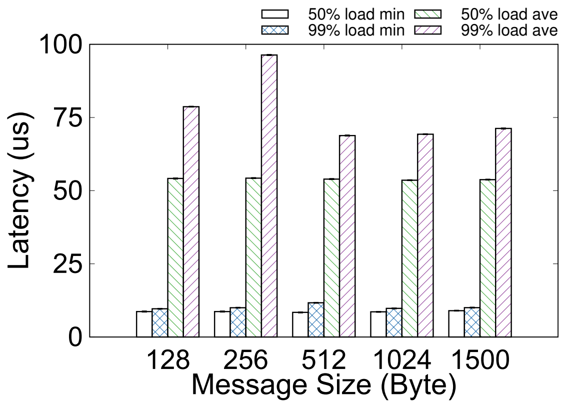

Figure 11: Dataplane latency under different loads

To maintain low latency and high throughput, we have introduced many software optimization techniques in the forwarding plane, *e.g.* kernel bypassing, minimizing cache miss and short pipeline. We measure the CPU consumption of the forwarding plane under moderate 50% and high 99% workloads with various packet sizes ranging from 128B to 1500B. For the load of 50% workload, the generated traffic consume 50% of the CPU while for 99% workload, the traffic consume 99% of the CPU. We can effectively utilize the CPU resource to provide high rate packet processing.

Dataplane throughput under different workloads. As shown in Figure 10, at 99% load, the datapath can process traffic at high rate under different packet sizes ranging from 128B to 1500B. It can achieve 24Mpps for packets of 128B. The throughput decreases proportionally with the workloads which shows graceful scaling property. The good performance stems from our optimizations, *i.e.* short pipeline design and FIB lookup optimization, as introduced in § 3.

Dataplane latency under different workloads. We measure the per-packet processing latency of DSR. As shown in Figure 11, the data plane can provide low and stable latency of 50-70μs for both 50% and 99% workloads. The minimum latency identifies the packet processing delay without ring-buffer queueing delay. It is 10μs. For average latency, it is stable across different packet sizes. With the increase of workloads, the software ring-buffer queue size also slightly increases which leads to a moderate increase in latency.

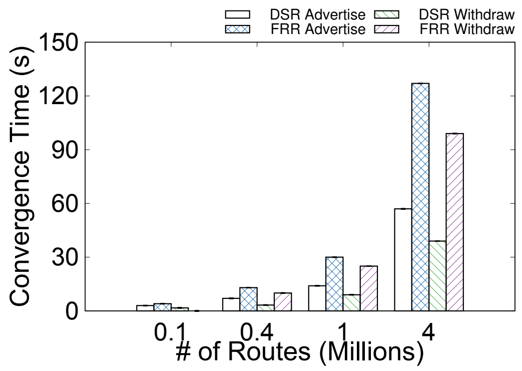

Figure 12: DSR BGP performance compared with FRR

Dataplane throughput during FIB update. To demonstrate the effectiveness of the datapath lockless design, we compare datapath throughput with and without FIB updates. The FIB update rate is 64Kbps. We generate VXLAN traffic for 30s and records the packet processing rate. The throughput can achieve 20Mpps with or without FIB updates, *i.e.* supporting lin-rate packet processing. This demonstrates that the lock-free design enables fast routing updates without impacting the datapath forwarding performance. We omit the figure due to space limit.

7.2 Routing Module Evaluation

We compare the routing module with the open source FRR [3] solution under 300 RTs, and demonstrate the performance of our home-made BGP speaker under a large number of VRFs and neighbors.

BGP advertising and withdrawal convergence time is the key metric to be reported. As shown in Figure 12, the DSR routing module outperforms the FRR under different number of routes, *e.g.* 0.1M, 0.4M, 1M and 4M. For BGP advertisement, when there are 0.1M routes, the convergence time of DSR is 33.3% lower than FRR. When the number of routes is 4M, DSR converges ~2.2× faster than FRR. For BGP withdraw, DSR has 1.5-2× lower convergence time than FRR. The performance gain is achieved based on the optimization introduced in § 4.2 which reduces the complexity for route insertion from $O(mn)$ to $O(n)$.

We then evaluate the performance of DSR routing module when there are 1K VRFs and each VRF has 8 neighbors. It is notable that the traditional commodity router deployed in our system can not support 1K VRFs. We record the time to advertise, withdraw and report different amounts of routes to the controller. As shown in Figure 13, the time increases moderately when the amount of routes increases, which demonstrates excellent scalability of the home-made BGP speaker. This performance gain mainly stems from the BGP optimization techniques introduced in § 4.2.

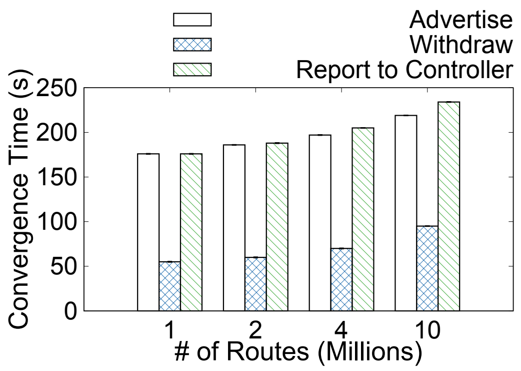

Figure 13: BGP performanec under many VRFs

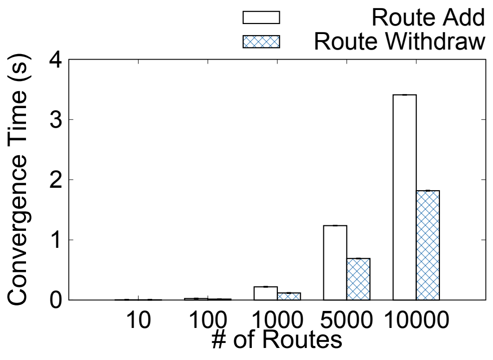
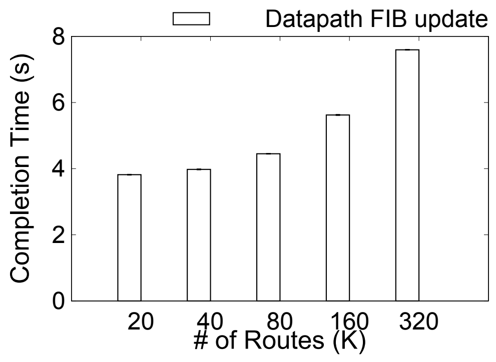


(a) Performance for handling reported BGP routes



(b) Performance for routing configuration to data path

Figure 14: SDN controller performance for BGP processing

7.3 Control Module Evaluation

The control module is responsible for computing FIB based on the routes collected from the routing module and installs the FIB entries to the datapath forwarding plane. We evaluate the effectiveness of control module for BGP routing configuration. As shown in Figure 14(a), it takes less than 200ms to add or withdraw 1K routes. For adding and withdrawing 10K routes, it takes about 3.4 seconds and 1.8 seconds respectively. More VRFs will add a little more overhead during the VRF insertion process. We then evaluate the control module's performance for updating the FIB entries of the underlying forwarding module. As shown in Figure 14(b), it takes ∼7.5 seconds to configure 320K routes, which meets our needs in most cases.

8 Operational Experiences

The DSR system has been in production for over three years and deployed at over 30 sites replacing the commodity routers there. We has delivered tens of new features with a release cycles of 2∼4 weeks. In contrast, the typical commodity router based solution releases new feature in several months or years. As a result, DSR can save an order of magnitude of monetary costs compared with the traditional solution. Now we introduce the efforts we have taken to operate DSR.

8.1 vNetVerifier System

DSR consists of multiple components built on x86 servers. During the operation, we found that x86 servers are not as reliable as commodity router. Despite the techniques we have used to improve reliability, we need a health monitoring system to discover and locate the failure. We have proposed a virtual network verification system, *i.e.* vNetVerifier, to solve the problem. We discuss some useful features of the system.

Transparent monitoring plane. We aim to achieve active monitoring without interfering with the customer traffic. For this purpose, we have created multiple virtual testing tenants and added monitoring rules in corresponding components. They act like real tenants using the same control and data paths as normal cloud tenants. We generate probing traffic continuously to monitor system faults.

Fine-grained probing. We carry out fine-grained datapath probing at single server granularity and single processing core granularity. As the datapath servers of the same forwarding fleets share the same Virtual IP using ECMP hashing, to monitor a targeted server, we craft probing packets with the underlay IP of the targeted server as the destination IP. For single core monitoring, we encode the processing core ID into the probing packets. Then the dispatchers on the datapath server examine the core ID and forward the packet to the targeted processing core. In this way, we achieved fine grained probing at server-level and core-level. As the decoupled components of DSR are connected via multiple paths. A single-path failure may lead to a wrong reaction as discussed in § 5.1. As a result, we intentionally eliminate the effect of single-path failure through multi-path probing similar to the operation introduced in § 5.1.

Online testing. Conventionally, before we update network components, *e.g.* software upgrade or hardware replacement, we test the components intensively in the small-scale testing environment. However, it is hard to mimic the realistic environment to find all the problems. To this end, we carry out online testing by leveraging the testing tenant in our production environment. To be specific, we convert different testing cases into corresponding network configurations and customized probing packets. Then we carry out online testing before and after the network updates. When abnormal traffic are detected, the ongoing network upgrading will be stopped and reverted. We are also investigating at high fidelity network emulation approaches similar as CrystalNet [26].

8.2 Fault Isolation and Localization

Fault domain isolation. An important principle during our operation is to guarantee that the datapath forwards packets correctly and continuously even when the control module and routing module fails. To achieve that, we need to do fault domain isolation for different components. A fault domain is defined as the "blast range" of a certain system failure, *e.g.* the failure of one BGP module node may affect the routing decision of a datapath forwarding node which may drop user traffic. The disaggregated design and deployment of control module, routing module and forwarding module makes it possible to isolate different fault domains. Since the control module stores all the routing information in a persistent database, if the BGP modules fail, the datapath can forwards traffic using the control module's routing information.

BGP events and traffic paths analysis. When fault happens, we need sufficient information to identify the root cause. The BGP events and traffic paths are two most important types of information. We have recorded all the BGP events in the database for post-mortem analysis. Since traffic paths can be dynamically changed, we use traceroute like tools to identify the path.

9 Related Work

To overcome the limitation of the traditional BGP protocol, Facebook [35] and Google [41] have developed SDN-based systems to control egress traffic routing for peering edges. Facebook EDGE FABRIC relies on vendor routers, which overrides the routers' normal BGP selection in each individual Points of Presence (PoP). Google Espresso removes the need for commodity BGP routers by employing centralized traffic engineering, which selects egress at distant PoPs. It is notable that DSR faces more complicated scenarios, including not only the peering routing for Internet users, which is the focus of EDGE FABRIC and Espresso, but also inter-connection between public cloud and customers' on-premise datacenters as well as customers' branch offices. Though we share the same idea with Espresso that separating the logic of the control plane from the data plane, DSR targets a different set of challenges on scalability, flexibility and reliability. In order to satisfy the requirements of diverse cloud access scenarios, the proposed disaggregated software router architecture is a general platform that is capable of customizing and scaling each module independently. DSR meets more stringent scalability requirements to support 10Ks VRF tables for PCS and 10M FIB entries for EIS. Therefore, we demonstrated the optimization for scaling the forwarding and routing plane, which is not addressed in Espresso. For flexibility, Espresso introduce the application-aware routing to serve Internet users. In contrast, DSR focuses on fast feature delivery to satisfy the demands of cloud customers, like self-defined routing policy and GRE encapsulation, etc. Furthermore, we solved multiple reliability issues when introducing the disaggregated software-defined router whose components are implemented in a distributed environment, which is not addressed in Espresso either.

NFV technologies are widely used to replace traditional proprietary middle boxes and switching devices. NFV technique reduces cost and provides high feature velocity [17, 24, 25, 30–34, 36, 40]. Previous works focus on several different aspects of the NFV, *e.g.* elastic scaling [22, 34, 40], NFV management [30, 39], performance optimization and implementation [9, 30], etc. DSR is an integration of multiple NFV techniques at cloud gateway. DSR applies DPDK [12] and VPP [8, 14] for the high performance data module. For the BGP speaker, we have evaluated the open source candidates like Quagga [2], GoBGP [4], BIRD [15] and FRR [3]. We developed our high performance BGP speaker based on FRR, which supports multiple functions like IPv6, BFD, etc. For IPSec gateway in the SWS scenario, both the control and data path of the IPSec protocol are coupled on the forwarding fleet. We plan to investigate similar approach as in [38] to separate the control and data plane of the IPSec protocol in order to achieve high scalability.

10 Conclusion

Cloud gateways play a significant role for enterprise customers and Internet users to access the resources in the cloud. With the rapid growth of users, we introduce DSR to replace the commodity routers based cloud gateways in Tencent Cloud. It employs a disaggregated software-defined architecture which provides high scalability and accelerates the features rollout velocity. Meanwhile, integration with the SDN technique achieves smart traffic steering and fast failure convergence. DSR has been deployed in production for over 3 years and has served tens of Tbps traffic for our customers.

Abstract

This paper presents CodedBulk, a system for high-throughput inter-datacenter bulk transfers. At its core, CodedBulk uses network coding, a technique from the coding theory community, that guarantees optimal throughput for individual bulk transfers. Prior attempts to using network coding in wired networks have faced several pragmatic and fundamental barriers. CodedBulk resolves these barriers by exploiting the unique properties of inter-datacenter networks, and by using a custom-designed hop-by-hop flow control mechanism that enables efficient realization of network coding atop existing transport protocols. An end-to-end CodedBulk implementation running on a geo-distributed inter-datacenter network improves bulk transfer throughput by $1.2-2.5\times$ compared to state-of-the-art mechanisms that do not use network coding.

1 Introduction

Inter-datacenter wide-area network (WAN) traffic is estimated to quadruple over the next five years, growing $1.3\times$ faster than global WAN traffic [2]. In the past, such an increase in demand has been matched by physical-layer technological advancements that allowed more data to be pumped on top of WAN fibers, thus increasing the capacity of existing inter-datacenter links [14]. However, we are now approaching the fundamental non-linear Shannon limit on the number of bits/Hz that can be practically carried across fibers [14]. This leaves datacenter network providers with the expensive and painfully slow proposition of deploying new fibers in order to keep up with increasing demands.

Several studies have reported that inter-datacenter traffic is dominated by geo-replication of large files (*e.g.*, videos, databases, etc.) for fault tolerance, availability, and improved latency to the user [3, 6, 8, 23, 25, 26, 31, 39, 40, 47, 49]. We thus revisit the classical multicast question: given a fixed network topology, what is the most throughput-efficient mechanism for transferring data from a source to multiple destinations? The answer to this question is rooted in network coding, a technique from the coding theory community that generalizes the classical max-flow min-cut theorem to the case of (multicast) bulk transfers [9, 30, 33]. Network coding guarantees optimal throughput for individual bulk transfers by using in-network computations [9, 24, 30, 33]; in contrast, achieving optimal throughput using mechanisms that do not perform in-network computations is a long-standing open problem [34]. We provide a primer on network coding in §2.2. While network coding has been successful applied in wireless networks [28, 29], its applications to wired networks have faced several pragmatic and fundamental barriers.

On the practical front, there are three challenges. First, network coding requires network routers to buffer and to perform computations on data, which requires storage and computation resources. Second, computing "network codes" that define computations at routers not only requires a priori knowledge about the network topology and individual transfers, but also does not scale to networks with millions of routers and/or links. Finally, network coding requires a single entity controlling the end-hosts as well as the network.

In traditional ISP networks, these challenges proved to be insurmountable but the equation is quite different for inter-datacenter WANs. The structure of typical inter-datacenter WAN topologies means that, instead of coding at all routers in the network, coding can be done only at resource-rich datacenters—either at border routers or on servers inside the datacenter—without any reduction in coding gains (§2.1). Inter-datacenter WAN operators already deploy custom border routers, so increase in computation and storage resources at these routers to achieve higher throughput using the available WAN bandwidth (that is expensive and increasingly hard-to-scale) is a good trade-off to make. The second and third challenges are also alleviated by unique characteristics [23, 25] of inter-datacenter WANs: (1) network sizes limited to hundreds of routers and links enables efficient computation of network codes and implementation of network coding; (2) SDN-enabled routers combined with the fact that transfers are known a-priori [39, 40] allow for centralized code computations which can, in turn, be programmed into routers; and (3) a single entity controlling end-hosts as well as the network.

While inter-datacenter WAN features lower the pragmatic barriers, one fundamental challenge still needs to be resolved. Traditional network coding assumes that there is no other traffic in the network, either foreground (*e.g.*, interactive traffic) or background (*e.g.*, other bulk transfers). More generally, network coding assumes that all links have the same latency and bandwidth, and that link latencies and bandwidths remain static over time. This assumption does not hold in practice, *e.g.*, due to sporadic high-priority interactive traffic, and due to multiple concurrent bulk transfers atop inter-datacenter WANs. We refer to this as the *asymmetric link* problem.

CodedBulk is an end-to-end system for high-throughput inter-datacenter bulk transfers that resolves the asymmetric link problem using a simple Hop-by-hop Flow Control (HFC) mechanism. The core idea in HFC mechanisms is to partition available buffer space at routers among active flows, so as to avoid buffer overflow [41, 45]. HFC mechanisms have been explored for traditional non-coded traffic [37, 41, 42, 51]; however, using HFC mechanisms for network coding imposes an additional constraint: all flows that need to be coded at any router must converge to the *same* rate. Simultaneously, routers need to work with limited storage and compute resources in the data plane. We show that *any* buffer partitioning scheme that assigns non-zero buffers to each (coded) flow achieves the following desirable properties: (i) for each individual bulk transfer, all incoming flows that need to be coded at a router converge to the same rate; (ii) for all bulk transfers sharing a link, the rate for all their flows through the link converge to the max-min fair rate; and (iii) the network is deadlock-free.

The use of network coding, coupled with HFC, also means that flow control at a router is correlated across multiple flows. While this could be implemented via modifications in the network stack, we introduce a *virtual link* abstraction which enables CodedBulk without any modifications to existing flow control-enabled transport layer and multipath-enabled network layer implementations. For instance, CodedBulk currently runs on top of unmodified TCP and MPLS-enabled network layer mechanisms supported by existing inter-datacenter WANs. Our implementation requires no special traffic shaping mechanism, allows co-existence of high-priority interactive traffic, and handles failures transparently.

We envision two deployment scenarios for CodedBulk. First, an infrastructure provider can provide CodedBulk as a service to geo-distributed services (including its own). In the second scenario, a geo-distributed service renting compute, storage and inter-datacenter bandwidth resources from an infrastructure provider can use CodedBulk to improve bulk transfer throughput without any support from the provider. We have implemented CodedBulk for both scenarios — an overlay service, a software proxy and a hardware proxy. The first two implementations currently run on geo-distributed inter-datacenter WAN. All the three implementations, along with a CodedBulk simulator, are available at: `https://github.com/SynergyLab-Cornell/codedbulk`.

The benefits of network coding depend on the underlying network topology, the number of destinations in individual bulk transfers, the source and set of destinations in each bulk transfer, the number of concurrent transfers and interactive traffic load. To understand the envelope of settings where CodedBulk provides benefits, we evaluate CodedBulk over a testbed comprising 13 geo-distributed datacenters organized around the B4 [25] and Internet2 [5] inter-datacenter WAN topologies, and perform sensitivity analysis of CodedBulk performance against all of the above factors. Our evaluation demonstrates that CodedBulk achieves $1.2-2.5\times$ higher throughput for bulk transfers when compared to existing state-of-the-art mechanisms that do not perform network coding. All the results presented in this paper are for real implementations of CodedBulk; this paper uses no simulation results.

2 CodedBulk Overview

We begin by describing our model for inter-datacenter WANs (§2.1). We then provide a primer for network coding (§2.2). Next, we discuss several pragmatic challenges that have posed a barrier to adoption of network coding in wired networks and how unique characteristics of inter-datacenter WANs enable overcoming these barriers (§2.3). We close the section with a high-level description of the CodedBulk design (§2.4).

2.1 Preliminaries

We follow the same terminology as in existing inter-datacenter WAN literature [26, 27, 31, 32, 39, 40, 49, 52]. Specifically, we model the inter-datacenter WAN as a directed graph $G = (V,E)$, where V is the set of nodes denoting datacenters and E is the set of links between pairs of datacenters. To account for the full-duplex nature of inter-datacenter WAN links, we create two links $u \rightarrow v$ and $v \rightarrow u$ for each pair of nodes $(u,v) \in V$ with a physical link between them. Each link has a capacity equal to its bandwidth available for bulk transfers.

We discuss two important aspects of the network model. First, while links in wired networks are full-duplex, the graph in inter-datacenter literature is usually modeled as a directed graph since links in two directions can have different *available* bandwidths at different times, *e.g.*, due to high-priority interactive traffic using (a fraction of) the bandwidth in one direction. Second, in practice, geo-distributed datacenters are often connected via intermediate routers operating at layer-1 or layer-3; these routers either operate exactly like a relay (have degree two, with incoming bandwidth equal to outgoing bandwidth), or have their bandwidth statically partitioned across multiple outgoing links. Both these cases are equivalent to having a direct link with a specific capacity in each direction between each pair of datacenters with a physical link between them.

We define bulk transfers as in prior work [23, 25, 26, 27, 31, 32, 38, 39, 40, 49, 52]: transfers that are bandwidth-intensive. A bulk transfer is a source s sending a file to a subset of nodes $T \subseteq V - \{s\}$.

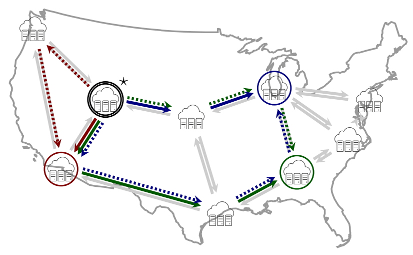
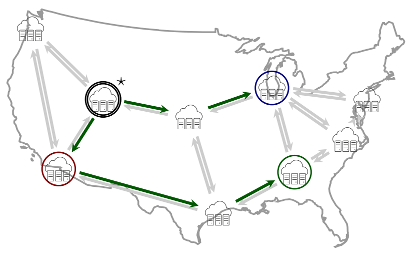
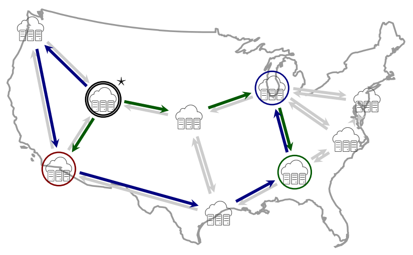
(b) single-path solution (suboptimal)



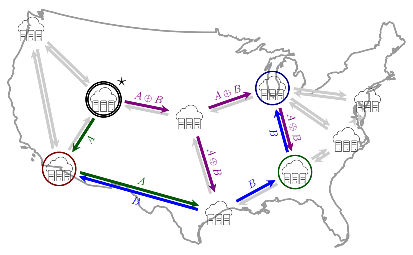
(c) multi-path solution (suboptimal)



(d) Steiner-tree solution (suboptimal)



(e) Optimal non-coded solution (computed by hand; efficient algorithms to compute such an optimal solution are not known).



(f) CodedBulk solution (optimal).

Figure 1: Understanding benefits of network coding. (a) An instance of the inter-datacenter bulk transfer problem on the Internet2 topology [5], with one source (marked by a circle with a $\star$) and three destinations (marked by circles). The network model is as described in §2.1. (b, c, d) Existing solutions based on single-path, multi-path and Steiner arborescence packing can be suboptimal (detailed discussion in §2.2). (e) An optimal solution with Steiner arborescence packing (computed by hand); today, computing such a solution requires brute force search which is unlikely to scale to inter-datacenter deployment sizes (tens to hundreds of datacenters) [23, 25]. (f) CodedBulk, using network coding, not only achieves optimal throughput but also admits efficient algorithms to compute the corresponding network codes. More discussion in §2.2.

2.2 Network coding background

Suppose a source wants to send a large file to a single destination, and that it is allowed to use as many paths as possible. If there are no other flows in the network, the maximum achievable throughput (the amount of data received by the destination per unit time) is given by the well-known max-flow min-cut theorem—the achievable throughput is equal to the capacity of the min-cut between the source and the destination in the induced graph. The corresponding problem for a source sending a file to multiple destinations was an open problem for decades. In 2000, a now celebrated paper [9] established that, for a multicast transfer, the maximum achievable throughput is equal to the minimum of the min-cuts between the source and individual destinations. This is also optimal. For general directed graphs, achieving this throughput is not possible using solutions where intermediate nodes simply forward or mirror the incoming data—it necessarily requires intermediate nodes to perform certain computations over the incoming data before forwarding the data [9, 30, 33].

For our network model that captures full-duplex links, network coding achieves optimal throughput (since it subsumes solutions that do not perform coding); however, it is currently not known whether optimal throughput can be achieved without network coding [10, 34]. Figure 1 demonstrates the space of existing solutions, using a bulk transfer instance from our evaluation (§4) on the Internet2 topology. We present additional discussion and examples in [46]. Single-path (also referred to as multiple unicast) solutions, where the source transfers data along a single path to each individual destination, can be suboptimal because they neither utilize all the available network bandwidth, nor do they allow intermediate nodes to forward/mirror data to other destinations. Multi-path solutions, where the source transfers data along all edge-disjoint paths to each individual destinations (paths across destinations do not need to be edge disjoint), can be suboptimal because they do not allow intermediate nodes to forward/mirror data to other destinations.

The current state-of-the-art solutions for our network model are based on Steiner tree (or, more precisely, Steiner arborescence) packing [7, 18, 34]. These solutions use multiple paths, and allow intermediate nodes to mirror and forward the data; however, they can be suboptimal because the problem of computing optimal Steiner tree (or arborescence) packing is NP-hard, and approximation algorithms need to be used [12]. To demonstrate the limitations of existing Steiner packing solutions, consider the example shown in Figure 1(d): here, once the shown Steiner tree is constructed, no additional Steiner trees can be packed in a manner that higher throughput can be achieved. Figure 1(e) demonstrates the complexity of computing an optimal solution (that we constructed by hand)—to achieve the optimal solution shown in the figure, one must explore intermediate solutions that use a suboptimal Steiner tree (shown in blue color). Today, computing such an optimal solution requires a brute force approach, which is unlikely to scale to inter-datacenter network sizes. Thus, we must use approximate suboptimal solutions; to the best of our knowledge, the state-of-the-art algorithms for computing approximate Steiner packing solutions for our network model do not even admit polylogarithmic approximation factors [11, 21].

Network coding avoids the aforementioned limitations of existing solutions by allowing intermediate nodes to perform certain computations, which subsume forwarding and mirroring, on data (as shown in the Figure 1(f) example)—it utilizes multiple paths, guarantees optimal throughput, and admits efficient computation of network codes that achieve optimal throughput [24]. Thus, while designing optimal non-coded solutions for bulk transfers remains an open problem, we can efficiently achieve throughput optimality for inter-datacenter bulk transfers *today* using network coding.

2.3 Resolving pragmatic barriers

While network coding is a powerful technique, its applications to wired networks have been limited in the past due to several pragmatic challenges. In this subsection, we use the example in Figure 1(f) to discuss these challenges, and how inter-datacenter WANs allow overcoming these challenges.

Buffering and computation at intermediate nodes. Network coding requires intermediate nodes to buffer data and perform computations. For instance, the bottom-center node in Figure 1(f) needs to perform XOR operations on packets from two flows A and $A \oplus B$. This requires the node to have storage (to buffer packets from A and $A \oplus B$), and computation resources (to compute $A \oplus (A \oplus B) = B$) in the data plane. While this was challenging in traditional ISP networks, inter-datacenter WANs allow overcoming this barrier easily: as noted in prior studies [31], each node in an inter-datacenter WAN is a datacenter with compute and storage resources that are significantly cheaper, more scalable and faster to deploy than inter-datacenter bandwidth.

Computing and installing network codes. Nodes in Figure 1(f) perform specific actions (forward, mirror, code-and-forward and code-and-mirror). These actions are specified using network codes, computing which requires a priori knowledge of the network topology, and the source and the set of destinations for each bulk transfer. This information was hard to get in ISP networks; however, inter-datacenter WANs already collect and use this information [23, 25, 31, 49]. Network coding also requires transmissions from end-hosts to be coordinated by the controller. In inter-datacenter WAN scenarios, this is feasible as a single entity controls the end-hosts as well as the network. Existing SDN infrastructure [23, 25] is also useful for this purpose—a centralized controller can compute the code, and can populate the forwarding tables of intermediate nodes (using existing support for MPLS tags and multi-path routing) before the bulk transfer is initiated.

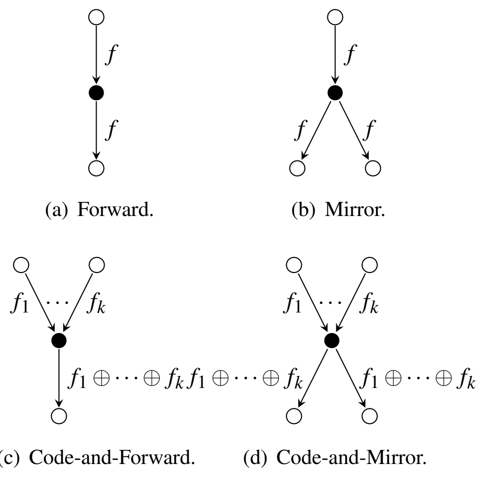


Figure 2: Four basic coding functions available at each intermediate node to implement the network code generated by CodedBulk.

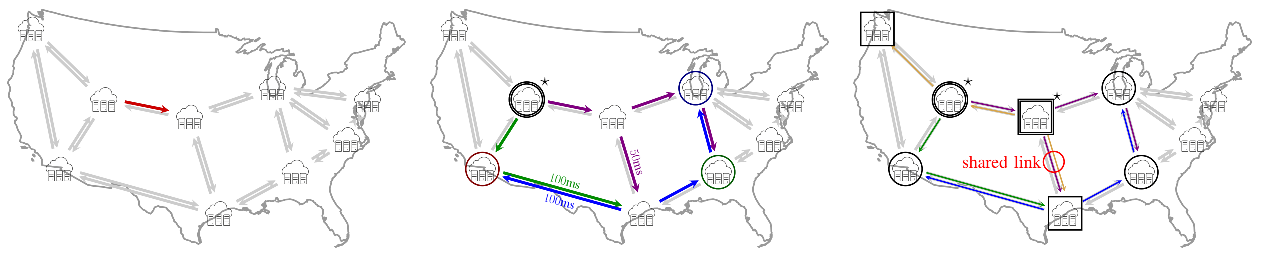
Existing algorithms [24] for computing network codes run in polynomial time, but may not scale to networks with millions of nodes and edges; however, this is not a concern for CodedBulk since inter-datacenter WANs comprise of only hundreds of nodes and links. Computation and installation of network codes, and buffering of data at intermediate nodes may also lead to increased latency for bulk transfers. However, since bulk transfers are not latency-sensitive [23, 25], a slight increase in latency to achieve significantly higher throughput for bulk transfers is a favorable tradeoff [31].

2.4 CodedBulk design overview

The high-level CodedBulk design for a single bulk transfer case can be described using the following five steps:

1. The source node, upon receiving a bulk transfer request, notifies the controller of the bulk transfer. The notification contains the source identifier, the identifiers for each destination, and an optional policy on the set of links or intermediate nodes not to be used (*e.g.*, for security and isolation purposes).
2. The controller maintains a static topology of the inter-datacenter network graph. While optimizations are possible to exploit real-time traffic information, the current CodedBulk implementation does not use such optimizations. The controller computes, for each destination, the set of edge-disjoint paths between the source and the destination, along with the bandwidth for each path. Using these paths, the controller computes the network code for the bulk transfer using the network coding algorithm from [24][1]. The network code comprises of the routing and forwarding

[1]The network coding algorithm in [24] requires as input a directed acyclic graph. However, the multipath set in our construction may lead to a cyclic graph. We use an extension similar to the original network coding paper [9] to generate network codes for cyclic graphs. Please see [46] for details.



(a) Reason: Interactive traffic.   (b) Reason: Non-uniform delay.   (c) Reason: Multiple bulk transfers.

Figure 3: Understanding asymmetric link problem. (a) Due to sporadic high-priority interactive traffic (*e.g.*, the one shown in red), different links may have different (time-varying) bandwidths; (b) If network links have significantly different round trip times, naïvely implementing traditional network coding would require large amount of fast data plane storage to buffer data that arrives early at nodes; (c) multiple concurrent bulk transfers, especially those that end up sharing links, make it hard to efficiently realize traditional network coding solutions that assume a single bulk transfer at all times. Detailed discussion in §3.1.

information for each flow, and the computations done at each intermediate node for the flows arriving at that node. These codes can be expressed as a combination of four basic functions shown in Figure 2.

3. Once the network code is computed, the controller installs the network code on each node that participates in the bulk transfer. We discuss, in §3.3, a mechanism to implement the forwarding and routing functions that requires no changes in existing inter-datacenter WAN infrastructure.

4. Once the code is installed, the controller notifies the source. The source partitions the bulk transfer file into multiple subfiles (defined by the code) and then initiates the bulk transfer using CodedBulk, as described in the remainder of the paper. For instance, for the example of Figure 1(f), the source divides the file into two subfiles (A and B) of equal sizes and transmits them using the code shown in the figure. Each intermediate node *independently* performs CodedBulk's hop-by-hop flow control mechanism. Importantly, a "hop" here refers to a datacenter on the network topology graph. CodedBulk assumes that interactive traffic is always sent with the highest priority, and needs two additional priority levels.

5. Once the bulk transfer is complete, the source notifies the controller. The controller periodically uninstalls the inactive codes from all network nodes.

The core of CodedBulk's mechanisms are to efficiently enable the fourth step. We describe these in the next section.

3 CodedBulk Design

We describe the core techniques in CodedBulk design and implementation. We start by building an in-depth understanding of the asymmetric link problem (§3.1). We then describe how CodedBulk resolves the asymmetric link problem using a custom-designed hop-by-hop flow control mechanism (§3.2). Finally, we discuss the virtual link abstraction that enables implementation of CodedBulk without any modifications in underlying transport- and network-layer protocols (§3.3).

3.1 Understanding fundamental barriers

We start by building an in-depth understanding of the asymmetric link bandwidth problem, and how it renders techniques in network coding literature infeasible in practice. We use Figure 3 for the discussion in this subsection.

Asymmetric links due to sporadic interactive traffic. Inter-datacenter WANs transfer both latency-sensitive interactive traffic (*e.g.*, user commits, like emails and documents) and bandwidth-intensive bulk traffic [23, 25]. While interactive traffic is low-volume, it is unpredictable and is assigned higher priority. This leads to two main challenges. First, links may have different bandwidths available at different times for bulk transfers (as shown in Figure 3(a)). Second, the changes in available bandwidth may be at much finer-grained timescales than the round trip times between geo-distributed datacenters.

Traditional network coding literature does not consider the case of interactive traffic. An obvious way to use traditional network coding solutions for non-uniform link bandwidths is to use traffic shaping to perform network coding on the minimum of the available bandwidth across all links. For instance, in the example of Figure 3(a), if the average load induced by interactive traffic is $0.1\times$ link bandwidth, then one can use network coded transfers only on $0.9\times$ bandwidth. However, the two challenges discussed above make this solution hard, if not infeasible: bandwidths are time-varying, making static rate allocation hard; and, bandwidth changing at much fine-grained timescales than geographic round trip times makes it hard to do dynamic rate allocation.

Asymmetric links due to non-uniform delay. Traditional network coding solutions, at least the practically feasible ones [24], require computations on data arriving from multiple flows in a deterministic manner: packets that need to be coded are pre-defined (during code construction) so as to allow the destinations to decode the original data correctly. To achieve this, existing network coding solutions make one of the two assumptions: either the latency from the source to each individual node is uniform; or, unbounded storage

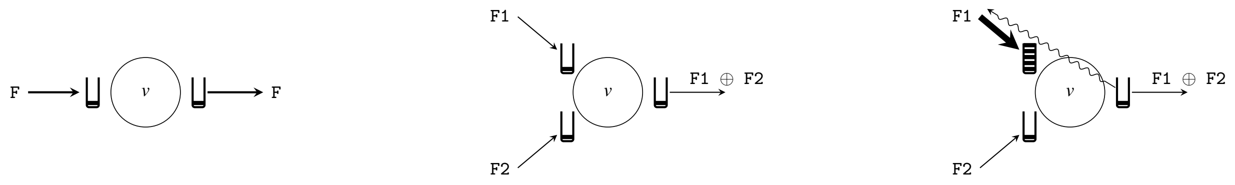


Figure 4: Understanding hop-by-hop flow control for a single bulk transfer. (left) if the outgoing link has enough bandwidth to sustain the rate of incoming traffic (flow `F` in this example), then all buffers will remain unfilled and flow control will not be instantiated; (center) the same scenario as the left figure holds as long as the two conditions hold: (1) both flows that need to be coded at some node v send at the same rate; and (2) the outgoing link has enough bandwidth to sustain the rate of incoming traffic; (right) If two flows need to be coded at some node v, and one of the flows `F1` is sending at higher rate, then the `Rx` buffer for `F1` will fill up faster than it can be drained (due to v waiting for packets of `F2`) and flow control to the downstream node of `F1` will be triggered, resulting in rate reduction for flow `F1`. Detailed discussion in §3.2.

at intermediate nodes to buffer packets from multiple flows. Neither of these assumptions may hold in practice. The delay from the source to individual intermediate nodes can vary by hundreds of milliseconds in a geo-distributed setting (Figure 3(b)). Keeping packets buffered during such delays would require an impractical amount of high-speed storage for high-bandwidth inter-datacenter WAN links: if links are operating at terabits per second of bandwidth, each intermediate node would require hundreds of gigabits or more of storage.

Asymmetric links due to simultaneous bulk transfers. Traditional network coding literature considers only the case of a single bulk transfer. Designing throughput-optimal network codes for multiple concurrent bulk transfers is a long-standing open problem. We do not solve this problem; instead, we focus on optimizing throughput for individual bulk transfers while ensuring that the network runs at high utilization.

Achieving the above two goals simultaneously turns out to be hard, due to each individual bulk transfer observing different delays (between respective source to intermediate nodes) and available link bandwidths due to interactive traffic. Essentially, as shown in Figure 3(c), supporting multiple simultaneous bulk transfers requires additional mechanisms for achieving high network utilization.

3.2 CodedBulk's hop-by-hop flow control

Network coding, by its very nature, breaks the end-to-end semantics of traffic between a source-destination pair, thus necessitating treating the traffic as a set of flows between the intermediate nodes or hops. Recall that a "hop" here refers to a (resource-rich) datacenter on the network graph. To ensure that we do not lose packets at intermediate nodes in spite of the fact that they have limited storage, we rely on a hop-by-hop flow control mechanism—a hop pushes back on the previous hop when its buffers are full. This pushback can be implicit (*e.g.*, TCP flow control) or explicit.

Hop-by-hop flow control is an old idea, dating back to the origins of congestion control [41, 45]. However, our problem is different: traditional hop-by-hop flow control mechanisms operate on individual flows—each downstream flow depends on precisely one upstream flow; in contrast, CodedBulk operates on "coded flows" that may require multiple upstream flows to be encoded at intermediate nodes. Thus, a flow being transmitted at a low rate can affect the overall performance of the transfer (since other flows that need to be encoded with this flow will need to lower their rate as well). This leads to a correlated rate control problem. For instance, in Figure 2(c) and Figure 2(d), flows f_1 to f_k must converge to the same rate so that the intermediate node can perform coding operations correctly without buffering large number of packets. To that end, CodedBulk's hop-by-hop flow control mechanism maintains three invariants:

- All flows within the same bulk transfer that need to be encoded at any node must converge to the same rate;
- All flows from different bulk transfers competing on the congested link bandwidth must converge to a max-min fair bandwidth allocation;
- The network is deadlock-free.

CodedBulk maintains these invariants using a simple idea: careful partitioning of buffer space to flows within and across bulk transfers. The key insight here, that follows from early work on buffer sharing [45], is that for large enough buffers, two flows congested on a downstream link will converge to a rate that corresponds to the fair share of the downstream link bandwidth. We describe the idea of CodedBulk's hop-by-hop flow control mechanism using two scenarios: single isolated bulk transfer and multiple concurrent bulk transfers.

Single bulk transfer. First consider the two simpler cases of forward (Figure 2(a)) and mirror (Figure 2(b)). These cases are exactly similar to traditional congestion control protocols, and hence do not require any special mechanism for buffer sharing. The main challenge comes from Code-and-Forward (Figure 2(c)) and Code-and-Mirror (Figure 2(d)). For these cases, the invariant we require is that the flows being used to compute the outgoing data converge to the same rate since otherwise packets belonging to the flows sending at a higher rate will need to be buffered at the node, requiring high storage. This is demonstrated in Figure 4, center and right figures.

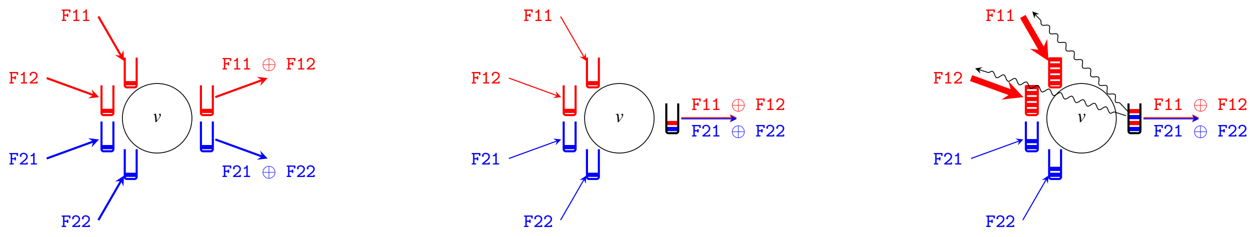

Figure 5: If concurrent bulk transfers use completely different outgoing links (left) or use the same outgoing link but with enough bandwidth (center), the hop-by-hop flow control mechanism does not get triggered. However, if the outgoing link is bandwidth-bottlenecked, and one of the bulk transfers is sending at higher rate (say the red one), then the buffers for the red flows will fill up faster than the buffers for blue flows; at this point, hop-by-hop flow control mechanism will send a pushback to the downstream nodes of the red flows, resulting in reduced rate for the red flows. Detailed discussion in §3.2.

Our insight is that a buffer partitioning mechanism that assigns *non-zero* buffers to each incoming flow maintains the second and the third invariants. It is known that non-zero buffer allocation to each flow at each link leads to deadlock-freedom [45]. It is easy to see that the second invariant also holds—if one of the flows sends at a rate higher than the other (Figure 4(right)), the buffer for this flow will fill up faster than the buffer for the other flow, the flow control mechanism will be triggered, eventually reducing the rate of the flow.

Multiple simultaneous bulk transfers. CodedBulk handles each bulk transfer independently using its hop-by-hop flow control mechanism. Again, we provide intuition using an example. Consider two simultaneous bulk transfers at some intermediate node. If the two bulk transfers use different incoming and outgoing links, these transfers remain essentially independent. So, consider the case when the two bulk transfers compete on one of the incoming or outgoing links. We first discuss when they compete on one of the outgoing links (see Figure 5). If the sum of "coded rates" for individual bulk transfers is less than the outgoing link bandwidth, no flow control is triggered and hence max-min fairness is achieved.

The situation becomes more interesting when the sum of coded rates for individual bulk transfers is greater than the outgoing link bandwidth. In this case, suppose the coded rate of the first bulk transfer is greater than the second one. Then, since outgoing link is shared equally across the two bulk transfers, the buffers for the flows in the first bulk transfer will fill more quickly, leading to triggering the flow control. Thus, flows in the second bulk transfer will reduce the transmission rate finally converging to outgoing link being shared equally across the two coded bulk transfers.

Multi-priority transfers to fill unfilled pipes. Asymmetric link problem, despite our hop-by-hop flow control mechanism, can lead to "unfilled pipes" (Figure 6). Essentially, due to different bulk transfers bottlenecked at different links, no more coded traffic can be pushed into the network despite some links having available bandwidth. CodedBulk fills such unfilled pipes by sending uncoded data; however, to ensure minimal impact on the coded traffic, CodedBulk uses a lower

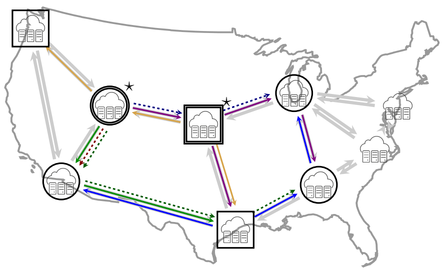

Figure 6: By sending non-coded flows at lower priority (the gray traffic), CodedBulk exploits the "unfilled pipes" left by coded traffic.

priority level for the uncoded data. Thus, CodedBulk uses three priority levels—the highest priority is for interactive traffic, the medium priority for coded traffic, and a lower priority level for uncoded traffic.

3.3 Virtual links

CodedBulk's hop-by-hop flow control mechanism from the previous section addresses the asymmetric link problem, at a design level. In this subsection, we first discuss a challenge introduced by network coding in terms of efficiently implementing the hop-by-hop flow control mechanism. We then introduce the abstraction of virtual links, that enables an efficient realization of CodedBulk's flow control mechanism without any changes in the underlying transport protocol. For this subsection, we use TCP as the underlying congestion control mechanism; however, the idea generalizes to any transport protocol that supports flow control.

The challenge. In traditional store-and-forward networks, implementing hop-by-hop flow control is simple: as data for a flow is received in the Rx buffer, it can be directly copied to the Tx buffer of the next hop, either using blocking or non-blocking system calls. When implementing network coding, this becomes non-trivial—since data from multiple flows needs to be coded together, neither blocking nor non-blocking calls can be used since these calls fundamentally operate on individual flows. For instance, consider the case of Figure 1(f), where a node needs to compute $(A \oplus B) \oplus A$ using packets

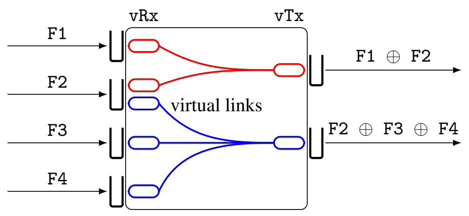

Figure 7: The figure demonstrates the virtual link abstraction used by CodedBulk to implement its hop-by-hop flow control mechanism without any modifications in the underlying network stack.

from the two flows. Blocking calls require expensive coordination between two buffers since the node requires data from *both* flows to be available before it can make progress. Non-blocking calls cannot be used either—the call will return the data from one of the flows, but this data cannot be operated upon until the data from the other flow(s) is also available. The fundamental challenge here is that we need efficient ways to block on multiple flows, and return the call only when data is available in all flows that need to be coded.

It may be tempting to have a shared buffer across different flows that need to be coded together. The problem, however, is that shared buffers will lead to deadlocks [41]—if one of the flows is sending data at much higher rate than the other flows, it will end up saturating the buffer space, the other flows will starve, and consequently the flow that filled up the buffer will also not make progress since it waits to receive data from other flows to be coded with. As discussed in §3.2, non-zero buffer allocation to each individual flow is a necessary condition for avoiding deadlocks in hop-by-hop flow control mechanisms.

Virtual links (see Figure 7). CodedBulk assigns each individual bulk transfer a virtual link per outgoing physical link; each virtual link has a single virtual transmit buffer `vTx` and as many virtual receive buffers `vRx` as the number of flows to be coded together for that outgoing link. For instance, consider four incoming flows in a bulk transfer `F1, F2, F3, F4` such that `F1 ⊕ F2` is forwarded on one of outgoing physical links, and `F2 ⊕ F3 ⊕ F4` is forwarded on another outgoing physical link. Then, CodedBulk creates two virtual links each having one `vTx`; the first virtual link has two `vRx` (one for `F1` packets and another for `F2` packets) and the second virtual link has three `vRx` (one for each of `F2, F3` and `F4` packets). Virtual links are created when the controller installs the network codes, since the knowledge of the precise network code to be used for the bulk transfer is necessary to create virtual links. As new codes are installed, CodedBulk reallocates the space to each `vTx` and `vRx`, within and across virtual links, to ensure that all virtual buffers have non-zero size.

Using these virtual links resolves the aforementioned challenge with blocking and non-blocking calls. Indeed, either of the calls can now be used since the "correlation" between the flows is now captured at the virtual link rather than at the flow control layer. Data from the incoming socket buffers for individual flow is now copied to their respective `vRx` buffers, either using blocking or non-blocking calls. A separate thread asynchronously checks when the size of all the `vRx` buffers is non-zero (each buffer has at least one packet); and when this happens, performs the coding operations and copies the resulting packet to the corresponding `vTx`.

4 Evaluation

We implement CodedBulk in C++ and use TCP Cubic as the underlying transport protocol. We use default TCP socket buffers, with interactive traffic sent at higher priority than bulk transfers (using TCP differentiated services field) set using standard Linux socket API. To enforce priority scheduling, we use Linux tc at each network interface.

We now evaluate CodedBulk implementation over two real geo-distributed cloud testbeds. We start by describing the experiment setup (§4.1). We then discuss the results for CodedBulk implementation over a variety of workloads with varying choice of source and destination nodes for individual bulk transfers, interactive traffic load, number of concurrent bulk transfers, and number of destinations in individual bulk transfers (§4.2). Finally, we present scalability of our CodedBulk prototype implementation in software and hardware (§4.3).

4.1 Setup

Testbed details. To run our experiments, we use two testbeds that are built as an overlay on geo-distributed datacenters from Amazon AWS. Our testbeds use 13 and 9 geo-distributed datacenters organized around B4 [25] and Internet2 [5] topologies, respectively. The datacenter locations are chosen to closely emulate the two topologies and the corresponding geographical distances and latencies. Within each datacenter, we take a high-end server; for every link in the corresponding topology, we establish a connection between the servers across various datacenter using the inter-datacenter connectivity provided by Amazon AWS. To reduce cost of experimentation, we throttle the bandwidth between each pair of servers to 200 Mbps for our experiments. The precise details on the inter-datacenter connectivity provided by Amazon AWS, whether they use public Internet or dedicated inter-datacenter links, is not publicly known. We run all the experiments for each individual figure within a short period of time; while the inter-datacenter links provided by Amazon AWS may be shared and may cause interference, we observe fairly consistent inter-datacenter bandwidth during our experiments. We use a server in one of the datacenters to act as the centralized controller (to compute and install network codes on all servers across our testbed).

Workloads. As mentioned earlier, the benefits of network coding depend on the underlying network topology, the number of destinations in individual bulk transfers, the location of the source and the set of destinations in each bulk transfer, the number of concurrent transfers and interactive traffic load.

While there are no publicly available datasets or workloads for inter-datacenter bulk transfers, several details are known. For instance, Facebook [43], Netflix [1], Azure SQL database [3] and CloudBasic SQL server [4] perform replication to (dynamically) locate their datasets closer to the customers; for such applications, the destinations for each replica are selected based on the diurnal traffic patterns and customer access patterns. Many other applications [13, 19, 23, 25, 31, 50] perform replication levels based on user needs, usually for fault tolerance; for such applications, the choice of destinations may be under the control of the service provider.

We perform experiments to understand the envelope of workloads where CodedBulk provides benefits. Our evaluation performs sensitivity analysis against all parameters—we use two inter-datacenter network topologies, interactive traffic load varying from $0.05-0.2\times$ of the link bandwidth, the number of destinations/replicas in individual bulk transfers varying from 2 to maximum possible (depending on the topology), and the number of concurrent bulk transfers varying from 1 to the maximum possible (depending on the topology). For each setting, we run five experiments; for individual bulk transfers within each experiment, we choose a source uniform randomly across all nodes, and choose the destinations from the remaining nodes. Each node can be the source of only a single bulk transfer but may serve as a destination for other bulk transfers; furthermore, each node may serve as a destination for multiple bulk transfers. We present the average throughput across all experiments, as well as the variance (due to different choices of the source and set of destination across different experiments).

We generate interactive traffic between every pair of datacenters, with arrival times such that the overall load induced by the interactive traffic varies between $0.05-0.2\times$ of the link bandwidth; while 0.2 load is on the higher end in real-world scenarios [23, 25], it allows us to evaluate extreme workloads. Interactive traffic is always assigned the highest priority and hence, all our evaluated schemes will get the same interactive traffic throughput. Our results, thus, focus on bulk traffic throughput.

As mentioned above, there are no publicly available datasets or workloads for inter-datacenter bulk transfers. We make what we believe are sensible choices, state these choices explicitly, and to whatever extent possible, evaluate the sensitivity of these choices on our results. Nonetheless, our results are dependent on these choices, and more experience is needed to confirm whether our results generalize to workloads observed in large-scale deployments.

Evaluated schemes. We compare CodedBulk with three mechanisms for bulk data transfers discussed earlier in Figure 1—single-path, multi-path, and Steiner arborescence packing—each of which take the graph described in §2.1 as an input. For the single-path mechanism, the bulk traffic is transferred along the shortest path between the source and each destination; when multiple choices are available, the mechanism selectively picks paths that minimize total bandwidth usage (*e.g.*, to send bulk traffic to two destinations d_1, d_2, the mechanism prefers the path $s \rightarrow d_1 \rightarrow d_2$, where d_1 can simply forward the data to d_2, over two different paths $s \rightarrow d_1$ and $s \rightarrow v \rightarrow d_2$ for some other node v). The multi-path mechanism selects edge-disjoint paths from the source to each destination so as to greedily minimize the sum of the path lengths. Our third baseline is a state-of-the-art Steiner arborescence based multicast mechanism that allows each node in the network (including the destinations) to forward (Figure 2(a)) and mirror (Figure 2(b)) incoming data. To compute the Steiner arborescence, we use the algorithm in [48] that is also used in other Steiner arborescence based inter-datacenter multicast proposals [38, 39, 40]. We take the arborescence computed by the algorithm, and integrate it with a store-and-forward model, along with TCP for transfers between every pair of nodes in the Steiner arborescence. For concurrent bulk transfers, paths and Steiner arborescence are computed independently for each individual bulk transfer.

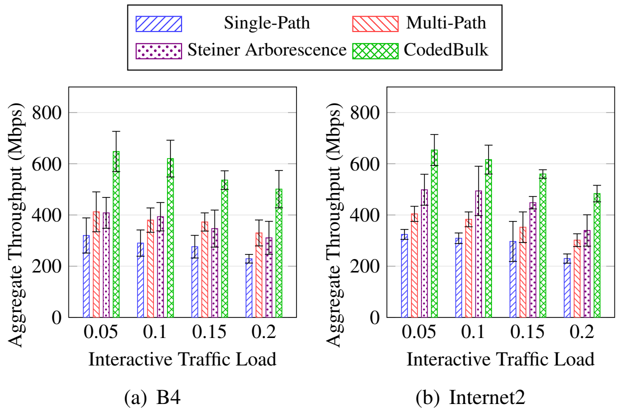

Figure 8: Performance of various bulk transfer mechanisms for varying interactive traffic load. For the B4 topology, CodedBulk improves bulk transfer throughput by $1.9-2.2\times$, $1.4-1.6\times$ and $1.5-1.6\times$ compared to single-path, multi-path, and Steiner arborescence based mechanisms, respectively. For the Internet2 topology, corresponding numbers are $1.9-2.1\times$, $1.6\times$, and $1.2-1.4\times$ (discussion in §4.2).

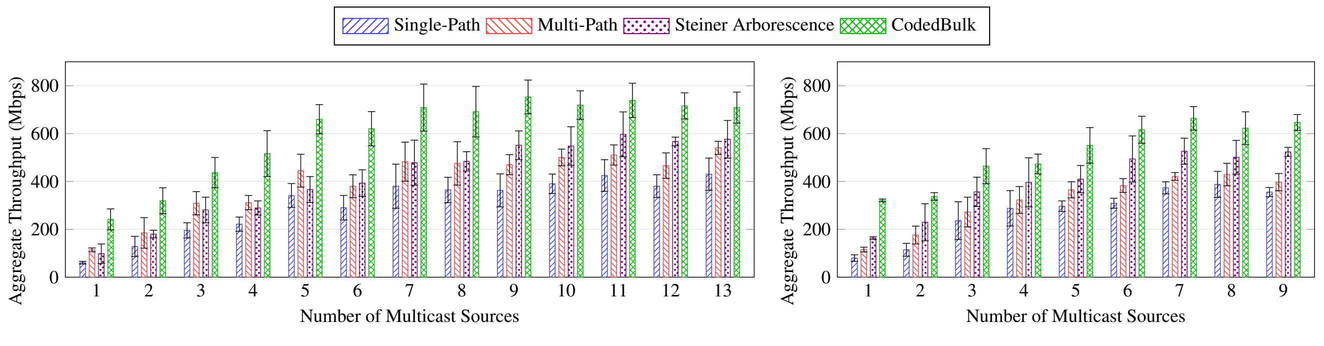
For CodedBulk, we use a finite field size of 2^8, that is all finite field operations are performed on individual bytes; this finite field size is sufficient for inter-datacenter networks with as many as 128 datacenters. We could have used a smaller finite field size since our topologies are much smaller than real inter-datacenter network topologies; however, this allow us to keep the operations byte aligned, which simplifies CodedBulk software and hardware implementation.

Performance metric. Our primary metric is the aggregate throughput for bulk transfers. For each individual bulk transfer, the throughput is computed as the maximum throughput at which the source can send to *all* destinations. We then calculate the aggregate throughput by summing up the throughput of all bulk transfers.



(a) B4 (b) Internet2

Figure 9: Performance of various bulk transfer mechanisms for varying number of concurrent bulk transfers. CodedBulk improves the bulk transfer throughput by $1.6-4\times$, $1.3-2.8\times$ and $1.2-2.5\times$ when compared to single-path, multi-path, and Steiner arborescence based mechanisms, respectively (discussion in §4.2).

4.2 Geo-distributed Testbed Experiments

We compare CodedBulk with the three baselines for varying interactive traffic loads, varying number of concurrent bulk transfers and varying number of replicas per bulk transfer.

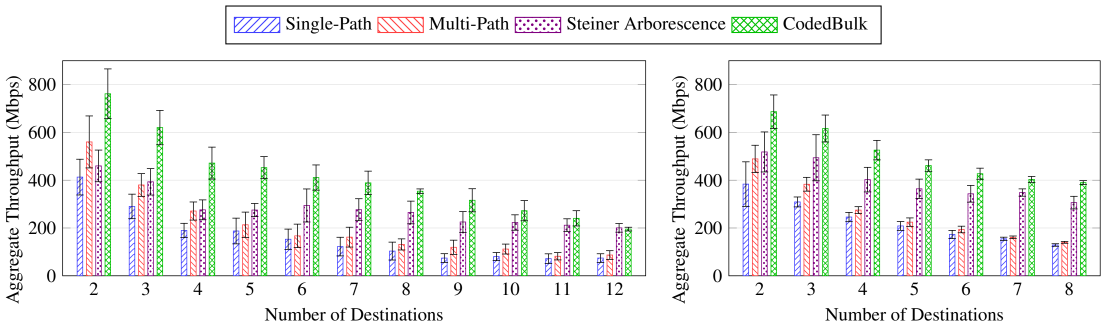
Varying interactive traffic load. Figure 8 presents the achievable throughput for each scheme with varying interactive traffic load. For this experiment, we use 3-way replication and 6 concurrent transfers (to capture the case of Facebook, Netflix, Azure SQL server and CloudBasic SQL server as discussed above), and vary the interactive traffic load from $0.05-0.2\times$ of the link bandwidth.

As expected, the throughput for all mechanisms decreases as interactive traffic load increases. Note that, in corner-case scenarios, the multi-path mechanism can perform slightly worse than single-path mechanism for multiple concurrent bulk transfers due to increased interference across multiple flows sharing a link, which in turn results in increased convergence time for TCP (see [46] for a concrete example). Overall, CodedBulk improves the bulk traffic throughput over single-path, multi-path and Steiner arborescence mechanisms by $1.9-2.2\times$, $1.4-1.6\times$ and $1.2-1.6\times$, respectively, depending on the interactive traffic load and the network topology. Single-path mechanisms perform poorly because they do not exploit all the available bandwidth in the network. Both multi-path and Steiner arborescence based mechanisms exploit the available bandwidth as much as possible. However, multi-path mechanisms suffer since they do not allow intermediate nodes to mirror and forward to the destinations. Steiner arborescence further improves upon multi-path mechanisms by allowing intermediate nodes to mirror and forward data, but they suffer due to approximation algorithm often leading to suboptimal solutions. CodedBulk's gains over multi-path and Steiner arborescence mechanisms are, thus, primarily due to CodedBulk's efficient realization of network coding—it not only uses all the available links, but also computes the optimal coding strategy (unlike Steiner arborescence mechanism that uses an approximation algorithm). The Steiner arborescence mechanism performs better on Internet2 topology because of its sparsity—fewer links in the network means a Steiner arborescence solution is more likely to be the same as network coding solution due to fewer opportunities to perform coding. Nevertheless, CodedBulk outperforms Steiner arborescence based mechanism by $1.4\times$.

Varying number of concurrent bulk transfers. Figure 9 shows the performance of the four mechanisms with varying number of concurrent transfers. For this evaluation, we use the same setup as earlier—3-way replication, multiple runs with each run selecting different sources and set of destinations, etc.—with the only difference being that we fix the interactive traffic load to 0.1 and vary the number of concurrent bulk transfers. With larger number of concurrent bulk transfers, Steiner arborescence mechanisms slightly outperform multi-path due to improved arborescence construction. Nevertheless, CodedBulk provides benefits across all sets of experiments, achieving $1.2-2.5\times$ improvements over Steiner arborescence based mechanisms. The gains are more prominent for B4 topology and for fewer number of concurrent transfers, since CodedBulk gets more opportunities to perform network coding at intermediate nodes in these scenarios.

Varying number of destinations/replicas per bulk transfer. Figure 10 shows the performance of the four mechanisms with varying number of destinations/replicas for individual bulk transfers. For this evaluation, we use the same setup as Figure 8—6 concurrent bulk transfers, multiple runs with each run selecting different sources and set of destinations, etc.—with the only difference being that we fix the interactive traffic load to 0.1 and vary the number of destinations/replicas per bulk transfer from 2 to the maximum allowable replicas for individual topologies. Notice the results show the aggregate throughput per destination.

As the number of destinations per bulk transfer increases, the per-destination throughput decreases for all schemes (although, as expected, the sum of throughput of all destinations increases). Note that multi-path outperforming single-path



(a) B4 (b) Internet2

Figure 10: Performance of various bulk transfer mechanisms for varying number of destinations/replicas per bulk transfer. CodedBulk improves the bulk transfer throughput over single-path and multi-path mechanisms by $1.8-4.3\times$ and $1.4-2.9\times$, respectively, depending on the number of destinations in each bulk transfer and depending on the topology. CodedBulk outperforms Steiner arborescence mechanisms by up to $1.7\times$ when the number of destinations is not too large. When each bulk transfer creates as many replicas as the number of datacenters in the network, CodedBulk performs comparably with Steiner arborescence. Note that the aggregate bulk throughput reduction is merely because each source is transmitting to increasingly many destinations, but the metric only captures the average throughput per destination. Discussion in §4.2.

and Steiner arborescence based mechanism in Figure 10(a) is primarily due to B4 topology being dense, thus providing enough path diversity to offset the benefits of approximate Steiner arborescence construction. Figure 10(a) and 10(b) show that CodedBulk outperforms single-path and multi-path mechanisms by $1.8-4.3\times$ and $1.4-2.9\times$, depending on the number of destinations and on the topology; moreover, the relative gains of CodedBulk improve as number of destinations increases. The comparison with Steiner arborescence based mechanism is more nuanced. CodedBulk achieves improved performance when compared to Steiner arborescence based mechanism when number of destinations is less than 10 for B4 topology, and less than 6 for Internet2 topology. The performance difference is minimal for larger number of destination. The reason is that for larger number of replicas/destinations, each source is multicasting to almost all other nodes in the network; in such cases, the benefits of coding reduce when compared to forwarding and mirroring of data at intermediate nodes and at the destination nodes as in Steiner arborescence based mechanism. Thus, the benefits of CodedBulk may be more prominent when the number of replicas is a bit smaller than the total number of datacenters in the network.

4.3 Microbenchmarks

We now evaluate CodedBulk performance in terms of scalability of its software and hardware implementations. Our goal here is to demonstrate the feasibility of CodedBulk implementation; deployment of CodedBulk in large-scale systems would typically require much more optimized implementation since the traffic volume is expected to be much higher.

Software implementation. CodedBulk software implementation runs on commodity datacenter servers, performing network coding as discussed in §3. Figure 11 shows the scalability of CodedBulk software implementation. We observe that CodedBulk implementation scales well with number of cores,

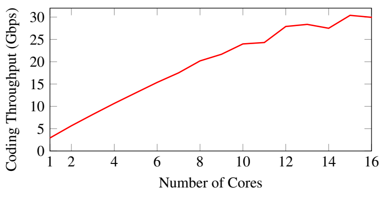


Figure 11: CodedBulk implementation performs network coding for as much as 31Gbps worth of traffic using a commodity 16 core server, achieving roughly linearly coding throughput scalability with number of cores.

Element	Used	Available	Utilization
LUT	69052	433200	15.94%
BRAM	1365	1470	92.86%

Table 1: Resource utilization of CodedBulk implementation on Xilinx Virtex-7 XC7VX690T FPGA (250 MHz clock). Our implementation provides up to 31.25 Gbps throughput with 15.94% LUTs and 92.86% BRAMs. No DSP is needed in our design.

with a single 16-core server being able to perform network coding at line rate for as much as 31Gbps worth of traffic.

Hardware implementation. We have synthesized an end-to-end CodedBulk implementation on an FPGA. For our CodedBulk hardware implementation, we had two choices. First, we could implement a finite field engine that performs finite field operations during the network coding process; or second, we could precompute and store finite field operation results, and use a simple look up table while performing network coding operations. The first approach requires multiple clock cycles to encode two bytes from two different packets; the second approach trades off BRAM to save cycles during coding operations. Since CodedBulk uses a small finite field size (2^8), the second approach offers a better tradeoff — it requires just 256×256 byte look up table per 16 bytes for individual operations to complete in one cycle. We replicate the lookup table accordingly to perform network coding for all bytes in an MTU-sized packet within a single clock cycle. Table 1 shows the results for CodedBulk hardware implementation on Xilinx Virtex-7 XC7VX690T FPGA, which offers 100, 200, and 250 MHz fabric clocks. With respect to the clocks, our FPGA-based codec can achieve throughput 12.5, 25, and 31.25 Gbps. Without needing any DSP, our hardware design consumes 92.86% BRAMs and only 15.94% LUTs.

We believe that trading off compute and storage resources to improve inter-datacenter bulk transfer throughput is a favorable tradeoff to make. However, more experience from industry is needed to do a thorough cost/benefit analysis.

5 Related Work

We have already discussed the differences between CodedBulk's goals and the traditional multicast problem in ISP networks; it would be futile to attempt to summarize the vast amount of literature from ISP multicast problem. We compare and contrast CodedBulk with two more closely related key areas of research: inter-datacenter WAN transfers, and network coding applications in computer networks.

Inter-datacenter bulk transfers. There has been significant amount of recent work on optimizing inter-datacenter bulk transfers [26, 27, 31, 32, 38, 39, 40, 49, 52]. These works optimize inter-datacenter bulk transfers along a multitude of performance metrics, including improving flow completion time [27, 38, 39, 40, 49, 52], and throughput for bulk transfers [26, 31, 32]. CodedBulk's goals are aligned more closely with the latter, and are complementary to the former—CodedBulk improves the throughput for bulk transfers; any bulk transfer scheduling mechanism can be used on top of CodedBulk to meet the needs for timely transfers.

As discussed earlier, the state-of-the-art approach for high-throughput inter-datacenter bulk transfers are based on packing of Steiner arborescence: here, each intermediate node as well as destination nodes are allowed to forward and mirror data toward other destination nodes. Several recent inter-datacenter bulk transfer proposals [38, 39, 40] are based on this approach. Our evaluation in §4 shows that CodedBulk achieves throughput improvements over state-of-the-art Steiner arborescence based mechanisms in a wide variety of scenarios. This is because all prior techniques are limited by network capacity, and by limitations of existing non-coded techniques to achieve this capacity.

CodedBulk, by using network coding, achieves improvement in throughput for bulk transfers by trading off a small amount of compute and storage resources.

Network coding in computer networks. Network coding has successfully been applied to achieve higher throughput in wireless networks [20, 29], in TCP-based networks [44], in content distribution [17, 35, 36], in peer-to-peer communication [16], to name a few; please see [15] for additional applications of network coding. Our goals are complementary—enabling network coding for high-throughput inter-datacenter WAN bulk transfers by exploiting the unique characteristics of these networks. Throughout the paper, we have outlined the unique challenges introduced by applications of network coding in wired networks, and how CodedBulk overcomes these challenges. Our design can be applied to any of the applications where network coding is useful.

Network code construction algorithms. Early incarnations of network coding solutions used a technique referred to as random linear network coding [9, 22]. These random linear network codes have the benefit of being independent of the network topology. However, they have high implementation cost: they require complex operations at intermediate nodes (due to computations over large finite field sizes and due to requiring additional packet header processing). In addition, realizing random linear network codes in practice also requires changes in packet header format. Follow-up research has led to efficient construction of network codes [24]—for a bulk transfer to T destinations, it suffices for intermediate nodes to perform computations over a finite field of size at most $2|T|$; if the min-cut is h, the complexity of computations at the source and at the destination are $O(h)$ and $O(h^2)$, respectively. In §4.1, we discussed how at the inter-datacenter WAN scale, these computations entail simple and efficient byte-level XOR operations. Furthermore, these codes can be realized without any changes in the packet header format. CodedBulk, thus, uses the network code construction algorithm of [24].

6 Conclusion

We have presented the design, implementation and evaluation of CodedBulk, an end-to-end system for high-throughput inter-datacenter bulk transfers. CodedBulk uses network coding, a technique that guarantees optimal throughput for individual bulk transfers. To achieve this, CodedBulk resolves the many pragmatic and fundamental barriers faced in the past in realizing the benefits of network coding in wired networks. Using an end-to-end implementation of CodedBulk over a geo-distributed inter-datacenter network testbed, we have shown that CodedBulk improves throughput for inter-datacenter bulk transfers by $1.2-2.5\times$ when compared to state-of-the-art mechanisms that do not perform coding.

Acknowledgments

We would like to thank our shepherd Keith Winstein, anonymous NSDI reviewers, Rashmi Vinayak and Robert Kleinberg for their insightful feedback. We would also like to thank the students in Cornell graduate computer networking class (CS6450) for many helpful discussions during the early parts of this project. This work was supported in part by a Google PhD fellowship, NSF 1704742, ONR N00014-17-1-2419, and gifts from Snowflake and Cornell-Princeton Network Programming Initiative.

Abstract

Core-Stateless Fair Queueing (CSFQ) is a scalable algorithm proposed more than two decades ago to achieve fair queueing without keeping per-flow state in the network. Unfortunately, CSFQ did not take off, in part because it required protocol changes (i.e., adding new fields to the packet header), and hardware support to process packets at line rate.

In this paper, we argue that two emerging trends are making CSFQ relevant again: (i) cloud computing which makes it feasible to change the protocol within the same datacenter or across datacenters owned by the same provider, and (ii) programmable switches which can implement sophisticated packet processing at line rate. To this end, we present the first realization of CSFQ using programmable switches. In addition, we generalize CSFQ to a multi-level hierarchy, which naturally captures the traffic in today's datacenters, e.g., tenants at the first level and flows of each tenant at the second level of the hierarchy. We call this scheduler Hierarchical Core-Stateless Fair Queueing (HCSFQ), and show that it is able to accurately approximate hierarchical fair queueing. HCSFQ is highly scalable: it uses just a single FIFO queue, does not perform per-packet scheduling, and only needs to maintain state for the interior nodes of the hierarchy. We present analytical results to prove the lower bounds of HCSFQ. Our testbed experiments and large-scale simulations show that CSFQ and HCSFQ can provide fair bandwidth allocation and ensure isolation.

1 Introduction

Fair queueing is a canonical mechanism to provide fair bandwidth allocation to network traffic by ensuring that each flow gets its fair share irrespective of the other flows. This way, fair queueing enforces isolation between competing flows, which ensures that normal flows are protected from ill-behaving flows. There is a long history of research on fair queueing [1–12]. Many of the proposed solutions require to maintain per-flow state in the switch, and rely on complex data structures and scheduling algorithms to realize fair queueing.

Core-Stateless Fair Queueing (CSFQ) [13] is a scalable algorithm to realize fair queueing. Compared to the alternatives, CSFQ has the unique property that it does not maintain per-flow state in the network. With CSFQ, the sources or switches at the edge classify traffic into flows and estimate per-flow rate. In turn, the switches in the network estimate the fair rate, and use probabilistic dropping to regulate each flow to its fair rate without maintaining per-flow state.

While CSFQ was proposed more than twenty years ago, it has not taken off. This is primarily due to two reasons. First, it requires changes to the IP protocol (i.e., adding a field to the IP header) and coordination across all switches (routers) in the network. Second, CSFQ requires switches to estimate the fair rate, compute a drop probability, and update the header of each packet. To perform these operations at line rate we need hardware support. These challenges are exacerbated by the fact that routers belong to different, often competing, Internet Service Provides (ISPs), which would all need to cooperate to upgrade their infrastructures to support CSFQ.

However, two emerging technologies are making CSFQ relevant again: (i) the advent of cloud computing and (ii) the increased popularity of programmable switches. Cloud providers own large datacenters consisting of many thousands of servers. Since a datacenter is typically owned by a single administrative entity (cloud provider) that controls both the software and hardware, it is relatively easy for a cloud provider to upgrade all its switches and servers to support CSFQ. FairCloud [14] proposes to apply CSFQ for network isolation in datacenters, but it does not have a hardware implementation for CSFQ. The emergence of programmable switches makes it possible to implement sophisticated packet processing at line rate. In particular, as we will show in this paper, existing programmable switches are powerful enough to support CSFQ at line rate.

While datacenter deployment removes the adoption barriers for CSFQ, it also raises new challenges. In particular, while CSFQ has been designed for a flat hierarchy, the traffic in today's datacenters is naturally structured in a multi-level hierarchy. For example, at the top level we typically have tenants and at the bottom level we have the flows of those tenants. The mechanism of choice to manage such traffic is hierarchical fair queueing [9,10,15], where each non-leaf node distributes its excess bandwidth (i.e., the bandwidths unused by some of its children) across its children. This allocation policy is consistent with a per-tenant payment granularity, i.e., network resources are divided between tenants in proportion to their payments [14]. In this case, if a flow of a tenant stops sending data, that tenant would want to re-allocate the flow's bandwidth to its other flows, and not to the flows of other tenants in the datacenter.

However, implementing hierarchical fair queueing is challenging. Existing solutions require per-flow state, and more importantly, require complex queue management and packet transfers in a hierarchy of queues [9, 10, 15]. Because of the implementation complexity, hierarchical fair queueing is not supported by today's high-speed hardware switches.

To address this challenge, we propose Hierarchical Core-Stateless Fair Queueing (HCSFQ). CSFQ only provides fair queueing, not hierarchical fair queueing. Directly extending CSFQ to support hierarchical fair queueing would require a hierarchy of queues. HCSFQ is able to accurately approximate hierarchical fair queueing and it is highly scalable. The key difference of our approach is that HCSFQ requires only a *single* queue, not a hierarchy of queues. HCSFQ also requires *no* packet scheduling. HCSFQ recursively computes the fair rate of each node starting from the root, and then limits the rate of each flow to its fair share rate. To the best of our knowledge, HCSFQ is the *first* solution that enables hierarchical fair queueing on commodity hardware at line rate while requiring neither per-flow state nor hierarchical queue management.

An important distinction of HCSFQ from CSFQ is that HCSFQ keeps the state of the interior nodes of the hierarchy in the switch. The state of the interior nodes is necessary to support hierarchical fair queueing, as the fair share rates of distinct interior nodes are typically *different*. The excess bandwidth of a flow is *only* shared with its *sibling* flows. That is, if a flow changes its sending rate, it would impact the fair rate of the sibling flows, but not necessarily of other flows in the hierarchy. Note that similar to CSFQ, HCSFQ does not maintain *per-flow* state (i.e., the state of the leaf nodes). Fortunately, for today's multi-tenant clouds, the number of tenants is orders of magnitude smaller than the number of flows, and commodity switches have sufficient on-chip memory to maintain the state for these interior nodes.

We exploit the capability of programmable switching to provide the first realization of CSFQ and HCSFQ on commodity hardware. While conceptually simple, implementing these schedulers on a programmable switch raises several technical challenges. First, they use a complex formula to estimate the rates, which includes several floating-point multiplication, divisions and exponentiation operations. Unfortunately, these operations are not supported by today's programmable switches. To get around this challenge, we leverage high-precision timestamps and a window-based mechanism to estimate these rates. Second, these algorithms rely on probabilistic packet dropping to limit the flows to their fair rates. Unfortunately, probabilistic packet dropping cannot be directly implemented in these switches. We discretize the probability computation to approximate the dropping probability with bounded error. To discretize these probabilities we leverage the switch's random number generator and take advantage of multiple stages. Third, computing the fair rate exhibits a circular dependency. Unfortunately, the switch data plane consists of a multi-stage processing pipeline, and the later stages cannot modify the state in the previous stages. To address it, we judiciously use packet recirculation, and periodically update the fair rate to minimize recirculation overhead.

In summary, we make the following contributions.

- We extend CSFQ to HCSFQ, the first scalable, practical solution to implement hierarchical fair queueing on commodity hardware at line rate with no per-flow state and no hierarchical queue management.
- We exploit the capability of programmable switching ASICs to provide the first data plane design for CSFQ and HCSFQ.
- We implement a prototype of CSFQ and HCSFQ on a Barefoot Tofino Wedge 100BF-65X switch. Our experiments show that CSFQ and HCSFQ can provide fair bandwidth allocation and ensure isolation.

2 Background and Motivation

Our work is motivated by the need for network isolation in multi-tenant datacenters. CSFQ is a scalable solution for fair queueing. We review the background of CSFQ, and identify the opportunities for CSFQ in modern datacenters.

2.1 Core-Stateless Fair Queueing

Fair queueing provides max-min fairness for competing flows. A max-min fair bandwidth allocation is one that any increase of the allocation to some flows would necessarily decrease the allocation of some other flows. The basic way to realize fair queueing in a switch is to keep one queue for each flow and use a scheduling algorithm to pick which queue to dequeue a packet each time. There has been decades of research on fair queueing [1–12]. While we leave the extensive discussion to related work (§7), we emphasize that most solutions are not scalable because of the need to maintain *per-flow* state to classify flows and shape their rates with per-flow queues and complex queue management. As a result, commodity switches only support 10–20 queues.

CSFQ is a *scalable* algorithm to achieve fair queueing with a unique property that it does *not* maintain per-flow state in the network. Figure 1 shows the architecture of CSFQ. CSFQ divides the network into edge and core. The switches

Figure 2: Fair queueing and hierarchical fair queueing.

or hosts at the edge, which do maintain per-flow state, use per-flow state to classify packets into flows and estimate per-flow arrival rate. Then the arrival rate of each flow is *carried* in a custom packet *header*. The switches in the core only estimate the *total* arrival rate of all flows, and then use it to estimate the *fair share rate* with an iterative algorithm. The switches compare the per-flow arrival rate in the packet header with the fair share rate to compute a drop probability, and drop packets to shape the rate of each flow to the fair share rate.

The key benefit of CSFQ is that the complexity (packet classification and flow rate estimation with per-flow state) is moved to the edge, making the core extremely simple. A core switch only maintains the state for *aggregate* variables (total arrival rate, total accepted rate and fair share rate), and only uses *one* queue for packet buffering. More importantly, the complexity of a core switch does *not* change with the number of flows, making the core scale-free.

2.2 Opportunities

CSFQ did not take off because it requires cooperation between ISPs to provide end-to-end isolation for Internet flows, and requires protocol and hardware changes. After twenty years, we believe the time for CSFQ has come because of two opportunities.

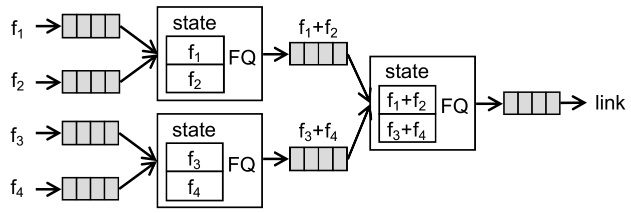
The first opportunity is from cloud computing. Cloud computing has become the fundamental infrastructure of today's Internet. Datacenters power large-scale Internet services we use everyday such as search, social networking and e-commerce, and enterprises are increasingly moving their workloads to the cloud. Fair bandwidth allocation and network isolation for datacenter networks is an important problem [14, 16–28]. While there has been many fair queueing algorithms proposed in the past [1–12], they are rarely deployed in practice because they need to maintain per-flow state in switches but switches can only support 10–20 queues. CSFQ provides a scalable solution to address this problem. Datacenter operators control the entire infrastructure, including both software and hardware. Adopting CSFQ to enforce isolation for datacenter networks naturally eliminates the need of cooperation between different operators or ISPs, as a datacenter network is under a single administrative domain.

The second opportunity is from programmable switching ASICs. Traditional switching ASICs are fixed-function, and adding a new feature like CSFQ requires switch vendors to design a new ASIC. Emerging programmable switching ASICs, such as Barefoot Tofino [29], Broadcom Trident 4 [30] and Cavium XPliant [31], allow users to program the data plane and develop new features. Specifically, to implement CSFQ on a programmable switch, we can program the parser to parse the custom header of CSFQ (to carry per-flow rate), program the match-action tables to implement the CSFQ algorithm, and program the on-chip memory to store the aggregate state. Because a datacenter network is under a single administrative domain, it is easy for the operator to adopt the protocol and hardware changes with programmable switching ASICs.

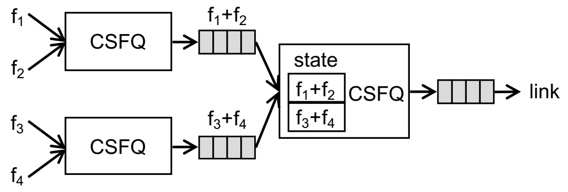
3 Hierarchical Fair Queueing

A multi-tenant cloud has a natural two-layer hierarchy, with the tenants at the first layer and the flows of each tenant at the second layer. Network isolation for multi-tenant datacenters naturally requires hierarchical fair queueing. CSFQ only supports fair queueing, but not hierarchical fair queueing. Hierarchical fair queueing provides fair queueing in a hierarchical manner. Flows are grouped into flow aggregates in multiple layers. The root of the tree includes all the flows. Each node in the tree includes a subset of the flows, called a *flow aggregate*, and fairly allocates its bandwidth to its child nodes. This is done recursively until leaf nodes, each of which contains one flow. The flows are broadly defined, e.g., based on five-tuple or network management considerations. In the case of multi-tenant clouds, it is a two-layer bandwidth allocation. The bandwidth is first allocated to the tenants in the first layer, and then each tenant allocates its bandwidth to its own flows in the second layer.

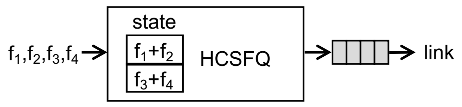
Fair queueing allocates bandwidth fairly to competing flows, and is work conserving, i.e., unused bandwidth share of a flow can be allocated to other flows. The key benefit of hierarchical fair queueing is that it allows unused share of a flow to be allocated to other flows in the same flow aggregate, instead of being shared by all the flows. Fair queueing can be considered as a special case of hierarchical fair queueing that contains only one layer. Two-layer fair queueing for multi-tenant clouds is desirable because the payment is based on



(a) Traditional design of hierarchical fair queueing.



(b) Naive design to extend CSFQ for hierarchical fair queueing.



(c) HCSFQ design.

Figure 3: Comparison of traditional hierarchical fair queueing design, naive design to extend CSFQ, and HCSFQ design.

per tenant. A tenant would want to share its bandwidth only between its own flows, as long as it has sufficient demand.

Example. We use an example in Figure 2 to contrast hierarchical fair queueing with fair queueing. There are four flows, i.e., f_1, f_2, f_3, and f_4. The arrival rates of the four flows are 1, 4, 5, and 5, respectively. The link capacity is 10. With only fair queueing, the unused share of f_1 is evenly allocated to all other three flows. As shown in Figure 2(a), the bandwidth allocation to the four flows is (1, 3, 3, 3). Suppose that f_1 and f_2 are in one flow aggregate (A_1), and f_3 and f_4 are in the other (A_2). With hierarchical fair queueing, the unused fair share of f_1 is only allocated to f_2, instead of also being shared by f_3 and f_4. Figure 2(b) shows the bandwidth allocation with two-layer hierarchical fair queueing, where the flows receive 1, 4, 2.5, and 2.5, respectively.

Challenge. Hierarchical fair queueing is known to be challenging to realize in switches at high speed. A traditional design to support hierarchical fair queueing is to leverage a hierarchy of queues, and each node in the hierarchy implements fair queueing for the queues of its child nodes. Figure 3(a) shows an example of such a design to support the two-layer hierarchy in Figure 2(b). This design has two major problems. First, the amount of state and the number of queues needed by this design is proportional to the number of nodes in the hierarchy. It needs to maintain per-flow state and the state of each interior node in the tree. Second, the design involves complex queue management with a hierarchy of queues, as packets need to be moved between queues in different layers. CSFQ does not require maintaining per-flow state, but naively extending CSFQ to support hierarchical fair queueing would still require a hierarchy of queues as shown in Figure 3(b). These two factors together make the design hard to scale to support a large number of flows. As a result, hierarchical fair queueing is not supported by today's high-speed switches.

4 HCSFQ Design

We propose Hierarchical Core-Stateless Fair Queueing (HCSFQ), which generalizes CSFQ to support hierarchical fair queueing. HCSFQ is the first scalable solution that enables hierarchical fair queueing on commodity hardware at line rate without per-flow state and complex hierarchical queue management.

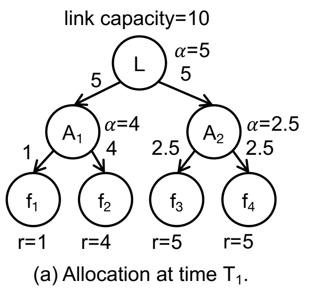
We give a high-level overview of HCSFQ in Figure 3(c). In contrast to the traditional design in Figure 3(a), HCSFQ has two unique properties: (i) it does not maintain per-flow state, but only keeps the state of interior nodes; (ii) it does not require a hierarchy of queues, but only uses one queue. These two properties together dramatically simplify the design, making HCSFQ amenable to be implemented on high-speed switches under strict timing and resource constraints.

The major distinction between HCSFQ and CSFQ is that HCSFQ needs to maintain the state of interior nodes. This is necessary because HCSFQ aims to provide hierarchical fair bandwidth allocation for a flow hierarchy. Note that the naive design of extending CSFQ in Figure 3(b) also requires maintaining the state of interior nodes. In fair queueing, CSFQ only requires to keep one fair share rate, which is the same for *all* flows. But in hierarchical fair queueing, the fair share rates for different flows can be *different* if two flows are not siblings (i.e., do not have the same parent node). If a flow changes its rate, it would affect the fair share rate of its sibling flows, but not necessarily those of non-sibling flows. Figure 4 illustrates this with a concrete example. There is a two-layer hierarchy with four flows. At time T_1, the arrival rates for the four flows are 1, 4, 5, and 5 (the same as Figure 2). The fair share rate at L is 5, and those at A_1 and A_2 are 4 and 2.5. Then at time T_2, f_1 increases its arrival rate from 1 to 2. Then under fair bandwidth allocation, the new fair share rate for the subtree under A_1 becomes 3, so that f_1 receives 2 and f_2 receives 3. The rate change of f_1, however, does not effect the fair share rate for f_3 and f_4. This is because f_3 and f_4 are not sibling nodes of f_1.

CSFQ can be considered as a special case of HCSFQ which contains only one layer, and as such, it only carries the state for one interior node—the root.

4.1 Fluid Model

We first use a fluid model to formalize hierarchical fair queueing. The fluid model considers a switch with output link capacity C, and the flows are modeled as a continuous stream of bits. The flow hierarchy is represented as a directed graph $G(V,E)$, where V is the set of nodes and E is the set of edges.



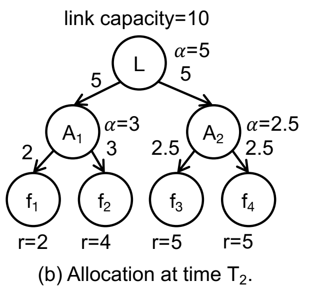


Figure 4: The flow arrival rates change from T_1 to T_2. It is necessary for the switch to keep the state for the interior nodes of the hierarchy in order to realize hierarchical fair queueing.

A node $v \in V$ represents a flow aggregate (i.e., a set of flows), where $r(v)$ is the arrival rate of the flow aggregate and $c(v)$ is the capacity allocated to v. A directed edge $e(v,u) \in E$ represents that u is a child of v.

Max-min fair bandwidth allocation ensures that the flows that are bottlenecked by a link receives the same output rate, which we call the fair share rate. Let $\alpha(v)$ be the fair share rate that node v allocates to its children. If max-min fair bandwidth allocation is achieved, for a child node u of node v, the flow aggregate at u receives a bandwidth allocation of $c(u) = min(r(u), \alpha(v))$. The arrival rate of v is the sum of the arrival rates of its children, i.e., $r(v) = \sum_{e(v,u)\in E} r(u)$. If $r(v) > c(v)$, the arrival rate of v exceeds the capacity allocated to v, and the fair rate $\alpha(v)$ is the unique solution to

$$c(v) = \sum_{e(v,u)\in E} \min(\alpha(v), r(u)). \tag{1}$$

If $r(v) \le c(v)$, the arrival rate of v is no more than the capacity allocated to v, and all flows in v can be forwarded without dropping packets. In this case, by convention we have

$$\alpha(v) = \max_{e(v,u)\in E} r(u). \tag{2}$$

The fair rate computation is done recursively from the root to the leaf nodes. When v is the root, we have $c(v) = C$, where C is the link capacity. Then starting from the root, we can compute $c(v)$ and $\alpha(v)$ for each node in the tree.

Based on this fluid model, there is a simple algorithm to achieve max-min fair bandwidth allocation. In this algorithm, we first use the recursive computation to compute $\alpha(v.parent)$ for each leaf node v, which is the fair share rate allocated by v's parent to v. If $r(v) \le \alpha(v.parent)$, then no bits need to be dropped; otherwise, a fraction of $(r(v) - \alpha(v.parent))/r(v)$ need to be dropped. Therefore, achieve max-min fair bandwidth allocation, each incoming bit of the flow in v is dropped by probability

$$\max(0, 1 - \frac{\alpha(v.parent)}{r(v)}). \tag{3}$$

4.2 HCSFQ Algorithm

The HCSFQ algorithm realizes the conceptual fluid algorithm in a real switch. Similar to CSFQ, HCSFQ does not maintain per-flow state, and only requires a single FIFO queue for packet buffering (Figure 3). The algorithm relies on two building blocks from CSFQ, which are arrival rate estimation and fair share rate estimation, and applies them recursively to compute the fair share rate for each leaf node.

Arrival rate estimation. The arrival rate estimation is used to estimate the arrival rate of a flow aggregate for a node in the hierarchy. Like CSFQ, it uses the canonical exponential averaging mechanism in networking for rate estimation. Let t_i and l_i be the arrival time and length of the i^{th} packet of the flow aggregate in node v. We use $r(v)$ to denote the estimated arrival rate of v. It is updated each time a new packet of v arrives, based on the following equation,

$$r(v)_{new} = (1 - e^{T_i/K})\frac{l_i}{T_i} + e^{T_i/K} r(v)_{old}, \tag{4}$$

where $T_i = t_i - t_{i-1}$ and K is a constant.

Fair share rate estimation. The fair share rate estimation is used to estimate the fair share rate that a node allocates to its children. The capacity of node v is $c(v)$. Eq.(4) gives the arrival rate of the node $r(v)$. If $r(v) \le c(v)$, then $\alpha(v)$ is calculated using Eq.(2). Otherwise, $\alpha(v)$ should be the unique solution to Eq.(1). We apply the iterative algorithm in CSFQ to approximately solve the equation. Specifically, for each node v, we maintain the accepted rate estimation $f(v)$, which is updated with Eq.(4) if the packet is not dropped. Then, $\alpha(v)$ is approximately computed with the following formula,

$$\alpha(v)_{new} = \alpha(v)_{old}\frac{c(v)}{f(v)}. \tag{5}$$

Note that the computation of $\alpha(v)$ is iterative. It converges to the solution of Eq.(1) after several iterations, i.e., processing several packets. Similar to CSFQ, HCSFQ also uses a window of size K_c to account for inaccuracies introduced by exponential averaging in rate estimation. That is, $\alpha(v)$ is updated only if the node is congested ($r(v) > c(v)$) or uncongested ($r(v) \le c(v)$) for an interval of length K_c.

Packet state. A packet *pkt* carries two pieces of state in the packet header, which are *pkt.r* and *pkt.nodes*.

- *pkt.r* is the arrival rate estimate of the flow the packet belongs to.
- *pkt.nodes* is a list of node IDs that indicate the flow aggregates the packet belongs to in the flow hierarchy, excluding the leaf. For example, in Figure 2, if a packet *pkt* belongs to f_1 or f_2, then $pkt.nodes = [L, A_1]$.

CSFQ only carries *pkt.r* in the packet header as there is no flow hierarchy. HCSFQ additionally carries *pkt.nodes* to track the set of flow aggregates the packet belongs to in the hierarchy. Similar to CSFQ, both *pkt.r* and *pkt.nodes* are

Algorithm 1 HCSFQ(pkt)

```
1:  $cur\_\alpha \leftarrow 0$
2:  for $v \in pkt.nodes$ do
        // estimate arrival rate
3:      $r[v] \leftarrow estimate\_rate(pkt)$
4:      $cur\_\alpha \leftarrow \alpha[v]$
    // calculate drop probability
5:  $prob \leftarrow max(0, 1 - cur\_\alpha/pkt.r)$
6:  if $prob > rand(0,1)$ then
7:      $drop\_flag \leftarrow TRUE$
8:  for $v \in pkt.nodes$ do
        // estimate accepted rate
9:      if $drop\_flag$ is $False$ then
10:         $f[v] \leftarrow estimate\_rate(pkt)$
        // allocate bandwidth
11:     if $v$ is root then
12:         $c[v] \leftarrow$ link capacity
13:     else
14:         $c[v] \leftarrow min(\alpha[v.parent], r[v])$
        // update fair share rate
15:     if $r[v] > c[v]$ then
16:         if $congest\_flag[v]$ is $FALSE$ then
17:             $congest\_flag[v] \leftarrow TRUE$
18:             $start\_time \leftarrow current\_time$
19:         else if $current\_time - start\_time > K_c$ then
20:             $\alpha[v] \leftarrow \alpha[v] \cdot c[v]/f[v]$
21:             $start\_time \leftarrow current\_time$
22:     else
23:         if $congest\_flag[v]$ is $TRUE$ then
24:             $congest\_flag[v] \leftarrow FALSE$
25:             $start\_time \leftarrow current\_time$
26:             $tmp\_\alpha[v] \leftarrow 0$
27:         else if $current\_time - start\_time \le K_c$ then
28:             $child\_r \leftarrow v.next = NULL\ ?\ pkt.r : r[v.next]$
29:             $tmp\_\alpha[v] \leftarrow max(tmp\_\alpha[v], child\_r)$
30:         else
31:             $\alpha[v] \leftarrow tmp\_\alpha[v]$
32:             $start\_time \leftarrow current\_time$
33:             $tmp\_\alpha[v] \leftarrow 0$
34:     $cur\_\alpha \leftarrow \alpha[v]$
    // drop or enqueue pkt
35: if $drop\_flag$ then
36:     $drop(pkt)$
37: else
38:     $enqueue(pkt)$
    // update the packet rate
39: $pkt.r \leftarrow min(cur\_\alpha, pkt.r)$
```

inserted at the edge. An edge switch (e.g., a software switch, a NIC or a ToR switch in datacenter networks) performs packet classification to get $pkt.nodes$, and uses Eq.(4) to estimate the flow rate $pkt.r$. Both $pkt.r$ and $pkt.nodes$ are transparent to end hosts and are removed by the switch at the last hop.

Hierarchical computation. The main difference between HCSFQ and CSFQ is that HCSFQ performs fair share rate estimation *recursively* in a hierarchical manner. In CSFQ, the arrival rate estimation for each flow is done at the edge, and a core switch only estimates the total arrival rate. In HCSFQ, because there is a hierarchy of flow aggregates, a core switch additionally estimates the arrival rate for each flow aggregate (i.e., the internal nodes in the tree). Similarly, in CSFQ, a core switch only calculates a fair share rate for the link, while in HCSFQ, a core switch additionally calculates a fair share rate for each flow aggregate. Importantly, the fair share rate estimation in HCSFQ is used to *bridge* the computation of different layers together. That is, for node v, the allocated bandwidth $c(v)$ is used to estimate the fair share rate $\alpha(v)$, which is then used to compute the allocated bandwidth of its children, i.e., $c(u)$ for $u \in v.children$, in the next layer.

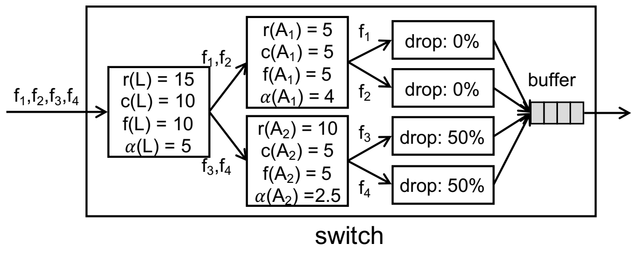

Figure 5: Example of the HCSFQ algorithm to provide hierarchical fair queueing for the scenario in Figure 2(b).

Algorithm 1 shows the pseudo code of the HCSFQ algorithm. When a packet pkt arrives at the switch, the switch updates the arrival rate estimate for each flow aggregate the packet belongs to using Eq.(4), and gets the fair share rate of the flow (line 1-4). Then the switch computes the dropping probability based on Eq.(3) and decides whether to drop the packet (line 5-7). After this, the switch recursively updates the fair share rate of each flow aggregate in the hierarchy (line 8-34). Based on whether the packet is dropped, the switch updates the accepted rate estimate for each flow aggregate (line 9-10). If node v is the root, then all flows are under this node, and its allocated capacity is the link capacity (line 11-12); otherwise, its allocated capacity is the max of the fair share rate allocated by its parent and its arrival rate (line 13-14). If the arrival rate of v is bigger than its allocated capacity, then the node is congested, and the fair share rate is updated based on Eq.(5) (15-21); otherwise, the fair share rate is the max arrival rate of its children, i.e., based on Eq.(2) (line 22-33). Note that we use a window of length K_c for fair share update to account for inaccuracies in rate estimation. Based on the dropping decision, the switch drops or enqueues the packet (line 35-38). Finally, the arrival rate $pkt.r$ is updated and will be used by the next-hop switch (line 39). Note that the loops (line 2-4 and line 8-34) are done in one pass and the fair share rate is updated based on $c[v.parent]$ from the last round.

Figure 5 illustrates how the algorithm works to realize hierarchical fair queueing for the example in Figure 2. At the root, the total arrival rate of all flows $r(L)$ is 15, and the capacity $c(L)$ is the link capacity 10, which is below the arrival rate. The root fairly allocates the capacity to the two flow aggregates, A_1 and A_2. The figure shows the stable state when the accepted rates and fair share rates of all the nodes have converged. After convergence, the accepted rate $f(L)$ is 10, and the fair share rate $\alpha(L)$ is 5. At node A_1, the arrival rate $r(A_1)$, which is the sum of $r(f_1)$ and $r(f_2)$, is 5, and the allocated capacity $c(A_1)$ is 5. The fair share rate is set as 4, and there is no need to drop packets for f_1 and f_2. At node A_2, the arrival rate $r(A_2)$, which is 10, is bigger than the allocated capacity, which is 5. A_2 allocates its capacity to f_3 and f_4 fairly. Each receives a fair share rate of 2.5. So the switch drops 50% of the packets for both f_3 and f_4.

Weighted HCSFQ. The HCSFQ algorithm can be extended to support flows and flow aggregates with weights. For node v, we use $w(v)$ to represent the weight of the flow or flow aggregate of v. Under max-min fair bandwidth allocation, competing flows or flow aggregates at the bottlenecked link have the same fair share rate $r(v)/w(v)$. There are two changes to the algorithm in order to incorporate the weight. The first change is on the equation to compute the fair rate $\alpha(v)$ when $r(v) > c(v)$. Eq.(1) is changed to

$$c(v) = \sum_{e(v,u)\in E} w(u) \cdot min(\alpha(v), \frac{r(u)}{w(u)}). \tag{6}$$

The second change is on the equation to compute the drop probability. Eq.(3) is changed to

$$\max(0, 1 - \alpha(v.parent) \cdot \frac{w(v)}{r(v)}). \tag{7}$$

4.3 Theoretical Guarantee

We have the following theorem to provide the theoretical guarantees for HCSFQ. The proof of the theorem is in Appendix.

Theorem 1. *Consider a link with a hierarchical fair queueing policy and a flow in the hierarchy. Let w_1, w_2, ..., w_n be the weights of the nodes from the root to the flow. Let α_1, α_2, ..., α_n be the constant normalized fair rate of the nodes from the root to the flow. Let $r_{\alpha_i} = \alpha_i w_i$. If probabilistic dropping is applied at the last layer, then the excess service received by the flow that sends at a rate at no larger than R, is bounded above by*

$$r_{\alpha_n} K(1 + ln\frac{R}{r_{\alpha_n}}) + l_{max} \tag{8}$$

where l_{max} is the maximum packet length.

Consider a parent and its children in the hierarchy. Let the number of children be k. Let $r_{\alpha'}$ be the weighted fair rate of the parent, and $r_\alpha^{(j)}$ be the weighted fair rate of the j-th child. Suppose the inter-arrival time of every packet is at least τ, and

$$r_{\alpha'} \geq \frac{1}{1 - e^{-\tau/K}} \sum_{j=1}^{k} r_\alpha^{(j)}.$$

The the parent node does not drop packets.

Remark. The first conclusion bounds the excess service that can be received by a flow. The second conclusion provides the theoretical condition for only performing probabilistic dropping at the leaf node.

5 Data Plane Design and Implementation

In this section, we describe a data plane design to implement CSFQ and HCSFQ on new-generation programmable switches. Programmable switches enable users to program the multi-stage match-action pipeline in the switch data plane to implement custom features. Users can also access the on-chip memory and implement stateful operations using the register arrays provided by programmable switches. Programmable switches also support a set of primitive actions (e.g., recirculate, bit shift, add and subtract) which make HCSFQ possible. Based on the constructs of programmable switches, we show how to design and implement the rate estimation, the fair rate computation and the flow shaping logic (i.e., Algorithm 1) on programmable switches. Our HCSFQ implementation contains 1952 lines of code in P4 and is compiled to Barefoot Tofino ASIC [29]. The code is open-source and available at `https://github.com/netx-repo/HCSFQ`.

5.1 Single Layer

We first describe how to implement CSFQ, i.e., single-layer HCSFQ, which is used as a building block to implement multi-layer HCSFQ. There are three challenges to implement single-layer HCSFQ on programmable switches: rate estimation, probabilistic drop, and fair rate update. We describe each challenge and its solution as follows.

Rate estimation. The switch needs to estimate two rates: the total arrival rate r, and the accepted rate f. Both rates are estimated with Eq.(4). Because switches have strict timing and resource requirements, an action in a match-action table can only contain a small number of operations in a limited operation set. The equation cannot be directly implemented in the switch data plane due to two reasons. First, the equation involves several multiplication, division and exponentiation operations on floating points. These operations are quite complex and require multiple clock cycles to compute. As such, they are not typically supported by the switch data plane. Second, a rate (r or f) is stored in a register of the on-chip memory. To update the rate, the switch needs to read the rate from the register, uses the equation to calculate the new rate, and then updates the register. A register can only be accessed by its own stage, but the equation includes multiple arithmetic operations, which requires multiple stages to compute.

We leverage the high-precision timestamps available in the data plane, and use a window-based mechanism to estimate the rates. Programmable switches are able to provide high-precision timestamps at the granularity of one nanosecond. To estimate a rate, the switch maintains a pair of registers ($reg.byte$ and $reg.start$). One register ($reg.byte$) stores the total bytes of packets the switch has received in the current window. The other register ($reg.start$) stores the start timestamp of the current window. For each incoming packet, the switch first checks the current timestamp and compares it with *reg.start* to see if the packet belongs to the current window. If so, the switch adds the size of the packet to *reg.byte*; otherwise, the switch clears *reg.byte* and sets *reg.start* to the current timestamp. The switch keeps another register *reg.rate* to store the current rate estimate. When a window is passed, the switch uses *reg.byte* to update *reg.rate*, which can be done with either a direct assignment, or a moving average. Our experiments indicate that using a moving average (implemented with several bit shift and addition operations) works better and avoids oscillation with the control loop that updates the fair share rate and drops packets.

The key benefit of this window-based mechanism is that because the switch can provide nanosecond-granularity timestamps, we can use a small window size to accurately estimate flow rate and capture sudden packet bursts. It is important to note that the rate estimation is local to the switch and only uses timestamps to divide time into windows. So there is no need for time synchronization between switches.

Probabilistic drop. Probabilistic drop is used to regulate the flows to the fair share rate. The switch uses the fair share rate α and the flow arrival rate r to compute the probability to drop packets of the flow (Eq.(3) and line 5 in Algorithm 1). Then the switch checks the condition $max(0, 1-\alpha/r) > rand(0,1)$ to decide whether to drop an incoming packet or not. Similar to rate estimation, the challenge is that switches do not support the division operation to compute the probability. One way to solve the problem is to use a similar window-based mechanism as rate estimation, i.e., divide time into windows with window size δ, and keep counters to allow up to $r\delta$ packets to pass in each window and drop all remaining packets. The drawback of this approach is that it introduces bursty packet drops, which do not work well with congestion control. We want to mimic the behavior of CSFQ to have random packet drops that are uniformly distributed in the packet stream.

We discretize the probability computation to approximate the drop probability with bounded error. We leverage the random number generator provided by the data plane and use multiple stages to realize the discretized computation. Specifically, to check the condition $max(0, 1-\alpha/r) > rand(0,1)$, it is sufficient to check $rand(0,1) > \alpha/r$. We multiply r to both sides of the inequality, and transform the condition to

$$rand(0,r) > \alpha.$$

If the switch can generate a random number between 0 and r, then we can simply compare the generated random number and α to decide whether to drop a packet. However, some switches can only generate a random number in a range of a power of two, i.e., in $[0, 2^n-1]$, where n is a given value at compilation time and cannot be a variable. One possible solution is to use a large value for n at compilation time and use $rand(0, 2^n-1)\%r$ to approximate $rand(0,r)$. But the modulo operation on an arbitrary number may not be supported, and the generated numbers are not uniformly distributed in $[0,r]$. We solve this problem by discretizing the probability computation. We use an integer, instead of a floating point, for the probability. We convert the condition to

$$rand(0, 2^n-1)\cdot r > (2^n-1)\cdot\alpha.$$

While multiplication is not directly supported, we can convert a multiplication operation into several bit shift and addition operations. Since n is small and one stage can do multiple operations, a multiplication can be done in a few stages. This solution introduces errors because the random number is an integer in $[0, 2^n-1]$, instead of a real number in $[0,1]$. However, the error is bounded by $1/2^n$, which reduces exponentially with n. When n is 7, the error introduced by the approximation is bounded by 1/128, which is smaller than 1%.

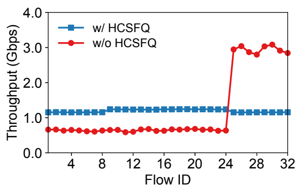
Fair rate update. When the link is congested, the fair share rate is the unique solution to Eq.(1). Because HCSFQ does not maintain per-flow state, it uses $\alpha_{new} = \alpha_{old}c/f$ (Eq.(5)) to approximately compute the fair share rate, where c is the capacity and f is the accepted rate. Like rate estimation and probabilistic drop, Eq.(5) cannot be supported because it contains multiplication and division. What is more challenging is that the fair rate update introduces the following circular dependency to the packet processing.

$$\text{read } \alpha \rightarrow \text{enqueue/drop} \rightarrow \text{update } f \rightarrow \text{update } \alpha$$

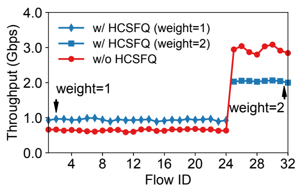
Specifically, the switch needs to read α to compute the drop probability. Then based on whether to enqueue or drop a packet, the switch updates the accepted rate f, which is then used to update α. Because a register can only be accessed by its own stage, the new value of α cannot be used to update the register that stores α in a previous stage.

To address these two problems, we first observe that the update equation $\alpha_{new} = \alpha_{old}c/f$ in HCSFQ is already an approximation, and the correct α is iteratively computed after several updates until f converges to c. As such, we replace the update equation with an additive-increase multiplicative-decrease method, which increases or decreases α each time if f is not equal to c. This ensures that the value for α converges to the correct value. Note that in the original CSFQ, α is also computed iteratively to converge to the correct value.

To address the circular dependency, we leverage packet recirculation available in programmable switches, and let the recirculated packets carry the new value of α to update the register for α in a previous stage. Switches have limited bandwidth for recirculation. We judiciously use packet recirculation to minimize recirculation overhead. We follow the same scheme as CSFQ: update α only when the node is congested or uncongested for a window length of K_c. Given the window size K_c, α is updated by at most $1/K_c$ times per second. As a concrete example, let K_c be 10 μs. Then α is updated by at most 100K times per second, and the amount of recirculation traffic is only a tiny fraction of the switch capacity.



(a) Equal weights.



(b) Different weights.

5.2 Multiple Layers

The single-layer design is used as a building block to support multiple layers. As shown in Algorithm 1 and Figure 5, the processing of HCSFQ on a packet is performed layer by layer, from the root to the leaf node. This well matches the multi-stage packet processing pipeline of programmable switches. The layers in HCSFQ can be mapped to the stages in the pipeline, which naturally processes packets sequentially stage by stage. The major difference between HCSFQ and CSFQ is that HCSFQ needs to store more states as it has multiple layers. CSFQ is a single-layer HCSFQ and only maintains the state for three variables, which are the total arrival rate r, the accepted rate f, and the fair share rate α. Each variable use multiple registers as described in §5.1. HCSFQ maintains the state for all interior nodes, each of which includes the three variables. Commodity switches have 10-100 MB on-chip memory [32], which is able to support a large number of interior nodes. For a two-layer HCSFQ for tenant-level and flow-level isolation in multi-tenant datacenters, a switch needs to maintain per-tenant state, but not per-flow state. With 10-100 MB memory, the switch can support millions of tenants. In terms of the number of layers, our prototype supports up to four layers on Barefoot Tofino. There is no theoretical limit on the number of layers given the scalable algorithm design. The constraints for practical implementations mainly come from the restricted hardware primitives to implement the algorithm as we describe in §5.1. These constraints are not fundamental. Newer programmable switches (e.g., Barefoot Tofino 2) have more stages and provide more hardware primitives to support more layers. Despite this, we expect HCSFQ with 2–4 layers should be sufficient to provide hierarchical isolation for many datacenter scenarios (e.g., multi-tenancy).

6 Evaluation

In this section, we provide experimental results to demonstrate the performance of HCSFQ. We first evaluate the performance of single-layer HCSFQ (i.e., CSFQ), and show that it can provide fair queueing (§6.1). We then evaluate the performance of two-layer HCSFQ, and show that it can provide hierarchical fair queueing to enforce tenant-level and flow-level isolation for multi-tenant datacenters (§6.2). Finally, we use simulations to evaluate HCSFQ in a large-scale datacenter environment and compare it with several alternatives (§6.3).

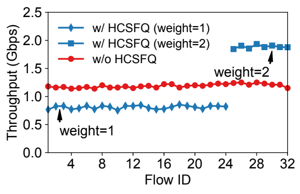
(a) Equal weights.



(b) Different weights.

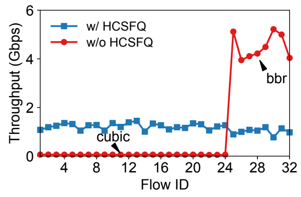
Figure 8: Testbed experiments of fair queueing for TCP.

All testbed experiments are conducted on a hardware testbed with a Barefoot Tofino Wedge 100BF-65X switch. Each server is configured with an 8-core CPU (Intel Xeon E5-2620 @ 2.1GHz), 64GB memory and one 40G NIC (Intel XL710), and runs Ubuntu 16.04.6 LTS with Linux kernel 4.10.0-28-generic. Our switch implementation contains both the edge and core functionalities for HCSFQ. Therefore, our prototype provides hierarchical fair queueing *without* modifications to either the software or hardware of the end hosts. By default, we use TCP Cubic provided by the Linux kernel.

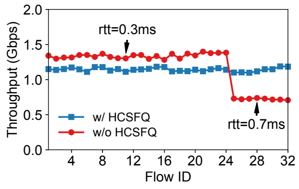
6.1 Fair Queueing Experiments

We first evaluate the capability of HCSFQ to provide fair queueing. Fair queueing requires one-layer HCSFQ. We cover both UDP and TCP traffic with equal or different weights. In the experiments, we use four servers as the senders and one server as the receiver. Each sender sends 8 flows (based on five-tuple), and a total of 32 flows are sent to a receiver. All servers are connected to the switch with 40Gbps links. The bottleneck link is the link between the switch and the receiver.

UDP. If all UDP flows have the same sending rate, they would get similar bandwidth under the tail-drop FIFO queue in the switch. To make the experiment more interesting, we assign different sending rates to the UDP flows. We let 24 flows (Flow 1–24) send at 2Gbps and 8 flows (Flow 25–32) send at 8Gbps. As shown in Figure 6(a), without HCSFQ, Flow 25–32 obtain higher bandwidth than Flow 1–24 because Flow 25–32 have larger sending rates. In comparison, HCSFQ is able to fairly allocate bandwidth to the flows.

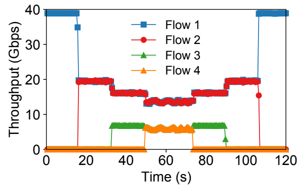


(a) Different TCP algorithms.

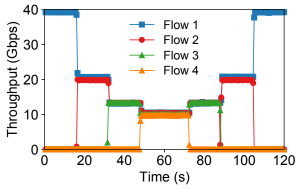


(b) Different RTTs.

Figure 9: Testbed experiments of fair queueing for TCP under different configurations.



(a) Without HCSFQ.



(b) With HCSFQ.

Figure 10: Testbed experiments of UDP convergence. Flow 1 and 2 send at 40Gbps, and Flow 3 and 4 send at 20Gbps.

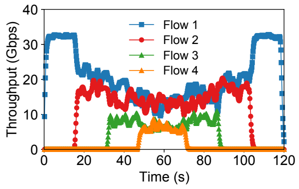
HCSFQ supports weighted fair queueing. We assign weight 1 to Flow 1–24 to and weight 2 to Flow 25–32. As shown in Figure 6(b), without HCSFQ, the result is the same as that with equal weights in Figure 6(a). On the other hand, HCSFQ is able to allocate the bandwidth based on the weights. Flow 25–32 achieve higher throughput than Flow 1–24.

We also evaluate HCSFQ when the UDP flows dynamically change their rates. We let Flow 1 send at a different rate every 2 seconds (10Gbps, 20Gbps, 30Gbps and 40Gbps, respectively) and let Flow 2 keep sending at 20Gbps. Without HCSFQ, when the link is congested (from 4s to 8s), each flow achieves a throughput in proportional to its sending rate. With HCSFQ, two flows get the fair share (20Gbps) when the link is congested.

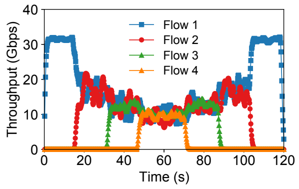
TCP. Figure 8(a) shows the throughput of the flows with and without HCSFQ. Because TCP congestion control provides fair bandwidth allocation, the flows have similar throughput even without HCSFQ. Adding HCSFQ to the switch does not change the bandwidth allocation and thus has a similar result.

However, TCP cannot support weighted fair queueing. To show the benefits of HCSFQ, we let Flow 1–24 have weight 1 and Flow 25–32 have weight 2. Without HCSFQ, the result in Figure 8(b) is similar to that in Figure 8(a). With HCSFQ, the flows get bandwidth in proportional to their weights. The flows with higher weights (Flow 25–32) receive more bandwidth than those with lower weights (Flow 1–24).

Different TCP algorithms. There are many TCP congestion control algorithms. Without in-network enforcement, the flows using aggressive congestion control algorithms would get more bandwidth. In this experiment, we let Flow 1–24 use TCP Cubic (provided by default in Linux) and Flow 25–32

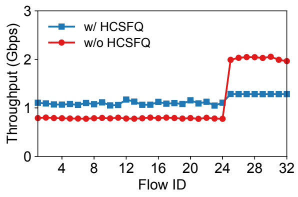


(a) Without HCSFQ.

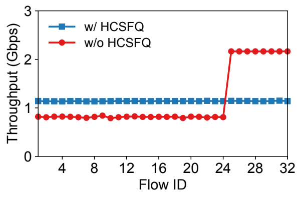


(b) With HCSFQ.

Figure 11: Testbed experiments of TCP convergence. Flow 1 and 2 have 0.3ms RTT, and Flow 3 and 4 have 0.7ms RTT.



(a) Testbed experiment.



(b) Packet-level simulation.

Figure 12: Evaluation result of mixed TCP and UDP traffic.

use TCP BBR. As shown in Figure 9(a), without HCSFQ, because TCP BBR is more aggressive than TCP Cubic, the flows with TCP BBR get almost all the bandwidth. On the other hand, HCSFQ is able to provide fair queueing, regardless of the TCP algorithms they use. We have also tried TCP Reno, which performs similar to TCP Cubic.

Different RTTs. In this experiment, we increase the RTT of Flow 25–32 by 0.4 ms using Linux Traffic Control (Linux tc). The default RTT measured by ping in the testbed, i.e., the RTT of Flow 1–24, is 0.3 ms (mostly host overhead). The TCP throughput is inverse proportional to RTT [33]. In our case, the flows with 0.3 ms RTT (Flow 1–24) should have $0.7/0.3 \approx 2\times$ higher bandwidth than the flows with 0.7 ms RTT (Flow 25–32), which is close to what we see in Figure 9(b). On the other hand, HCSFQ is able to provide fair queueing even when the flows have different RTTs.

Convergence. We let four flows from different clients join and leave a link every 16 seconds to evaluate convergence. Figure 10 shows the UDP result. Flow 1 and 2 send at 40Gbps (using DPDK [34]), and Flow 3 and 4 send 20Gbps. When HCSFQ is enabled, the four flows quickly converge to a similar rate, even though they have different sending rate. Figure 11 shows the TCP result. We set the RTTs of Flow 3 and 4 to 0.7ms using Linux tc, and the RTTs of of Flow 1 and 2 are around 0.3ms by default. With HCSFQ, the four flows quickly converge to a similar rate, regardless of different RTTs.

Mixed UDP and TCP traffic. We evaluate HCSFQ under a mixed workload with both UDP and TCP traffic, and consider the impact of ill-behaved UDP flows on TCP flows. In the experiment, Flow 1–24 are TCP flows, and Flow 25–32 are UDP flows that send at 3.2Gbps. As shown in Figure 12(a), without HCSFQ, because UDP flows are not affected by TCP

Figure 16: Simulation result under the web search workload with injected UDP traffic.

congestion control, Flow 25–32 get 84% higher throughput than their fair share. In comparison, HCSFQ is able to allocate bandwidth fairly between all flows.

Gap between prototype implementation and theoretical algorithm. Although the above experiment demonstrates the effectiveness of HCSFQ on protecting TCP flows from aggressive UDP flows, there is still a small gap from the theoretical upper bound. Figure 12(b) shows the simulation result on the same setup using a packet-level simulator Netbench [35]. In the simulation, the TCP and UDP flows get almost identical throughput with HCSFQ. The reason for the gap between Figure 12(a) and Figure 12(b) is that to realize HCSFQ on a real switch, we make several approximations described in §5. These approximations cause extra jitters for TCP flows, and UDP flows occupy the spare bandwidth caused by the jitters and obtain higher throughput. We believe as programmable switches get more capable, these approximations can be removed to enable more accurate implementation of HCSFQ in the future.

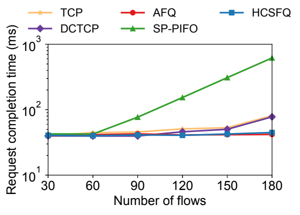
6.2 Hierarchical Fair Queueing Experiments

We now evaluate the capability of HCSFQ to provide hierarchical fair queueing. We show that two-layer HCSFQ can provide tenant-level and flow-level isolation for multi-tenant datacenters. Similar to the previous experiments, we use 4 servers to send a total of 32 flows to a receiver. To evaluate hierarchical fair queueing, we let tenant A contain 24 flows (Flow 1–24) and tenant B contain 8 flows (Flow 25-32).

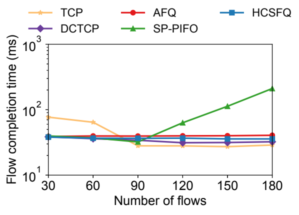
UDP. We set the sending rates of all 32 UDP flows to 8 Gbps. As shown in Figure 13(a), without HCSFQ, the flows have similar throughput. Because tenant A has three times as many flows as tenant B, the total throughput of A is three times as that of B. With HCSFQ, two tenants get the same total throughput. Because A has more flows, each flow in A has lower throughput than that in B.

To evaluate weighted hierarchical fair queueing, we assign different weights to tenant A's flows. We let Flow 1–8 have weight 2 and Flow 9–24 have weight 1. We assign the same weight to tenant A and B. As shown in Figure 13(b), the result without HCSFQ is the same as it in Figure 13(a). All flows receive the same bandwidth, regardless of tenants and weights. With HCSFQ, because the two tenants have the same weight, the bandwidth allocation to the two tenants stays the same. In tenant A, a flow with weight 2 has double throughput as a flow with weight 1. In tenant B, all flows have the same weight, and thus they have the same throughput.

TCP. TCP congestion control does not recognize tenants. Figure 14(a) shows the throughput of 32 TCP flows. Similar to the UDP experiment, without HCSFQ, every flow receives the same amount of bandwidth, and tenant A has higher total throughput. With HCSFQ, the bandwidth is allocated equally to the two tenants, and each flow in A has lower throughput than each flow in B. We also assign weights to the TCP flows as the UDP experiment, and the result is in Figure 14(b). Similarly, with HCSFQ, Flow 1–8 in tenant A have lower throughput than Flow 9–24, because Flow 1–8 lower higher weight. The flows in tenant B have the same throughput because we do not change their weights.



(a) Total request.



(b) Individual flows.

Figure 17: Simulation result under the incast scenario.

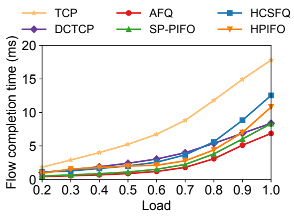
6.3 Large-Scale Simulation

We use simulations to evaluate HCSFQ in a large-scale datacenter environment. The simulations are conducted with a packet-level simulator Netbench [35]. Following the setting in SP-PIFO [12], we use a leaf-spine topology with 144 servers, 9 leaf switches and 4 spine switches, and set the access and leaf-spine links to 1Gbps and 4Gbps, respectively. We compare HCSFQ with TCP, DCTCP, and two state-of-the-art approaches AFQ (32 queues) [11] and SP-PIFO (32 queues) [12]. As in [11, 12], we enable ECN marking and use DCTCP as the transport layer for HCSFQ, AFQ and SP-PIFO.

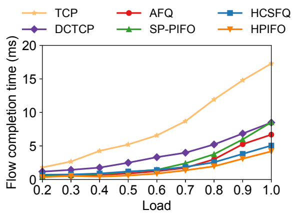
Web search workload. We generate traffic based on the web search workload [36]. Figure 15(a) shows the flow completion time (FCT) for small flows less than 100KB, and Figure 15(b) shows the flow completion time breakdown when the network is at 70% utilization. HCSFQ achieves up to 60% lower FCT than vanilla TCP and DCTCP. AFQ and SP-PIFO are 15% better than HCSFQ on FCT because HCSFQ enforces fairness by packet dropping and cannot provide guarantee for sensitive packets which can be a drawback for datacenter workload. However, the gap is small and does not grow as the traffic load gets larger. The result demonstrates that HCSFQ is compatible with DCTCP, and can provide significant improvement under a representative datacenter topology and workload as the smaller flows can finish faster with a fair share rate.

Web search workload with injected UDP traffic. To evaluate performance isolation, we inject additional ill-behaved UDP flows to the web server workload. The UDP flows are evenly distributed in the topology and occupy about half of the total bandwidth of the network. Figure 16 shows that TCP and DCTCP perform significantly worse than others, because they do not have performance isolation between TCP and UDP flows. HCSFQ performs better than AFQ and SP-PIFO, because AFQ and SP-PIFO map different flows to a small number of queues and aggressive UDP traffic overloads the queues shared by multiple TCP and UDP flows, while HCSFQ drops excessive UDP packets before they enter the queues.

Incast. This experiment evaluates HCSFQ in an incase scenario where a receiver requests for a 4.5MB file distributed over N (=30–180) sender nodes. We follow the common practice to use a small RTO_{min} (200μs) for all schemes [37]. As



(a) Average flow completion time for flows less than 100KB (Tenant 1).



(b) Average flow completion time for flows less than 100KB (Tenant 2).

Figure 18: Simulation result under the web search workload with two tenants. Tenant 1 sends five times as many flows as tenant 2, and should have higher FCT than tenant 2.

shown in Figure 17(a), when the number of flows grows, HCSFQ achieves a lower request completion time compared with SP-PIFO, TCP and DCTCP, and is close to AFQ. SP-PIFO does not handle the incast traffic pattern well, because there are many packets arriving at the same time with similar ranks saturating some queues and getting dropped. Figure 17(b) shows that HCSFQ achieves low average completion times for individual flows as the number of flows changes.

Web search workload with two tenants. This experiment evaluates hierarchical fair queueing with two tenants. Tenant 1 sends five times as many flows as tenant 2, and the flow size and arriving time follow the web search workload [36]. As shown in Figure 18, HCSFQ can provide tenant-level fairness, so that since tenant 1 has more flows, the average flow completion time of tenant 1 is higher than that of tenant 2. We also implement a hierarchical version of PIFO (HPIFO) as an upper bound for comparison. Note that although HPIFO delivers the best result, it needs to maintain three queues (one in the first layer and two in the second layer) for two tenants. It cannot be implemented on today's switches and it is hard to support many tenants due to the need of hierarchical queues. Other approaches do not distinguish between tenants, and the average flow completion times of the two tenants are similar.

Scalability with many tenants. We show the scalability of HCSFQ on supporting many tenants and flows. When there are many tenants and flows, the share of each tenant/flow is small and the bias from rate estimation and rate update in each step will accumulate. In this experiment, we examine 50 tenants. Half of the tenants (tenant 1-25) have one VM in each server, and the other half (tenant 26-50) have two VMs in each server. Each VM has a long-lasting TCP flow with another VM of the same tenant in another rack. We set the bandwidth of access links and leaf-spine links to 10Gbps and 40Gbps respectively in order to accommodate more tenants and flows than previous experiments. Figure 19 shows that TCP, DCTCP, AFQ and SP-PIFO do not provide tenant-level fairness, and the tenants with more flows have higher total throughput. In comparison, HCSFQ provides fair bandwidth allocation between tenants, regardless of the number of flows each tenant has.

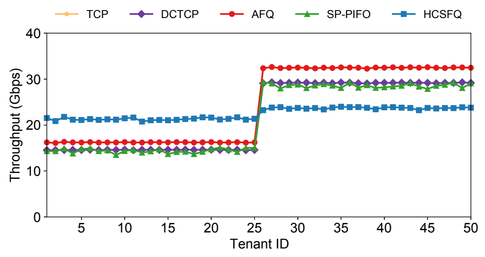


Figure 19: Throughput of different tenants. Each tenant of Tenants 1-25 has one VM in each server, while each tenant of Tenants 26-50 has two VM in each server. Each tenant is sending pairwise TCP traffic between its VMs.

7 Related Work

Fair queueing. There is a long history of work on fair queueing. The original proposal from Nagle [1] introduces the idea of using separate FIFO queues for flows to achieve fair bandwidth allocation. The bit-by-bit round robin (BR) algorithm [2, 3] computes a bid number to estimate the departure time for each packet, and transmits the packet with the lowest bid number with a priority queue. To avoid expensive priority queues, several algorithms, such as SFQ [4] and DRR [5], propose to map flows to a small number of FIFO queues, which do not work well when the number of flows are far larger than the number of queues. Another approach is probabilistic packet dropping, which maintains per-flow state to estimate drop probability, such as FRED [6], RED-PD [7] and AFD [8]. CSFQ [13] is distinct from these algorithms in that it does not require per-flow state, per-flow queues or an expensive priority queue. Hierarchical fair queueing adds a hierarchy to fair queueing, which require not only per-flow state, but also a hierarchy of queues [9, 10, 15]. HCSFQ eliminates both requirements, making hierarchical fair queueing feasible to be implemented in high-speed hardware switches.

Network isolation in multi-tenant cloud. Prior work has proposed techniques to provide performance guarantees and share bandwidth between multiple tenants [14, 16–28, 38, 39]. However, existing works either can only enforce hierarchical fairness at end hosts, or can not be efficiently implemented in today's hardware. For example, BwE [39] is a WAN bandwidth allocation mechanism which enforces hierarchical fair allocation at end hosts. FairCloud [14] proposes to apply CSFQ for network isolation in datacenters, but it does not have a hardware implementation for CSFQ and does not support hierarchical fair queueing. HCSFQ is to the best of our knowledge, the *first* solution to provide hierarchical fair queueing on commodity switches with small switch memory footprint and a single FIFO queue.

Programmable switches. Programmable switches have triggered many innovations in recent years [32, 40–60]. Programmable packet scheduling is the most relevant to HCSFQ. UPS [61] shows that Least Slack Time First (LSTF) provides a good approximation for many scheduling algorithms in practice. PIFO [10] provides a hardware design to realize the abstraction of a push-in first-out (PIFO) queue. It relies on a tree of PIFO queues to implement hierarchical fair queueing. AFQ [11] approximates fair queueing by using a few queues to emulate many queues. It stores per-flow counters in a count-min sketch, and does not support hierarchical fair queueing. SP-PIFO [12] uses several strict priority queues to emulate a PIFO queue, which can support fair queueing, not hierarchical fair queueing. Compared to them, we show how to leverage programmable switches to support fair queueing without per-flow state based on CSFQ, and present a new algorithm HCSFQ to support hierarchical fair queueing.

8 Conclusion

We present HCSFQ, a scalable algorithm for hierarchical fair queueing. Hierarchical fair queueing is a long standing problem in networking. Instead of relying on a hierarchy of queues with complex queue management, HCSFQ only keeps the state for the interior nodes and uses only one queue to achieve hierarchical fair queueing. This dramatically simplifies the design, and makes the design possible to be implemented in high-speed switches. Indeed, we have built a prototype for HCSFQ on programmable switches. Our prototype shows that HCSFQ works well with both UDP and TCP without any changes to either the hardware (e.g., NICs) or software (e.g., TCP/IP stack) of the end hosts.

To the best of our knowledge, HCSFQ is the first solution that has been demonstrated to provide hierarchical fair queueing on hardware switches at line rate. HCSFQ is not only theoretically interesting, but also has important practical implications. Network isolation is critical to multi-tenant clouds, which have a natural two-layer hierarchy. This hierarchy naturally requires the datacenter network to first allocate the bandwidth to the tenants, and then allocate each tenant's bandwidth between the tenant's flows. HCSFQ provides the first solution to enable this two-layer isolation in datacenter networks. Our prototype shows that this can be done without any changes to either the hardware (e.g., NICs) or software (e.g., TCP/IP stack) of the end hosts, and it works well with both UDP and TCP. We believe HCSFQ is a promising solution for network isolation in multi-tenant datacenters.

A Proof of Theorem 1

Proof. The first conclusion is directly derived from the guarantee of CSFQ [13].

For the second conclusion, we consider a model with a parent and k children. We add a script $'$ to represent the notations related to the parent, e.g., r'_i is the estimated arrival rate of the i-th packets at the parent. We add a script (j) to represent the notations related to the j-th child, e.g., $r_i^{(j)}$ is the estimated arrival rate of the i-th packets at the j-th child. Suppose the time episode is universal for all children. Suppose that $r_0^{(j)} = r'_0 = 0$ for $j = 1, \dots, k$.

Suppose the inter-arrival time $T_i \geq \tau$ for all i. Suppose

$$r_{\alpha'} \geq \frac{1}{1 - e^{-\tau/K}} \sum_{j=1}^{k} r_\alpha^{(j)}.$$

Then we will show that the parent node $r_{\alpha'}$ does not drop packets. To this end, we only need to prove that

$$r'_i \leq r_{\alpha'}, \quad \forall i. \tag{9}$$

After the first drop, the package length is $h_i = h_i^{(1)} + \cdots + h_i^{(k)}$, where

$$h_i^{(j)} = \begin{cases} \ell_i^{(j)} & r_i^{(j)} \leq r_\alpha^{(j)}, \\ \ell_i^{(j)} \frac{r_\alpha^{(j)}}{r_i^{(j)}} & r_i^{(j)} > r_\alpha^{(j)}. \end{cases}$$

And by definition,

$$r'_i = (1 - e^{-T_i/K}) \frac{h_i}{T_i} + e^{-T_i/K} r'_{i-1}, \quad 1 \leq i \leq n.$$

We now recursively prove Eq. (9).

(i) First let $i = 1$.

We will use the following inequality to prove Eq. (9):

$$(1 - e^{-T_1/K}) \frac{h_1^{(j)}}{T_1} \leq r_\alpha^{(j)}, \quad \forall j. \tag{10}$$

On the one hand, if Eq. (10) is true, we have

$$r'_1 = (1 - e^{-T_1/K}) \frac{\sum_{j=1}^{k} h_1^j}{T_1} \leq \sum_{j=1}^{k} r_\alpha^j \leq r_{\alpha'},$$

which implies Eq. (9) for $i = 1$.

On the other hand, recall $r_1^{(j)} = (1 - e^{-T_1/K}) \frac{\ell_1^{(j)}}{T_1}$, we then prove Eq. (10) as following:

1. If $r_1^{(j)} < r_\alpha^{(j)}$, then $h_1^{(j)} = \ell_1^{(j)}$, thus

$$(1 - e^{-T_1/K}) \frac{h_1^{(j)}}{T} = (1 - e^{-T_1/K}) \frac{\ell_1^{(j)}}{T} = r_1^{(j)} \leq r_\alpha^{(j)}.$$

2. If $r_1^{(j)} \geq r_\alpha$, then $h_1^{(j)} = \ell_1^{(j)} \frac{r_\alpha^{(j)}}{r_1^{(j)}}$, thus

$$(1 - e^{-T_1/K}) \frac{h_1^{(j)}}{T_1} = (1 - e^{-T_1/K}) \frac{\ell_1^{(j)}}{T_1} \frac{r_\alpha^{(j)}}{r_1^{(j)}} = r_\alpha^{(j)}.$$

Thus Eq. (10) holds.

(ii) Now suppose that $r'_{i-1} \leq r_{\alpha'}$.

We will use the following inequality to prove our claim:

$$(1 - e^{-T_i/K}) \frac{h_i^{(j)}}{T_i} \leq r_\alpha^{(j)}, \quad \forall j. \tag{11}$$

On the one hand, if Eq. (11) is true, we have

$$\begin{aligned} r'_i =& (1 - e^{-T_i/K}) \frac{\sum_{j=1}^{k} h_i^{(j)}}{T_i} + e^{-T_i/K} r'_{i-1} \\ \leq& \sum_{i=1}^{k} r_\alpha + e^{-a/K} r'_\alpha \leq r'_\alpha, \end{aligned}$$

which implies Eq. (9) for i.

On the other hand, recall

$$r_i^{(j)} = (1 - e^{-T_i/K}) \frac{\ell_i^{(j)}}{T_i} + e^{-T_i/K} r_{i-1}^{(j)},$$

we then prove Eq. (11) as following:

1. If $r_i^{(j)} < r_\alpha^{(j)}$, then $h_i^{(j)} = \ell_i^{(j)}$, thus

$$\begin{aligned} (1 - e^{-T_i/K}) \frac{h_i^{(j)}}{T_i} =& (1 - e^{-T_i/K}) \frac{\ell_i^{(j)}}{T_i} \\ =& r_i^{(j)} - e^{-T_i/K} r_{i-1}^{(j)} \\ \leq& r_i^{(j)} \leq r_\alpha^{(j)}. \end{aligned}$$

2. If $r_i^{(j)} \geq r_\alpha^{(j)}$, then $h_i^{(j)} = \ell_i^{(j)} \frac{r_\alpha^{(j)}}{r_i}^{(j)}$, thus

$$\begin{aligned} (1 - e^{-T_i/K}) \frac{h_i^{(j)}}{T_i} =& (1 - e^{-T_i/K}) \frac{\ell_i^{(j)}}{T_i} \frac{r_\alpha^{(j)}}{r_i^{(j)}} \\ =& (r_i^{(j)} - e^{-T_i/K} r_{i-1}^{(j)}) \frac{r_\alpha^{(j)}}{r_i^{(j)}} \\ \leq& r_i^{(j)} \frac{r_\alpha^{(j)}}{r_i^{(j)}} = r_\alpha^{(j)}. \end{aligned}$$

Thus Eq. (10) holds. By (i) and (ii) and mathematical induction our proof is finished. $\square$

Breaking the Transience-Equilibrium Nexus: A New Approach to Datacenter Packet Transport

Shiyu Liu[1], Ahmad Ghalayini[1], Mohammad Alizadeh[2], Balaji Prabhakar[1], Mendel Rosenblum[1], and Anirudh Sivaraman[3]

[1]Stanford University, [2]MIT, [3]NYU

Abstract

Recent datacenter transport protocols rely heavily on rich congestion signals from the network, impeding their deployment in environments such as the public cloud. In this paper, we explain this trend by showing that, without rich congestion signals, there is a strong tradeoff between a packet transport's equilibrium and transience performance. We then propose a simple approach to resolve this tension without complicating the transport protocol and without rich congestion signals from the network. Our approach factors the transport into two separate components for equilibrium and transient handling. For equilibrium handling, we continue to use existing congestion control protocols. For transients, we develop a new underlay algorithm, On-Ramp, which intercepts and holds any protocol's packets at the network edge during transient overload. On-Ramp detects transient overloads using accurate measurements of one-way delay, made possible in software by a recently developed time-synchronization algorithm.

On the Google Cloud Platform, On-Ramp improves the 99th percentile request completion time (RCT) of incast traffic of CUBIC by 2.8× and BBR by 5.6×. In a bare-metal cloud (CloudLab), On-Ramp improves the RCT of CUBIC by 4.1×. In ns-3 simulations, which model more efficient NIC-based implementations of On-Ramp, On-Ramp improves RCTs of DCQCN, TIMELY, DCTCP and HPCC to varying degrees depending on the workload. In all three environments, On-Ramp also improves the flow completion time of non-incast background traffic. In an evaluation at Facebook, On-Ramp significantly reduces the latency of computing traffic while ensuring the throughput of storage traffic is not affected.

1 Introduction

Datacenter packet transport has been an active area of research within the networking community for over a decade. The primary goals of datacenter transport protocols are to achieve high throughput and low latency and to effectively deal with bursty traffic, especially incast [51]. To achieve these goals, the research community has pursued two broad lines of work. The first is a series of congestion control algorithms that have relied on progressively richer forms of congestion signals from the network. These signals run the gamut from single-bit ECN marking [13] to multi-bit signals [53] and all the way to queue size and link utilization information [44]. The second line of work has focused on packet scheduling mechanisms that proactively prevent congestion from occurring in the first place [21, 34], or explicitly optimize for objectives like flow completion times [16, 17, 20, 49]. These schemes often require more elaborate network and application support, such as in-switch priority queues and application hints about flow sizes or deadlines.

Taking a step back from recent developments, we ask: *is it possible for a congestion control algorithm to achieve good behavior without rich congestion signaling or packet scheduling support from the network?* This question is not merely of academic interest; it has significant practical implications. In many environments, there is no way for the network to export rich signaling information or perform sophisticated packet scheduling. A particularly important example is the environment in which public cloud customers find themselves today. Cloud customers have access to the edge of the network, whether it is within a VM or in a bare metal server or potentially within SmartNICs in the future. However, they do not have access to the network infrastructure.

Motivated by the above question, we show that the trend towards rich congestion signals in state-of-the-art schemes is rooted in an inherent tension between the two main functions of a datacenter transport protocol: (i) converging quickly to a fair and stable equilibrium point as large flows arrive and depart, and (ii) handling transients of the incast-type effectively. Specifically, we consider two widely-deployed algorithms (TIMELY [47] and DCQCN [53]) and show that a parameter setting that works well in equilibrium performs poorly in transience and vice versa. On the other hand, protocols such as HPCC [44] which use richer congestion signaling from the network (e.g., queue size information and link utilization from INT [41]) can improve performance in both equilibrium and transience, as discussed in [44, §2.3 and §5.2].

Informed by these results, we ask a second question: *can congestion control be modularized into two simpler components, one each to deal with equilibrium and transient concerns?* This paper answers the question by proposing a new approach to congestion control that breaks the nexus between transience and equilibrium behavior. It delegates transient handling to a protocol, called *On-Ramp*, which is tailor-made for transients, leaving the congestion control algorithm to deal with equilibrium behavior.

On-Ramp (OR) can be coupled with any datacenter congestion control protocol to improve its performance during transients; indeed, implementing On-Ramp requires only end-host modifications and we have combined On-Ramp with CUBIC [33], BBR [19], DCQCN [53], TIMELY [47], DCTCP [13] and HPCC [44]. The core idea behind On-Ramp is extremely simple: when the congestion control protocol at a sender decides to transmit a packet, the sender temporarily holds back the packet if the sender-to-receiver one-way delay of the most-recently acknowledged packet exceeds a threshold. Thus, On-Ramp lets congestion control algorithms do what they are good at—determining transmission rates or window sizes in dynamic settings to improve metrics such as throughput and fairness—while giving them a leg up with functionality they struggle with: transience.

As a very useful by-product, On-Ramp also enhances the performance of existing congestion control algorithms in equilibrium by making them more robust to the choice of algorithm parameters. This is because of a phenomenon that we term *state-space compaction*. The state space of a network is the size of the queues within the network at any time. It spans a large dynamic range of queues sizes from transient (high queue) to equilibrium (low, but non-zero) to unstable (zero queues and link underflows). By compacting the state space, On-Ramp reduces the dynamic range of the state space observed by the congestion control algorithm and keeps it in a tight band around the desired operating point. This attenuates the large and frequent congestion signals from the network which, in turn, can cause an overreaction by the congestion control algorithm.

Key to making On-Ramp practical is an accurate measurement of one-way delay, which requires synchronized clocks between the sender and receiver. Since the one-way delays in a datacenter can be a few tens of microseconds or lower, this implies that the sender and receiver clocks must be synchronized to within a few microseconds. Such high-accuracy clock synchronization has traditionally required hardware-intensive protocols like Precision Time Protocol (PTP) [37]. But a recently developed system, Huygens [30], showed that it is possible to achieve nanosecond-level clock synchronization without special hardware or dedicated priorities. On-Ramp leverages the Huygens algorithm, making it easier to deploy.

We evaluated On-Ramp in three different environments: the public cloud, a CloudLab cluster (bare-metal cloud) and ns-3 simulations. We find:

1. **Performance improvements.** On Google Cloud, On-Ramp improves the 99th percentile request completion time (RCT) of incast traffic of CUBIC by $2.8\times$ and BBR by $5.6\times$. In CloudLab, On-Ramp improves the tail RCT of CUBIC by $4.1\times$. In ns-3 simulations, which model more efficient NIC-based implementations, On-Ramp improves RCTs to varying degrees depending on the workload under DCQCN, TIMELY, DCTCP and HPCC. In all three environments, On-Ramp also improves the flow completion time of non-incast background traffic.
2. **CPU overhead of On-Ramp.** When running at 40% network load on a 10 Gbps NIC and an 8-core CPU, the total CPU utilization is 15.1% without On-Ramp, and 18.7% with On-Ramp. If On-Ramp is implemented in the NIC, this overhead can be eliminated.

2 Transience–Equilibrium Tension

Congestion control algorithms execute one of the following update equations:

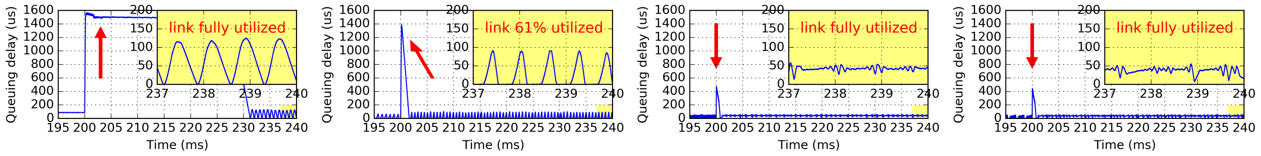
$$\begin{aligned} W(next) &= f(W(now),\ congestion\ signals,\ K), \text{ or} \\ R(next) &= g(R(now),\ congestion\ signals,\ K). \end{aligned} \tag{1}$$

That is, based on congestion signals received from the network, the algorithm updates the window size W or the transmission rate R. This is taking place constantly and iteratively, as flows arrive or depart or the path bandwidth changes (e.g., due to prioritization). K here is the gain in the control loop, which is typically very carefully chosen to provide stability in equilibrium and quick reaction to congestion in transience.[1] However, in the high bandwidth and small-buffered environment of data centers, we shall see that it is quite hard to pick the gain K so as to get great performance in *both* transience and equilibrium: a high value of K gives the responsiveness needed to react quickly to congestion but suffers from bad performance and instability in equilibrium when there are lags in the control loop; conversely, a low value of K can provide good performance in equilibrium but make the source sluggish during transience. We refer to this as the *transience-equilibrium tension* and we shall see that industrial-grade and commercially-deployed algorithms like TIMELY and DCQCN suffer from the transience-equilibrium tension.

With elaborate and frequent congestion signals from the network (e.g., queue depths, link utilization and flow rate, sent on a per-packet basis using in-band telemetry [41]), the congestion control algorithm can be improved simultaneously in transience and equilibrium (e.g., HPCC [44]). Unfortunately, such elaborate signals are not available in virtual environments such as the public clouds.

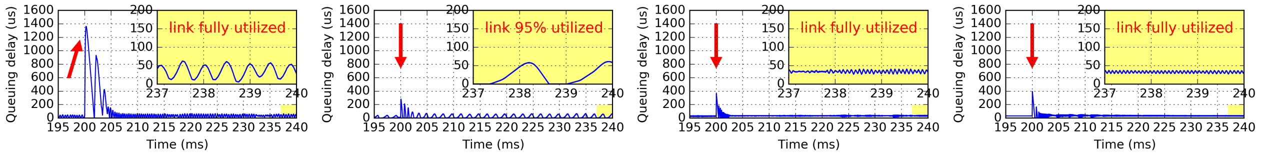
An alternative is to bake in two different modes of congestion handling within the same algorithm, e.g., slow start for transients and congestion avoidance for equilibrium. However,

[1] Indeed, an extensive literature in congestion control theory is devoted to the careful choice of the gain parameters, e.g. [14, 15, 24, 27, 40, 45, 52].



(a) β=0.2, no OR **(b)** β=0.8, no OR **(c)** β=0.2, with OR **(d)** β=0.8, with OR

Figure 1: 12 100G servers sending traffic to one receiver using TIMELY. 2 of them start at t=0, the other 10 start at t=200ms. From ns-3 runs using the setup in §5.1.1. The red arrow points to transience, and the yellow box is a zoom-in of equilibrium. OR threshold T=30μs.



(a) T_i=55μs, T_d=50μs, no OR **(b)** T_i=300μs, T_d=4μs, no OR **(c)** T_i=55μs, T_d=50μs, with OR **(d)** T_i=300μs, T_d=4μs, with OR

Figure 2: DCQCN study. OR threshold T=30μs.

this approach is fragile because it requires defining precise conditions to trigger switches between modes. Further, when a congestion control algorithm in equilibrium encounters severe congestion and drastically cuts its window or rate, it must make a difficult choice between remembering and forgetting its previous equilibrium state (rate/window). This choice is difficult because it depends on the duration of congestion, which is hard to predict. If the congestion is transient, such as an incast, the algorithm must remember its previous state so as to rapidly restore the old equilibrium without under utilization, once the incast ends. On the other hand, if the congestion is sustained, such as the simultaneous arrival of many long-lived flows, the algorithm must forget its previous state so that it can rapidly find a new equilibrium.

In this context, On-Ramp makes two key contributions: (i) when the one-way delay (OWD) on the path exceeds a given threshold, T, On-Ramp can quickly and forcefully react by pausing transmissions at the source, reducing congestion; and (ii) On-Ramp also reduces the sensitivity to the choice of the gain parameter K by ensuring good transient and equilibrium performance over a wide range of values of K.

We shall show that On-Ramp achieves the above by *compacting the state space* in the network. By that we mean that On-Ramp maintains network state variables such as queuing delays around their desired operating points, preventing large excursions (high or low) which occur during transience or in equilibrium when the value of K is high. Essentially, state space compacting *attenuates* (but does not eliminate) the congestion signals, preventing an overreaction at a source with high gain K while providing the throttling necessary for a source with low gain K.

Let us now illustrate the above points by considering the following scenario: 12 100G servers sending traffic to one receiver; all machines are connected to a single switch. 2 servers start sending at time 0; the other 10 start at 200 ms.

Figures 1a and 1b show the queuing delays at the switch during transience (t=200ms) and equilibrium (t=237-240ms) when TIMELY is used with its gain parameter $\beta = 0.2$ and $\beta = 0.8$, respectively. Note that $\beta = 0.8$ is the value recommended in [47,54], and $\beta = 0.2$ is the largest value to achieve full utilization in equilibrium.

At $\beta = 0.2$, TIMELY performs well in equilibrium: the queue stays above zero and the link rate is maintained close to 100G. However, it performs poorly in transience: it takes a long time to react to the congestion caused by the newly arriving 10 flows—the queuing delay converges very slowly. At $\beta = 0.8$, it reacts much more quickly to transience, but due to aggressive congestion control, the queue underflows during equilibrium and leads to a link utilization of just 61%.

The trend is similar for DCQCN. The rate-increase timer T_i and rate-decrease timer T_d are varied to change its control gains. Note that the values T_i = 55 μs and T_d = 50 μs are the settings recommended in [53] and T_i = 300 μs and T_d = 4 μs are the default settings recommended by a vendor of network hardware (cf. [44]). At less aggressive gains (Fig. 2a), DCQCN performs well in equilibrium but reacts slowly during transience. Aggressive gain settings (Fig. 2b) give the opposite behavior.

Figures 1c and 2c respectively consider the scenario where the low (equilibrium-friendly) gain parameters for TIMELY and DCQCN are used in conjunction with On-Ramp. We observe that both algorithms react very quickly to transient congestion and converge smoothly to a stable equilibrium with full link utilization. Indeed, the equilibrium performance is actually improved by On-Ramp: the oscillation of queues during equilibrium is reduced! Figures 1d and 2d consider the high gain parameter scenario. We see that On-Ramp helps here as well by preventing severe queue undershoots and providing a high link utilization.

In conclusion, On-Ramp helps to cope with severe transient congestion by lowering queuing delays rapidly; conversely, it also prevents queues from underflowing, hence keeping a high link utilization. It achieves this by compacting the state space to a region around the desired queue size. As a useful by-product of this, it also reduces the sensitivity of the congestion control algorithm to gain parameters. It is critical to note here that On-Ramp *does not* perform the window or rate updates at Equation 1. This is left to the congestion control algorithm.

One might wonder if a more sophisticated delay-based protocol could make better use of precise one-way delay measurements. While an interesting possibility, we did not pursue this route for two reasons. First, On-Ramp allows us to decouple transient and long-term congestion management, and handle each at its own appropriate timescale without burdening a single protocol with both. Second, On-Ramp also composes very naturally with existing congestion control algorithms. It lets congestion control algorithms do what they are good at—improving long-term metrics such as throughput and latency, while taking care of transients for them. This factorized approach has allowed us to combine On-Ramp with several existing congestion control algorithms [13, 19, 33, 44, 47, 53].

3 On-Ramp Design

On-Ramp is a simple end-to-end flow control algorithm, sitting as a shim between the congestion control algorithm and the network (see Figure 3). On-Ramp aims to bring down the path queuing delays as quickly as possible by pausing the flow at the sender's end of the network when the measured OWD (which we denote as O) exceeds a threshold T. For a congestion control algorithm that does not control queuing delays on its own (e.g., TCP CUBIC), On-Ramp adds this functionality. For a congestion control algorithm that does control queuing delays on its own (e.g., DCTCP), On-Ramp works like a safeguard, for example, by reducing queue spikes during transience.

We first present a simple version of the On-Ramp algorithm that is intuitive but has queue oscillations and the possibility of under-utilization in the presence of feedback delay. We update On-Ramp by amending the rule for pausing, resulting in the final version of the algorithm.

3.1 Strawman Proposal for On-Ramp

As shown in Figure 3, On-Ramp is implemented underneath the congestion control protocol (CC) between the sender S and receiver R. It consists of two parts:

(i) Receiver side: Upon receiving a packet, the receiver sends an OR-ACK to the sender, which contains (1) the flow indicator (i.e., the 5-tuple representing the flow), (2) the sequence number of the received packet, and (3) the time at which the packet was received.

(ii) Sender side: The sender maintains two data structures for each flow: (1) a queue of outstanding packets belonging to that flow waiting to be transmitted; and (2) a value called $t_{NextPkt}$ representing when the next packet from the flow will be transmitted. Initially, $t_{NextPkt}$ is set to 0 and, upon the receipt of an OR-ACK, it is updated as follows:

$$t_{NextPkt} \leftarrow \begin{cases} t_{Now} + O - T, & \text{if } O > T \\ t_{NextPkt}, & \text{else.} \end{cases} \quad (2)$$

Here t_{Now} is the current system time. The flow will be paused until $t_{NextPkt}$ if that is larger than t_{Now}. If an OR-ACK is dropped, the sender will not be able to measure OWD O at

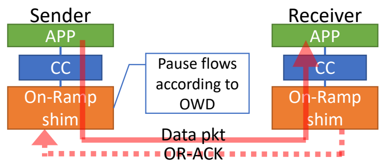


Figure 3: The On-Ramp Underlay.

this time, so $t_{NextPkt}$ will not be changed. The sender dequeues packets of the active (non-paused) flows in round-robin order.

The strawman proposal is simple and intuitive: upon receiving an OR-ACK with an OWD value of O exceeding threshold T, pause for $O - T$. The goal is to drain the queue such that the OWD after the pause is under T. This reasoning would have been correct *if there were no delay* in getting acks from the receiver. In the presence of feedback delay, however, the sender will actually pause for a significantly longer time than necessary.

To understand what is going on, suppose that the sender receives an ack with OWD O exceeding T for the first time at time t, and it immediately pauses for duration $O - T$. Notice that it will take at least one additional round-trip-time (RTT) after t for the sender to see the impact of this pause on the OWD values carried in acks. In particular, acks received for packets that were transmitted before pausing are likely to also carry OWD values exceeding T. Hence a sender using the strawman design will actually pause for at least the next RTT, even if the OWD exceeds T by a small amount. By the time it resumes sending traffic, the queue will have significantly undershot T, which risks under-utilization.

3.2 The Final Version of On-Ramp

To fix the above problem, we propose a simple mechanism to compensate for the sender's feedback delay in receiving the OWD signal. The key is to observe that it is possible the sender was paused when the green packet (see Figure 4) was in flight and before the sender received its ack. The update equation (2) doesn't take these previous pauses into account, and therefore it overestimates how much additional time it needs to pause for the OWD to drop down to T.

One approach to correct for previous pauses would be to subtract the total time the sender was paused while the green packet was in flight from the OWD value O obtained in the ack. This approach assumes that if the sender was paused for some duration P, then the current value of OWD is no longer O but rather $O - P$. However, this ignores the contribution of other senders to the OWD. The reduction in OWD due to a pause of duration P is *at most* P, but it may be less if other senders transmit in that time.

To account for other senders, On-Ramp estimates the relationship between the actions it takes (i.e., its own pause duration) and the effect of these actions (i.e., reduction in OWD). To this end, it dynamically measures a parameter β_m, which equals the change in OWD per unit of On-Ramp pause time; in other words, the *gain* of the On-Ramp control mechanism. Refer to Figure 4, and let O_B and O_G be the OWDs

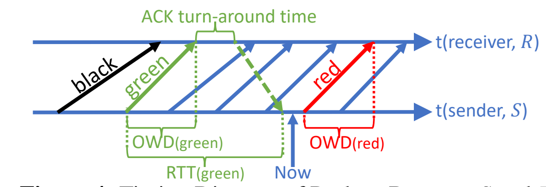

Figure 4: Timing Diagram of Packets Between S and R

(d) Flow rates, Final OR

Figure 5: Two long-lived CUBIC flows sharing a link

of the black and green packets, where the black packet is the one which has been acked immediately prior to the green packet being acked. Let P_{BG} be the total time On-Ramp had paused the sender in between the times it transmitted these two packets. If $P_{BG} > 0$, then $\beta_m = (O_B - O_G)/P_{BG}$ captures the effect of the sender pausing on the reduction in the OWD. We threshold β_m to be between 0 and 1. A value of β_m close to 1 indicates that the reduction in OWD is roughly the same as the sender's pause time. This would occur, for example, if there is little traffic from other senders, or if the senders are synchronized and all pause together. On the other hand, β_m near 0 indicates that On-Ramp must pause for a long amount of time to reduce OWD.

On-Ramp obtains one such β_m measurement for each new packet that it transmits for which $P_{BG} > 0$. It computes a moving average of these values with each new measurement:

$$\beta \leftarrow (1-g)\cdot\beta + g\cdot\beta_m \qquad (\text{if } P_{BG} > 0) \tag{3}$$

Here g is the EWMA gain. Finally, upon receiving an OR-ACK, the sender replaces the first line in Equation (2) with

$$\begin{aligned} t_{NextPkt} &\leftarrow t_{Now} + O - T - \beta\cdot P_{LastPktRTT} \\ &\quad (\text{if } O - \beta\cdot P_{LastPktRTT} > T) \end{aligned} \tag{4}$$

Here, $P_{LastPktRTT}$ is the total time pause was asserted during the time period spanned by the RTT of the most recently acked packet (the green packet).

Figure 5 demonstrates the effectiveness of lag compensation. It shows the OWDs and the flow rates when two CUBIC flows share a bottleneck link in a bare-metal environment (Cloudlab [26]). The second flow is on during 6–16 seconds. The threshold T is set to 50μs. It's clear that the strawman On-Ramp leads to significant queue undershoot under T and causes under-utilization, and the final On-Ramp fixes this problem. Figure 24 in Appendix shows the case of 12 flows, where final On-Ramp removes most fluctuations in queue lengths and achieves better fair sharing among all flows.

Parameter Selection. The threshold T should clearly be higher than the minimal OWD on the path, plus some headroom to tolerate errors in the OWD measurement. §5.1.4 describes how to pick T in practice. We choose the EWMA gain $g = 1/16$ and find that the end-to-end performance of On-Ramp is relatively insensitive to g, shown in §7.4.

3.3 Importance of Accurate One-way Delay

To measure OWD accurately, On-Ramp uses Huygens [30], a recently developed system for highly-accurate clock synchronization. The Huygens algorithm uses a random probe mesh among all the clocks; the mesh is formed by each clock probing typically 10 other clocks. The clocks exchange probes and acks on this mesh. We note that probes and acks are UDP packets *not* using higher priorities in switches. The send and receive timestamps of each probe and ack are processed through a combination of local and central algorithms every 2–4 secs. The local algorithm performs filtering using coded probes and support vector machines to estimate the discrepancies between two clocks. These techniques make Huygens robust to network queuing delays, random jitter, and timestamp noise. Then, the central algorithm, dubbed "network effect" in the paper, determines errors in the accuracy of clock sync using the transitivity property: the sum of the clock offsets A-B, B-C, and C-A is zero; else, errors exist. By looking at clock offset surpluses over *loops* of the probe mesh, Huygens pins down clock sync errors and provides corrections which can be applied offline or online.

Since the probe mesh is set up end-to-end at the hosts, there is no need for special hardware support (in contrast to other high-accuracy algorithms like PTP [37], DTP [43], or DPTP [39]). With NIC hardware timestamps, [30] reports a 99th percentile synchronization accuracy of 20–40 nanoseconds even under network loads of 80%. The probe mesh makes Huygens robust to high loads and link or node failures. Further, the local-central processing distributes effort across all nodes, making the algorithm scalable to 1000s of nodes. In the present paper, we use Huygens with CPU (software) timestamps because software timestamps are universally available in both VMs in public clouds and bare-metal machines. In this case, we see a median accuracy of a few hundred nanoseconds and 99th percentile accuracy of 2–3 microseconds under high network loads such as 80% in a single data center.

To see the importance of accurate one-way delay, we compare three signals that On-Ramp could use to measure path congestion: (i) OWD measured with accurately synchronized clocks using Huygens, (ii) round-trip time (RTT), and (iii) OWD measured with less accurately synchronized clocks using NTP [46]. Referring to Figure 4, we evaluate how well each of these signals, measured for the green packet, correlates with the OWD of the red packet. If the correlation is high, then the fate of the green packet is a good predictor of the congestion to be experienced by the red and immediately succeeding packets. As Figure 6a and 6d show, the OWD of the green packet measured using Huygens is highly corre-

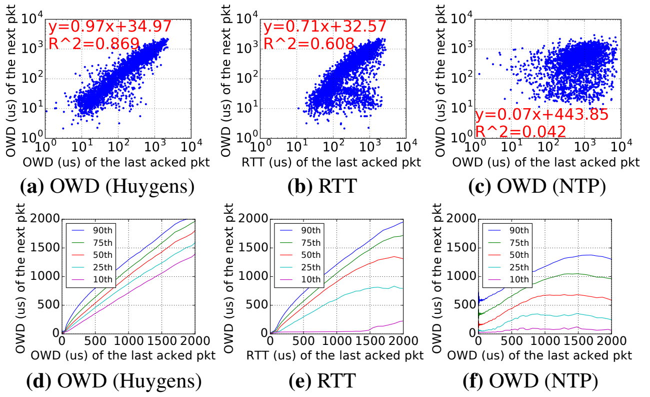

Figure 6: The OWD of the next packet vs. the OWD (Huygens), RTT, and OWD (NTP) of the *last-acked packet*. (a)–(c) are samples plotted in log scale. (d)–(f) are percentiles plotted in linear scale. The test is conducted on 100 machines in a bare metal cloud with *WebSearch* [13] traffic and 40% network load.

lated with the OWD of the red packet. However, neither the RTT nor the OWD measured using NTP correlates well with the actual OWD experienced by the red packet. This makes On-Ramp much less effective with the latter two signals.

4 Implementation

In this section, we describe the Linux implementation of On-Ramp using kernel modules, which allows us to install On-Ramp by just loading a few kernel modules rather than reinstalling (or worse still, recompiling and then reinstalling) the whole kernel. We will also comment on the benefits—both implementation and performance—of implementing On-Ramp in Smart NICs in the future.

Figure 7: Linux implementation of On-Ramp

Figure 7 shows our On-Ramp implementation. It consists of four parts, described below. For each of them, we mention whether it involves changes to the sender, receiver, or both.

1. **On-Ramp controller.** This module runs at the sender and calculates OWDs and makes decisions to pause or not on a per-flow basis.
2. **NIC driver.** The NIC driver at the receiver is modified to timestamp packets (before GRO). The NIC driver at the sender is modified to timestamp packets, sniff OR-ACKs and forward them to the On-Ramp controller for implementing the On-Ramp algorithm. The NIC driver could be either a physical or a virtual NIC's driver.
3. **QDisc.** We modify the fair queueing (FQ) Qdisc [25] at the sender to queue packets into per-flow queues and exert pause on a per-flow basis.
4. **On-Ramp acker.** This module at the receiver sends OR-ACKs. These are UDP packets that use the same Ethernet priority as the received data packets, so they don't require any priority queues in Ethernet switches. We avoid piggybacking receive timestamps onto TCP ACKs, because they may be delayed by the TCP stack, and modifying the TCP stack requires recompiling the kernel.

Note that On-Ramp does not modify the existing data packets, and OR-ACKs are standard UDP packets.

There are three important details regarding the implementation that pertain to three critical aspects of On-Ramp: (i) the accuracy of measuring the OWD, (ii) the granularity of control (exerting pause), and (iii) the behavior after a pause ends. Accordingly, the On-Ramp implementation may vary depending on the deployment scenario, e.g., public cloud (Google Cloud Platform), bare-metal cloud (CloudLab), or bare-metal cloud with SmartNICs. We expand on these details below.

1. **Timestamp collection.** To compute OWD, we need to collect both sender and receiver timestamps. These timestamps are taken within the NIC driver and based on the system clock on both the sender and receiver sides. We choose the NIC driver because it is close to the wire and therefore minimizes additional software stack latency being added to the OWDs. This is important because stack latencies can be quite variable and confound the accurate detection of one-way delays in the *network* which are caused by congestion. Even though this makes On-Ramp's implementation NIC-driver-specific, the patch is only 20 lines of code and is quite easy to add to the NIC driver.[2] In bare-metal machines, if the NICs support hardware timestamping (e.g., through PHC [1]), NIC timestamps can also be captured, yielding less noisy OWD measurements, which, in turn, can lead to better control.

2. **The effect of generic send offload (GSO).** On the sender side, when GSO is enabled, the data segments handled by QDisc and the driver are GSO segments, which can be up to 64 KB (~43 packets). This limits the granularity of control by On-Ramp, as well as the accuracy of capturing transmit timestamps. §5 shows that On-Ramp already gives satisfactory performances with the default setting of GSO enabled and the max GSO size of 64KB. §7.2 shows that reducing max GSO size will further improve On-Ramp's performance, but increase CPU overhead, so there is a tradeoff here.

3. **Behavior after a pause ends.** One might wonder whether a burst of packets will be sent into the network after a pause ends, causing spikes in the queuing delay. This does not happen in practice. (1) For window-based CCs like CUBIC and DCTCP, although packets are also queued in the On-Ramp module, thanks to the TCP small queues patch [2] in Linux, the total number of bytes queued in the TCP stack and On-

[2]In a given public cloud, the vNIC implementations are the same, making the addition of the patch a one-time effort for each public cloud.

Ramp modules are limited. Furthermore, because On-Ramp is based on the FQ Qdisc, it dequeues in round-robin order across flows, smoothing out traffic after a pause ends. (2) For rate-based CCs like BBR, DCQCN and TIMELY, On-Ramp exerts pause by letting the rate pacer[3] hold back the next packet until $t_{Now} \geq \max(t_{NextTx}, t_{NextPkt})$, where t_{NextTx} is the time of sending the next packet determined by CC algorithm; $t_{NextPkt}$ is the value maintained by On-Ramp for each flow (see §3.1). When a pause ends, the rate pacer will resume releasing packets into the network according to the rate determined by CC, therefore the transmission will not be burstier.

Network and CPU overhead. The network overhead of On-Ramp comes from OR-ACKs; typically, 1 OR-ACK is sent per about 10 MTU-sized packets. Therefore, at 40% load on a 10 Gbps network and 78 Bytes per OR-ACK, the bandwidth consumed by OR-ACKs is about 21 Mbps, or 0.2% of the line rate. Huygens provides the clock synchronization service for On-Ramp. Its probe mesh adds negligible network overhead, which is about 3 Mbps, or 0.03% of the line rate.

For a typical scenario in §5, running 40% load of *Web-Search* traffic plus 2% load of incast on a 10 Gbps NIC and an 8-core Intel Xeon D-1548 CPU, the total CPU utilization is 15.1% without On-Ramp, and 18.7% with On-Ramp. If On-Ramp is implemented in the NIC as described later, this overhead can be eliminated. The CPU usage of Huygens is only around 0.5%.

We consider On-Ramp's overhead under higher network speeds. Table 1 shows overheads when two servers send iPerf flows to a third server simultaneously. Each server has a 25 Gbps NIC and a 10-core Intel Xeon E5-2640v4 CPU. We use the default GSO settings: enabled, max GSO size = 64KB. In this experiment, we get the same throughput with and without On-Ramp, both saturating the 25G link at the receiver. Most of the CPU overhead of On-Ramp is at the receiver, caused mainly by parsing, timestamping, and sending OR-ACKs. At the senders, On-Ramp operates at the granularity of GSO segments, so the overhead is small. Note that the On-Ramp implementation has not yet been optimized for CPU overhead.

	No On-Ramp[4]	With On-Ramp
Sender	1.01%	1.04%
Receiver	5.50%	6.99%

Table 1: The CPU usage in an iPerf experiment with 25G NIC

4.2 NIC Implementation

With the advent of programmable SmartNICs [3,7], On-Ramp can ideally be offloaded to the NIC in the future, conserving host CPU cycles. Moreover, a SmartNIC implementation can further improve On-Ramp's performance due to (1) shorter ack turn-around times at the receiver and (2) the exertion of pauses on MTU-sized packets, rather than GSO segments. §5.2.3 uses ns-3 [8] to emulate On-Ramp's performance using a NIC implementation.

[3] BBR uses FQ Qdisc to pace packets, which is compatible with the Linux kernel module implementation of On-Ramp. DCQCN's rate pacing is inside NICs, TIMELY's rate pacing can be in software or NICs, and we use ns-3 simulation to study On-Ramp's performance on top of them, as in §4.2.

[4] Since On-Ramp is built based on FQ QDisc, for a fair comparison of CPU overhead, we use FQ without On-Ramp as a baseline in this experiment. We note that FQ_CoDel [9] (the default QDisc in many modern Linux distributions such as Ubuntu 18.04) incurs a higher CPU overhead than FQ QDisc (when On-Ramp is not used): sender 1.41%, receiver 5.68%.

5 Evaluation

We evaluate the effectiveness of On-Ramp in a variety of environments and under different workloads and congestion control algorithms. In terms of performance, we consider:

1. Application-level performance measures: (i) request completion times for incast traffic, and (ii) flow completion times for non-incast background traffic.
2. Network-level performance measures: (i) number of packet drops and (ii) number of TCP timeouts.

5.1 Evaluation Setup

5.1.1 Evaluation environments

We consider three environments: public clouds, bare-metal clouds, and ns-3 [8] simulations. In the clouds we use On-Ramp's Linux implementation with different CC algorithms. The ns-3 simulations help us understand On-Ramp's performance in RDMA networks with different CC algorithms such as DCQCN, TIMELY, DCTCP, and HPCC.

VMs in Google Cloud. We use 50 VMs of type `n1-standard-4` [6]. Each VM has 4 vCPUs, 15 GB memory, and 10 Gbps network bandwidth. The OS is Ubuntu 18.04 LTS with Linux kernel version 5.0.

Bare-metal cloud in CloudLab. CloudLab [26] is an open testbed for research on cloud computing. We use the `m510` cluster [10] in CloudLab, which has 270 servers in 6 racks, 6 top-of-the-rack (ToR) switches, and 1 spine switch. The bandwidth is 10 Gbps between each server and ToR, and 4×40 Gbps between each ToR and the spine switch. Each ToR switch has a 9 MB shared buffer. Each server has an 8-core Intel Xeon CPU, 64GB memory, and a Mellanox ConnectX-3 10 Gbps NIC. For the On-Ramp evaluation, we rented 100 servers in this cluster (randomly chosen from these 6 racks by Cloudlab), and installed Ubuntu 18.04 LTS with Linux kernel version 4.15 on each server.

ns-3. We implement On-Ramp in ns-3 based on the open-source ns-3 simulator of HPCC [4,44]. We also use the same simulation setup as in [44, §5.1]. There are 320 servers in 20 racks, 20 aggregation switches and 16 core switches. The network topology is a 3-stage FatTree [12], consisting of ToR, aggregation and core switches. Each server has a 100 Gbps link connected to the ToR switch. All links between core, aggregation and ToR switches are 400 Gbps. Each link has 1 μs delay.[5] Each switch has a 32 MB shared buffer. Because

[5] Consisting of the link propagation delay and the packet processing delay in the corresponding switch.

the ns-3 simulations consider RDMA flows, we have priority flow control (PFC) [38] in effect. Note that neither the Google Cloud nor the CloudLab experiments has PFC; hence, buffers overflow and result in packet drops.

5.1.2 Traffic loads

We have two categories of traffic: incast type traffic [51] where requests generate bursts of small equal-sized flows simultaneously, and background traffic consisting of flows of varying sizes.

The incast traffic has a fanout of 40, where each of the 40 flows is either 2KB [13] or 500KB [44], so the total request size is 80KB and 20MB, respectively. The 2KB-sized flows are common in query-type scenarios while the 500KB-sized flows occur in query- and storage-type settings. The average load due to incast traffic is 2% or 20%.

For the background traffic, we use three data center workloads, namely: (1) *WebSearch* [13]: the web search traffic measured in Microsoft production clusters; (2) *FB_Hadoop* [50]: the traffic measured in Hadoop clusters at Facebook; (3) *GoogleSearchRPC* [5,49]: the RPC traffic generated by search applications at Google. Figure 8 shows the distribution of flow sizes. We adjust the average interval between adjacent flows to make the average traffic load to be 40%, 60% or 80%.

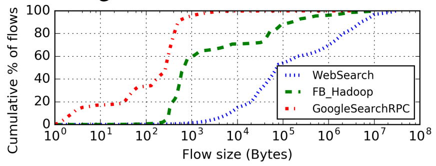

Figure 8: Distribution of flow sizes in the background traffic

5.1.3 Clock synchronization and packet timestamping

On-Ramp needs clock synchronization across servers to measure OWD. For bare-metal cloud and VMs in the public cloud, we use Huygens [30] as the clock synchronization algorithm. We find that the standard deviation of clock offsets after synchronization is around 200 ns in Google cloud, 100 ns in CloudLab, and the 99th percentile is less than 3 μs in both cases. In ns-3, by default the clocks are perfectly synchronized. However, to mimic clock inaccuracy in the real world even under good clock synchronization, we add a random offset to each server's clock according to a Gaussian distribution with a standard deviation of 200 ns.

For VMs in Google Cloud, the packet timestamps are taken inside the VMs with system clocks. In CloudLab, although the ConnectX-3 NIC supports hardware timestamping, we use software timestamps provided by the system clocks so that we can compare a public cloud and a bare-metal cloud by making the CloudLab setup as close as possible to a bare-metal cloud.

5.1.4 Selection of On-Ramp parameters

The EWMA gain g is set to $1/16$ (§3.2). The threshold T should be higher than the minimal OWD on the path, plus some headroom to tolerate errors in OWD measurements.

In Google Cloud, (i) as reported in [23], the VM-VM minimal RTT for TCP traffic is typically 25 μs, so the minimal OWD is less than that; (ii) the inaccuracy of Tx and Rx timestamps can be around 50 μs due to GSO in VM on Tx side and the merging of Rx segments in the hypervisor; (iii) the high percentile clock sync inaccuracy under Huygens is less than 3 μs. Taken together, we pick $T = 150\mu s$ to be safe.

In Cloudlab, following similar steps, we pick $T = 50\mu s$, because the minimal OWD is smaller, and there is no VM hypervisor involved in Cloudlab evaluations.

In ns-3, the minimal OWD is up to 6 μs inside the network. It emulates a NIC implementation of On-Ramp so the timestamps are accurate. To be safe, we pick $T = 6 + 10 = 16\mu s$.

§7.4 shows that the end-to-end performance of On-Ramp is only mildly sensitive to the value of T and g.

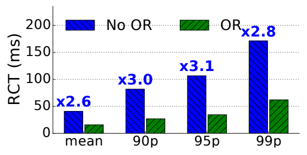
5.2 On-Ramp Performance

5.2.1 Google Cloud Platform (GCP)

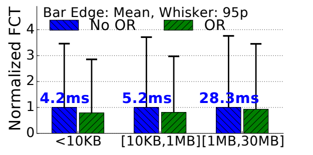
We first consider the **following basic scenario** in GCP: *WebSearch* traffic at 40% load, and an incast load at 2% with a fanout of 40 where each of the 40 flows is 2KB (on each server, the average interval between two consecutive incast requests is 3.2 ms), and CUBIC congestion control.

Incast RCT. As can be seen in Figure 9a, the mean, 90th, 95th and 99th percentile RCTs of an incast request are reduced by 2.6×, 3.0×, 3.1× and 2.8×, respectively.

Background traffic FCT. We group background traffic flows into three buckets by size: small (≤10KB), medium (10KB–1MB), and large (1MB–30MB) flows. On-Ramp improves the mean FCT of the *WebSearch* background traffic flows by 21%, 19%, and 7% compared to the baseline for the flows of small, medium and large sizes respectively. The 95th percentile FCT shows similar improvements. This means that time-critical short flows get lower FCTs and the throughput of long flows does not degrade. Thus, On-Ramp *does not adversely affect* the congestion control of the long flows; indeed, it even improves it mildly by reducing packet drops and timeouts, so the long flows avoid unnecessary window cuts in CUBIC algorithm. See Figure 9b.[6] Finally, the percentage of packets retransmitted reduces from 0.0693% to 0.0314%.



(a) Incast RCT



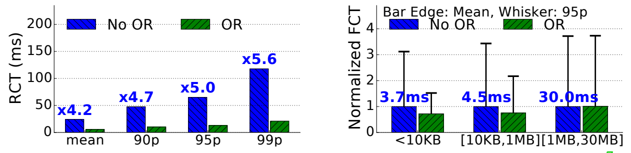
(b) FCT of Background Traffic, normalized by mean FCT without OR[7]

Figure 9: Cloud VM, CUBIC, *WebSearch* at 40% load + Incast at 2% load (fanout=40, size of each flow=2KB).

[6]Note that, for this and all following experiments in GCP and CloudLab, the baseline "No OR" already includes the benefits of per-flow queueing and round-robin dequeueing, because the default QDisc (FQ_CoDel [9] for CUBIC and FQ [25] for BBR) in Ubuntu 18.04 provides this functionality. Therefore, the performance gain from "no OR" to "OR" purely comes from the On-Ramp algorithm.

Varying congestion control algorithms. We generalize the basic scenario by swapping out CUBIC for BBR [19]. BBR is an out-of-box alternative to CUBIC in VMs of public clouds. Figure 10a shows the mean and tail RCTs of an incast request are reduced by On-Ramp by 4.2× – 5.6×. On-Ramp also reduces the mean FCT of the *WebSearch* background traffic flows by 28% and 25% for the small and medium sizes respectively, and tail FCT by 51% and 37%, while maintaining the same performance as the baseline for the large flows, as shown in Figure 10b. In this scenario, the fraction of packets retransmitted reduces by 21×, from 0.0105% to 0.0005%.

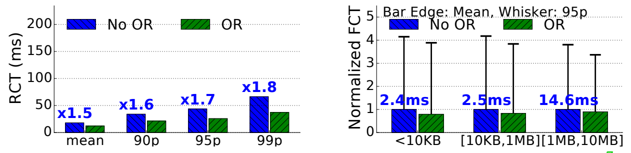
Note that BBR gives smaller RCTs of incast requests and FCTs of short flows than CUBIC because it controls delays. On-Ramp is able to further improve BBR's performance under the incast traffic.



(a) Incast RCT **(b)** FCT of Background Traffic[7]

Figure 10: Cloud VM, **BBR**, *WebSearch* at 40% load + Incast at 2% load (fanout=40, size of each flow=2KB).

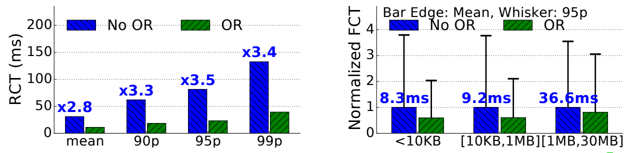
Varying background traffic pattern. Next, we consider the *FB_Hadoop* traffic at 40% load with an incast load as above and the CUBIC algorithm. Figure 11 shows the results.



(a) Incast RCT **(b)** FCT of Background Traffic[7]

Figure 11: Cloud VM, CUBIC, **FB_Hadoop** at 40% load + Incast at 2% load (fanout=40, size of each flow= 2KB).

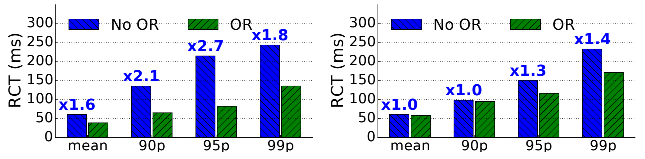
Varying the load level of background traffic. To test the robustness of On-Ramp under high load, we increase the background traffic to 80% load in the basic scenario, leaving everything else fixed. The results are in Figure 12. The performance gains achieved by On-Ramp are larger under higher loads. Figure 25 in Appendix shows the results at 60% load.



(a) Incast RCT **(b)** FCT of Background Traffic[7]

Figure 12: Cloud VM, CUBIC, *WebSearch* at **80% load** + Incast at 2% load (fanout=40, size of each flow 2KB).

Varying the pattern and load level of incast traffic. Finally, in order to understand the effect of On-Ramp on RCT of larger incast requests (modeling storage-type traffic), we increased the size of incast flows from 2KB to 500KB in the basic scenario at incast loads of 20% and 2%. The findings are shown in Figure 13. Also, the total number of timeouts is reduced by 21× and 13× in the cases of 20% and 2% incast load respectively.



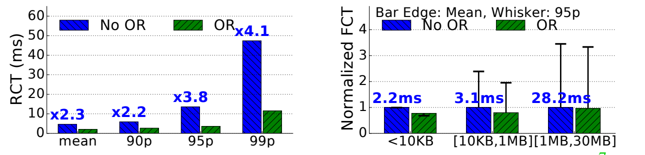
(a) Incast RCT (20% Incast Load) **(b)** Incast RCT (2% Incast Load)

Figure 13: Cloud VM, CUBIC, *WebSearch* at 40% load + Incast (fanout=40, **size of each flow 500KB**).

This scenario highlights an interesting aspect of On-Ramp, namely, that the potential one RTT delay in obtaining OWD measurement when a new flow starts can be avoided by using the OWD measurements from previous flows. Specifically, under 2% load, the average interval between two consecutive incast requests is 800 ms, which is which is about one order of magnitude higher than the average RCT for requests of size 20MB (500KB × 40). Therefore, the gap between two request responses is large, and each request starts by getting new OWD measurements. When the incast load is 20%, the average inter-request interval (80 ms) is comparable to the average RCT. Therefore, a new request is able to leverage the OWD measurement of the previous one and help On-Ramp detect and throttle the incast episodes.[8]

5.2.2 CloudLab

For the evaluation on CloudLab, we consider the basic scenario described in the GCP evaluation except that the *WebSearch* traffic is at 60% load. As can be seen in Figure 14a, we observe similar improvements as GCP: the mean and tail RCTs of an incast request improves by 2.3× – 4.1×. The mean FCTs of the *WebSearch* background traffic flows are improved by 23%, 20%, 4% across flows of small, medium and large sizes respectively, as shown in Figure 14b.



(a) Incast RCT **(b)** FCT of Background Traffic[7]

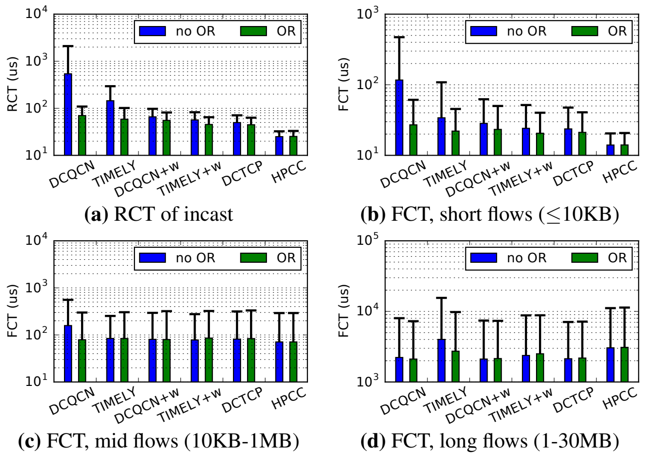
Figure 14: Bare-metal, CUBIC, *WebSearch* at 60% load + Incast at 2% load (fanout=40, size of each flow=2KB).

5.2.3 Large-scale ns-3 simulations

To understand the performance of On-Ramp when combined with recently developed congestion control schemes which use detailed network congestion information, we use ns-3 simulations. We use *WebSearch* traffic at 60% load, plus incast with a fanout of 40 and flow sizes of 2KB at 2% load. As

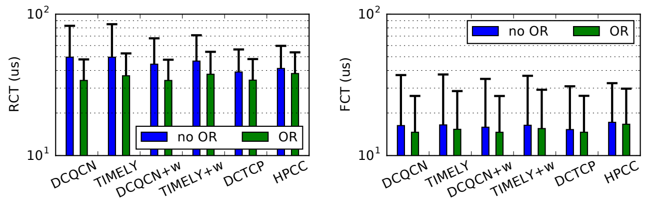
[7]Fig. 10b, 11b, 12b, 14b, 19b has the same normalization as Fig. 9b.

[8]Note that when the incast flow sizes are 2KB and the load is 2%, the average inter-request interval is 3.2 ms, 250 times smaller than when the flow sizes are 500KB. Therefore, in this case, an On-Ramp sender-side module *does* receive frequent-enough OWD measurements even at low load.



(a) RCT of incast **(b)** FCT, short flows (≤10KB) **(c)** FCT, mid flows (10KB-1MB) **(d)** FCT, long flows (1-30MB)

Figure 15: ns-3, *WebSearch* of 60% load + incast of 2% load. Bars: mean, whiskers: 95th percentile. *Y-axis in log.*



(a) RCT of incast **(b)** FCT, GoogleSearchRPC flows

Figure 16: ns-3, **GoogleSearchRPC** of 60% load + incast of 2% load. Bars: mean, whiskers: 95th percentile. *Y-axis in log.*

a reminder, to mimic realistic deployments, PFC is in effect and each server's clock is jittered by an additional random offset according to a Gaussian distribution with a standard deviation of 200 ns, so OWD measurement is not precise. The congestion control algorithms used are DCQCN, TIMELY, DCTCP and HPCC. Following [44], a sending window is added to DCQCN and TIMELY to limit the bytes-in-flight. These algorithms are called DCQCN+w and TIMELY+w.

As seen in Figure 15, the mean and tail RCT of incast traffic is reduced significantly for DCQCN, TIMELY, DCQCN+w, TIMELY+w and DCTCP. The performance of HPCC is not significantly improved because it utilizes recent and detailed congestion information from the network elements and is already highly performant. Further, the FCT of the *WebSearch* flows is improved across all categories, including the large flows (1MB-30MB). Again, the extent of improvement is algorithm-specific.

Then, we change the background traffic to *FB_Hadoop*, leaving the other settings the same. The improvement given by On-Ramp is similar to the above. See Appendix Figure 26.

Next, we consider the *GoogleSearchRPC* workload. Since this traffic has mostly (>99.85%) small flows (≤10KB), we simply consider the mean and high percentile FCT across all flows rather than categorizing by flow size, as shown in Figure 16. This workload is challenging for most congestion control algorithms because nearly 80% of bytes are due to flows under 10 KB in size—too short for congestion control algorithms to address.[9] However, just by more efficiently controlling the transient events caused by the remaining 20% of bytes from the relatively long flows, On-Ramp improves the performance of all algorithms, including HPCC.

6 Evaluation in Facebook's Network

We have also evaluated On-Ramp at Facebook, where On-Ramp was used to throttle large, high-bandwidth storage file transfers so that they don't eat up all the switch buffers, causing severe packet drops for latency-sensitive compute application traffic. This scenario is canonical in data centers where multiple types of traffic with different objectives share the same network fabric. Our goal is to use On-Ramp to ensure storage traffic gets the bandwidth it needs while not affecting the latency of the compute applications.

Environment. Two racks inside a Facebook production cluster are used in the evaluation. As a typical setup, in the first rack, 15 machines work as application clients and 12 work as storage clients. In the second rack, 30 machines work as application servers and 6 work as storage servers. The two ToR switches are connected to 3 spine switches. The link bandwidth is 100 Gbps for each storage server, 25 Gbps for all other machines, and 100 Gbps between each ToR and each spine switch. Huygens runs on all machines to synchronize their clocks.

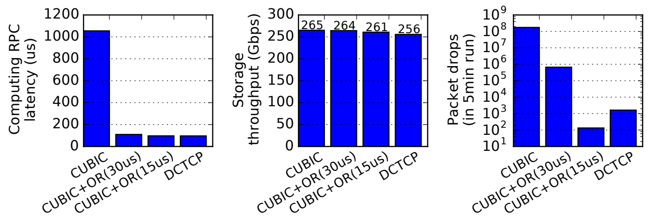
Traffic loads. Two types of traffic are run simultaneously: (1) Computing traffic: They are latency-sensitive short flows carrying RPCs generated by computing jobs. They run between the application clients and servers. (2) Storage traffic: Each pair of storage clients read files from one storage server via NVMe-over-TCP [11], which generates throughput-sensitive long flows consisting of 16–128KB bursts. When 12 or more storage clients are reading, the total amount of storage traffic requested will be $25 \times 12 = 300$ Gbps or more, enough to saturate the uplinks from the second ToR switch to the spine switches. Severe congestion happens at this load.

Results. Figure 17 shows the results when 12 storage clients are reading from storage servers.[10] When using the default CC CUBIC, the latency of computing RPCs is severely hurt by the storage traffic, and numerous packets are dropped. Deploying On-Ramp with CUBIC reduces the latency of computing RPCs by 10× while maintaining the throughput of storage traffic. The number of packets dropped is reduced by about 260×. Here we pick On-Ramp threshold T=30μs following the guideline in §3.2. The more aggressive setting of T=15μs reduces the packet drops even more while only marginally reducing the storage throughput, as shown in the figure.

On-Ramp's performance was compared with DCTCP as well, and we found that, under saturation loading of storage traffic (300 Gbps), both achieve a similar performance in

[9]DCQCN, TIMELY and HPCC have no slow start phase. Following [44], DCTCP's slow start phase is removed for fair comparisons.

[10]See Appendix §10.3 for results with 0–12 storage clients.



(a) Latency **(b)** Throughput **(c)** Packet drops

Figure 17: On-Ramp's performance in a Facebook cluster

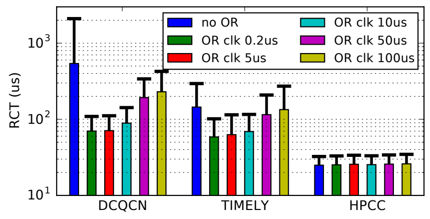


Figure 18: RCT of incast traffic under different levels of clock inaccuracy. Bars: mean, whiskers: 95th percentile.

terms of compute application latency,[11] but DCTCP achieves a slightly lower storage throughput compared to On-Ramp + CUBIC. A drawback of DCTCP is that it needs ECN marking at all the switches which is not only operationally burdensome, but challenging when many non-DCTCP flows (e.g., flows whose source or destination is an external server) share switches with the DCTCP flows. Being purely edge-based, On-Ramp sidesteps these burdens and challenges.

7 On-Ramp Deep Dive

7.1 The Accuracy of OWD Signals

To study the effect of the accuracy of OWD signals on On-Ramp's end-to-end performance, we repeat the ns-3 scenario described in §5.2.3 and consider DCQCN, TIMELY and HPCC. We add a constant random Gaussian offset to each clock of standard deviation σ_{clk}, and vary σ_{clk} to model different levels of clock inaccuracy.

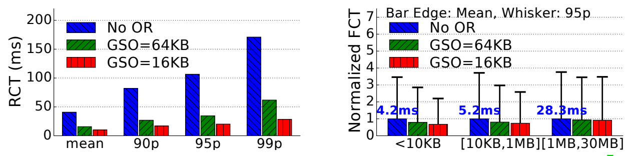
Recall that $0.2\mu s$ is the default σ_{clk} we use throughout our ns-3 evaluation, with a corresponding threshold $T = 16\mu s$. Here, we increase σ_{clk} up to $100\mu s$ and, following the guidelines in §3.2, we change the threshold T according to the formula $T = 2\sigma_{clk} + minOWD$ ($minOWD = 6\mu s$ in ns-3). Essentially, inaccurate clocks lead to inaccurate measurements of OWD which become confounded with path congestion. Choosing a value of T as per the formula above allows for inaccurate clocks. In practice, Huygens reports an estimation of clock inaccuracy via the network effect [30], so we can adapt the threshold T according to it using this formula.

Figure 18 shows the RCT of incast requests under different σ_{clk}. We observe that for DCQCN and TIMELY, as σ_{clk} increases, the mean and tail incast RCT also increases. The performance degradation becomes more significant when σ_{clk} becomes comparable to the OWDs under congestion (roughly $20-100\mu s$). Since HPCC maintains very small queues (due to its bandwidth headroom), it operates well under the threshold T of queuing delay needed to trigger On-Ramp. Hence, On-Ramp doesn't affect its performance.

7.2 The Granularity of Control

As discussed in §4.1, GSO affects the granularity of control by On-Ramp. We study its effect by reducing the max GSO size from the default value of 64 KB to 16 KB. As shown in Figure 19, the mean and 90th, 95th, 99th percentile of incast traffic RCT are *further* reduced by 36%, 37%, 41%, 54%, respectively. The FCT of short and mid-sized flows in the *WebSearch* traffic are further reduced by 8-14% (mean) and 13-22% (95th percentile). The throughput of long flows is well-maintained. However, reducing max GSO size adds more CPU overhead to the sender, so we let the user decide on it.

Remark. This experiment explains the significant performance improvement of On-Ramp in ns-3 when compared to the Google Cloud and CloudLab implementations. In ns-3, we are effectively simulating a NIC implementation where On-Ramp has per-packet control and highly accurate time synchronization, which leads to better performance.



(a) Incast RCT **(b)** FCT of Background Traffic[7]

Figure 19: Cloud VM, CUBIC, *WebSearch* at 40% load + Incast at 2% load (fanout=40, each flow 2KB).

7.3 Co-existence

A public cloud user is unaware of other users and the amount of traffic (not controlled by On-Ramp) they insert into the network. Hence, it is possible that the effect of On-Ramp can be blunted when other traffic is present. In fact, if non-On-Ramp traffic shares links with On-Ramp traffic, the latter may unilaterally do worse because On-Ramp may pause transmission when congestion due to the non-On-Ramp traffic increases. The results in §5.2.1 show that this dire situation may not happen: a cloud user can achieve better performance by enabling On-Ramp in their own VM cluster even though there *may* be non-On-Ramp traffic on their paths. In this section, we revisit this question in the controlled environment of CloudLab.

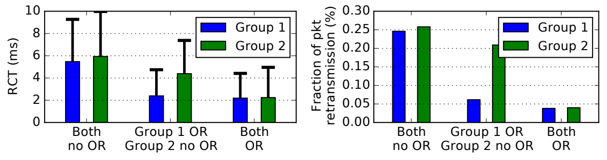
We consider the scenario in §5.2.2 and divide the 100 servers in CloudLab randomly into two groups with 50 servers each. The same workload as in §5.2.2 is run inside each group, but we don't run cross-group traffic. This models 2 users renting servers in a cloud environment unbeknownst to each other. We evaluate the performance in the following cases: (i) both groups do not use On-Ramp, (ii) Group 1 uses On-Ramp but not Group 2, and (iii) both groups use On-Ramp.

Figure 20 summarizes the results. Interestingly, when Group 1 uses On-Ramp and Group 2 does not, *both groups* do

[11]Indeed, both DCTCP and On-Ramp + CUBIC achieve an RPC latency under saturation loading nearly equal to the case when there is no storage traffic, which is the best possible. See Appendix §10.3 for details.

better than when neither uses On-Ramp. Essentially, during periods of congestion, On-Ramp enables Group 1 senders to transmit their traffic at moments when Group 2 traffic is at low load. Conversely, the improvement in Group 2's performance is due to a reduction in overall congestion.

When Group 2 also uses On-Ramp, the improvement in Group 1's performance is only slight. Thus, Group 1 obtains almost the same benefit from using On-Ramp whether or not Group 2 uses it; this is desirable for incremental deployment.



(a) RCT of incast **(b)** Pkt retransmission

Figure 20: Co-existence of traffic with and without OR.

7.4 On-Ramp Parameters T and g

To explore the sensitivity of On-Ramp on the threshold T and EWMA gain g, we run the same basic evaluation scenario described in 5.2.1 in GCP, but now vary T between 50μs and 500μs, and g between $\frac{1}{4}$ and $\frac{1}{64}$. Recall that for GCP, the default parameter values are $T = 150\mu s$ and $g = \frac{1}{16}$. Figure 21a shows that the performance of On-Ramp worsens noticeably as T increases beyond 300 μs. Figure 21b shows that On-Ramp's performance is relatively insensitive to the value of g in the range between $\frac{1}{4}$ and $\frac{1}{64}$.

8 Related Work

Congestion control (CC). CC algorithms can be broadly categorized into two groups: (i) those which need no network assistance, e.g., drop-based schemes (TCP NewReno [28], CUBIC [33]) or delay-based schemes (TCP Vegas [18], TIMELY [47], and Swift [42]); and (ii) those which rely on network assistance, e.g., use ECN signals (DCTCP [13], DCQCN [53]), leverage in-band network telemetry (HPCC [44]), or rely on the network's ability to perform some functions like scheduling or trimming packets [16,17,29,31,34,47,49]. On-Ramp is complementary to CC. It is meant to be deployed underneath any CC algorithm, providing a fast and accurate response to transient congestion purely from the edge of the network. Swift [42] is a recent algorithm that uses RTT measurements and carefully chosen delay targets with support for fractional congestion windows to obtain good performance across a wide range of deployment scenarios. Swift couples the handling of equilibrium (on ACK) and transient (on timeout). This coupling is likely to lead to the equilibrium-transient tension mentioned in §2. By contrast, On-Ramp explicitly decouples the two, providing more robust performance.

In-network pause. Schemes such as Priority-based Flow Control (PFC) [38] have been widely deployed to eliminate packet drops in switches. However, PFC causes several safety and performance challenges including PFC deadlocks and congestion spreading [32,36,48,53]. By pausing flows at the edge, On-Ramp avoids these challenges.

Congestion Control (CC) in cloud environments. Previous works like AC/DC TCP [35] and Virtualized Congestion Control (VCC) [22] give cloud admins control over the CC of the users' VMs by translating between the target CC and the VM's CC. Their architectures are similar to On-Ramp: they also operate as a shim layer between the VM applications and the physical network, intercepting packets without requiring network infrastructure changes. However both AC/DC TCP and VCC rely on ECN support from the network infrastructure to implement the target CC (DCTCP) and need to be implemented by the cloud provider within the hypervisor. On-Ramp makes no assumptions of the underlying network infrastructure and can be implemented by cloud users within their VMs.

Flow scheduling in data centers. On-Ramp performs a form of flow scheduling because it pauses packets at the edge for a short period of time. Previous work in this space like pHost [29], NDP [34], and Homa [49] propose algorithms with varying levels of network support to enable flow scheduling within the network and improve end-to-end performance. On-Ramp requires no network support and is done purely at the edge. It can therefore be readily deployed, especially by users of public cloud environments.

9 Conclusion and Future Work

Datacenter packet transport over the last decade has relied increasingly on network support (e.g., ECN marking, queue size information), making it hard to deploy in environments such as the public cloud. We show empirically that the move towards increasingly rich network support is rooted in a tension between equilibrium and transience performance. Motivated by these results, we take a step back and modularize congestion control into two separate components, one responsible for equilibrium and the other for transients. We leave equilibrium handling to existing congestion control algorithms and design a new underlay scheme, On-Ramp, for transient handling. On-Ramp uses one-way delay measurements enabled by synchronized clocks to hold back packets transmitted by any congestion control algorithm at the edge of a network during transient congestion. Intellectually, On-Ramp contains two ideas that are of independent interest. First is the use of synchronized clocks to improve network performance. Second is the factoring of datacenter congestion control—traditionally a single control loop—into two separate control loops, one each for transience and equilibrium. We hope this paper is the beginning of a more in-depth investigation of both ideas.

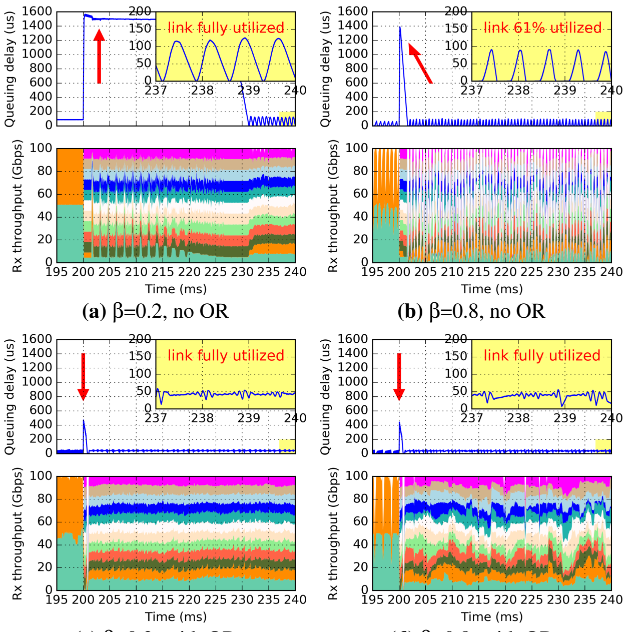
10 Appendix

10.1 Supplemental Material for §2 and §3

Figures 22 and 23 extend the results shown in Figures 1 and 2 of §2, by displaying the throughputs received by each flow as a stack. When the gain parameter is low (Figs. 22a and 23a), both TIMELY and DCQCN suffer from a long convergence time in transience, during which the flow throughputs are unstable and unfair. Under a high gain parameter, both algorithms under-utilize the link during equilibrium; see Figs. 22b and 23b. When On-Ramp is enabled, both CCs have shorter time in transience and smoother, fairer flow throughputs in equilibrium.



(a) β=0.2, no OR **(b)** β=0.8, no OR **(c)** β=0.2, with OR **(d)** β=0.8, with OR

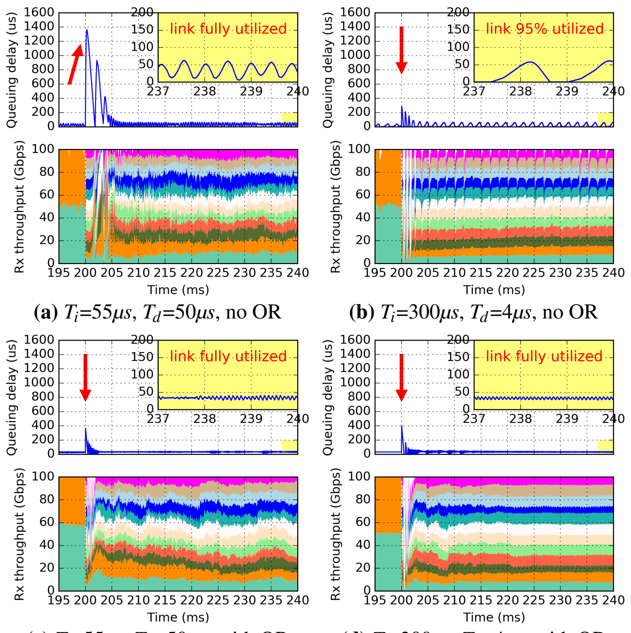
Figure 22: TIMELY study, the red arrow points to transience, and the yellow box is a zoom-in of equilibrium. OR T=30μs.

Figure 24 is a follow-up of Figure 5 in §3.2, which shows the OWDs and the flow rates when 12 CUBIC flows share a bottleneck link in a bare-metal environment (Cloudlab). The threshold T is also 50μs. When using strawman On-Ramp, similar to the case of 2 flows, the queue also suffers from significant undershooting. When using the final version of On-Ramp, most fluctuations in queue lengths are removed, and it achieves better fair sharing among all flows.

10.2 Supplemental Evaluation

Figure 25 corresponds to the evaluation scenario referred to in §5.2.1 of the main text, where the background *WebSearch* load is 60% for the base scenario in GCP.

Figure 26 corresponds to the ns-3 evaluation in §5.2.3. Here, we run *FB_Hadoop* traffic at 60% load, plus incast with



(a) T_i=55μs, T_d=50μs, no OR **(b)** T_i=300μs, T_d=4μs, no OR **(c)** T_i=55μs, T_d=50μs, with OR **(d)** T_i=300μs, T_d=4μs, with OR

Figure 23: DCQCN study. OR T=30μs.

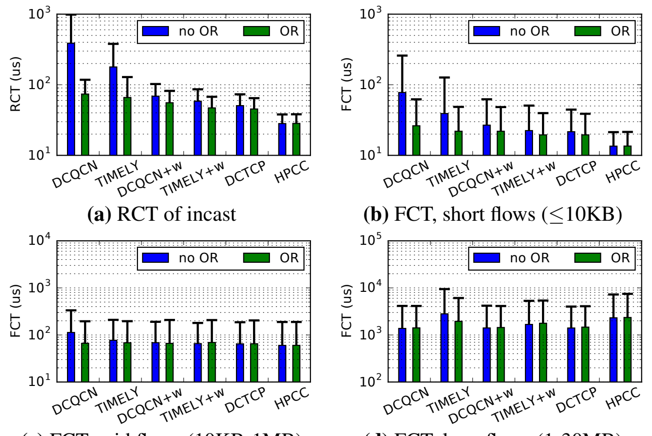
Figure 25: Cloud VM, CUBIC, *WebSearch* at **60% load** + Incast at 2% load (fanout=40, each flow 2KB).



(a) RCT of incast **(b)** FCT, short flows (≤10KB)

(c) FCT, mid flows (10KB-1MB) **(d)** FCT, long flows (1-30MB)

Figure 26: ns-3, **FBHadoop** of 60% load + incast of 2% load. Bars: mean, whiskers: 95th percentile. *Y-axis in log.*

a fanout of 40 and flow sizes of 2KB at 2% load. The findings are similar to the experiment with *WebSearch* workload (Figure 15). With On-Ramp, the RCT of incast requests and FCT of short flows in background traffic are significantly reduced, while the throughput of long flows is well-maintained (even improved e.g. in TIMELY). Again, the extent of improvement is algorithm-specific.

10.3 Supplemental Results: Facebook

Figure 27 corresponds to the evaluation in Facebook described in §6. The number of storage clients reading from storage servers is set to be 0, 2, 4, ..., 12, so the requested load of storage traffic is 0, 50, 100, ..., 300 Gbps respectively. When the requested load is less than or equal to 250 Gbps, the network is not congested yet, CUBIC, CUBIC + On-Ramp and DCTCP give similar performances. When the requested load hits 300 Gbps, the computing RPC latency shoots up dramatically under CUBIC, meaning it is severely hurt by the storage traffic. Using CUBIC + On-Ramp or DCTCP brings the latency down to the level similar to the non-congested case, while keeping the throughput of storage traffic well-maintained, as we discussed in §6.

Abstract

Border Gateway Protocol (BGP) forms the foundation for routing in the Internet. More recently, BGP has made serious inroads into data centers on account of its scalability, extensive policy control, and proven track record of running the Internet for a few decades. Data center operators are known to use BGP for routing, often in different ways. Yet, because data center requirements are very different from the Internet, it is not straightforward to use BGP to achieve effective data center routing.

In this paper, we present Facebook's BGP-based data center routing design and how it marries data center's stringent requirements with BGP's functionality. We present the design's significant artifacts, including the BGP Autonomous System Number (ASN) allocation, route summarization, and our sophisticated BGP policy set. We demonstrate how this design provides us with flexible control over routing and keeps the network reliable. We also describe our in-house BGP software implementation, and its testing and deployment pipelines. These allow us to treat BGP like any other software component, enabling fast incremental updates. Finally, we share our operational experience in running BGP and specifically shed light on critical incidents over two years across our data center fleet. We describe how those influenced our current and ongoing routing design and operation.

1 Introduction

Historically, many data center networks implemented simple tree topologies using Layer-2 spanning tree protocol [5, 11]. Such designs, albeit simple, had operational risks due to broadcast storms and provided limited scalability due to redundant port blocking. While centralized software-defined network (SDN) designs have been adopted in wide-area networks [28, 29] for enhanced routing capabilities like traffic engineering, a centralized routing controller has additional scaling challenges for modern data centers comprising thousands of switches, as a single software controller cannot react quickly to link and node failures. Thus, as data centers grew, one possible design was to evolve into a fully routed Layer-3 network, which requires a distributed routing protocol.

[*]Work done while at Facebook. Authors contributed equally to this work.
[†]Currently works at ByteDance.

Border Gateway Protocol (BGP) is a Layer-3 protocol which was originally designed to interconnect autonomous Internet service providers (ISPs) in the global Internet. BGP has supported the Internet's unfettered growth for over 25 years. BGP is highly scalable, and supports large topologies and prefix scale compared to intra-domain protocols like OSPF and ISIS. BGP's support for hop-by-hop policy application based on communities makes it an ideal choice for implementing flexible routing policies. Additionally, BGP sessions run on top of TCP, a transport layer protocol that is used by many other network services. Such explicit peering sessions are easy to navigate and troubleshoot. Finally, BGP has the support of multiple mainstream vendors, and network engineers are familiar with BGP operation and configuration. Those reasons, among others, make BGP an attractive choice for data center routing.

BGP being a viable routing solution in the data center (DC) networks has been well known in the industry [11]. However, the details of a practical implementation of such a design have not been presented by any large-scale operator before. This paper presents a first-of-its-kind study that elucidates the details of the scalable design, software implementation, and operations. Based on our experience at Facebook, we show that BGP can form a robust routing substrate but it needs tight co-design across the data center topology, configuration, switch software, and DC-wide operational pipeline.

Data center network designers seek to provide reliable connectivity while supporting flexible and efficient operations. To accomplish that, we go beyond using BGP as a mere routing protocol. We start from the principles of configuration *uniformity* and operational *simplicity*, and create a baseline connectivity configuration (§2). Here, we group neighboring devices at the same level in the data center as a peer group and apply the same configurations on them. In addition, we employ a uniform AS numbering scheme that is reused across different data center fabrics, simplifying ASN management across data centers. We use hierarchical route summarization on all levels of the topology to scale to our data center sizes while ensuring forwarding tables in hardware are small. Our policy configuration (§3) is tightly integrated with our baseline connectivity configuration. Our policies ensure reliable communication using route propagation scopes and predefined backup paths for failures. They also allow us to maintain the network by seamlessly diverting traffic from problematic/faulty devices in a graceful fashion. Finally, they ensure services remain reachable even when an instance of the service gets added, removed, or migrated.

While BGP's capabilities make it an attractive choice for routing, past research has shown that BGP in the Internet suffers from convergence issues [33, 37], routing instabilities [32], and frequent misconfigurations [21, 36]. Since we control all routers in the data center, we have flexibility to tailor BGP to the data center which wouldn't be possible to achieve in the Internet. We show how we tackled common issues faced in the Internet by fine-tuning and optimizing BGP in the data center (§4). For instance, our routing design and predefined backup path policies ensure that under common link/switch failures, switches have alternate routing paths in the forwarding table and do not send out fabric-wide re-advertisements, thus avoiding BGP convergence issues.

To support the growing scale and evolving routing requirements, our switch-level BGP agent needs periodic updates to add new features, optimization, and bug fixes. To optimize this process, i.e., ensure fast frequent changes to the network infrastructure to support good route processing performance, we implemented an in-house BGP agent (§5). We keep the codebase simple and implement only the necessary protocol features required in our data center, but we do not deviate from the BGP RFCs [6–8]. The agent is multi-threaded to leverage multi-core CPU performance of modern switches, and leverages optimizations like batch processing and policy caches to improve policy execution performance.

To minimize impact on production traffic while achieving high release velocity for the BGP agent, we built our own testing and incremental deployment framework, consisting of unit testing, emulation and canary testing (§6.1). We use a multi-phase deployment pipeline to push changes to agent (§6.2). We find that our multi-phase BGP agent pushes ran for 52% of the time in a 12 month duration, highlighting the dynamic nature of the BGP agent in our data center.

In spite of our tight co-design, simplicity, and testing frameworks, network outages are unavoidable. On the operational side, we discuss some of the significant BGP-related network outages known as SEVs [38] that occurred over two years (§6.3)—these outages were either caused by incorrect policy configurations, bugs in the BGP agent software, or interoperability issues between different agent versions during the deployment of the new agent. Using our operational experience, we discuss current directions we are pursuing in extending policy verification and emulation testing to improve our operational framework, and changing our routing design to support weighted load-balancing to address load imbalances under maintenance/failures.

Contributions.

- We present our novel BGP routing design for the data center which leverages BGP to achieve reliable connectivity along with operational efficiency.
- We describe the routing policies used in our data center to enforce reliability, maintainability, scalability, and service reachability.
- We show how our data center routing design and policies overcome common problems faced by BGP in Internet.
- We present our BGP operational experience, including the benefits of our in-house BGP implementation and challenges of pushing BGP upgrades at high release velocity.

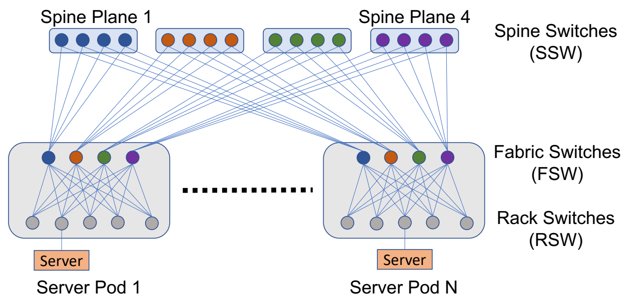

Figure 1: Data Center Fabric Architecture

2 Routing Design

Our original motivation in devising a routing design for our data center was to *build* our network quickly while keeping the routing design *scalable*. We sought to create a network that would provide high availability for our services. However, we expected failures to happen - hence, our routing design aimed to minimize the blast radius of those.

In the beginning, BGP was a better choice for our needs compared to a centralized SDN routing solution for a few reasons. First, we would have needed to build the SDN routing stack from scratch with particular consideration for scalability and reliability, thus, hindering our deployment pace. Simultaneously, BGP has been demonstrated to work well at scale; thus, we could rely on a BGP implementation running on third-party vendor devices. As our network evolved, we gradually transitioned to our custom hardware [18] and in-house BGP agent implementation. This transition would have been challenging to achieve without using a standardized routing solution. With BGP, both types of devices were able to cooperate in the same network seamlessly.

At the time, BGP was a better choice for us compared to the Interior Gateway protocols (IGP) like Open Shortest Path First (OSPF) [39] or Intermediate System to Intermediate System (ISIS) [25]. The scalability of IGPs at scale was unclear, and the IGPs did not provide the flexibility to control route propagation, making it harder to manage failure domains.

We used BGP as the sole protocol and did not pursue a hybrid BGP-IGP routing design as maintaining multiple protocols would add to the complexity of the routing solution. Our routing design builds on the eBGP (External BGP) peering model: Each switch is a BGP speaker and the neighboring BGP speakers are in different autonomous systems (AS). In this section, we provide an overview of our BGP-based routing design catered for our scalable data center fabric topology.

2.1 Topology Design

Application requirements evolve constantly, and our data center design must be capable of scaling out and handling additional demand in a seamless fashion. To this end, we adopt a modular data center fabric topology design [4], which is a collection of *server pods* interconnected by multiple parallel *spine planes*. We illustrate our topology in Figure 1.

A server pod is the smallest unit of deployment, and it has the following properties: (1) each pod can contain up to 48 server racks, and thus, up to 48 rack switches (RSWs), (2) each pod is serviced by up to 16 fabric switches (FSWs), and (3) each rack switch connects to all FSWs in a pod.

Multiple spine planes interconnect the pods. Each plane has multiple spine switches (SSW) connecting to FSWs using uniform high-bandwidth links (FSW-SSW). The number of spine planes corresponds to the number of FSWs in one pod. Each spine plane provides a set of disjoint end-to-end paths between a collection of server pods. This modular design enables us to scale server capacity and network bandwidth as needed—we can increase compute capacity by adding new server pods, while inter-pod bandwidth scales by adding new SSWs on planes.

2.2 Routing Design Principles

We employ two guiding design principles in our DC-wide BGP-based routing design: *uniformity* and *simplicity*. We realize these principles by tightly integrating routing design and configuration with the above topology design.

We strive to minimize the BGP feature set and establish repeatable configuration patterns and behaviors throughout the network. Our BGP configuration is homogeneous within each network tier (RSW, FSW, SSW). The devices serving in the same tier have the same configuration and policies, except for the originated prefixes and peer addresses.

We generate the network topology data and configuration which includes port-maps, IP addressing, BGP, and routing policy configurations for our switches irrespective of the underlying switch platforms. The abstract generic configurations are then translated into the target platform's configuration syntax by our automation software. This ensures that we can easily adapt to changing hardware capabilities in the data center. The details of our configuration management and platform-specific syntax generation can be found in Robotron [44].

2.3 BGP Peering & Load-Sharing

Peering. For uniformity and simplicity in configuration and operations, we treat the whole set of the BGP peers of the same adjacent tier (RSW/FSW/SSW) on a network switch as an *atomic group*, called peer group. Each data center switch connects to groups of devices on each adjacent tier. For example, a FSW aggregates a set of RSWs and has uplinks to multiple SSWs—this makes two distinct peer groups. All BGP peering sessions between adjoining device tiers—for example RSW↔FSW and FSW↔SSW—utilize the same protocol features, timers, and other parameters. Thus, all peers within a group operate in a uniform fashion.

We apply BGP configuration and routing policies on a peer group level. Individual BGP peer sessions belong to a peer group and do not have any additional configuration information beside the neighbor specification. This grouping helps us to simplify configuration and streamline processing of routing updates, as all peers in the same group have identical policies.

For peering, we use direct single-hop eBGP sessions with BGP NEXT_HOP attribute, set to the remote end of the point-to-point subnet. This makes the link usable for BGP routing purposes as soon as it is up. If there are multiple parallel links between the devices, we treat them as individual point-to-point Layer-3 subnets with corresponding BGP sessions. This design allows us to clearly associate BGP sessions with the corresponding network interfaces and simplifies RIB (routing information base) and FIB (forwarding information base) navigation, manipulation, and troubleshooting.

Load-Sharing. To support load-sharing of traffic along multiple paths in the data center, we use BGP with Equal Cost Multipath (ECMP) feature. Each switch forwards traffic equally among paths with equivalent attributes according to BGP best path selection and routing policy in effect. With the presence of multiple paths of equal cost, the vast majority of the switch FIB programming involves removing next hops (when failure occurs) or adding them back (when switch/link comes back up) in the existing ECMP groups. Updating ECMP groups in the FIB is a lightweight and simple operation.

We do not currently use weighted load-balancing inside our data centers for various reasons. Our fabric topology is highly symmetric with wide ECMP groups. We provision the bandwidth uniformly to maximize flexibility of dynamic service placement in the data center. Coupled with the design of our failure domains, this ensures sufficient capacity for services under most common failure scenarios. Moreover, WCMP [48] requires more hardware resources due to the replication of next-hops to perform weighted load-balancing. This does not align well with our goal of minimizing the FIB size requirements in hardware.

2.4 AS Numbering

Following the design principles of uniformity and simplicity, we design a uniform AS numbering scheme for the topology building blocks, such as server pods and spine planes. Our AS numbering scheme is canonical, i.e., the same AS numbers can be reused across data centers in the same fashion. For example, each SSW in the first spine plane in each data center would have the same AS number (e.g., AS 65001). Similarly, the RSWs and FSWs in every server pod of every data center share the same AS numbering structure. To accomplish this goal, we leverage BGP confederations [7]. A confederation

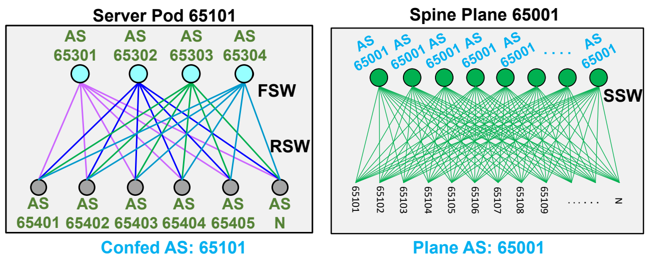

Figure 2: BGP Confederation and AS Numbering scheme for server pods and spine planes in the data center.

divides an AS into multiple sub-ASes such that the sub-ASes and internal paths between them are not visible to the BGP peers outside the confederation.

The uniformity facilitated by our use of confederations and the reusable ASNs (as opposed to a flat routing space) establishes well-structured AS_PATHs for policies and automation. This also helps operators to reason about a routing path easily by inspecting a given AS_PATH during troubleshooting. Inside the data center, we utilize the basic two-octet Private Use AS Numbers, which are sufficient for our design.

Server Pod. To create a reusable ASN structure for server pods—the most numerous building blocks inside our data center network—we implement each server pod as a BGP Confederation. Inside the pod, we allocate unique internal confederation-member ASNs for each FSW and each RSW. We then peer between the devices in a fashion similar to eBGP. The structure of these internal sub-AS numbers repeats within each pod. We assign a unique private AS number per pod (Pod ASN) within a data center as a Confederation Identifier ASN, which is how the pod presents itself to the data center spine and servers. The numbering pattern of unique pod Confederation Identifier ASNs repeats across different data centers. In Figure 2, in each pod, RSWs are numbered from ASN 65401 to N, FSWs are numbered from ASN 65301 to ASN 65304, and server pods are numbered as Confederation Identifier ASN 65101, 65102 and so on.

Spine Plane. Each spine plane in the data center fabric has its own unique (within the data center) private ASN assigned to all SSWs in it. In Figure 2, in the first spine plane, all SSWs are numbered ASN 65001. Similarly, all SSWs in the next spine plane would be numbered ASN 65002. This simplicity is possible because each SSW device operates independently from the others, serving as a member of the ECMP groups for the paths between pods. As no two SSWs directly peer with each other, they can use the same AS number. Reuse of ASNs acts as a *loop breaking mechanism*, ensuring that no route will traverse through multiple SSWs. The unique per-plane ASNs also aid us in simple identification of the operationally available planes for paths visible on rack switches.

2.5 Route Summarization

There are two principal categories of IP routes in our data centers: infrastructure and production. Infrastructure prefixes facilitate network device connectivity, management, and diagnostics. They carry relatively low traffic. In the event of a device or link failure, their reachability may be non-critical or can be supported by stretched paths. Production prefixes carry high-volume live traffic of our applications and must have continuous reachability in all partial failure scenarios, with optimal routing and sufficient capacity of all involved network paths and ECMP groups.

There are many routes in our data centers. To minimize the FIB size requirements in hardware and ensure lightweight control plane processing, we use hierarchical route summarization on all levels of the network topology. For production routes, we design IP addressing schemes which closely reflect the multi-level hierarchy. The RSWs aggregate the IP addresses of their servers and the FSWs aggregate the routes of their RSWs. For infrastructure routes, we have the following aggregates. Each device aggregates the IP addresses of all its interfaces, i.e. per-device aggregate. FSWs aggregate per-device RSW/FSW infrastructure routes into per-pod aggregates. And SSWs aggregate per-device SSW infrastructure routes into per-spine aggregates.

Depending on the route type and associated reachability criteria, switches advertise prefixes into BGP either unconditionally, or upon meeting the requirement of the minimal number of more-specific prefixes. The more-specific prefixes have a more limited propagation scope, while the coarser aggregates propagate farther on the network. For example, rack prefixes circulate only within their local pod, while pod-level aggregates propagate to the other pods and racks within the local data center fabric.

Hence, despite the sheer scale of our data center fabrics, our structured uniform route summarization ensures that the sizes of routing tables on switches are in low thousands of routes. Without route summarization, each router would have over hundred thousand routes, each route corresponding to the switches' interfaces and server racks. Our approach has many benefits: it allows us to use inexpensive commodity switch ASICs at the data center scale, enables fast and efficient transmission of routing updates, speeds up convergence (§5), and speeds up programming forwarding hardware.

3 Routing Policies

A key feature of BGP is the availability of well-defined attributes that influence the best path selection. Together with the ability to intercept route advertisements and admission at any hop and session, it allows us to control route propagation in the network with high precision. In this section, we review the use cases for routing policies in our data centers. We also describe how we configure the policies in BGP, while

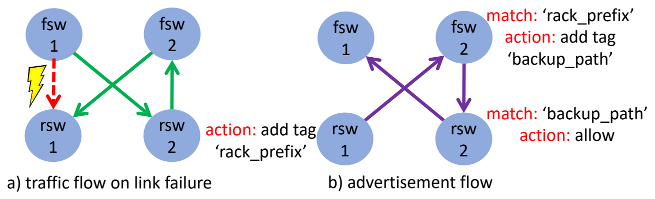

Figure 3: Example of predefined backup path policy.

realizing our principles of uniformity and simplicity.

3.1 Policy Goals

The Internet comprises multiple ASes owned by different ISPs. ISPs coordinate with each other to ensure routing objectives across the Internet. The routing policies mainly pertain to peering based on business relationships (customer-peer-provider) among different ISPs. However, since all the routers in our data centers are controlled by us, we do not have to worry about peering based on business relationships. Our data center routing design uses routing policies to ensure reliability, maintainability, scalability, and service reachability. We summarize these policy goals in Table 1.

Goal	Description
Reliability	Enforce route propagation scopes, predefine backup paths for failure
Maintainability	Isolate and remediate problematic nodes without disrupting traffic
Scalability	Enforce route summarization, avoid backup path explosion
Service reachability	Avoid service disruptions when instances of services are added, removed or migrated

Table 1: Policy goals

We use BGP Communities/tags to categorize prefixes into different types. We attach a particular *route type* community during prefix origination at the network device. This type *tag* persists with the prefix as it propagates. We perform matching on these communities to implement all our BGP policies in a uniform scalable fashion. We demonstrate how we use them with the examples in this section.

Reliability. Our routing policies allow us to safeguard the data center network stability. The BGP speakers only accept or advertise the routes they are supposed to exchange with their peers according to our overall data center routing design.

The BGP policies match on tags to enforce the intended route propagation scope. For example, in Fig. 3b, routes tagged with $rack\_prefix$ only propagate within the pod (i.e., not to the SSW layer).

Using BGP policies, we establish deterministic backup paths for different route types. This uniformly-applied procedure ensures the traffic will take predictable backup paths in the event of failures. We use backup path policies to protect FSW-RSW link failures. Consider the example in Fig. 3. We use tags to implement the backup policy, as shown in Fig. 3b. When $rsw1$ originates a route, it adds a $rack\_prefix$ tag. The $fsw2$ matches on that tag, adds another tag $backup\_path$, and forwards the route to $rsw2$. $rsw2$ ensures routes tagged with $backup\_path$ are advertised to $fsw1$. When $fsw1$ detects the tag $backup\_path$, it installs the backup route and adds the tag $completed\_backup\_path$ (not shown in figure) which stops any unnecessary continued backup route propagation. In Fig. 3a, when the fsw1-rsw1 link fails, fsw1 will not send a new advertisement to its SSWs to signal the loss of connectivity to rsw1. Instead, BGP will reconverge to use the backup path ($fsw1 \rightarrow rsw2 \rightarrow fsw2 \rightarrow rsw1$) to reroute traffic through another RSW within the pod. And due to route summarization at the FSW (§2.5), these failures within a pod will not be visible to the SSWs and hence the routers outside the pod.

Backup paths are computed and distributed automatically as a part of BGP routing convergence. They are readily available when link failure happens. Typically, an FSW has multiple backup paths, of the same AS path length, to each RSW. When the direct fsw-rsw link fails, all of the backup paths will be used for ECMP.

In our network, each device has inbound (import) and outbound (export) match-action rules. Routes get advertised between two neighboring BGP speakers (X and Y) if they are allowed at both ends of the BGP session, i.e., they need to match an outbound rule of device X and an inbound rule of its neighboring device Y. This logic protects against routing misconfigurations on the peer. Additionally, on each device, routes that do not match on any of its rules are dropped to prevent unintended network behaviors.

Maintainability. In a data center, many events occur every hour and we expect things to fail. We see events like rack removal or addition, link flap or transceiver failure, network device reboot or software crash, software or configuration push failure, etc. Additionally, network devices are undergoing routine software upgrades and other maintenance operations. To avoid disruption of production traffic, we gracefully *drain* the device before maintenance—production traffic gets diverted from the device without incurring losses. For this, we define multiple distinct operational states for a network device. The state affects the route propagation logic through the device, as shown in Table 2. We change the routing policy configuration of a device based on its operational state. These configurations implement the logic specified in Table 2.

To gracefully take a device or a group of devices out of service (DRAINED) or put it back in service (LIVE), we apply policies corresponding to the current state on the peer groups. This initiates the new mode of operation across all affected BGP peers. Previous works [23] have used a multi-stage draining to gracefully drain traffic without disruptions. We also implement a multi-stage drain process with an interim WARM state. In the WARM state, we change the BGP policies to de-prioritize routes traversing through the device about to be drained. We also adjust the local and/or remote

State	Description
LIVE	The device is operating in active mode and carries full production traffic load.
DRAINED	The device is operating in passive mode. It doesn't carry any production traffic. Only the traffic to/from infrastructure/diagnostic prefixes may be allowed. Transiting infrastructure prefixes are lowered in priority.
WARM	The device is in process of changing states. It maintains full local RIB and FIB ready to support the production traffic, but adjusts route propagation and signals to avoid attracting live traffic.

Table 2: Operational states of a network switch

ECMP groups and ensure that network links do not become overloaded during the transition from LIVE to DRAINED state and vice-versa. Once BGP converges, all production traffic is rerouted to/from the device, and we can change the state of the network device again into the final state.

In the DRAINED state, BGP policies allow us to propagate only selected prefixes through the devices, and change route priorities. For example, this feature allows us to maintain reachability to the infrastructure (e.g., the switch's management plane) and advertise diagnostic prefixes through the devices under maintenance, while keeping the production traffic away from such devices.

Drain/undrain is a frequently used operation in data center maintenance. On average, we perform 242 drain and undrain operations daily. These operations take on average 36*s* to complete. The multi-stage state change ensures that there are no transient drops during this process.

Scalability. The routing policies allow us to implement and enforce our hierarchical route summarization design (§2.5). For example, in our network, our policy in FSW summarizes rack-level prefixes into pod-specific aggregates. They advertise these aggregates to the SSW tier. These policies also control propagation scopes for different route aggregation levels and minimize the routing table sizes in our switches.

The predefined backup paths also aid in scalability. These paths ensure our reaction to failures are deterministic and avoid triggering large-scale advertisements during failures which can cause BGP convergence problems.

To reduce policy processing overhead, we design all our policies to first apply rules which accept or deny the most number of prefixes. For example, in a drained state (Table 2), the FSW's outbound policy toward SSW first rejects routes marked to (i) avoid propagation to SSWs, or (ii) carry any production traffic. After that, it matches and lowers the priority of infrastructure routes before sending them to SSW. This design ensures we minimize the policy processing overhead on routes that will be dropped.

Service Reachability. One important goal of the data center network design is providing service reachability. A service should remain reachable even when an instance of the service gets added, removed, or migrated. As one of the mechanisms for providing service reachability in the network, we use Virtual IP addresses (VIPs). A particular service (e.g., DNS) may advertise a single VIP (serviced by multiple instances). In turn, anycast routing will provide reachability to one of the instances for traffic destined to the VIP.

To support flexible instance placement without compromising uniformity and simplicity, we create a VIP injector service in the form of a software library integrated with a service instance. The injector establishes a BGP session with the RSW and announces a route to signal the VIP reachability. When the service instance gets terminated, the injector sends a route withdrawal for the VIP. The routing policy on the RSW relays VIP routes to FSW after performing safety checks, such as ensuring that the injected VIP prefix conforms to the design intent. FSW's inbound policy from RSWs tags and sets different priorities for different VIP routes. This method allows for network-wide VIP priorities for active/backup applications.

By directly injecting VIP routes from services, we do not need to make changes to the network when creating/destroying service instances or adjusting active/backup service behaviors. That is, we do not need to change RSW configurations to start/stop advertising the VIPs or change VIP instance priorities. Our services integrate the injector library into their code (§5) and fully control when and how they want to update their VIPs.

3.2 Policy Configuration

For scalability and uniformity reasons, our policies primarily operate on BGP Communities and AS_PATH regular expression matches, and not on specific IP prefixes. To implement policy actions, we may accept or deny a route advertisement, or modify BGP attributes to manipulate the route's priority for best-path selection. We configure our routing policies on the BGP *peer group* level—therefore, any policy change is simultaneously applied to all peers in the group. Our reusable ASN design (§2.4) also allows us to use the same policies across our multiple data center fabrics.

The number of policy rules that exist between tiers of our data center network are relatively lightweight: 3-31 inbound rules (average 11 per session) and 1-23 outbound rules (average 12 per session). The majority of outbound policies tag routes to specify their propagation scope, and the majority of inbound policies perform admission control based on the route propagation tags and adjust LOCAL_PREF or AS_PATH length to influence route preference.

For the most numerous device role in our fleet, RSW, we keep the policy logic at the necessary minimum to reduce the need for periodic changes. To compensate for this, the FSWs in the pods have larger policies that offload some processing logic from the RSWs.

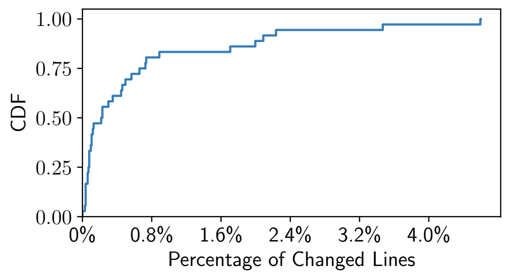

Figure 4: Network Policy Churn

For the commonly used BGP communities and other prefix attributes we maintain structured naming and numbering standards, suitable both for humans and automation tools. For the purposes of this paper, we elide the low-level details of our policy language syntax, objects, and rules.

3.3 Policy Churn

We maintain a global set of abstract policy templates and use them to generate individual switch configurations via an automated pipeline [44]. The routing policy used in our data center is fairly stable—we have made 40 commits to the routing policy templates over a period of three years. We show the cumulative distribution function (CDF) of the number of lines of changes made to the routing policy templates in Figure 4. We observe that most changes to the policy are incremental—80% of commits change less than 2% of policy lines. However, small changes to policy can have drastic service impacts, therefore they are always peer-reviewed and tested before production deployment (§6.2).

4 BGP in DCs versus the Internet

Multiple papers have studied issues with BGP convergence [33, 37], routing instabilities [32] and misconfigurations [21, 36], in the context of the Internet. This section summarizes these issues and describes how we address them in the data center context.

4.1 BGP Convergence

BGP convergence at the Internet-scale is a well-studied problem. Empirically, BGP can take minutes to converge. Labovitz et al. [33] proposed an upper bound on BGP convergence. During convergence, BGP attempts to explore all possible paths in a monotonically increasing order (in terms of AS_PATH length)—a behavior known as the path-hunting problem [2]. In the worst case, BGP convergence can require O(n!) messages, where n is the number of routers in the network. Using *MinRouteAdvertisementInterval* (MRAI) timer—minimum time between advertisements from a BGP peer for a particular prefix—BGP convergence can take O(n) x MRAI seconds. As mentioned in §3.1, our data centers experience many drain/undrain operations daily. These operations will cause BGP to reconverge, and this makes convergence a frequent event in our data centers.

To alleviate the BGP path-hunting problem, we define route propagation scopes and limit the set of backup paths that a BGP process needs to explore. For example, rack prefixes circulate only within a fabric pod; thus, an announcement or withdrawal of a rack prefix should only trigger a pod's reconvergence. To prevent slow convergence during network failures, we employ BGP policies that limit the AS_PATH that a prefix may carry, thus curbing the path-hunting problem.

Our topology design with broad path diversity (§2) and our predefined backup path policies (§3.1) ensure we only trigger fabric-wide re-advertisements when a particular router has lost all connections to its peers. Such events require tens to hundreds of links to fail, which is very unlikely. Thus, BGP convergence delays are infrequent in our data center. Since we want the network to converge as quickly as possible, we set the MRAI timer to 0. This could lead to increased advertisements (as each router would advertise any changes immediately), but our route propagation scopes ensure these advertisements do not affect the entire network.

4.2 Routing Instability

Routing instability is the rapid change of network reachability and topology information caused by pathological BGP updates. These pathological BGP updates lead to increasing CPU and memory utilization on routers, which can result in processing delays for legitimate updates, or router crashes; these can lead to delay in convergence or packet drops. Labovitz et al. [32] show that a significant fraction of routing updates on the Internet was pathological and do not reflect real network changes. With fine-grained control over the routing design, BGP configuration, and software implementation, we ensure that these pathological cases do not manifest in the data center. We describe the common pathological cases of routing instabilities and the solution in our data center to mitigate these cases in Table 3.

The most frequent pathological BGP message pattern reported by Labovitz et al. was WWDup. WWDup is a repeated transmission of BGP withdrawals for a prefix, which is unreachable. The cause of WWDup was stateless BGP implementation: a BGP router does not store any state regarding information advertised to its peers. The router would send a withdrawal to all its peers, irrespective of whether it had sent the same message. Internet-scale routers deal with millions of routes, so it was not practical to store each prefix's state for each peer. In data centers, BGP works at a much smaller scale (tens of thousands of prefixes) and typically has more memory resources. Thus, we can maintain the state of advertisements sent to each peer and check if a particular update needs sending. This feature eliminates pathological BGP withdrawals. Another class of pathological routing messages is AADup: a

Update Type	Description	DC Solution
WWDup	Repeated BGP withdrawals for unreachable prefixes	Store advertisement state in routers to suppress duplicate withdrawals
AADup	Implicit route withdrawal replaced by a duplicate of the same route	Store advertisement state in routers to suppress duplicate announcements
AADiff	Route is replaced by an alternate route	Fixed set of LOCAL_PREF values to avoid pathological metric changes
TUp/TDown	Prefix reachability oscillation	Monitor failures and automatically drain traffic from faulty devices

Table 3: Pathological BGP Updates found in the Internet by Labovitz et al. [32] and how we fix those in the data center

route is implicitly withdrawn and replaced by a duplicate. We stop AADups with our stateful BGP implementation as well.

The other types of BGP messages causing routing instabilities are AADiff (an alternate route replacing the old one) and TUp/TDown (prefix reachability oscillation). AADiffs happen due to MED (multi-exit discriminator) or LOCAL_PREF (local preference) oscillations in configurations that map these values dynamically from the IGP metric. As a result, when internal topology changes, BGP will announce advertisements to its peers with new MED/LOCAL_PREF values, even though the inter-domain BGP paths are unaffected. Hot-potato BGP routing [46] is a similar type of routing instability where the internal IGP cost affects the BGP best path decision. We use a fixed set of LOCAL_PREF values. Thus, any change in LOCAL_PREF indicates a legitimate update in the routing preference. We do not use MED. TUp and TDown come from the actual *oscillating* hardware failures. Our monitoring tools detect such failures and automatically reroute traffic from malfunctioning components to restore stability.

4.3 BGP Misconfigurations

Mahajan et al. [36] analyzed BGP misconfigurations in the Internet. They found that those affected up to 1% of the global prefixes each day. The misconfigurations increase the BGP control plane overhead with generation of pathological route updates. They can also lead to disruption of connectivity. The two types of BGP misconfigurations were the following. First, the origin misconfiguration is when a BGP router injects an incorrect prefix to the global BGP table. Second, the export misconfiguration is when an AS_PATH violates the routing policy for an ISP. The former can happen in the data center. For example, imagine a router advertising more specific /64 prefixes instead of the aggregated /56 prefix. A router could also inject a prefix from a different pod's address space, hijacking the traffic. The latter is also possible in the data center. A router may incorrectly advertise a prefix outside the prefix's intended propagation scope due to a bug in the routing policy. However, in practice, they are rare in our data center, as all our route advertisement configurations are automatically generated and verified. Since we have visibility and control over the data center, we can detect these issues with monitoring/auditing tools and promptly fix them. We further discuss the causes of misconfigurations reported by Mahajan et al. and demonstrate how we can avoid these in our architecture.

Incorrect BGP Attributes. One of the leading causes for incorrect prefix injection is a router advertising prefixes assuming that they will get filtered upstream. For reliability (§3), we add filters on both ends of the BGP session to ensure incorrect prefixes get filtered at either end. Errors can also happen due to wrong BGP communities, address typos, and inaccurate summarization statements. We use a centralized framework [44] to generate the configuration for individual routers from templates. Thus, we can catch errors from a single source, instead of dealing with separate routers.

Interactions with Other Protocols. A typical pattern is to use IGPs such as OSPF for intra-domain routing and configure redistribution to advertise the IGP routes into BGP for inter-domain routing. Configuring redistribution can end up announcing unintended routes. However, that is not a problem with a single-protocol design that we have.

Configuration Update Issues. Mahajan et al also observed cases when upon BGP restart, unexpected prefixes got advertised due to misconfigurations. For instance, in one scenario, configuration changes were not committed to persistent storage, and a router restarted using the old configuration. In our implementation, we ensure BGP does not advertise prefixes until after processing all configuration constructs. Each router has a configuration database, and we use transactions to update it consistently. We can afford slower upgrade mechanisms in the data center due to increased redundancy; routers in the Internet cannot be unavailable for long periods of time.

Thus, our BGP-based routing design tailored for the data center, that realizes the high-level DC-oriented goals of uniformity and simplicity, is able to overcome BGP problems common in the Internet.

5 Software Implementation

Like any other software, our BGP agent needs updates to add new features/optimizations, apply bug fixes, be compatible with other services, etc. Extending a third-party BGP implementation (by network vendors or open source [22, 30]) is not trivial and can add substantial complexity. Additionally, they have long development cycles for upstreaming or releasing their updates, and this affects our pace of innovation. To overcome those challenges, we develop an in-house BGP agent in C++ to run on our FBOSS [18] switches. In this section, we

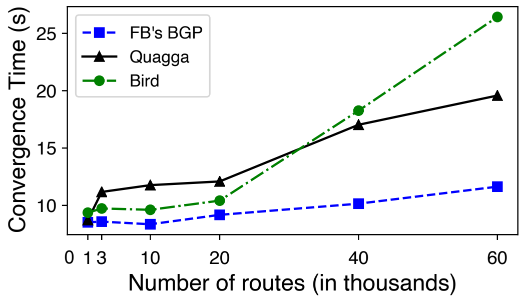

Figure 5: FB's BGP vs Quagga vs Bird (convergence time)

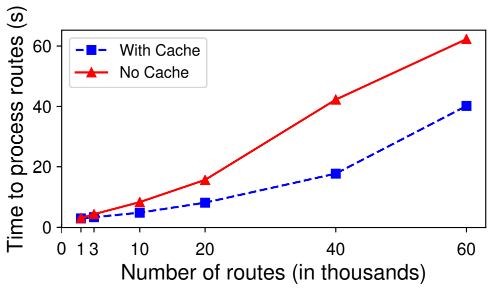

Figure 6: Impact of Policy Cache

present the main attributes of our agent.

Limited Feature Set. There are dozens of RFCs related to BGP features and extensions, especially to support routing for the Internet. Third-party implementations have support for many of these features and extensions. This increases the size of the agent codebase and its complexity due to interactions between various features. A large and complex codebase makes it harder for engineers to debug an issue and find a root cause, extend the codebase to add new features, or to refactor code to improve software quality. Therefore, the implementation of our BGP agent contains only the necessary protocol features required in our data center, but it does not deviate from the BGP RFCs [6–8]. Additionally, we only implement a small subset of matches and actions to implement our routing policies. We summarize the limited protocol features and match-action fields in Appendix A.

Multi-threading. Many BGP implementations are single-threaded (e.g., Quagga [30] and Bird [22]). Modern switches contain server-grade multi-core CPUs which allow us to run the BGP control plane at the scale of our data center. Our implementation employs multiple system threads, such as the peer thread and RIB thread, to leverage the multi-core CPU. The peer thread maintains the BGP state machine for each peer and handles parsing, serializing, sending, and receiving BGP messages over TCP sockets. The RIB thread maintains Loc-RIB (the main routing table), calculates the best path and multipaths for each route, and installs them to the switch hardware. To further maximize parallelism in the context of each system thread, we employ lightweight application threads `folly::fibers` [3]. These have low context-switching cost and execute small modular tasks in a cooperative manner. The fiber design is ideal for the peer thread as BGP session management is I/O intensive. To ensure lock-free property between system threads, we use message queues between fiber threads, running on the same or different systems threads.

To evaluate our BGP agent's performance, we compare it against two popular open source BGP stacks: Quagga [30] and Bird [22]. We run them on a single FSW device that is receiving both IPv4 and IPv6 routes from 24 SSWs. We compare their initial convergence time; this represents the time period between starting the BGP process to network convergence; this includes time for session establishment, and receiving and processing all route advertisements. In Fig. 5, we show the average over 5 runs. We observe that our BGP agent constantly outperforms other software and provides a speedup as high as 1.7X (Quagga) and 2.3X (Bird).

Policy. To improve policy execution performance, we added a few optimizations again building on our uniform design. Most of the peering sessions, from a device's point of view, are either towards uplink or downlink devices sharing the same inbound/outbound policies. Here, we made two observations: (1) prefixes learned from the same peer usually share the same BGP attributes, and (2) when routes are sent to the same type of peers (uplink or downlink peers), the same policy is applied for each peer separately. Peer groups help to avoid repetition in configuration, however, policies are still executed for routes sent/received from each peer separately. To leverage (1), we implemented *batching* in policy execution, where a set of prefixes and their shared BGP attributes are given as input to the policy engine. The policy engine performs the operation of *matching* the given BGP attributes and the prefixes sharing those attributes, and returning the accepted prefixes and their modified BGP attributes, based on the policy *action*. To avoid re-computations of (2), we introduced a policy cache, implemented in the form of an LRU (least recently used) cache containing <policy name, prefix, input BGP attributes, output BGP attributes> tuples. Once we apply the policy for routes to a peer and store that result in the policy cache, other peers in the same tier sharing the same policy can use the cached result and avoid re-execution of the policy. To show its impact, we run an experiment with and without the cache. We run them on a single FSW device that is sending IPv6 routes to 24 SSWs. We compare their time to process all route advertisements, which includes the time to apply outbound policy for each peer. In Fig. 6, we show the average over 5 runs. We observe that policy cache improves the time to process all routes by 1.2-2.4X.

Service Reachability. For flexible service reachability (§3), we want a service to inject routes for virtual IP addresses (VIPs) corresponding to the service directly to the RSW. However, current vendor BGP implementations commonly do not allow multiple peering sessions from the same peer address, which meant we would have to run a single injector service on every server and the applications on the server will need to interact with the injector to inject routes to the RSW. This becomes operationally difficult since application owners do not have visibility to the injection process. There also exists a failure dependency as (i) applications need to monitor the health of the injector service to use it, and (ii) the injector needs to withdraw routes if the application fails. Instead, our BGP agent can support multiple sessions from the same peer address. Applications running on a server can directly initiate a BGP peer session with the BGP agent on the RSW and inject VIPs for service reachability. Thus, we do not have to maintain the cumbersome injector service to workaround the vendor BGP implementation constraint, and we also remove the application-injector dependency.

Instrumentation. Traditionally, operators used network management tools (e.g. SNMP [27], NETCONF [20], etc) to collect network statistics, like link load and packet loss ratio, to monitor the health of the network. These tools can also collect routing tables and a limited set of BGP peer events. However, extending these tools to collect new types of data—such as BGP convergence time, the number of application peers, etc—is not trivial. It requires modifications and standardization of the network management protocols. Facebook uses an in-house monitoring system called ODS [9,18]. Using a Thrift [1] management interface, operators can customize the type of statistics they want to monitor. Next, ODS collects these statistics into an event store. Finally, operators both manually and through an automated alerting tool, query and analyze the data to monitor their system. By integrating our BGP agent with this monitoring framework, we treat BGP like any other software. This allows us to collect fine-granular information on BGP's internal operation state, e.g. the number of peers established, the number of sent/received prefixes per peer, and other BGP statistics mentioned above. We monitor these data to detect and troubleshoot network outages (§6.3).

6 Testing and Deployment

The two main components we routinely test and update are configurations and the BGP agent implementation. These updates introduce new BGP features and optimizations, fix security issues, change BGP routing policies for improving reliability and efficiency. However, frequent updates to the control plane lead to increased risk of network outages in production due to new bugs or performance regressions. We want to ensure smooth network operations, avoid outages in the data center, and catch regressions as early as possible. Therefore, we developed continuous testing and deployment pipelines for quick and frequent rollouts to production.

6.1 Testing

Our testing pipeline comprises three major components - unit testing, emulation and canary testing.

Emulation is a useful testing framework for production networks. Similar to CrystalNet [35], we develop a BGP emulation framework for testing BGP agent, BGP configurations, and policy implementations, and modeling BGP behavior for the entire network. Emulation is used also for testing BGP behavior under failure scenarios – link flaps, link down, or BGP restart events. We also use emulation to test agent/config upgrade processes. The advantage of catching bugs in emulation is that they do not cause service disruptions in production. Emulation testing can greatly reduce developer's time and amount of physical testbed resources required. However, emulation cannot achieve high fidelity as it does not model the underlying switch software and hardware. Using emulation for BGP convergence regression is challenging as linux containers are considerably slower than hardware switches.

After successful emulation testing, we proceed to canary testing in production. We run a new version of the BGP agent/config on a small fraction of production switches called canaries. Canary testing allows us to run a new version of the agent/config in production settings to catch errors and gain confidence in the version before rolling out to production. We pick switches such that canaries can catch issues arising in production due to scale – e.g., delayed switch convergence. Canaries are used to test the following scenarios: (i) transitioning from old to new BGP agent/config (this occurs during deployment), (ii) transitioning from new to old BGP agent/config (when issues were found in production, we have to rollback to stable BGP version), and (iii) BGP graceful restart (which is an important feature for smooth deployment of BGP agent/config). Daily canaries are used to run new versions for longer periods (typically a day). Production monitoring systems will generate alerts for any abnormal behaviors. Canary testing helps us catch bugs not caught in emulation as it closely resembles BGP behavior in production, such as problems created by changes in underlying libraries.

6.2 Deployment

Once a change (agent/config) has been certified by our testing pipeline, we initiate the deployment phase of pushing the new agent/config to the switches. There is a trade-off between achieving high release velocity and maintaining overall reliability. We cannot simply switch off traffic across the data centers and upgrade the control plane in one-shot, as that would drastically impact services and our reliability requirements. Thus, we must ensure minimal network disruption while deploying the upgrades. This is to support quick and frequent BGP evolution in production. We devise a push plan which starts rolling out the upgrade gradually to ensure we can catch problems earlier in the deployment process.

Push Mechanisms. We classify upgrades in two classes: disruptive and non-disruptive, depending on if the upgrade affects existing forwarding state on the switch. Most upgrades in the data center are non-disruptive (performance optimizations, integration with other systems, etc.). To minimize routing instabilities during non-disruptive upgrades, we use BGP *graceful restart (GR)* [8]. When a switch is being upgraded, GR ensures that its peers do not delete existing routes for a

Phase	Specification
P1	Small number of RSWs in a random DC
P2	Small number of RSWs (> P1) in another random DC
P3	Small fraction of switches in all tiers in DC serving web traffic
P4	10% of switches across DCs (to account for site differences)
P5	20% of switches across DCs
P6	Global push to all switches

Table 4: Specification of the push phases

period of time during which the switch's BGP agent/config is upgraded. The switch then comes up, re-establishes the sessions with its peers and re-advertises routes. Since the upgrade is non-disruptive, the peers' forwarding state are unchanged. Without GR, the peers would think the switch is down, and withdraw routes through that switch, only to re-advertise them when the switch comes back up after the upgrade.

Disruptive upgrades (e.g., changes in policy affecting existing switch forwarding state) would trigger new advertisements/withdrawals to switches, and BGP re-convergence would occur subsequently. During this period, production traffic could be dropped or take longer paths causing increased latencies. Thus, if the binary or configuration change is disruptive, we drain (§3) and upgrade the device without impacting production traffic. Draining a device entails moving production traffic away from the device and reducing effective capacity in the network. Thus, we pool disruptive changes and upgrade the drained device at once instead of draining the device for each individual upgrade.

Push Phases. Our push plan comprises six phases P1-P6 performed sequentially to apply the upgrades to agent/config in production gradually. We describe the specification of the 6 phases in Table 4. In each phase, the push engine *randomly* selects a certain number of switches based on the phase's specification. After selection, the push engine upgrades these switches and restarts BGP on these switches. Our 6 push phases are to progressively increase scope of deployment with the last phase being the global push to all switches. P1-P5 can be construed as extensive testing phases: P1 and P2 modify a small number of rack switches to start the push. P3 is our first major deployment phase to all tiers in the topology. We choose a single data center which serves web traffic because our web applications have provisions such as load balancing to mitigate failures. Thus, failures in P3 have less impact to our services. To assess if our upgrade is safe in more diverse settings, P4 and P5 upgrade a significant fraction of our switches across different data center regions which serve different kinds of traffic workloads. Even if catastrophic outages occur during P4 or P5, we would still be able to achieve high-performance connectivity due to the in-built redundancy in the network topology and our backup path policies—switches running the stable BGP agent/config would re-converge quickly to reduce impact of the outage. Finally, in P6, we upgrade the rest of the switches in all data centers.

Push Monitoring. To detect problems during deployment, we have BGPMonitor, a scalable service to monitor all BGP speaking devices in the data center. All BGP speakers relay advertisements/withdrawals they receive to BGPMonitor. BGPMonitor then verifies the routes which are expected to be unchanged, e.g., routes for addresses originating from the switch. If we see route advertisements/withdrawals within the window of a non-disruptive upgrade, we stop the push and report the potential issue to an engineer, who analyzes the issue and determines if push can proceed. One of our outages was detected using BGPMonitor (§6.3).

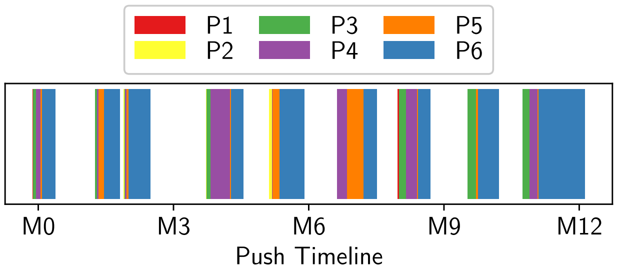

Figure 7: Timeline of BGP push phases over a year

Release	Total	P1	P2	P3	P4	P5	P6
7	0.57	0	0	0.28	0.20	0.82	0.56
8	0.43	0	0	0	0.12	0.13	0.54
9	0.51	0	0.94	0.95	1.12	0.25	0.49

Table 5: Push error percentages for the last 3 pushes for different push phases.

Push Results. Figure 7 shows the timeline of push releases over a 12 month period. We achieved 9 successful pushes of our BGP agent to production. On average, each push takes 2-3 weeks. Figure 7 highlights the high release velocity that we are able to achieve for BGP in our data center. We are able to fix performance and security issues as well as support new features at fast timescales. This also allows other applications, which leverage the BGP routing features, to innovate quickly. P6 is the most time-consuming phase of the push as it upgrades majority of the switches. We catch various errors in P1-P5, and thus, some of these phases can take longer (more than a day). Figure 7 also highlights the highly evolving nature of the data center. Our data centers are undergoing different changes to the BGP agent (adding support for BGP constructs, bug fixes, performance optimizations and security patches) for over 52% of the time in the 12 month duration.

Ideally, each phase should upgrade all the switches (100%). For instance, in one push, we fixed a security bug and we needed all the switches to run the fixed BGP agent version to ensure the network is not vulnerable. However, various devices were not reachable for a multitude of reasons. Devices are often brought down for various maintenance tasks, thus making them unreachable during push. Devices can also be experiencing hardware or power issues during the push phases. We cannot predict the downtime for such devices, and we do not want to block the push indeterminately because of a small fraction of these devices. Hence, for each phase, we set a threshold of 99% on the number of devices we want to upgrade in each phase, i.e., 1% of the devices in our data centers could be running older BGP versions. We expect these devices will be upgraded in the next push phases. We report the push errors (number of devices which did not get upgraded) encountered in the last 3 pushes of Figure 7 in Table 5. We upgrade more than 99.43% of our data center in each push. These numbers indicate that there is always a small fraction of the data center which is undergoing maintenance. We try to upgrade these devices in the next push.

6.3 SEVs

Despite our testing and push pipeline, the scale and evolving nature of our data center's control plane (§6.2), the complexity of BGP and its interaction with other services (e.g. push, draining, etc), and the inevitable nature of human errors make network outages an unavoidable obstacle. In this section, we discuss some of the major routing-related Site EVents (SEVs) that occurred over a 2 year period. Errors and routing issues can arise due to (1) a recent change in configuration or BGP software, or (2) latent bugs in the code which are triggered due to a previously unseen scenario. We use multiple monitoring tools to detect anomalies in our network. These include (i) event data stores (ODS [9]) to log BGP statistics like downtime of BGP sessions at a switch, (ii) netsonar [34] to detect unreachable devices, and (iii) netnorad [10] to measure server-to-server packet loss ratio and network latency.

We experienced a total of 14 SEVs. These BGP-related SEVs were caused due to a combination of errors in its policy, software and interaction with other tools (e.g. push framework, draining framework, etc) in our data centers.

One set of SEVs were caused due to incomplete/incorrect deployment of policies. For example, one of the updates required both changing communities set in a policy at one tier and changing policies that act on those communities at another tier. It also required the first to be applied after the latter. However, during a push, policies were applied in an incorrect order. This created blackholes within the data center, degrading performance of multiple services.

Another set of SEVs were caused due to an error in BGP software. One SEV was caused by a bug in implementation of a feature called max-route limit that limits the number of prefixes received from a peer. The bug was that the max-route counter was getting incremented incorrectly for previously announced prefixes. This made BGP tear down multiple sessions, leading services to experience SLA violations.

We also experienced problems due to interactions between different versions of the BGP software. In one SEV, different versions were using different graceful restart parameters [8]. During graceful restart, the old version of BGP used stale paths for $30s$. However, the new version deferred sending new routes for as long as $120s$, waiting for receiving End-of-RIB from all peers. Hence, the old version purged stale paths learned from its peer before receiving them from the new version. This resulted in temporary traffic loss for $\sim 90s$. BGPMonitor detected this outage during the push phases.

All these outages were resolved by rolling back to a previous stable version of BGP, followed by pushing a new fixed version in the next release cycle. Our design principles of uniformity and simplicity, while helpful, do not address issues such as software bugs and version incompatibilities, for which special care is needed. Our aim is to create a good testing framework to prevent these outages. We created the emulation platform during the later phases of our BGP development process and evolved ever since. As a follow-up to the aforementioned SEVs, we added new test cases to emulate those scenarios. As part of our ongoing work (§7), we are exploring ideas to further improve our testing pipeline.

7 Future Work

This section describes some of our ongoing work based on the gaps we have identified during our past years of data center network operations.

Policy Management. BGP supports a rich policy framework. The inbound and outbound policy is a decision tree with multiple rules capturing the policy designer's intent. Although the routing policies are uniform across tiers in our design, it is non-trivial to manage and reason about the full distributed policy set. Control plane verification tools [13, 15, 24, 40] verify policies by modeling device configurations. However, existing tools cannot scale to the size of our data centers, and they do not support such complex intent as flexible service reachability. Extending network verification to support our policy design at scale is an important future direction. Network synthesis tools [12, 16, 17, 19, 43] use high-level policy intents to produce policy-compliant configurations. Unfortunately, the policy intent language used by these tools cannot model all our policies (§2). Additionally, the configurations generated by them do not follow our design choices (§3). Extending network synthesis to support our BGP design and policies is also an ongoing direction we are pursuing.

Evolving Testing Framework. Policy verification tools assume the underlying software is error-free and homogeneous across devices. 8 of our SEVs occurred due to software errors. Existing tools cannot proactively detect such issues. To compensate, we use an emulation platform to detect control-plane errors before deployment. Some routing issues, like transient forwarding loops and black holes, materialize while deploying BGP configuration and software updates in a live network. Our deployment process monitoring (§6.2) demonstrates that the control plane is under constant churn. 10 of our SEVs were triggered while deploying changes. To address that, we are extending our emulation platform to mimic the deployment pipeline and validate the impact of various deployment strategies. We are further exploring techniques to closely emulate our hardware switches and combined hardware/software failure scenarios. We are also extending our testing framework to include network protocol validation tools [45] and fuzz testing [31]. Protocol validation tools can ensure our BGP agent is RFC-compliant. Fuzz testing can make our BGP agent robust against invalid, unexpected, or random external BGP messages with well-defined failure handling.

Load-sharing under Failures. Over the past few years, we observe that hardware failures or drains can create load imbalance. For example, SSW's uplinks to the DC aggregation layer are not balanced when the failure of an SSW-FSW link (or SSW/FSW node) creates topology asymmetry in the spine plane. If one of an RSW's (say R) four upstream FSWs (say F) cannot reach one of its four SSWs, then F's SSWs would serve 1/4 of the traffic over 3 uplinks unlike the other 3 FSWs that serve 1/4 of the traffic over 4 uplinks. To balance traffic load across SSW's uplinks, R should reduce the traffic sent towards F from 1/4 to 3/15, and shift the remaining traffic to the other 3 FSWs. Although a centralized controller would be the most direct way to shift traffic to balance the load, we are considering an approach like Weighted ECMP [48] to leverage our BGP-based routing design.

8 Related Work

Routing in Data Center. There are different designs for large-scale data center routing, some are based on BGP while others use a centralized software-defined networking (SDN) design. An alternative BGP-based routing design for data centers is described in RFC7938 [11]. Our design differs in a few significant ways. One difference is the use of BGP Confederations for pods (called "clusters" in RFC7938). That enables our design to stick with the two-octet private ASN numbering space and reuse the same ASN on all rack switches. Thus, we also do not use the "AllowAS In" BGP feature in our design and maintain native BGP loop prevention. The second difference is our extensive use of route summarization in order to keep the routing tables small and improve the stability and convergence speed of the distributed system. The RFC7938 proposes keeping full routing visibility for all prefixes on all rack switches. Another major difference is our extensive use of the routing policies to implement strict adherence to the reachability and reliability goals, realize the different operational states of the devices, establish pre-determined network backup paths, and provide means for host-signaled traffic engineering, such as primary/secondary path selection for VIPs.

Singh et. al [42] showed that Google uses an SDN-based design for its data center network routing. It has a central route controller to collect and distribute link state information over a reliable out-of-band Control Plane Network (CPN) that runs a custom IGP for topology state distribution. Their reasoning behind building a centralized routing plane from scratch was to be able to leverage the unique characteristics and homogeneity of their network which comprises custom hardware. We decided to use a decentralized BGP approach to take advantage of BGP's extensive policy control, scalability, third-party vendor support, operator familiarity, etc.

Operational Framework. CrystalNet [35] is a cloud-scale, high-fidelity network emulator used by Microsoft to proactively validate all network operations before rolling out to production. We use an in-house emulation framework to easily integrate with our monitoring tools and deployment pipelines. Janus [14] is a software and hardware update planner that uses operator specified risks to estimate and choose the push plan with minimal availability and performance impact on customers. We use a framework similar to Janus for our maintenance planning, which includes disruptive BGP agent/config push. Govindan et. al [26] conducted detailed analysis of over 100 high-impact network failure events at Google. They discovered that a large number of failures happened when a network management operation was in progress. Motivated by these failures, they proposed certain design principles for high availability, e.g. continuously monitor the network, use in-house testing and rollout procedures, make (network) update the common case, etc. We acknowledge these principles; they have always been a part of our operational workflow.

BGP at Edge. EdgeFabric [41] and Espresso [47] also run BGP at scale. However, they are deployed at the edge for the purpose of CDN traffic engineering. They are both designed by content providers to overcome challenges with BGP when dealing with large traffic volumes. They have centralized control over routing while retaining BGP as the interface to peers. They control which PoP and/or path traffic to a customer should choose as a function of path performance.

9 Conclusion

This paper presents our experience operating BGP in large-scale data centers. Our design follows the principles of *uniformity* and *simplicity*, and it espouses tight integration between the data center topology, configuration, switch software, and DC-wide operational pipeline. We show how we realize these principles and enable BGP to operate efficiently at scale. Nevertheless, our system is a work in progress. We describe some major operational issues we faced and how these are informing our routing evolution.

A BGP Agent Features

As mentioned in §5, our BGP agent contains only those necessary protocol features that are required in our data center. We summarize the different agent features in Table 6. Additionally, we only implement a small subset of matches and actions mentioned in Table 7 to implement our routing policies specified in §3.

	Feature	Description	Rationale
Core Feature	eBGP	Establish external BGP session	To Exchange and forward route updates
	Confederations	Divide an AS into multiple sub ASes	To use the same private ASNs within a pod
	eBGP Multipath	Select and program multipath	To implement ECMP-based load-sharing
	IPv4/IPv6 Addresses	Support IPv4/IPv6 route exchange	To enable dual-stack
	Route Origination	Send update for IP prefixes assigned to a switch	
	Route Aggregation	Send update for less-specific IP prefixes aggregating (summarizing) more-specific routes	To minimize number of route updates
	Remove Private AS	Remove Private ASNs within AS-PATH	To reuse private ASNs.
	In/Out-bound Policy	Support BGP policies specified in §2	
	Dynamic Peer	Accept BGP session initiation from a range of peer addresses	To allow VIP injection from any server
Operational Feature	Graceful Restart	Wait for small graceful time period before removing routes	To reduce network churn
	Link Fail Detection	Fast BGP session termination upon link failure	To converge faster
	Propagation Delay	Delay advertisements of new routes	To wait for convergence before receiving traffic
	FIB Acknowledgement	Advertise routes after installation to hardware	To avoid blackholes if peer converges before us
	Max-route-limit	Limit number of prefixes received from a peer	To disallow unexpected volume of updates
	Peer Groups	Define and reuse peer configurations for multiple peers	To make configuration compact

Table 6: Core and operational BGP features

Match Fields	Action Fields
as-path	add/delete/set as-path
community-list	add/delete/set community
origin	set origin
local preference	inc/dec/set local preference
as-path-length	permit
prefix-list	deny

Table 7: Policy match-action fields

Orion: Google's Software-Defined Networking Control Plane

Abstract

We present Orion, a distributed Software-Defined Networking platform deployed globally in Google's datacenter (Jupiter) and Wide Area (B4) networks. Orion was designed around a modular, micro-service architecture with a central publish-subscribe database to enable a distributed, yet tightly-coupled, software-defined network control system. Orion enables intent-based management and control, is highly scalable and amenable to global control hierarchies.

Over the years, Orion has matured with continuously improving performance in convergence (up to 40x faster), throughput (handling up to 1.16 million network updates per second), system scalability (supporting 16x larger networks), and data plane availability (50x, 100x reduction in unavailable time in Jupiter and B4, respectively) while maintaining high development velocity with bi-weekly release cadence. Today, Orion enables Google's Software-Defined Networks, defending against failure modes that are both generic to large scale production networks as well as unique to SDN systems.

1 Introduction

The last decade has seen tremendous activity in Software-Defined Networking (SDN) motivated by delivering new network capabilities, fundamentally improving network reliability, and increasing the velocity of network evolution. SDN starts with a simple, but far-reaching shift in approach: moving network control, such as routing and configuration management, from individual hardware forwarding elements to a central pool of servers that collectively manage both real-time and static network state. This move to a logically centralized view of network state enables a profound transition from defining pairwise protocols with emergent behavior to distributed algorithms with guarantees on liveness, safety, scale, and performance.

For example, SDN's global view of network state presents an opportunity for more robust network verification and intent-based networking [16, 17]. At a high level, SDN affords the opportunity to transition the network from one consistent state to another, where consistency can be defined as policy compliant and blackhole-free. This same global view and real-time control enables traffic engineering responsive to topology, maintenance events, failures, and even fine-grained communication patterns such that the network as a whole can operate more efficiently and reliably [2, 12, 13]. There is ongoing work to tie end host and fabric networking together to ensure individual flows, RPCs, and Coflows meet higher-level application requirements [1, 11, 22], a capability that would be hard or impossible with traditional protocols. Perhaps one of the largest long-term benefits of SDN is support for software engineering and qualification practices to enable safe weekly software upgrades and incremental feature delivery, which can hasten network evolution by an order of magnitude.

While the promise of SDN is immense, realizing this promise requires a production-grade control plane that meets or exceeds existing network performance and availability levels. Further, the SDN must seamlessly inter-operate with peer legacy networks as no network, SDN or otherwise, operates solely in its own tech island.

In this paper, we describe the design and implementation of Orion, Google's SDN control plane. Orion is our second generation control plane and is responsible for the configuration, management, and real-time control of all of our data center (Jupiter [28]), campus, and private Wide Area (B4 [15]) networks. Orion has been in production for more than four years. The SDN transition from protocols to algorithms, together with a micro-services based controller architecture, enables bi-weekly software releases that together have not only delivered over 30 new significant capabilities, but also have improved scale by a factor of 16, availability by a factor of 50x in Jupiter and 100x in B4, and network convergence time by a factor of 40. Such rapid evolution would have been hard or impossible without SDN-based software velocity

Orion's design centers around a constellation of independent micro-services, from routing to configuration management to network management, that coordinate all state through an extensible Network Information Base (NIB). The NIB sequences and replicates updates through a key-value abstraction. We describe the performance, semantic, and availability requirements of the NIB and the development model that allows dozens of engineers to independently and simultaneously develop, test, and deploy their services through well-defined, simple, but long-lived contractual APIs.

While Orion has been a success at Google, neither our design nor the SDN approach are panaceas. We describe four key challenges we faced in Orion—some fundamental to SDN and some resulting from our own design choices—along with our approach to addressing them:

#1: Logically centralized control require fundamentally high performance for updates, in-memory representation of state, and appropriate consistency levels among loosely-coordinating micro-service SDN applications.

#2: The decoupling of control from hardware elements breaks fate sharing in ways that make corner-case failure handling more complex. In particular, control software failure does not always mean the corresponding hardware element has failed. Consider the case where the control software runs in a separate physical failure domain connected through an independent out-of-band control network. Either the physical infrastructure (control servers, their power or cooling) or control network failure can now result in at least the perception of a sudden, massively correlated failure in the data plane.

#3: Managing the tension between centralization and fault isolation must be balanced carefully. At an extreme, one could imagine a single logical controller for all of Google's network infrastructure. At another extreme, one could consider a single controller for every physical switch in our network. While both extremes can be discarded relatively easily, finding the appropriate middle ground is important. On the one hand, centralization is simpler to reason about, implement, and optimize. On the other, a centralized design is harder to scale up vertically and exposes a larger failure domain.

#4: In a global network setting, we must integrate existing routing protocols, primarily BGP, into Orion to allow inter-operation with non-SDN peer networks. The semantics of these protocols, including streaming updates and fate sharing between control and data plane, are a poor match to our choice of SDN semantics requiring adaptation at a number of levels.

This paper presents an introductory survey of Orion. We outline how we manage these concerns in its architecture, implementation, and evolution. We also discuss our production experiences with running Orion, pointing to a number of still open questions in SDN's evolution. We will share more details and experiences in subsequent work.

2 Related Work

Orion was designed with lessons learned from Onix [18]. Unlike Onix's monolithic design with cooperative multi-threading, Orion introduced a distributed design with each application in a separate process. While Onix introduced a NIB accessible only to applications in the same process, Orion's is accessible by applications within and across domains, providing a mechanism for hierarchy, which few existing controllers incorporate (Kandoo [35] being an exception). Hierarchy enabled fabric-level drain sequencing [1] and optimal WCMP-based (Weighted Cost Multi-Pathing) routing [36].

We distribute Orion's logic over multiple processes for scalability and fault-tolerance, a feature shared with other production-oriented controllers such as ONOS [4] and OpenDaylight [24], and originally proposed by Hyperflow [30]. Unlike our previous design, Orion uses a single configuration for all processes, applied atomically via the NIB, precluding errors due to inconsistent intended state.

Orion uses database-like tables to centrally organize state produced and consumed by SDN programs, a feature shared with a few other OpenFlow controllers such as ONOS [4], Flowlog [27], and Ravel [32]. The combination of all of these techniques – hierarchy, distribution, and database-like abstractions – allowed Orion to meet Google's availability and performance requirements in the datacenter and WAN.

While Orion is an evolution in the development of OpenFlow controllers, its modular decomposition of network functions (e.g., routing, flow programming, switch-level protocols, etc.) is a design goal shared with pre-OpenFlow systems such as 4D/Tesseract [33] and RCP [6]. Single-switch operating systems that similarly employ microservices and a centralized database architecture include Arista EOS [3] and SONiC [25].

3 Design Principles

We next describe principles governing Orion's design. We established many of these during the early stages of building Orion, while we derived others from our experience operating Orion-based networks. We group the principles into three categories: environmental – those that apply to production networks, architectural – those related to SDN, and implementation – those that guide our software design.

3.1 Principles of production networks

Intent-based network management and control. Intent-based networks specify management or design changes by describing the new intended end-state of the network (the "what") rather than prescribing the sequence of modifications to bring the network to that end-state (the "how"). Intent-based networking tends to be robust at scale, since high-level intent is usually stable over time, even when the low-level state of network elements fluctuates rapidly.

For example, consider a situation where we wish to temporarily "drain" (divert traffic away from) a cluster while we simultaneously add new network links to augment the ingress and egress capacity of the cluster. As those new links turn up, the stable drain intent will also apply to them, causing the underlying networking control system to avoid using them.

In Orion, we use an intent-based approach for updating the network design, invoking operational changes, and adding new features to the SDN controller. For example, we capture

[1]Fabric-level drain sequencing refers to redirecting traffic in a loss-free manner, throughout the fabric, away from a target device being drained.

intended changes to the network's topology in a model [26], which in turn triggers our deployment systems and operational staff to make the necessary physical and configuration changes to the network. As we will describe later, Orion propagates this top-level intent into network control applications, such as routing, through configuration and dynamic state changes. Applications react to top-level intent changes by mutating their internal state and by generating intermediate intent, which is in turn consumed by other applications. The overall system state evolves through a hierarchical propagation of intent ultimately resulting in changes to the programmed flow state in network switches.

Align control plane and physical failure domains. One potential challenge with decoupling control software from physical elements is failure domains that are misaligned or too large. For misalignment, consider the case in which a single SDN controller manages network hardware across portions of two buildings. A failure in that controller can cause correlated failures across two buildings, making it harder to meet higher-level service SLOs. Similarly, the failure of a single SDN controller responsible for all network elements in a campus would constitute too large a vulnerability even if it improved efficiency due to a centralized view.

We address these challenges by carefully aligning network control domains with physical, storage, and compute domains. As one simple example, a single failure in network control should not impact more than one physical, storage, or compute domain. To limit the "blast radius" of individual controller failures, we leverage hierarchical, partitioned control with soft state progressing up the hierarchy (§5.1). We explicitly design and test the network to continue correct, though likely degraded, operation in the face of controller failures.

3.2 Principles related to an SDN controller

SDN enables novel approaches to handling failures, but it also introduces new challenges requiring careful design. The SDN controller is remote from the network switches, resulting in the lack of fate sharing but also the possibility of not being able to communicate with the switches.

Lack of fate sharing can often be used to our advantage. For example, the network continues forwarding based on its existing state when the controller fails. Conversely, the controller can repair paths accurately and in a timely manner when individual switches fail, by rerouting around them.

React optimistically to correlated unreachability. The loss of communication between controller and switches poses a difficult design challenge as the controller must deal with incomplete information. We handle incomplete information by first deciding whether we are dealing with a minor failure or a major one, and then reacting pessimistically to the former and optimistically to the latter.

We start by associating a ternary health state with network elements: (i) *healthy* with a recent control communication (a switch reports healthy link and programming state with no packet loss), (ii) *unhealthy*, when a switch declares itself to be unhealthy, when neighbouring switches report unhealthy conditions or indirect signals implicate the switch, and (iii) *unknown*, with no recent control communication with a switch and no indirect signals to implicate the switch.

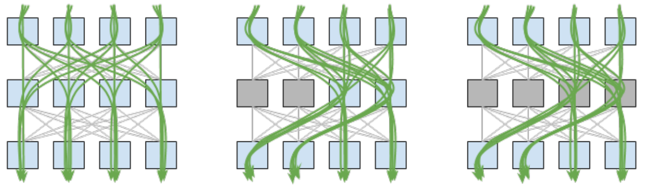

Figure 1: Network behavior in three cases: **Normal** (left): A network with healthy switches. Flows from top to bottom switches use all middle switches. ***Fail Closed*** (mid): With few switches in unknown state (grey), the controller conservatively routes around them. ***Fail Static*** (right): With enough switches in unknown state, the controller no longer routes around newly perceived failed switches.

A switch in the *unknown* state could be malfunctioning, or it could simply be unable to communicate with a controller (a fairly common occurrence at scale). In comparison, the *unhealthy* state is fairly rare, as there are few opportunities to diagnose unequivocal failure conditions in real time.[2]

The controller aggregates individual switch states into a network-wide health state, which it uses to decide between a pessimistic or an optimistic reaction. We call these ***Fail Closed*** and ***Fail Static***, respectively. In *Fail Closed*, the controller re-programs flows to route around a (perceived) failed switch. In *Fail Static*, the controller decides not to react to a switch in an *unknown*, potentially failed, state, keeping traffic flowing toward it until the switch state changes or the network operator intervenes. Figure 1 illustrates an example of normal operation, *Fail Closed* reaction, and *Fail Static* condition.

In *Fail Static*, the controller holds back from reacting to avoid worsening the overall state of the network, both in terms of connectivity and congestion. The trade-off between *Fail Closed* and *Fail Static* is governed by the cost/benefit implication of reacting to the *unknown* state: if the element in the *unknown* state can be avoided without a significant performance cost, the controller conservatively reacts to this state and triggers coordinated actions to steer traffic away from the possible failures. If the reaction would result in a significant loss in capacity or loss in end-to-end connectivity, the controller instead enters Fail Static mode for that switch. In practice we use a simple "capacity degradation threshold" to move from *Fail Closed* to *Fail Static*. The actual threshold value is directly related to: (1) the operating parameters of the network, especially the capacity headroom we typically reserve, for example, to support planned maintenance; (2) the level of redundancy we design in the topology and control

[2]It is not common for a software component to be able to self-diagnose a failure, without being able to avoid it in the first place, or at least repair it. Slightly more common is the ability to observe a failure from an external vantage point, e.g. a neighboring switch detecting a link "going down."

domains. We aim to preserve a certain amount of redundancy even in the face of capacity degradation.

In our experience, occurrences of *Fail Static* are fairly common and almost always appropriate, in the sense that they are not associated with loss of data plane performance. Often *Fail Static* is triggered by failures in the control plane connectivity between the SDN controller and the network elements, or by software failures in the controller. Neither of these directly affect the data plane health.

We view the ability to *Fail Static* as an advantage of SDN systems over traditional distributed-protocol systems. Distributed systems are also subject to some of the failures that could benefit from a *Fail Static* response. However, they are not easily amenable to realize a *Fail Static* behavior because they only have a local view. It is far easier for a centralized controller to assess if it should enter *Fail Static* when it can observe correlated network failures across its entire domain.

Exploit both out-of-band and in-band control plane connectivity. In a software-defined network, a key consideration is connectivity between the "off box" controller and the data plane switches. We must solve the bootstrap problem of requiring a functioning network to establish baseline control. Options include using: i) the very network being controlled ("in-band") or ii) a (physically or logically) separate "out-of-band" network. While a seemingly simple question, considerations regarding pure off-box SDN control, circular dependencies between the control and dataplane network, ease of debuggability, availability, manageability and cost of ownership make this topic surprisingly complex.

The simplest approach is to have a physically separate out-of-band control/management plane network (CPN) for communication between controller and switches orthogonal to the dataplane network. This approach cleanly avoids circular dependencies, keeping the control model simple and enabling easy recovery from bugs and misconfiguration. Ideally, we would like the out-of-band control network to be highly available, easy to manage and maintain, and cost effective. In the end, a separate CPN means installing and operating two distinct networks with different operational models and independent failure characteristics. While failure independence is often a desirable property, subtle or rare failure scenarios mean the entire data plane could go down if *either* the dataplane or control plane fails. We describe our choice of hybrid CPN for Orion in §5.

3.3 Software design principles

Enabling a large-scale software development environment was a key motivation for building our own SDN controller. Critical to the success of SDN is the ability to safely deploy new functionality across the network incrementally with frequent software releases. This, in turn, means that a substantial team of engineers must be able to develop multiple independent features concurrently. The need to scale engineering processes led to a modular system with a large number of decoupled components. At the same time, these components had to interact with one another to realize a tightly-coupled control system reflecting the structure and dynamics of network control. We achieved this goal through:

- a *microservice architecture* with separate processes rather than a monolithic block which we adopted in our first generation SDN controller [18], for software evolvability and fault isolation.
- a *central pub-sub system* (NIB) for all the communication between microservices, which took care of the tightly-coupled interaction across processes.

Failure domain containment (§3.1) imposes an upper limit to the size of control domains. Nevertheless, we were concerned with the performance, scalability, and fault model of a single NIB to coordinate all communication and state within a control domain. We satisfied our performance concerns through benchmarking efforts, and fault tolerance concerns by limiting control domain scope and the ability to fail static, including between control domains.

Based on years of experience, the NIB has been one of our most successful design elements. It manages all inter-component communications, allows us to create a "single arrow of time," establishing an order among the otherwise concurrent events across processes. This brought significantly useful side effects including much improved debuggability of the overall system. It also allows us to store event sequences (NIB traces) in external systems and use them for offline troubleshooting and independent validation of subsystems, which we use in component-level regression testing.

Next, we discuss the principles of intent based control, introduced in 3.1, reconciliation of state as well as the implications of various failure modes in an SDN-based system:

Intent flows from top to bottom. The top level intent for the system as a whole is the operator intent and the static configuration. As intent propagates through the system via NIB messages, it triggers local reactions in subsystems that generate *intermediate intent* consumable by other sub-systems. Higher-level intent is authoritative and any intermediate intent (also known as *derived state*) is rebuilt from it. The programmed switch state is the *ground truth* corresponding to the intent programmed into dataplane devices.

The authoritative intent must always be reflected in the ground truth. The controller ensures that any mismatch is corrected by migrating the ground truth toward the intended state in a way that is minimally disruptive to existing data plane traffic. We refer to this process as "state reconciliation".

Reconciliation is best performed in the controller which has a global view since minimal disruption often requires coordination across switches such that changes are sequenced in a graceful and loop-free manner. Reconciliation is a powerful concept that allows reasoning about complex failure modes such as Orion process restarts as well as lack of fate sharing between the data and control planes.

Availability of high level intent is crucial to keep the top-

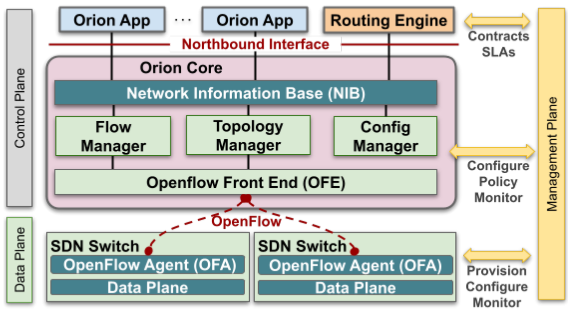

Figure 2: Overview of Orion SDN architecture and core apps.

down intent-based system simple. To achieve this goal we minimize the time when the intent is temporarily unavailable (e.g., because of process restarts or communication failure between components).

4 Architecture

Figure 2 depicts the high-level architecture of Orion, and how it maps to the textbook ONF view [7]. For scalability and fault isolation, we partition the network into domains, where each domain is an instance of an Orion SDN controller.

The data plane consists of SDN switches at the bottom. Orion uses OpenFlow [23] as the *Control to Data Plane Interface (CDPI)*. Each switch runs an OpenFlow Agent (OFA) for programmatic control of forwarding tables, statistics gathering, and event notification. The control plane consists of *Orion Core* in the center and *SDN applications* at the top. The control plane is physically separate from the data plane and *logically* centralized, providing a global view of the domain. Though logically centralized, the Orion Core controls the network through distributed controller processes. The NIB provides a uniform SDN *NorthBound Interface* for these applications to share state and communicate requirements. The Orion Core is responsible for (i) translating these requirements into OpenFlow primitives to reconcile switches' programmed state with intended state and (ii) providing a view of the runtime state of the network (forwarding rules, statistics, data plane events) to applications.

4.1 Orion Core

The **NIB** is the intent store for all Orion applications. It is implemented as a centralized, in-memory datastore with replicas that reconstruct the state from ground-truth on failure. The NIB is coupled with a publish-subscribe mechanism to share state among Orion applications. The same infrastructure is used externally to collect all changes in the NIB to facilitate debugging. The NIB must meet the following requirements:

- *Low External Dependency*. As Orion programs the network supporting all higher-level compute and storage services, it cannot itself depend on higher-level services.
- *Sequential Consistency of Event Ordering*. To simplify coordination among apps, all apps must see events in the same order (*arrow of time* [20]).

Of note, *durability* [14] was not a requirement for the NIB because its state could be reconstructed from network switches and other sources in the event of a catastrophic failure.

NIB Entities. The NIB consists of a set of NIB *entity* tables where each entity describes some information of interest to other applications or observers both local or external to the domain. Some of the entity types include:

- *Configured network topology*. These capture the configured identities and graph relationship between various network topological elements. Examples include `Port`, `Link`, `Interface`, and `Node` tables.
- *Network run-time state*. This could be topological state, forwarding state (e.g. `ProgrammedFlow` table), protocol state (e.g. `LLDPPeerPort` table), statistics (e.g. `PortStatistics` table).
- *Orion App Configuration*. Each app's configuration is captured as one or more NIB tables, e.g. `LLDPConfig`.

Protocol Buffer Schema. We represent the schema for each NIB entity as a protocol buffer message [8]. Each row in that NIB entity table is an instantiation of this schema. The first field of each entity schema is required to be a *NIBHeader* message which serves as the key for that entity. The NIB does not enforce referential integrity for foreign keys; however, inconsistencies fail an internal health-check.

An example entity represented in the NIB is a `Link` entity. A link is modelled as foreign key references to `Port` and `Node` entities respectively. This expresses the connection between two ports of two switches. Additionally, a status (up, down, or unknown), is modelled as part of the Link entity. The full protocol buffer is shown in the appendix.

Protocol buffers allow us to reuse well-understood patterns for schema migrations. For example, adding a new field to a table has built-in support for backward and forward compatibility during an upgrade despite some applications still running with the previous schema.

NIB API. The NIB provides a simple RPC API (*Read, Write, Subscribe*) to operate on NIB tables. The *Write* operation is atomic and supports batching. The *Subscribe* operation supports basic filtering to express entities of interest. The NIB notification model provides sequential consistency of event ordering. It also supports coalescing multiple updates into a single notification for scale and efficiency reasons.

The **Config Manager** provides an external management API to configure all components in an Orion domain. The domain configuration is the set of app configurations running in that domain. For uniformity and ease of sharing, an app config consists of one or more NIB tables. To ensure a new configuration is valid, it is first validated by the running instance. The semantics of pushing config need to be atomic, i.e. if one or more parts of the overall config fail validation, the overall config push must fail without any side effects. Since Orion apps that validate various parts of the config run decoupled, we employ a two-phase commit protocol to update the NIB: The config is first staged in *shadow* NIB tables, and each app verifies its config. Upon success, we commit the shadow tables to live tables atomically.

The **Topology Manager** sets and reports the runtime state of network dataplane topology (node, port, link, interface, etc.). It learns the intended topology from its config in the NIB. By subscribing to events from the switches, it writes the current topology to tables in the NIB. The Topology Manager also periodically queries port statistics from the switches.

The **Flow Manager** performs flow state reconciliation, ensuring forwarding state in switches matches intended state computed by Orion apps and reflected in the NIB. Reconciliation occurs when intent changes or every 30 seconds by comparing switch state. The latter primarily provides Orion with switch statistics and corrects out-of-sync state in the rare case that reconciliation on intent change failed.

The **OFE (Openflow FrontEnd)** multiplexes connections to each switch in an Orion domain. The OpenFlow protocol provides programmatic APIs for (i) capabilities advertisement, (ii) forwarding operations, (iii) packet IO, (iv) telemetry/statistics, and (v) dataplane event notifications (e.g. link down) [23]. These are exposed to the Topology and Flow Manager components via OFE's northbound RPC interface.

Packet-I/O. Orion supports apps that send or receive control messages to/from the data plane through OpenFlow's Packet-I/O API: a ***Packet-Out*** message sends a packet through a given port on the switch, while a ***Packet-In*** notification delivers a data plane packet punted by the switch to the control plane. The notification includes metadata such as the packet's ingress port. Orion apps can program punt flows and specify filters to receive packets of interest.

Orion Core apps are network-type agnostic by design. No "policy" is baked into them; it belongs to higher-level SDN applications instead. Core apps program, and faithfully reflect, the state of the data plane in the NIB in a generic manner.

4.2 Routing Engine

Routing Engine (RE) is Orion's intra-domain routing controller app, providing common routing mechanisms, such as L3 multi-path forwarding, load balancing, encapsulation, etc.

RE provides abstracted topology and reachability information to client routing applications (e.g. an *inter-domain routing* app or a *BGP speaker* app). It models a configured collection of switches within an Orion domain as an abstract routing node called a *supernode* [13] or *middleblock* [28]. Client routing applications provide *route advertisements* at supernode granularity, specifying nexthops for each route in terms of aggregate or singleton external ports.

RE disaggregates the route advertisements from its clients into individual node-level reachability over respective external ports and computes SPF (Shortest Path First) paths for each prefix. RE avoids paths that traverse drained, down or potentially miscabled links.[3] It also reacts to local failure by computing the next available shortest path when the current set of nexthops for a prefix becomes unreachable. For improved capacity, RE performs load balancing within a domain by spreading traffic across multiple viable paths, and through non-shortest-path forwarding, as requested by client apps. RE also manages the associated switch hardware resources (e.g. Layer-3 tables) among its client routing apps.

A key highlight of Orion Routing Engine is the ability to do loss-free sequencing from the currently programmed pathing solution to a new pathing solution. This may happen in reaction to changes in network states (e.g. a link being avoided). In a legacy network, the *eventually consistent* nature of updates from distributed routing protocols (e.g. BGP) can result in transient loops and blackholes in the data plane. In contrast, RE exploits its global view to sequence flow programming: before programming a flow that steers traffic to a set of switches, RE ensures the corresponding prefixes have been programmed on those nexthop switches. Analogous checks are done before removing a flow.

Figure 3 walks through an end-to-end route programming example. As evident from the sequence of operations, the NIB semantics lend themselves to an asynchronous ***intent-based programming model*** (as opposed to a strict *request-response* interaction). A common design pattern is to use a pair of NIB tables, where one expresses the *intent* from the producer, while the other captures the *result* from the consumer. Both *intent* and *result* tables are versioned. An app can change the intent many times without waiting for the result, and the result table is updated asynchronously.

4.3 Orion Application Framework

The Orion Application Framework is the foundation for every Orion application.The framework ensures developers use the same patterns to write applications so knowledge of one SDN application's control-flow translates to all applications. Furthermore, the framework provides basic functionality (e.g. leader-election, NIB-connectivity, health-monitoring) required by all applications in all deployments.

High Availability. Availability is a fundamental feature for networks and thereby SDN controllers. Orion apps run as separate binaries distributed across network control server machines. This ensures applications are isolated from bugs (e.g., memory corruption that leads to a crash) in other applications.

Beyond isolation, replicating each application on three different physical machines ensures fault tolerance for both planned (e.g. maintenance) as well as unplanned (e.g. power failures) outages. The application framework facilitates replication by providing an abstraction on top of leader election as well as life-cycle callbacks into the application.

An application goes through a life-cycle of being activated, receiving intent/state updates from the NIB, and then being deactivated. Identifying/arbitrating leadership and its transition (referred to as *failover*) among replicas is abstracted and

[3] A link is considered miscabled when a port ID learned by a neighbor node via LLDP and reported to Orion does not match the configured port ID.

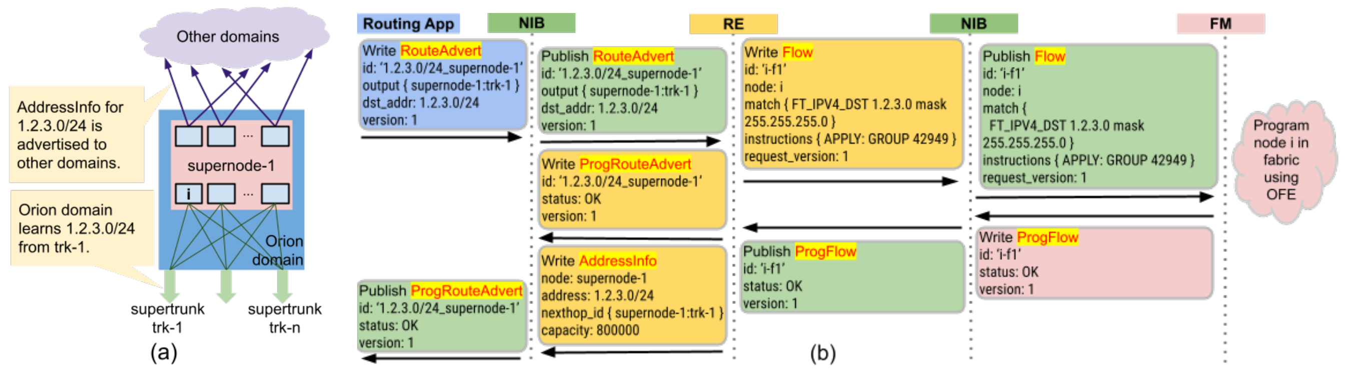

Figure 3: Intent-based route programming on abstracted domain topology: (a) Routing Engine learns external prefix 1.2.3.0/24 over trk-1, and programs nodes to establish reachability. (b) Example of end-to-end route programming. The Routing App provides a high-level RouteAdvert on supernode-1 via the NIB. Routing Engine translates the RouteAdvert to a low-level Flow update on node i and sends to Flow Manager. Acknowledgements follow the reverse direction to the Routing App. Similar route programming applies to all domain nodes.

thereby hidden from the application author, reducing surface area for bugs as well as complexity.

Capability Readiness Protocol. One of the challenges we faced previously was an orderly resumption of operation after controller failover. In particular, when a controller's NIB fails, the state of the new NIB needs to be made consistent with the runtime state of the network, as well as the functional state of all apps and remote controllers. In an extreme case, an Orion requirement is to be able to, without traffic loss, recover from a complete loss/restart of the control plane. To support this, the Orion architecture provides a *Capability Readiness Protocol*. With this protocol, applications have a uniform way of specifying which data they require to resume operation, and which data they provide for other applications.

A *capability* is an abstraction of NIB state, each can be provided and consumed by multiple apps. Capability-based coordination keeps the Orion apps from becoming "coupled", in which a specific implementation of one app relies on implementation details or deployment configuration of another app. Such dependencies are a problem for iteration and release velocity. For example, multiple apps can provide the capability of "producing flows to program", and the Flow Manager can be oblivious to which ones are present in the domain.

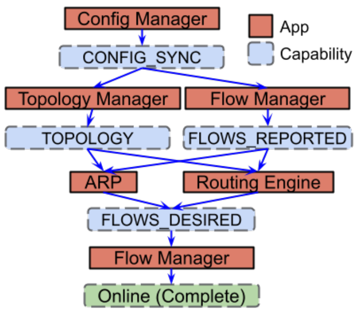

Figure 4: Capability Readiness graph for flow programming.

The Capability Readiness protocol requires, after a NIB failover, that all apps report readiness of their flows before Flow Manager begins reconciling NIB state to the physical switches. This prevents unintentional erasure of flow state from switches, which would lead to traffic loss. As Figure 4 shows, the required and provided data that each application specifies creates a directed acyclic graph of capabilities *depended upon* and *provided*, and thus the complete NIB state is reconciled consistently after any restart. Apps can have mutual dependency on different capabilities as long as they do not form a loop. A healthy Orion domain completes the full capability graph quickly on reconciliation, a condition we check in testing and alert on in production. Since this graph is static, such testing prevents introducing dependency loops.

In the event of a total loss of state, Config Manager retrieves the static topology from Chubby [5], an external, highly-available service for locking and small file storage. It then provides a `CONFIG_SYNC` capability to unblock Topology Manager and Flow Manager. The two connect to switches specified in the config and read switch states and programmed flows. Then, ARP and Routing Engine can be unblocked to generate intended flows that need to be programmed; they also provide their own `FLOWS_DESIRED` capability to Flow Manager, which proceeds to program the switches.

Apps that retrieve their state from a remote service must explicitly manage and support the case in which the service is unavailable or disconnected to prevent prolonged domain reconciliation delays. Cached data is typically used until the authoritative source of the inputs can be reached.

5 Orion-based Systems

Among the many design choices when implementing Orion to control a specific network, three prominent ones include the mapping of network elements to controllers, the method of controller to switch communication, and connectivity to external networks running standard routing protocols. We first review these common choices across two Google network architectures, Jupiter and B4, and then describe specific details for each architecture. Less relevant in a networking context, details of the NIB implementation are in the appendix.

Control domains. The choice of elements to control in an Orion domain involves multiple tradeoffs. Larger domains yield optimal traffic distributions and loss-free route sequencing for more intent changes, at the price of increased blast radius from any failure. In Jupiter, we use a hierarchy of partitioned Orion domains; in B4, a flat partitioning of Orion domains communicating with non-Orion global services. Each came with challenges in production, which we review in §7.

Control channel. As discussed in §3.1, we faced tradeoffs when designing the Control Plane Network (CPN) connecting Orion controllers to the data plane. The cost and complexity of a second network led us to a hybrid design where only the Top-of-Rack (ToR) switches were controlled in-band.

- *Separation of control and data plane:* When we embarked on building B4 and Jupiter, we embraced the SDN philosophy in its purest form: software-defined control of the network based on a logically centralized view of the network state outside the forwarding devices. To this end, we did not run any routing protocols on the switches. For the control plane, we ran a separate physical network connected to the switches' management ports. We ran conventional on-box distributed routing protocols on the CPN. Compared to the data plane network, the CPN has smaller bandwidth requirements, though it required N+1 redundancy.
- *CPN scale and cost:* Typical Clos-based data center networks are non-oversubscribed in the aggregation layers [28] with oversubscription of ToR uplinks based on the bandwidth requirements of compute and storage in the rack. A Clos network built with identical switches in each of its N stages will have the same number of switches (say, K) in all but two stages. The topmost stage will have $K/2$ switches since all ports are connected to the previous stage. The ToR stage will have SK switches, where S is the average oversubscription of uplinks compared to downlinks. Thus, the number of ToR switches as a fraction of the total is $2S/(2S+2N-3)$. In a Clos network with $N=5$ stages and an average ToR oversubscription, S, ranging from 2-4, ToR switches account for 36% to 53% of the total. Thus, not requiring CPN connectivity to them substantially reduces CPN scale and cost.
- *CPN cable management:* Managing ToRs inband removes the burden of deploying individual CPN cables to each rack spot in the datacenter.
- *Software complexity of inband ToRs:* Since ToRs are the leaf switches in a Clos topology, their inband management does not require on-box routing protocols. We designed simple in-band management logic in the switch stack to set the return path to the controller via the ToR uplink from which the ToR's CPU last heard from the controller.
- *Availability and debuggability considerations:* Over the years, we have hardened both the CPN and the inband-controlled ToR to improve availability. "Fail static" has been a key design to reduce vulnerability to CPN failures. Furthermore, we introduced in-band backup control of devices connected to the CPN for additional robustness.

External connectivity. We use BGP at the border of datacenter networks to exchange routes with Google's wide-area networks: B2 (which also connects to the Internet) and B4. These routes include machine addresses and also unicast and anycast IPs for Google services. BGP attributes such as communities, metrics, and AS path propagate state throughout Google's networks. In addition to reachability, this can include drain state, IPv6-readiness, and bandwidth for WCMP.

The use of BGP is a necessity for eventual route propagation to the Internet, but a design choice internally. The choice was made to simplify inter-connection with traditional, non-SDN routers as well as previous SDN software [18]. BGP also brings operator familiarity when defining polices to specify path preferences during topological changes.

An Orion app, **Raven** [34], integrates BGP and IS-IS into Orion. Raven exchanges messages with peers via Orion's Packet-I/O. Raven combines these updates with local routes from the NIB into a standard BGP RIB (Route Information Base). Routes selected by traditional Best-Path Selection are then sent, depending on policy, to peer speakers as BGP messages, as well as the local NIB in the form of `RouteAdvert` updates. To reduce complexity, Raven's associated BGP "router" is the abstract supernode provided by RE (§4.2).

Unfortunately, BGP is somewhat mismatched with our design principles: it uses streaming rather than full intent updates, its local view precludes a threshold-based fail static policy and global rebalancing during partial failures, and it ties control-plane liveness to data-plane liveness. In our production experience, we have had both kinds of uncorrelated failures, which, as in non-SDN networks, become correlated and cause a significant outage only due to BGP. By contrast, Orion's fail static policies explicitly consider control-plane and data-plane failure as independent. Adding fail static behavior to these adjacencies is an area of ongoing development.

5.1 Jupiter

We initially developed Jupiter [28], Google's datacenter network, with our first generation SDN-based control system, Onix [18]. The Orion-based solution presented here is a second iteration based on lessons from the Onix deployment.

The Jupiter datacenter network consists of three kinds of building blocks, each internally composed of switches forming a Clos-network topology: (i) aggregation blocks [28] connected to a set of hosts, (ii) FBRs (Fabric Border Routers, also called Cluster Border Routers in [28]) connected to the WAN/Campus network, and (iii) spine blocks that interconnect aggregation blocks and FBRs.

We organize Orion domains for Jupiter hierarchically as shown in Figure 5. First, we map physical Orion domains to the Jupiter building blocks. Each physical domain programs switches within that domain. Aggregation block domains es-

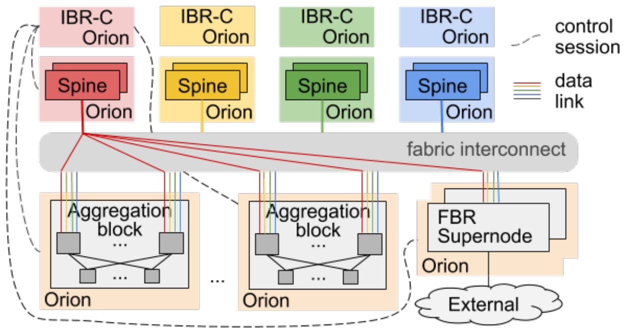

Figure 5: Jupiter topology overlaid with Orion domains partitioned by color. Colored links and spine domains are controlled by the respectively colored IBR-C. Uncolored aggregation block/FBR domains are controlled by all IBR-Cs. Only control sessions and data links of the red color are displayed.

tablish connectivity among hosts attached to it. FBR domains use Raven to maintain BGP sessions with fabric-external peers. Multiple spine blocks can map to a single Orion domain, but each domain must contain fewer than 25% of all spine blocks to limit the blast radius of domain failure.

Second-level Orion domains host a partitioned and centralized routing controller IBR-C (Inter-Block Routing Central). Operating over Routing Engine's abstract topology, IBR-C aggregates network states across physical domains, computes fabric-wide routes, and programs physical domains to establish fabric-wide reachability. While these virtual domains start from the same foundations, they do not contain some Orion core apps for controlling devices directly.

To avoid a single point of failure, we partitioned (or *sharded*) IBR-C into four planes called "colors," each controlling 25% of the spine blocks and hence a quarter of paths between each pair of spine blocks and aggregation blocks/FBRs. Therefore, the blast radius of a single controller does not exceed 25% of the fabric capacity. Sharding centralized controllers avoids failures where a single configuration or software upgrade affects the whole fabric. Additional protection was added to stage configuration changes and upgrades to avoid simultaneous updates across colors. While sharding provided higher resiliency to failures, the trade-off was an increased complexity in merging routing updates across colors in aggregation block and FBR domains, as well as a loss in routing optimality in case of asymmetric failures across colors. We have considered even deeper sharding by splitting aggregation blocks into separate domains, each controlling a portion of the switches. This option was rejected due to even higher complexity while marginally improving availability.

Figure 6 illustrates the fabric-level control flow of one IBR-C color. IBR-C subscribes to NIBs in all aggregation block/FBR domains and spine domains of the same color for state updates. After aggregation at Change Manager, the Solver computes inter-block routes and Operation Sequencer writes the next intended routing state into NIB tables of corresponding domains. IBR-D (Inter-Block Routing Domain), a

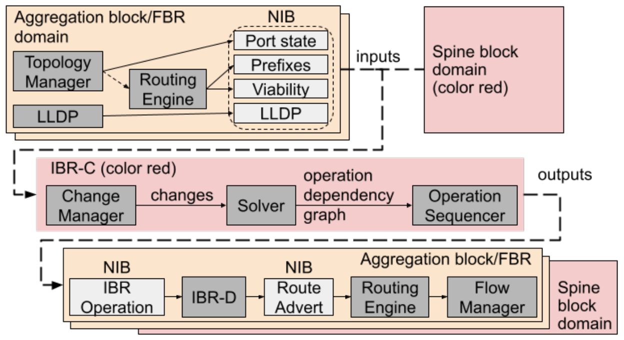

Figure 6: Jupiter fabric-level IBR-C control flow of one color.

domain-level component, merges routes from different IBR-C colors into `RouteAdvert` updates. Finally, Routing Engine and Orion Core program flows as shown in Figure 3.

Convergence. We care about two types of convergence in Jupiter: data plane convergence and control plane convergence. Data plane convergence ensures there are valid paths among all source/destination pairs (no blackholing) while control plane convergence restores (near) optimal paths and weights in the fabric. Workflows that require changes to the network use control plane convergence as a signal they can proceed safely. Convergence time is the duration between a triggering event and all work complete in data/control plane.

Jupiter's reaction to link/node failures is threefold. First, upon detection of link-layer disruption, switches adjacent to the failed entity perform local port pruning on the output group. However, this is not possible if no alternative port exists or peer failure is undetectable (e.g., switch memory corruption). Second, RE programs the domain to avoid this entity. This is similar to switch port pruning, but could happen on non-adjacent switches within the domain. For failures that do not affect inter-block routing, the chain of reaction ends here. Otherwise, in a third step, RE notifies IBR-C of the failure, as shown in Figure 6. When fabric-wide programming is complete, IBR-C signals the control plane has converged. This multi-tier reaction is advantageous for operations, as it minimizes data plane convergence time and thus traffic loss.

Since a single entity failure can lead to successive events in different domains (e.g., spine switch failure causing aggregation block links to fail), it could trigger multiple IBR-C and domain programming iterations to reach final convergence. Many independent events also happen simultaneously and get processed by Orion together, which can further delay convergence. Hence, we will evaluate Orion's performance in example convergence scenarios in §6.

Implementation Challenges. One challenge with the original Jupiter implementation [28] was optimally distributing traffic across multiple paths. Capacity across paths can differ due to link failures and topology asymmetry (e.g., different link count between a spine-aggregation block pair). In order to optimally allocate traffic, Jupiter/Orion employs WCMP to vary weights for each path and nexthop. Due to the precise

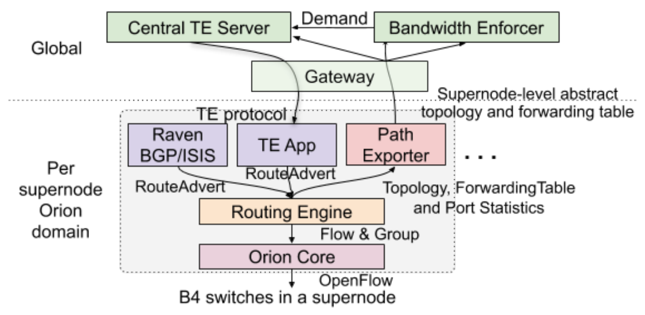

Figure 7: B4 Control Diagram

weight computation for each forwarding entry, weights need to be adjusted across the entire fabric to fully balance traffic. Another challenge was transient loops or blackholes during route changes. This is due to asynchronous flow programming in traditional routing protocols and in our previous SDN controller [18]. With Orion-based Jupiter, we implement end-to-end flow sequencing in both IBR-C and RE.

At the scale of Jupiter, network events arrive at IBR-C at a high frequency, which sometimes surpasses its processing speed. To avoid queue buildup, IBR-C prioritizes processing certain loss-inducing events (e.g., link down) over noncritical events (e.g., drain). Upon an influx of events, IBR-C only preempts its pipeline for loss-inducing events. It reorders/queues other events for batch processing upon the completion of higher priority processing. This is a trade-off to minimize traffic loss while avoiding starvation of lower priority events. §6 quantifies the benefits of this approach in more detail.

5.2 B4

Onix [18], the first-generation SDN controller for B4, ran control applications using cooperative multithreading. Onix had a tightly-coupled architecture, in which control apps share fate and a common threading pool. With Onix's architecture, it was increasingly challenging to meet B4's availability and scale requirements; both have grown by 100x over a five year period [13]. Orion solved B4's availability and scale problems via a distributed architecture in which B4's control logic is decoupled into micro-services with separate processes.

Figure 7 shows an overview of the B4 control architecture. Each Orion domain manages a B4 supernode, which is a 2-stage folded-Clos network where the lower stage switches are external facing (see details in [13]). In B4, Routing Engine sends ingress traffic to all viable switches in the upper stage using a link aggregation group (LAG), and uses two-layer WCMP to load-balance traffic toward the nexthop supernode.

The **TE App** is a traffic engineering agent for B4. It establishes a session with global TE server instances to synchronize the tunnel forwarding state. It learns TE tunneling ops from the primary TE server, and programs the ops via the `RouteAdvert` table. In addition, TE App also supports Fast ReRoute (FRR), which restores connectivity for broken tunnels by temporarily re-steering the traffic to the backup tunnel set or BGP/ISIS routes.

The **Path Exporter** subscribes to multiple NIB tables and exports the observed dataplane state to the global services. It reports the dataplane state at the supernode level, including the abstract topology (e.g., supernode-supernode link capacities), the abstract forwarding table (TE tunnels and BGP routes), and the abstract port statistics.

The **Central TE Server** [13,15] is a global traffic engineering service which optimizes B4 paths using the TE protocol offered by the TE App in each domain. The **Bandwidth Enforcer** [19] is Google's global bandwidth allocation service which provides bandwidth isolation between competing services via host rate limiting. For scalability, both the Central TE Server and Bandwidth Enforcer use the abstract network state provided by the Path Exporter.

6 Evaluation

We present microbenchmarks of the Orion NIB, followed by Jupiter evaluation using production monitoring traces collected since January 2018. Orion also improved B4 performance, as published previously [13].

NIB performance. To characterize NIB performance, we show results of a microbenchmark measuring the NIB's read/write throughput while varying the number of updates per batch. A batch is a set of write operations composed by an app that updates rows of different NIB tables atomically. In Figure 8, we observe throughput increase as the batch size becomes larger. At 50K updates per batch, the NIB achieves 1.16 million updates/sec in read throughput and 809K updates/sec in write throughput.

Write throughput at 500 updates per batch sees a decline. This reveals an implementation choice where the NIB switches from single-threaded write to multi-threaded write if the batch size is greater than 500. When the batch size is not large enough, up-front partitioning to enable parallelism is more expensive than the performance improvement. This fixed threshold achieves peak performance on sampled production test data and performs well in production overall. It could be removed in favor of a more dynamic adaption strategy to smooth the throughput curve.

Data and control plane convergence. One key Jupiter performance characteristic is convergence time (§5.1). We measure convergence times in several fabrics, ranging from 1/16-size Jupiter to full-size Jupiter (full-size means 64 aggregation blocks [28]). Figure 9 captures data and control plane convergence times of three types of common daily events in our fleet. The measurements are observed by Orion; switch-local port pruning is an independent decision that completes within a few milliseconds without Orion involvement.

In node/link down scenarios, the data plane converges within a fraction of a second. Both data and control plane convergence times become longer as the fabric scales up by 16x. This is mainly because a larger number of aggregation

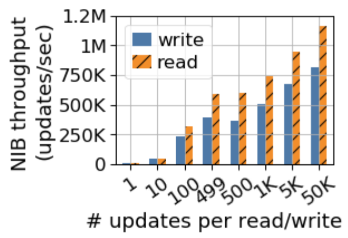

Figure 8: NIB throughput.

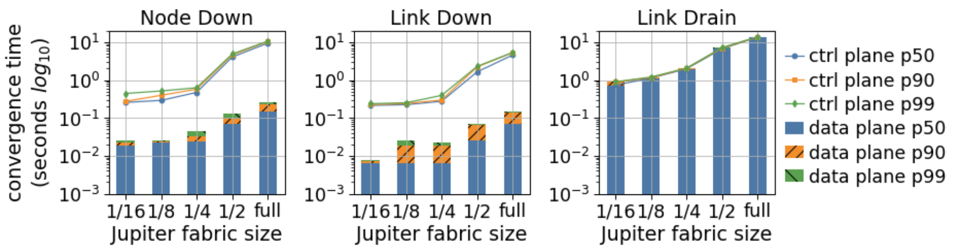

Figure 9: Jupiter data/control plane convergence time in response to various network events.

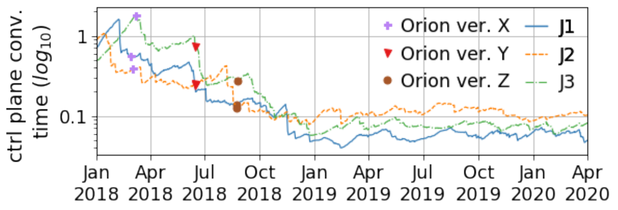

Figure 10: Time series of full fabric control plane convergence on three large Jupiter fabrics. Y-axis is normalized to the baseline convergence time in January 2018. Orion releases with major performance improvements are highlighted by markers.

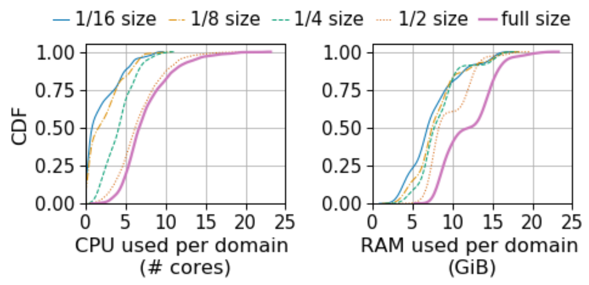

Figure 11: Orion CPU/RAM usage in Jupiter domains.

blocks and spine blocks require more affected paths to be re-computed and re-programmed. Data plane convergence is 35-43x faster than control plane convergence, which effectively keeps traffic loss at a minimum.

Jupiter's reaction to link drains is slightly different from failure handling. Drains are lossless, and do not include an initial sub-optimal data plane reaction to divert traffic. Instead, Orion only shifts traffic after computing a new optimal routing state. Therefore, data and control plane convergence are considered equal. Overall, control plane convergence time for link drain is on par with node/link down scenarios.

We have continuously evolved Orion to improve Jupiter scalability and workflow velocity. Key to this were enhancements in IBR-C such as prioritized handling of select updates, batch processing/reordering, and a conditionally preemptive control pipeline. Figure 10 shows the trend of three large fabrics from January 2018 to April 2020; the control plane convergence time in January 2018 was before these improvements. Deployed over three major releases, each contributing an average 2-4x reduction, the new processing pipeline (§5.1) delivered a 10-40x reduction in convergence time.

Controller footprint: CPU and memory. Orion controller jobs run on dedicated network control servers connected to the CPN. This pool is comprised of regular server-class platforms. We measure CPU and memory usage of each controller job (including all three replicas) and group them by domain. Figure 11 shows that even in a full-size Jupiter, Orion domains use no more than 23 CPU cores and 24 GiB of memory.

7 Production Experience

We briefly review some challenging experiences with Orion when adhering to our production principles of limited blast-radius and fail-static safety, and some more positive experiences from following our software design principles.

7.1 Reliability and robustness

Failure to enforce blast radius containment. As described in §5.1, the inter-block routing domain is global but sharded into four colors to limit the blast radius to 25%. A buggy IBR-C configuration upgrade caused a domain to revoke all forwarding rules from the switches in that domain resulting in 25% capacity loss. Since high-priority traffic demand was below 25% of the fabric's total capacity, only after all four domains' configurations were pushed did the workflow flag (complete) high-priority packet loss in the fabric. To prevent such a "slow wreck" and enforce blast radius containment, subsequent progressive updates proceeded only after confirming the previous domain's rollout was successful, and not simply the absence of high-priority packet loss.

Failure to align blast radius domains. A significant Orion outage occurred in 2019 due to misalignment of job-control and network-control failure domains. Like many services at Google, these Orion jobs were running in Borg cells [31]. Although the Orion jobs were themselves topologically-scoped to reduce blast radius (§3.1), their assignment to Borg cells was not. As described in the incident report [9], when a facility maintenance event triggered a series of misconfigured behaviors that disabled Orion in those Borg cells, the resulting failure was significantly larger than Google's networks had been previously designed to withstand. This outage highlighted the need for all management activities (job control, configuration update, OS maintenance, etc.) to be scoped and rate-limited in a coordinated manner to fully realize the principle of blast-radius reduction. In addition, it highlighted a gap in our fail-static implementation with regards to BGP.

Failure to differentiate between missing and empty state. In 2018, a significant B4 outage illustrated a challenge when integrating Orion and non-Orion control layers. A gradual increase in routes crossed an outdated validation threshold on the maximum number of routes a neighborhood should receive from attached clusters. Consequently, the TE app suppressed the data to the B4-Gateway, which correctly failed static using cached data. However, subsequent maintenance restarted B4-Gateway instances while in this state, clearing the cached data. Lacking any differentiation between *empty* data and *missing* data, subsequent actions by the TE Server and Bandwidth Enforcer resulted in severe congestion for low-priority traffic. Within Orion, the capability readiness protocol prevents reading missing or invalid derived state.

Orion's post-outage improvements and continuous feature evolution such as loss-free flow sequencing and in-band CPN backup, brought substantial improvements in data plane availability to Jupiter (50x less unavailable time) and B4 (100x less unavailable time [13]).

7.2 Deployability and software design

With Orion, we moved to a platform deeply integrated with Google's internal infrastructure. This enabled us to leverage existing integration testing, debugging, and release procedures to increase velocity. We also moved from a periodic release cycle to a continuous release: we start software validation of the next version as soon as the current version is ready. This reduces the amount of "queued up" bugs, which improves overall velocity.

Release cadence. SDN shifts the burden of validation from "distributed protocols" to "distributed algorithms", which is smaller. Software rollouts are also faster: the number of Network Control Servers is orders of magnitude smaller than the number of network devices. The embedded stack on the devices is also simpler and more stable over time.

Orion's micro-service-based architecture leads to clear component API boundaries and effective per-component testing. Onix, on the other hand, was more monolithic, and our process required more full-system, end-to-end testing to find all newly introduced bugs which was less efficient.

In steady state, after initial development and productionization, it took about five months to validate a new major Onix release. The process was manual, leveraging a quality assurance team and iterative cherry-picking of fixes for discovered issues. With Orion, we shrank validation latency to an average of 14.7 days after the initial stabilization phase, with a target of eventually qualifying a release every week.

Release granularity. As a distributed, micro-service-based architecture, each Orion application could release at its own cadence. In our move from the monolithic Onix to Orion, we have not yet leveraged this flexibility gain. Since Orion is widely deployed and has high availability demands, we strive to test all versions that run at the same time in production, for instance as some applications are upgraded but other upgrades are still pending. An increase in release granularity would increase both the skew duration and total number of combinations that need to be tested. Therefore, we releas all Orion applications that make up a particular product (e.g., B4 or Jupiter) together.

Improved debugging. Serializing all intent and state changes through the NIB facilitates debugging: Engineers investigating an issue can rely on the fact that the order of changes observed by all applications in the distributed system is the same and therefore establish causality more easily.

Storing the stream of NIB updates for every Orion deployment also allowed us to build replay tooling that automatically reproduces bugs in lab environments. This was first used in the aftermath of an outage: only the precise ordering of programming operations that occurred in production, replayed to a lab switch, reliably reproduced a memory corruption bug in Google's switch firmware. This enabled delivering as well as, more importantly, verifying the fix for this issue.

8 Conclusion and future work

This paper presents Orion, the SDN control plane for Google's Jupiter datacenter and B4 Wide Area Networks. Orion decouples control from individual hardware elements, enabling a transition from pair-wise coordination through slowly-evolving protocols to a high-performance distributed system with a logically centralized view of global fabric state. We highlight Orion's benefits in availability, feature velocity, and scale while addressing challenges with SDN including aligning failure domains, inter-operating with existing networks, and decoupled failures in the control versus data planes.

While Orion has been battle-tested in production for over 4 years, we still have open questions to consider as future work. These include (i) evaluating the split between on-box and off-box control, (ii) standardizing the Control to Data Plane Interface with P4Runtime API [10], (iii) exploring making the NIB durable, (iv) investigating fail-static features in BGP, and (v) experimenting with finer-grained application release.

Acknowledgments For their significant contributions to the evolution of Orion, we thank Deepak Arulkannan, Arda Balkanay, Matt Beaumont-Gay, Mike Bennett, Bryant Chang, Xinming Chen, Roshan Chepuri, Dharti Dhami, Charles Eckman, Oliver Fisher, Lisa Fowler, Barry Friedman, Goldie Gadde, Luca Giraudo, Anatoliy Glagolev, Jia Guo, Jahangir Hasan, Jay Kaimal, Stephen Kratzer, Nanfang Li, Zhuotao Liu, Aamer Mahmood, John McCullough, Bhuva Muthukumar, Susan Pence, Tony Qian, Bharath Raghavan, Mike Rubin, Jeffrey Seibert, Ruth Sivilotti, Mukarram Tariq, Malveeka Tewari, Lisa Vitolo, Jim Wanderer, Curt Wohlgemuth, Zhehua Wu, Yavuz Yetim, Sunghwan Yoo, Jiaying Zhang, and Tian Yu Zhang. We also thank our shepherd, Katerina Argyraki, Jeff Mogul, David Wetherall, and the anonymous reviewers for their valuable feedback.

9.1 Orion Core Implementation

To productionize the Orion systems described in this paper, we address some common engineering challenges in the Orion Core. In particular, Orion's architectural choices require great care with both the memory footprint and performance of all data flowing through the NIB. Here, we illustrate multiple implementation choices we made to scale this architecture.

State replication and synchronization. Orion enables a large group of developers in Google to author new SDN applications. To simplify interacting with the intent/state stored in the NIB, we synchronize all relevant data into an app-local cache that trails the NIB's authoritative state. The state visible to each application is always a prefix of the sequential atomic writes applied to the NIB. Each application's ability to see a prefix and therefore (potentially) not the most recent NIB state is acceptable given that the NIB itself is only a trailing reflection of the global system state. Applications do not subscribe to the NIB data they wrote as they were previously responsible for the write.

The app-local cache allows developers to access data as they would access an in-memory hash table. Additionally, since data is local, developers write fast applications by default as they do not have to reason about network round-trips to load data from the NIB. This replication approach requires transmitting cached data efficiently to reduce reaction time to data-plane events. While sequential communication through the NIB has many upsides, e.g., reduced complexity and traces for debugging, it should not dominate reaction time to data-plane events.

Additionally, we require a compact memory representation of all state to support a large number of micro-services, with overlapping subsets of the NIB state in their local caches. Protocol buffers are not well-suited for this requirement because they hold copies of the same nested and repeated fields in more than one entity (e.g., the same output port ID string in multiple forwarding rules). Orion works around this space inefficiency by exploiting the read-only nature of cached data. As all entity mutations are sent directly to the NIB for full serializability, it is possible to de-duplicate select sub-messages and data types in the app-local cache to conserve memory. Given our schema, this reduces memory overhead by more than 5x while retaining the same read-only API offered by regular protocol buffers.

Hash table / key size. Both the dictionary implementation as well as the key length used for the data in the NIB influence memory utilization. In early testing, about 50% of memory was consumed by key-strings and dictionary data structures.

Many data entries in the NIB use descriptive identifiers. For instance, a physical port on a switch, represented in the `Port` table of the NIB, combines the FQDN (Fully Qualified Domain Name) of its parent switch and its own port name identifier as the entity key in the NIB. As the payload per port is only a handful of simple data types, the key size may be larger than the payload. To reduce the memory impact of many entities with relatively small payloads, the NIB initially stored all data in a *trie* modelled after [21]. This was advantageous both because of prefix compression and because it enables inexpensive creation of consistent snapshots.

While we retain the M-Trie data structure for its copy-on-write capability, we have changed to storing a SHA-1 hash of the identifier only. This reduces the NIB memory footprint at the price of a theoretical, but not practical [29], collision risk. If a collision occurred, it would require human intervention.

Large updates. Large updates must be reflected in all SDN apps that consume changed data as their input. In some situations, for instance extensive rerouting, or, when an SDN app restarts and needs to be brought in sync with the NIB, the size of changed intent/state can be multiple gigabytes.

To reduce wall-clock time for such synchronization and peak memory spikes, Orion handles large atomic writes by splitting them into many small ones with special annotations delineating that the small writes are part of one atomic batch. This allows pipeline processing in the NIB, data transfer and cache application on the receiver. As long as the partial small updates are guaranteed to be exposed only after the complete set is available, this optimization is transparent.

In case of synchronizing client application and NIB state after a disconnect, the update size is kept to a minimum to reduce transmission delay. Each application supplies the NIB with a vector of ID-hashes of entities and entity hashes. Matching ID-hashes and entity hashes between the NIB and the application cache tells the NIB to skip updating such entities. All other entities with mismatched or missing hashes will be replaced/deleted/inserted accordingly.

Software upgrade strategy. Since the controller is distributed across multiple apps running in separate binaries, software upgrades lead to version skew across applications. While this version skew is commonly short-lived, it can persist in rare cases as manual intervention is required to resolve the skew when an upgrade is stuck in a partially succeeded state. Given this, a key functionality that Orion provides to developers is enabling features atomically across applications when all are ready. Likewise, Orion can deactivate features atomically in case a participating app no longer supports it.

As an example, take two applications that interact through a NIB table A. Consider that the interaction pattern is changed to go through table B in a later version. Both applications have to ensure that the appropriate table is used depending on the readiness of the peer application. To reduce bug surface, Orion allows describing which applications need to support a certain feature for it to be enabled and abstracts this negotiation from the application developers. Developers simply protect the new interaction through table B inside a condition check, the condition is automatically marked true by Orion based on the feature readiness of both sides. If one of the two applications interacts through the old table, the feature stays disabled. Once both applications support the feature, Orion will enable it atomically.

9.2 Jupiter Fabric Drain

Orion provides support for network management operations. In order to take a network element out of service for repair or upgrade, the control systems needs to first drain it, i.e. divert traffic from it. Orion provides explicit handling and tracking of drain state. Drain Conductor (DC) is an Orion application in a separate non-sharded virtual control domain, providing an external API for network management systems to drain, undrain and check drain status for each element. Once DC receives a drain request for a networking element, it persists the new drain intent in Chubby [5] and dispatches the drain intent to the NIB in a physical domain. Drain Agent (DA), an application running in each physical domain, subscribes to drain intent changes published by DC, and dispatches the drain intent across routing applications. A routing app processes the drain intent by de-preferencing a networking element and updates the drain status. Finally, DC subscribes to drain statuses across physical domains and provides drain acknowledgements via its API.

Metha: Network Verifiers Need To Be Correct Too!

ETH Zürich

Abstract

Network analysis and verification tools are often a godsend for network operators as they free them from the fear of introducing outages or security breaches. As with any complex software though, these tools can (and often do) have bugs. For the operators, these bugs are not necessarily problematic except if they affect the precision of the model as it applies to their specific network. In that case, the tool output might be wrong: it might fail to detect actual configuration errors and/or report non-existing ones.

In this paper, we present Metha, a framework that systematically tests network analysis and verification tools for bugs in their network models. Metha automatically generates syntactically- and semantically-valid configurations; compares the tool's output to that of the actual router software; and detects any discrepancy as a bug in the tool's model. The challenge in testing network analyzers this way is that a bug may occur very rarely and only when a specific set of configuration statements is present. We address this challenge by leveraging grammar-based fuzzing together with combinatorial testing to ensure thorough coverage of the search space and by identifying the minimal set of statements triggering the bug through delta debugging.

We implemented Metha and used it to test three well-known tools. In all of them, we found multiple (new) bugs in their models, most of which were confirmed by the developers.

1 Introduction

It's Friday night and you are about to push an important (network) configuration update in production. Usually, you would feel terribly nervous doing so as there is always the possibility that you may have missed something. You are only too aware that misconfigurations happen frequently and can lead to major network outages [22,24,27]. Tonight though you feel confident when pressing "deploy" as you have confirmed the correctness of your configuration update using a state-of-the-art configuration verifier. A few minutes later, your phone rings: none of your customers can reach the Internet anymore.

This fictitious situation illustrates an intrinsic problem with validation technologies: their results can only be completely trusted if their analysis is sound and complete. As with any complex software though, these tools can (and often do) have bugs. To be fair, this is not surprising: building an accurate and faithful network analysis tool is extremely difficult. Among others, one not only has to precisely capture all the different protocols' behaviors, but also all of the quirks of their specific implementations. Unfortunately, every vendor, every OS, every device can exhibit slightly different behaviors under certain conditions. For all it takes, these behaviors might be the results of bugs themselves. And yet, failing to accurately capture these behaviors—as we show—can lead to incorrect and possibly misleading analysis results.

A fundamental and practical research question is therefore: *How can developers make sure that their network analysis and verification tools are correct?*

Metha We introduce Metha, a system that thoroughly tests network analysis and verification tools to find subtle bugs in their network models using black-box differential testing. Metha automatically finds model discrepancies by generating input configurations and comparing the output of the tool under test with the output produced by the actual router software. For every discovered discrepancy, Metha provides a minimal configuration that helps developers pinpoint the bug. Later on, these configurations can be used to build up an adequate test suite for current and future network tools.

Challenges Precisely identifying bugs in network analyzers' models is challenging for at least three reasons. First, the search space of possible configurations is gigantic: there are hundreds of configuration statements, each of which can take many possible parameters. And yet, as our analysis reveals, most of the bugs only manifest themselves when specific configuration statements/values are present. Second, systematically exploring the search space is highly non-trivial (independently of its size) as one not only needs to generate syntactically-valid configurations, but also semantically-valid ones that involve all features and their interactions. Failing to do so could lead to miss bugs, hence lowering coverage.

Finally, upon finding a configuration triggering a discrepancy, figuring out the exact subset of statements requires to solve another tricky combinatorial search.

Insights Metha addresses the above challenges by first reducing the search space through restricting the parameters to their boundary values. Metha ensures thorough coverage of the search space by phrasing the search as a combinatorial testing problem and targeting the search towards single and pairwise interactions of configuration statements. To ensure syntactically- and semantically-valid configurations Metha relies on a hierarchical grammar-based approach. Finally, Metha employs delta debugging to identify the minimal bug-inducing set of configuration statements to help the developer better understand and reproduce the bug.

Bugs found We demonstrate Metha's effectiveness in practice by finding 62 *real-world bugs* across three popular network analysis and verification tools – Batfish [17], NV [13], and C-BGP [28] – 59 of which have been confirmed by the tools' developers. The majority of the discovered bugs are subtle, silent bugs that undermine the soundness of the tools' results. That is, they could lead operators to incorrect conclusions that their networks behave correctly, while, in fact, they do not.

Our experiments also demonstrate that Metha's key components are essential for its effectiveness. In particular, a random baseline only found 3 bugs, while Metha found 20 bugs with the same number of tests. Last but not least, through our interactions with the tools' developers, we confirm that Metha's minimal configuration examples are indeed useful: some of the developers are already using them to analyze and fix the bugs Metha has discovered.

Contributions In summary, our main contributions are:

- A testing system capable of finding bugs in the network models of state-of-the-art network analyzers (§3).
- A formulation of the search problem in terms of combinatorial testing (§5).
- A precise localization procedure relying on delta debugging to isolate bugs and pinpoint the configuration statements causing them (§6).
- An end-to-end implementation of Metha[1] supporting both Cisco IOS and Juniper configurations (§7).
- An evaluation showing that Metha finds real (and unknown) bugs in all the tested tools (§8).

Limitations Metha treats the network verification tool it is testing as a black box. Hence, it cannot localize the bug within the tool's actual code. This task is left to the developer. However, by identifying the configuration statements responsible for the bug and by creating a minimal configuration that showcases it, the developer has a good starting point for her work. Similarly, Metha cannot detect whether two observed bugs that are triggered by different configuration statements are caused by the same bug in the underlying network model.

config of Z 1's border router

```
...
ip access-list ISOLATE_Z51
  deny ip any 200.51.0.0/24
  permit ip any any
...
```

config of Z 10's border router

```
...
router bgp 10
  aggregate-address 128.0.0.0/1
...
```

Figure 1: Zone 51 has to be isolated from all the other zones. This is achieved through access-lists at the border routers with the exception of zone 10 where it was forgotten.

2 Motivation

We now illustrate how subtle bugs in the network model of network analyzers can lead operators to deploy erroneous configuration changes. We start with two case studies on common configuration features known for easily causing forwarding anomalies: route aggregation and redistribution. In these situations, validating the change with an analyzer is of utmost importance, provided the analysis is correct. We end with a collection of Cisco IOS configuration statements whose semantics were not correctly captured by Batfish [17]. The bugs in this Section were discovered by Metha.

2.1 Example 1: Excess Null Route

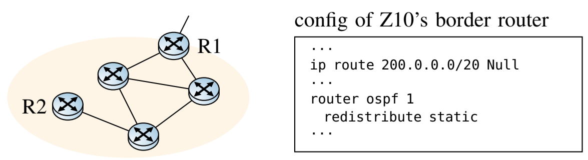
Consider the network in Fig. 1. It consists of a backbone with multiple zones attached to it. The backbone and the zones are interconnected using BGP. Each zone receives a default-route from the backbone. Zone 51 hosts critical infrastructure in the prefix `200.51.0.0/24`, which should not be accessible from any other zone. To enforce this, the routers connecting the zones to the backbone have an access-list (ACL) in place to filter that traffic. However, in zone 10, this ACL was forgotten and, instead, there happens to be a left-over statement from a previous configuration: "`aggregate-address 128.0.0.0 128.0.0.0`". This statement directs the router to advertise the specified aggregate route *if* any more-specific BGP routes in that range exist in the routing table.

Property violation Due to the lack of an ACL on the border router, the requirement that mandates to keep zone 51 isolated is violated: traffic from zone 10 can reach zone 51.

Analyzer mishap When used on the network above, Batfish, a recent network validation tool, will falsely assert that zone 51 is isolated. The problem is due to the semantics of the left-over `aggregate-address` statement. Batfish wrongly activates the aggregate because of a non-BGP route in the routing table and installs the `null` route. Because of this `null` route, Batfish wrongly assumes that all traffic in zone 10 falling within the aggregate range will be dropped. In practice, the routers only install a `null` route if a BGP route within the aggregate is present, which is not the case here.

Feature	Description	Possible Consequence
`max-metric router-lsa`	The model sets maximum metric not only for point-to-point links, but also for stub links. This should only be done when the keyword `include-stub` is used.	A router might appear to be free of traffic and safe to reboot, even though it is not.
`default-information originate`	The OSPF routing process should only generate a default-route if the route table has a default-route from another protocol. The model, however, also announces a default-route if there is one in the routing table of different OSPF type, i.e., E1 type.	Additional default-routes might appear in the routing tables.
`distance XX`	The model does not consider any changes to the administrative distance.	The forwarding state could be completely wrong.
`area X range A.B.C.D/Y`	When summarizing routes between OSPF areas, the model does not insert a null route for the summary to prevent routing loops.	A routing loop could be falsely detected.
`set community no-export`	When redistributing a static route into BGP and setting the `no-export` community, the model still advertises the route to its eBGP neighbors.	Reachability properties could be falsely asserted.
`neighbor A.B.C.D maximum-prefix X`	Even when a BGP neighbor advertises more prefixes than the specified threshold, the model does not drop the peering to the neighbor.	Reachability properties could be falsely asserted.

Table 1: A selection of Cisco IOS configuration features that are not correctly modelled by Batfish [17] as discovered by Metha.



```
...
ip route 200.0.0.0/20 Null
...
router ospf 1
  redistribute static
...
```

Figure 2: All routers should be able to reach the Internet. The static route at R2 creates a blackhole and violates that.

2.2 Example 2: Incomplete Redistribution

Consider the small company network depicted in Fig. 2. It consists of a single OSPF area. R1 acts as Internet gateway and announces a default-route internally. A static route on R2 drops all the traffic for `200.0.0.0/20` by directing it to the `null` interface. This is intended. What is not intended, however, is the `redistribute static` command at R2.

Property violation The following reachability property must always hold: all routers, with the exception of R2, are able to reach the entire Internet. However, this property, is violated since R2 redistributes the static route in the network and, in turn, creates a blackhole for `200.0.0.0/20`.

Analyzer mishap When run on this network, Batfish will falsely attest that all routers, with the exception of R2 can reach the entire Internet. The problem is the redistribution command. By default, Cisco routers only redistribute classful networks [7] and only by specifying the `subnets` keyword, they also redistribute any subnets of them. Less-specific networks however are redistributed regardless of the `subnets` keyword (e.g., `200.0.0.0/20` is less-specific than the corresponding class C network `200.0.0.0/24`). Batfish's network model does not incorporate that as it only redistributes classful networks and not less-specific networks.

2.3 Selection of Bugs

In addition to the two bugs illustrated in the previous examples, we found several other configuration statements that trigger bugs. We present a selection of them in Table 1 alongside a short description of the observed behavior and possible consequences. All of the presented bugs concern Cisco IOS configuration statements. In our tests, we also used Juniper configurations and found that, in many cases, the same bugs occur. Hence, some of these bugs are not due to vendor-specific behaviors, but due to general inaccuracies of the network model.

3 Overview

In this section, we first present the key insights enabling Metha to efficiently uncover bugs in network analyzers. Then, we provide a high-level overview of Metha.

3.1 Key Insights

The main challenge in testing network analyzers is that bugs may occur rarely and only for very specific configurations, which we address with a combination of five insights:

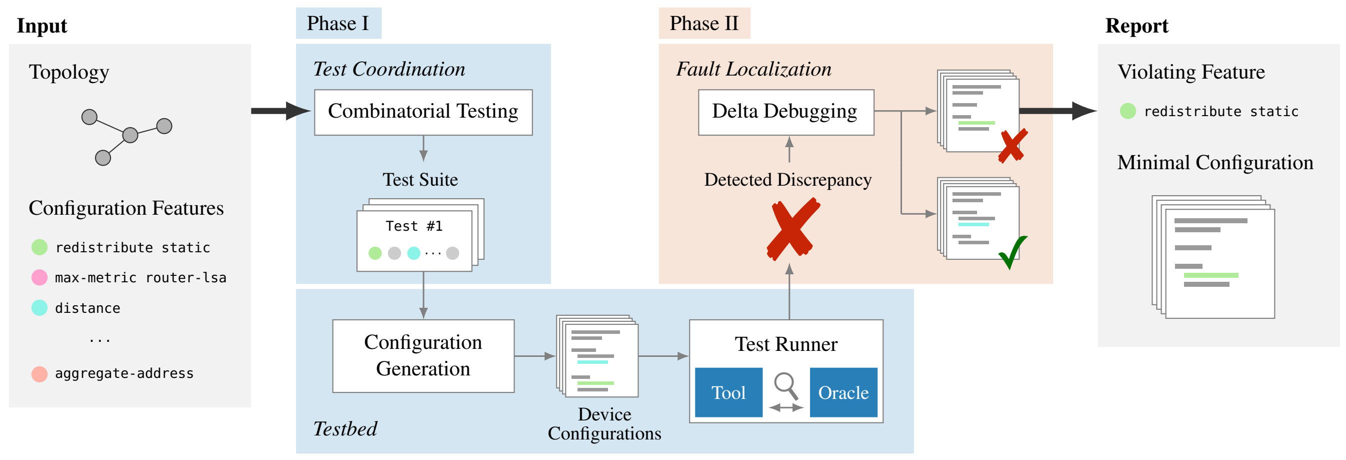


Figure 3: Metha generates a test suite based on the test topology and supplied configuration features. The testbed runs one test after another and compares the computed routing tables of the tool under test to those of an oracle. It then analyzes every discrepancy to localize all the bugs and creates a report for each one of them.

Producing valid inputs with grammar-based generation When testing network analyzers, it is of utmost importance to use syntactically- and semantically-valid configurations, meaning the configurations need to be parseable and constraints have to be met such that actual computation takes place in the network. Our key insight is to use a hierarchical grammar-based approach. Approaching it hierarchically allows to resolve the intra- and inter-device constraints. This provides the structure that is then completed using grammar-based configuration generation ensuring syntactical validity.

Reducing the search space through boundary values The search space of all possible configurations is prohibitively large. Even a single parameter, such as an OSPF cost, for example, already has 2^{16} possible values to test. By focusing the testing on the boundary values (the minimum, maximum, and a normal value), we reduce the search space significantly.

Exploring the search space with combinatorial testing Network devices support a wide variety of configuration features that all need to be tested not just by themselves, but also their interactions. Hence, we use combinatorial testing to design a test suite that systematically covers all pairwise interactions of configuration features.

Comparing the tested tool's output to ground truth Detecting crash bugs is straightforward as the tool will just fail or report an error. Silent bugs, on the other hand, can only be detected by comparing the output to a ground truth, which is hard to come by. We address this by leveraging a testbed running real router images as an oracle.

Isolating bugs with delta debugging Lastly, once one identifies a network configuration that triggers a bug, one needs to identify the configuration statements causing it to provide any useful insights to the tool's developer. Therefore, we use iterative delta debugging to obtain a minimal configuration example reproducing the bug.

3.2 Metha

Metha operates in two phases as shown in Fig. 3: First, it aims to find network configurations exhibiting discrepancies between the tool under test and the oracle. To that end, the test coordination determines all the tests to run in the testbed. Second, it identifies the configuration statements responsible for the observed discrepancies through fault localization.

Input and output Metha takes two inputs: *(i)* a physical topology, i.e., an undirected graph; and *(ii)* a set of configuration features to be tested, such as, route-maps, and route-summarization. For every discovered bug, Metha creates a report, which consists of the identified discrepancy between the routing tables of the tool and the oracle, the configuration statements causing it and a configuration set to reproduce it.

Phase I: Test coordination (§4, §5) The configuration features and the topology provided as input define the search space of Metha's testing efforts which consists of all possible configurations that can be built using these features.

This search space of network configurations is prohibitively large. Therefore, Metha first reduces the values of all parameters to their boundary values, which means it only uses the two extreme values (i.e., the minimum and the maximum) and one "normal" value. Even with this reduction, it is difficult to systematically cover the search space. Hence, Metha creates a test suite relying on combinatorial testing, which allows it to cover all pairs of feature and parameter combinations requiring a minimal number of tests. Each test in the test suite is a set of configuration statements that should be active.

Phase I: Testbed (§7) For every single test, Metha generates the device configurations based on the statements as defined by the test suite. Then, it runs these configurations in the tool and the oracle. Once both converged, Metha analyzes the routing tables of the two tools and reports any discrepancies.

BGPProcess	→	`router bgp` *Integer16* [*Options*]
Options	→	*Option* | *Options Option*
Option	→	*Redistribute* | *Neighbor* | *Network* | ···
Redistribute	→	`redistribute` *Source*
Source	→	`direct` | `static` | ···
Neighbor	→	`neighbor` *Address Property*
Property	→	*RemoteAS* | *RouteMap* | ···
RemoteAS	→	`remote-as` *Integer16*
RouteMap	→	`route-map` *String Direction*
Direction	→	`in` | `out`

Figure 4: Partial BNF grammar for device configurations.

Phase II: Fault localization (§6) A discovered discrepancy can be caused by multiple bugs in the network analyzer. Therefore, Metha applies delta debugging to identify every single bug and the configuration statements causing it. It does so by iteratively testing subsets of the active configuration statements until the entire discrepancy is resolved.

4 Search Space

In this section, we define the search space of all possible configurations. We also show how we reduce the search space by restricting the parameter values used in configuration statements to *boundary* values.

4.1 Network Configurations

The search space is given by all possible configurations that one can deploy at the network's routers.

Configurations A device configuration defines the enabled features along with their parameter values. Formally, the set of all possible configurations is defined by a context-free grammar whose terminals consist of feature names and parameter values. To illustrate this, in Fig. 4 we show a subset of the production rules in Backus-Naur form (BNF). An example configuration derived from this grammar is:

```
router bgp 100
  redistribute static
  neighbor 1.1.1.2 remote-as 50
  neighbor 1.1.1.2 route-map map10 out
```

This configuration defines the AS identifier, neighbors, neighbor properties, and route redistribution associated with the BGP routing process `100`. Here, `router bgp`, `redistribute`, `neighbor A.B.C.D remote-as`, and `neighbor A.B.C.D route-map` are configuration statements, while the values to the right define their parameter values. We distinguish three types of parameter values:

Keywords are used in configuration statements parameterized by a value drawn from a fixed set of options. For example, the configuration statement `neighbor A.B.C.D route-map` is parameterized by a direction, which is set to either `in` or `out`. For some statements, one can also omit the parameter value altogether, which we model with the designated value ∅. For example, `redistribute connected` is parametrized by a value drawn from the set {∅,`subnets`}, and so both `redistribute connected` and `redistribute connected subnets` are valid statements.

Integers are used to define 16- and 32-bit numbers. For example, the configuration statement `router bgp` is parameterized by a 16-bit integer defining the AS number.

Strings are used in configuration statements parameterized by custom names. For example, `neighbor A.B.C.D route-map` is parameterized by the route-map's name.

Semantic constraints Besides conforming to the syntax in Fig. 4, configurations must also comply with semantic constraints. For example, consider the following configurations:

```
1    interface FastEthernet0/0
2      ip address 1.1.1.1 255.255.255.0
3    !
4    router bgp 100
5      neighbor 1.1.1.2 remote-as 50
6      neighbor 1.1.1.2 route-map map10 out
7    !
8    route-map map10 permit 10
9      match ip address prefixList
```

```
1    interface FastEthernet0/0
2      ip address 1.1.1.2 255.255.255.0
3    !
4    router bgp 50
5      neighbor 1.1.1.1 remote-as 100
```

The top configuration (C_1) defines a BGP process with AS number `100` (Line 4), and declares that announcements sent to its BGP neighbor with IP `1.1.1.2` (Line 5) are processed using route-map `map10` (Line 6). The bottom configuration (C_2) defines a BGP process with AS number 50 (Line 4), and declares `1.1.1.1` in AS `100` as a neighbor (Line 5). These two configurations illustrate two kinds of semantic constraints:

Intra-device constraints, which stipulate conditions that must hold on any (individual) configuration. For example, the route-map `map10` used at Line 6 must be defined within the configuration C_1. This constraint holds as `map10` is defined at Line 8.

Inter-device constraints, which stipulate conditions across multiple configurations. For example, the AS number assigned to neighbor `1.1.1.2` in C_1 at Line 5 must match the AS number declared in C_2 at Line 4. This constraint holds as at both lines the AS number is 50.

Finally, we note that we specify the semantic constraints separately from the syntactic production rules as some are not context-free and thus cannot be encoded in the grammar.

Search space The search space used by Metha is defined by the set of configurations that one can deploy at the network's routers. As the set of configurations derived from the grammar is, in general, infinite, we restrict all recursive rules so that its language consists of finitely many configurations. For instance, for the grammar given in Fig. 4, we fix the set of BGP options (such as route redistribution) that can appear when defining a BGP routing process. Finally, the search space of Metha is defined as C^R, where C is the set of all configurations and R is the set of routers. Note that each element of C^R defines a *network-wide configuration*, assigning a configuration from C to each router in R.

4.2 Boundary Values

The search space is extremely large due to the enormous number of configurations and the exponentially many combinations in which they can be deployed at the routers. To cope with the large set of configurations, we apply a *boundary values* reduction by restricting the parameters to a small set of representative values. The intuition behind this reduction is that most parameter values lead to the same behavior such that testing them individually provides no additional insights.

The reduction to boundary values ensures that various behaviors of a feature are exercised. For example, the Cisco BGP feature `neighbor X.X.X.X maximum-prefix n` terminates the session when the neighbor announces more than `n` prefixes. When randomly choosing `n`, the feature will most likely not come into action. However, with the boundary values, both the minimum and maximum value are tested, ensuring that the feature is at least once active and once not.

For integer parameters, the values are restricted to: the maximum value, the minimum value, and a non-boundary value. For example, for 16-bit integers, which contain all integers in the range $[0,65535]$, our boundary value reduction selects three values: 0, 65535, and a value x such that $0 < x < 65535$. Similarly, we reduce the values assigned to string parameters by predefining a fixed set of strings.

5 Effective Search Space Exploration

Metha must cover a wide variety of different network configurations to thoroughly test the tool, including many combinations of device features and parameter values. The key challenge is that it is impossible to iterate through every single combination of features and their respective parameter values, even after considering our reduction to boundary values. To address this, Metha relies on *combinatorial testing* [16, 20], which is able to uncover all bugs involving a small number of interacting features. In the following, we first provide relevant background on combinatorial testing, and then we show how Metha uses it to effectively test network tools.

5.1 Combinatorial Testing

Combinatorial testing is a black-box test generation technique which is effective at uncovering *interaction bugs*, i.e., bugs that occur because of multiple interacting features and their parameter values. The main assumption behind combinatorial testing is that interaction bugs are revealed by considering a small number of features and parameter values. In this case, one can generate a test suite, called *combinatorial* test suite, that uncovers all such bugs.

To use combinatorial testing, one needs to define a specification of the system's parameters and their values:

Definition 1 (Combinatorial specification)**.** A combinatorial specification $\mathcal{S}$ is a tuple (P,V,Δ), where P is a set of parameters, V is a set of values, and $\Delta\colon P \to 2^V$ defines the domain of values $\Delta(x) \subseteq V$ for any parameter $x \in P$.

For example, the combinatorial specification for a program that accepts three boolean flags as input has parameters $P = \{a,b,c\}$, values $V = \{0,1\}$, and domains $\Delta(a) = \Delta(b) = \Delta(c) = \{0,1\}$. A *test case* is a total function $tc\colon P \to V$ mapping parameters to values from their respective domains, i.e., with $P(x) \in \Delta(x)$ for any x. An example test case for our program is $tc = \{a \mapsto 0, b \mapsto 0, c \mapsto 1\}$. In contrast to test cases, a *t-wise combination* maps only some parameters to values:

Definition 2 (t-wise combination)**.** Given a combinatorial specification $\mathcal{S} = (P,V,\Delta)$, a t-wise combination for $\mathcal{S}$ is a function $c\colon Q \to V$ such that $Q \subseteq P$ with $|Q| = t$ and $c(x) \in \Delta(x)$ for any $x \in P$.

An example pairwise combination (i.e., $t = 2$) for our example is $c = \{a \mapsto 0, b \mapsto 1\}$. We write $C_t^{\mathcal{S}}$ to denote the set of all t-wise combinations for a given combinatorial specification $\mathcal{S}$. Note that a test case can cover multiple t-wise combinations:

$$comb_t(tc) = \{c \subseteq tc \mid |c| = t\}$$

For instance, our example test case above covers the following three pairwise combinations: $\{a \mapsto 0, b \mapsto 0\}$, $\{a \mapsto 0, c \mapsto 1\}$, and $\{b \mapsto 0, c \mapsto 1\}$.

Definition 3 (t-wise combinatorial coverage)**.** Given a combinatorial specification $\mathcal{S}$, we define the t-wise combinatorial coverage of a test suite T as:

$$cov_t(T) = \frac{|\bigcup_{tc \in T} comb_t(tc)|}{|C_t^{\mathcal{S}}|}\,.$$

A test suite T is called a *t-combinatorial test suite* if $cov_t(T) = 1$. If the assumption that interaction faults are caused by up to t-wise interactions holds, then T finds all bugs. The goal of combinatorial testing is to generate the smallest t-wise combinatorial test suite.

5.2 Combinatorial Testing of Configurations

In Metha, we apply pairwise combinatorial testing to the generation of network configurations. Concretely, we phrase the search space defined in §4 as a combinatorial specification $\mathcal{S} = (P, V, \Delta)$ as follows. First, each statement that can appear in the configuration, such as route redistribution or route-map as defined in §4, defines a configuration feature. We set F to be the set of all configuration features. The set of parameters P is then given by $R \times F$, where R is the set of routers. Namely, the parameters consist of all configuration features one can define in the device configurations.

Second, the domains of values for each configuration feature contain the boundary values that can be used in the given configuration statement, along with the designated value $\perp$, which indicates whether the configuration feature is enabled or not. That is, $\perp$ results in omitting the configuration statement altogether. We note that for configuration statements with multiple parameters, we take the product as the domain of possible values. For example, the Cisco OSPF configuration feature `default-information-originate` has three optional parameters: `always`, `metric` combined with an integer value, and `metric-type` combined with 1 or 2. After reduction to boundary values this leads to the following three parameters:

$$A = \{\varnothing, \texttt{always}\}$$
$$B = \{\varnothing, \texttt{metric 1}, \texttt{metric 100}, \texttt{metric 1677214}\}$$
$$C = \{\varnothing, \texttt{metric-type 1}, \texttt{metric-type 2}\}$$

The domain of values for this configuration feature is then given by $\{\perp\} \cup (A \times B \times C)$.

Finally, Metha uses the above combinatorial specification to derive a test suite of configurations that covers all pairwise combinations.

6 Fault Localization

A discovered discrepancy between the network model and the oracle is only of limited use as the developer still needs to isolate its cause. Often understanding the bug is the most time-consuming part of the debugging process, and fixing it can be done relatively quickly. To help with this, Metha pinpoints the configuration features that cause a discrepancy and finds a minimal configuration, i.e., a configuration with as few configuration features enabled as possible. To do this, Metha uses *iterative delta debugging*, an extended version of classic delta debugging, which lifts the assumption that a single fault causes failures. This extension is important as network configurations are large and complex, and discrepancies are often caused by multiple faults. In the following, we first introduce classic delta debugging and then present its iterative extension.

6.1 Delta Debugging

Delta debugging [35] is a well-established fault localization technique, which finds minimal failure-inducing inputs from failing test cases. Below, we present delta debugging in our context, and then define its assumptions and algorithmic steps.

Terminology As defined in §5, a test case tc assigns configuration features F to either parameter values or $\perp$, where $\perp$ indicates that a given feature is disabled (i.e., it is omitted from the configuration). Given a test case tc and features $Q \subseteq F$, we write $tc|_Q$ for the test case obtained by disabling all features in tc that are not contained in Q:

$$tc|_Q(f) = \begin{cases} tc(f) & \text{if } f \in Q \\ \perp & \text{otherwise} \end{cases}$$

Given a failing test case tc, the goal of delta debugging is to find the minimal set Q of features such that $tc|_Q$ fails. We denote the complement of Q by $\bar{Q} = F \setminus Q$.

Assumptions Delta debugging relies on three assumptions: *(i)* test cases are *monotone*, i.e., if $tc|_Q$ fails, then for any superset $Q' \supseteq Q$ of features $tc_{Q'}$ also fails; *(ii)* test cases are *unambiguous*, meaning that for a failing test case tc there is a unique minimal set Q that causes the failure; and *(iii)* every subset of features is *consistent*, meaning that for any $Q \subseteq F$, $tc|_Q$ terminates with a definite fail or success result.

Algorithm Given a test case tc, delta debugging finds a minimal set of features Q that causes a failure. Initially, Q contains all enabled features in tc, i.e., $Q = \{f \in F \mid tc(f) \neq \perp\}$. Then it applies the following steps:

1. *Split:* Split Q into n partitions $Q_1, \ldots, Q_n$, where n is the current granularity. Test $tc|_{Q_1}, \ldots, tc|_{Q_n}$ for failures. If some $tc|_{Q_i}$ fails, then use Q_i as the new current set of features and continue with step 1.

2. *Complement:* If none of the new tests $tc|_{Q_1}, \ldots, tc|_{Q_n}$ fail, check the complement of each partition by testing $tc|_{\bar{Q}_1}, \ldots, tc|_{\bar{Q}_n}$. If some $tc|_{\bar{Q}_i}$ fails, then use $\bar{Q}_i$ as the new current set of features and continue with step 1.

3. *Increase Granularity:* If no smaller set of features is found and $n < |Q|$, then set n to $\min(2n, |Q|)$ and continue with step 1.

4. *Terminate:* If it is not possible to split the current set of features into a smaller set, terminate and return Q.

6.2 Iterative Delta Debugging

In our setting, test cases are often ambiguous as a discrepancy often arises due to multiple faults in the network model. To this end, we apply the delta debugging algorithm *iteratively* and find all minimal sets of features that cause a given discrepancy. Intuitively, starting with a test case tc with enabled features Q, we first apply the delta debugging steps (given

Algorithm 1: Iterative Delta Debugging

```
Input   : Test case $tc$, initially enabled features $Q$ in $tc$.
Output  : A set of minimal feature subsets $\mathcal{S} = \{Q_1, \ldots, Q_n\}$.
1  $\mathcal{S} = \emptyset$
2  $Queue = \texttt{queue()}$
3  put($Queue, Q$)
4  while $\neg$empty($Queue$) do
5      $H = \texttt{head}(Queue)$
6      if $run(tc|_H) = \textit{failure}$ then
7          $Q' = minimize(H)$
8          for $f$ in $Q'$ do
9              put($Queue, H \setminus \{f\}$)
10         $\mathcal{S} = \mathcal{S} \cup \{Q'\}$
11 return $\mathcal{S}$
```

in §6.1) to find a minimal configuration feature set Q' such that $tc|_{Q'}$ triggers the discrepancy. Then, we generate new test cases $tc_1, \ldots, tc_{|Q'|}$, by disabling a feature from Q in each new test case tc_i, and iteratively apply delta debugging to these. We apply this process repeatedly until no further failing test cases are found. Once Metha identifies all minimal sets of configuration features that trigger a given bug, Metha creates a minimal configuration for the developer to reproduce it.

We present our iterative delta debugging algorithm in Algorithm 1. We start from a set of initially enabled features Q in tc and return all minimal subsets of Q that trigger a discrepancy. We keep all sets of features to be checked in a queue and continue until the queue is empty (Line 2 - Line 4). For every set H of features in the queue, we check if the test case $tc|_H$ triggers a discrepancy (Line 5, Line 6). If this is the case, then we find a minimal subset $Q \subseteq H$ of features that triggers the discrepancy using classic delta debugging, and create new subsets that need to be checked (Line 8, Line 9). For example, if we find a minimal set of features $Q = \{a, b\}$ that triggers the discrepancy, then we check if there are any other minimal sets of features that do not contain a or b (and are thus non-comparable to Q). We note that we generate two new sets of features $H \setminus \{a\}$ and $H \setminus \{b\}$ instead of a single one $H \setminus \{a, b\}$ because there may be overlapping discrepancies. For example, even though we know that b can trigger a discrepancy with a, b might also trigger a discrepancy with another feature c. Finally, the algorithm keeps all found minimal feature subsets and returns them (Line 10, Line 11). We conclude by stating the correctness of our algoirthm:

Theorem 1. *For any test case tc with enabled features Q, Algorithm 1 finds all minimal fault-inducing subsets of features.*

We present the proof of this theorem in App. A.

Runtime The running time of Algorithm 1 is $O(|Q|!)$. The worst-case behavior is when the size of the set H of features is reduced by 1 element in each step, introducing $|H - 1|$ new features sets to the set $\mathcal{S}$. To improve the running time, we cache (not shown in Algorithm 1) feature sets that have been added to the queue. This strictly reduces the algorithm's running time and yields a worst-case running time complexity of $O(2^{|Q|})$. We note that the running time in practice is reasonable as the reduction of the set H by the delta debugging minimization step (Line 7) is significant (down to $2-3$ elements in practice).

Limitations As with classic delta debugging, there may be a fault in the interaction between a set of parameters, say a, b, and c, as well as a different fault in the interaction between a subset of these parameters, say a and b. We cannot distinguish these two faults and will only identify the latter fault. However, once the identified fault is fixed, our algorithm will then identify the fault in the interaction among a, b, and c as well, assuming it is still present in the verification tool.

7 System

We have fully implemented Metha in 7k lines of Python code.[2] This covers the entire testing pipeline from the input, the list of configuration features to be tested and the topology, to the outputs, the bug reports. In the following, we highlight key points of Metha's implementation, which consists of a vendor- and tool-agnostic core that uses runners to interface with the different network analysis and verification tools.

Semantic constraints To run the tests, Metha uses a logical topology, which consists of the physical topology extended with logical groupings. These groupings map the routers to BGP ASes and their interfaces to OSPF areas. This trivially ensures that the base configuration meets all the necessary semantic constraints (cf. §4.1). In a next step, Metha starts to randomly assign IP subnets to links and IP addresses to the router interfaces on these links. Specifically, every router is assigned a router ID, which is also assigned to the loopback interface of that router. Finally, Metha generates additional resources that are needed to test specific configuration features. For example, Metha adds several prefix-lists and static routes which can then be used in the test generation, for example, for a match statement of a route-map and route redistribution, respectively. All these additional resources are generated based on the predefined logical topology. Hence, a prefix-list, for example, will only consist of prefixes that are actually defined in the network, such that a route-map statement using that list for a match will also be reachable.

Testing coordination Once Metha laid the groundwork, it has to define a test strategy based on the specified configuration features. At the moment, Metha supports configuration features pertaining to four categories: static routes, OSPF, BGP and route-maps. As part of that, the system supports additional constructs such as prefix-lists and community-lists. These are currently not tested on their own, but added when needed to test the main features, such as route-maps. Metha

[2] Available at https://github.com/nsg-ethz/Metha

then uses all features and the logical topology to prepare the parameters to come up with the test suite. To do that, Metha passes all the parameters and their possible values to a state-of-the-art combinatorial testing tool: PICT [25]. PICT devises a test suite that consists of a set of tests ensuring complete coverage of all pairwise feature interactions.

Configuration generation A single test from the PICT test suite is an abstract network configuration. It simply specifies which feature and corresponding value needs to be activated and where (i.e., on which router and, if applicable, at which interface). Metha then translates the abstract network configuration to concrete device configurations using a grammar-based approach to ensure lexical and syntactical validity.

Metha implements a large portion of both Cisco IOS and Juniper grammars for which we relied on the respective official command references. This means Metha can generate both Cisco IOS and Juniper configurations for the tests. Metha even supports to test hybrid networks in which devices of both vendors are used at the same time.

Testbed Metha runs the generated configurations in parallel on both the tool under test and the oracle. After both of them converged, it retrieves the routing tables and compares them. Metha is able to test any tool that takes the device configurations as inputs and provides direct access to the computed routing tables out-of-the-box. Otherwise, Metha uses tool-specific runners to process the inputs such that they meet the tool's requirements and map the output back to Metha's format. Metha comes with runners for three well-known network analysis and verification tools: Batfish [17], NV [13] and C-BGP [28]. For NV, for example, Metha first has to compile the simulation program from the network configurations. As a source of ground truth, Metha uses a virtualized network running real device images of both Cisco and Juniper routers. It connects to these devices over Telnet and retrieves the routing tables (e.g., `show ip route` for Cisco devices). To ensure full convergence, Metha retrieves the routing tables every 10 seconds and proceeds once the tables have not changed for ten consecutive checks. With this setup, Metha allows to freely choose any oracle (e.g., hardware testbed) as long as it exposes the computed routing tables.

Output Finally, Metha localizes all bugs within a discovered discrepancy by relying on delta debugging. For every single bug, it generates a report highlighting the observed difference in the routing tables of the tool under test and the oracle, such as a mismatch in a route's metric or a missing route. This helps the developer understand the expected behavior. In addition, it identifies the configuration statements required to trigger the bug and comes up with a minimal network configuration to reproduce the bug. This allows Metha to provide actionable feedback to the developers of the tool, helping them to faster locate and understand the bug. The minimal configuration example can also be used as an extra test case for traditional system testing.

8 Evaluation

In this section, we evaluate Metha to address the following research questions:

RQ1 How does Metha's semantical configuration generation, the search space reduction using boundary values and the test suite from combinatorial testing contribute to Metha's effectiveness? We show that Metha finds 20 bugs and achieves a higher combinatorial coverage than the random baseline, which only discovers 3 bugs with the same number of tests.

RQ2 How many test cases does Metha need to localize all bugs in a single discrepancy between the tool under test and the oracle? Metha requires on average 14.1 test cases to isolate all the bugs causing a discrepancy.

RQ3 Is Metha practical? We ran Metha on three different state-of-the-art network analysis and verification tools and found a total of 62 bugs, 59 of them have been confirmed by the respective developers.

8.1 Comparison to Random Baseline

We begin our evaluation by studying how the three components of Metha contribute to its effectiveness. To this end, we compare a random baseline to three versions of Metha: step-by-step, we enable each component starting with semantic Metha, then we add the reduction to boundary values, and finally, we use full Metha using combinatorial testing to define a test suite. The results show that the semantical configuration generation is the most fundamental part of Metha. Reducing the parameters to boundary values and applying combinatorial testing help to find additional bugs as both manage to increase the combinatorial coverage.

In the following, we introduce the four approaches:

Random baseline The random baseline relies on random syntactic test generation, meaning it uses a traditional grammar-based fuzzing approach. Thanks to the grammar, the configurations generated by the baseline are lexically- and syntactically-valid, but they are not necessarily semantically-valid: the baseline generates device configurations that are parseable and look realistic. However, the configurations might not always be practical: for example, referenced route-maps and prefix-lists do not always exist, and IP addresses on interfaces might not match those of their neighbors. Inter- and intra-device dependencies are not factored in.

Semantic Metha The initial Metha approach implements random semantic test generation. Similar to the random baseline, it uses a grammar-based fuzzing approach with the only difference that it ensures semantical validity within the configuration: while, for example, interface costs are completely random, other values are more constrained based on inter- and intra-device dependencies. This approach ensures, for example, that only defined route-maps are referenced, and that BGP sessions are configured with matching parameters.

Approach	# Discovered Bugs
Random Baseline	3
Semantic Metha	16
Bounded Metha	17
Full Metha	**20**

Table 2: Every component of Metha allows it to find more bugs with the same number of test runs.

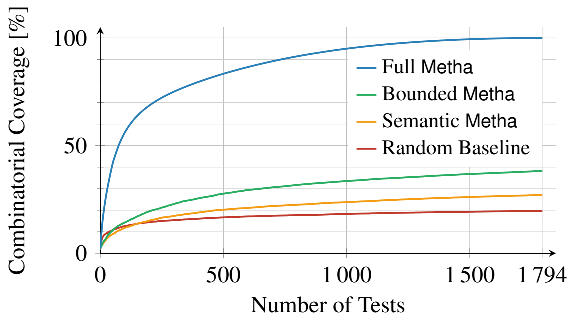

Figure 5: The achieved combinatorial coverage increases with every single component of Metha. Full Metha achieves complete combinatorial coverage.

Bounded Metha The bounded approach adds the reduction to boundary values as introduced in §4.2 to semantic Metha. This means instead of assigning completely random numeric values, the approach reduces the allowed values to three options: the minimum, the maximum, and a "normal" value, randomly chosen between the two extremes.

Full Metha Finally, we run the full testing system. We add combinatorial testing as introduced in §5 to define a test suite that maximizes combinatorial coverage on top of the semantic configuration generation and the boundary values reduction.

Experiment setup We ran all four approaches for the same number of tests and used them to test Batfish [17]. Whenever one of them detected a discrepancy between Batfish and the oracle, we applied the full fault localization procedure as described in §6 to detect the underlying bugs and the features causing it. Thanks to that, we are able to detect duplicates and count only the unique bugs that each approach discovered.

For all the tests, we used the same simple topology consisting of four routers connected in a star topology and tested configuration features belonging to the following four categories: static routes, BGP, OSPF, and route-maps. For the entire experiment, we used Cisco IOS configurations. For the given configuration features, combinatorial testing generated a test suite consisting of 1 794 tests. While the full Metha approach followed the test suite, the other approaches randomly chose the active configuration statements for every single test.

Results Table 2 shows the number of unique bugs that every approach found within the 1 794 test runs. The full Metha detected 20 unique bugs, while the random baseline only found 3 bugs. The semantic configuration generation is the most fundamental component of Metha. It comes as no surprise as without semantical validity, many of the configurations do not allow for any meaningful control plane computations and will not fully exercise the network model of the tool under test.

Boundary values and combinatorial testing allow finding 1 and 3 additional bugs within the 1 794 test runs, respectively. This is because both approaches achieve higher combinatorial coverage and therefore test a wider variety of features. These results show that the boundary values reduction strikes a good balance between testing different parameter values, while keeping the search space tractable. It is important to note that the detected bugs are inclusive, meaning that full Metha detected all 17 bugs that bounded Metha detected and 3 additional bugs. There is one exception: the baseline found a bug in the parser, which the other approaches did not find.

The random baseline is strong at discovering parser bugs since that is where grammar-based fuzzing excels. Two out of its three discovered bugs are parser bugs. In both cases, the problem was an, according to the specification, unsigned 32-bit integer being parsed as signed. For example, `ip ospf 100 area 3933914791` could not be parsed. Metha did not catch this bug as it uses fixed area numbers as part of the logical topology. By adding the area numbers to the set of configuration features being tested, Metha also finds this bug.

Fig. 5 shows the combinatorial coverage achieved by the four approaches, i.e., it shows the pairwise feature combinations covered during testing. We focus on feature instead of code coverage for two reasons: First, one can easily achieve high code coverage with random, semantically-invalid configurations. Second, code coverage is specific to the tool under test and makes it difficult to compare. To measure the combinatorial coverage of the random baseline and semantic Metha, we partitioned the input space in the same manner as we did for bounded Metha, i.e., into minimum, maximum, and middle values. Any configuration which did not specifically use the minimum or maximum value for a parameter was then considered as a middle configuration. Metha achieves full combinatorial coverage by design as it is guaranteed by combinatorial testing. These results underline the importance of semantically-valid configurations. While both the random baseline, which relies on syntactically-valid configurations, and semantic Metha achieve a similar combinatorial coverage, semantic Metha finds many more bugs as its configuration actually ensures control plane computations.

Performance Running a single test case took an average of two minutes. We run both the tool under test as well as the virtualized testbed in parallel and found that most of the time is spent waiting on the testbed to converge. The generation of a combinatorial test suite with PICT for the baseline network with 4 routers took an average of 6 minutes. Over the entire test suite, this time is negligible. Running the entire setup took us several days. The runtime depends highly on the number of discrepancies and the number of bugs causing them.

	Bugs		Type		Feature Category			
	discovered	confirmed	crash	silent	OSPF	BGP	route-filter	other
Batfish [17]	29	29	5	24	10	10	9	0
NV [13]	30	30	5	25	13	9	7	1
C-BGP [28]	3	?	0	3	1	1	1	0

Table 3: Bugs discovered by Metha for Batfish, NV and C-BGP and classification.

8.2 Fault Localization

Whenever Metha detects a discrepancy between the routing tables of the tool under test and those of the oracle, it goes into fault localization to isolate all independent bugs. Fault localization relies on delta debugging (cf. §6) which creates additional test cases to identify the configuration statements causing the bugs. In the following, we evaluate its overhead, i.e., the number of additional test cases Metha had to create.

Experiment setup For this experiment, we ran Metha using the same topology as before and tested the full set of configuration features. Whenever Metha detected a discrepancy, we recorded the number of additional test cases required to find all independent bugs and the number of discovered bugs.

Results On average, Metha used 14.1 additional test cases to locate all bugs within a test case. The number of additional test cases ranged from as low as 7, to localize a single bug, up to as high as 58, to localize 5 independent bugs. The number of additional test cases mostly depends on the number of independent bugs within a single detected discrepancy. The number of configuration statements that actually cause the bug plays a minor role. Also, we have observed that the detected bugs are all caused by a few configuration statements (one or two), even though multiple configuration statements were active during the tests. This confirms the observation that bugs are often caused by the interaction of few features [20, 31] and shows that combinatorial testing is a useful technique in this setting.

8.3 Real Bugs

In addition, we showcase our end-to-end implementation of Metha by testing three different network analysis and verification tools: Batfish [17], NV [13], and C-BGP [28]. We show that Metha finds real bugs and report them in Table 3.

Experiment setup We ran Metha for several days on all three tools and with several different setups. Batfish is the most complete and advanced tool as it can handle configurations of many different vendors and supports a wide variety of configuration features. NV itself is an intermediate language for control plane verification that allows to build models of any routing protocols and their configurations. It provides simulation and verification abilities. We tested the simulation only, the discovered bugs, however, most likely also exist in the verification part as both rely on the same network model. For Batfish and NV, we used both Cisco IOS and Juniper configurations. C-BGP has its own configuration language.

Results As shown in Table 3, Metha found a total of 62 bugs. The developers of both Batfish and NV confirmed the discovered bugs to be real bugs. To better understand the nature of the bugs, we classified them by their type (i.e., whether they lead to a crash or go unnoticed) and by the configuration feature category itself (e.g., OSPF). Only a few of the bugs produce a clear error. This is most likely also because these are noticed more often and reported. The large majority of the bugs are silent semantic bugs which are extremely difficult to notice. These are the sneakiest bugs and can lead to false analyses and answers by the verifier. These bugs include all the configuration features discussed in §2 showing that they affect the analysis of commonly used features, such as route redistribution and aggregation, and named communities.

The bugs are distributed quite evenly among all tested parts of the network model. We did not find one specific protocol or configuration feature that is especially error-prone.

9 Discussion

What about the testbed? Metha detects bugs by looking for discrepancies between the tool under test and an oracle. For the oracle, Metha uses a testbed running real router firmwares. The testbed just needs to be large enough to fully exercise all configuration features. Normally, a small testbed of few routers suffices and also helps speed up the testing. In this paper, we rely on a virtualized testbed. To use a physical testbed instead, one simply has to change the SSH/Telnet configurations to connect to the physical devices.

A virtualized testbed comes with several advantages. It provides more flexibility in terms of the settings one can test and the time needed to setup. For example, there is no re-wiring needed to test different topologies. In addition, it is very simple to test the same topology with a different device category or with devices from another vendor: one simply has to exchange the router image.

What about more targeted tests? Metha's test suite can be adjusted to the developers requirements by restricting the set of configuration features, adjusting the number of values per feature, and changing the number of interacting features. The tests required to cover the search space mainly depend on the number of values per feature and the number of simultaneous feature interactions, while the set of features is secondary. By default Metha tests three values per feature and considers pairwise interactions. This choice strikes a good balance between the number of tests required and thorough testing, as our results confirm: Metha found all bugs that the random approaches discovered with fewer tests, despite using "only" the boundary values; and all discovered bugs are caused by one or two interacting configuration features, despite considering interactions of more than just two features.

Metha does not replace traditional unit and system testing, but provides an additional way to find latent bugs anywhere in the system. The advantage of Metha is that it requires minimal developer involvement and can be run alongside traditional tests without any additional effort. If desired one can run extensive tests by considering more elaborate feature interactions and more than three values per feature. Often with fuzz testing, one just lets the testing system run indefinitely and collect bug reports along the way.

10 Related Work

In this section, we first discuss current network analysis and verification tools. Then, we survey related work on testing static analyzers and verifiers, the various testing initiatives in the field of networking, delta debugging, and fuzz testing.

Network analyzers & verifiers Our work aims to facilitate the development of network analysis and verification tools through thorough testing. Over the years, we have seen a rise in tools that simulate networks [28], verify properties of networks and their configurations [3, 14, 19, 30], and tools that analyze aspects of networks [11, 12, 18, 23]. All of these tools have in common that they in some way or another use a network model to analyze and verify the network. Any bug or inaccuracy that exists within that network model undermines the soundness of the tools' results and analyses.

In contrast, CrystalNet [21] is a cloud-scale, high-fideltiy network emulator running real network device firmwares instead of relying on a network model. Hence, it accurately resembles the real network (e.g., vendor-specific behaviors and bugs in device firmwares are captured).

Testing analyzers and verifiers The problem of ensuring the correctness of analysis and verification tools is not specific to networks. In the field of static analysis, several works exist that pursue the same goal. Bugariu et al. [5] apply a unit testing approach, meaning they do not test the entire system but components thereof which simplifies the test generation. Since Metha treats the tool under test as a black box it cannot test certain components separately. Cuoq et al. [8] randomly generate input programs. This technique is mostly effective at testing the robustness of the analyzers. Similar to Metha, Andreasen et. al [1] apply delta debugging to find small input programs that help developers understand the bug faster.

Testing in networking Prior work on testing in networking has mainly focused on testing the network and its forwarding state [36], and SDN controllers [2, 6, 29].

Closest to Metha is Hoyan [32], a large-scale configuration verifier, in which the results of the verifier (i.e., network model) are continuously compared to the actual network for inaccuracies. It does so during operation and only covers cases that have actually occurred in the network. Metha in contrast proactively tests to detect the bugs before deployment.

Delta debugging In automated testing tools, delta debugging is a well-established technique [33, 35] that allows to automatically reduce a failing test case to the relevant circumstances (e.g., lines of code or input parameters). Over the years, researchers came up with several extensions to the general delta debugging algorithm, such as a hierarchical approach [26] that takes the structure of the inputs into account. It first explores the more important inputs allowing to prune larger parts of the input space and hence, requiring fewer test cases.

Traditional delta debugging finds one bug at a time even if the test case is ambiguous and exhibits multiple independent bugs. The developer then fixes one bug and reruns delta debugging to find the next. Metha automatically detects the causes of all independent bugs without developer involvement.

Fuzz testing Fuzz testing [15, 34] is an umbrella term for various testing techniques relying on "randomized" input generation. Metha uses a form of grammar-based fuzzing. Due to the complex dependencies within network-wide configurations, Metha first builds a basic configuration structure to ensure semantical validity. Then, it uses fuzzing to test different feature combinations restricted to that structure.

11 Conclusion

We presented Metha, an automated testing framework for network analysis and verification tools that discovers the bugs in their network models before deploying them to production. It does so by generating a wide variety of network configurations according to a test suite defined through combinatorial testing. Metha provides developers with actionable reports about all discovered bugs including a configuration to reproduce them. We implemented Metha and evaluated it on three state-of-the-art tools. In all tools, Metha discovered a total of 62 bugs, 59 of them have been confirmed by the developers. An interesting avenue for future work would be to extend Metha so that it can also test configuration synthesizers such as [4, 9, 10] as bugs in their models would render them useless.

A Proof of Theorem 1

Proof. By contradiction. Assume that there is a minimal subset $Q' \subseteq Q$ such that $tc|_{Q'}$ fails which is not returned in $\mathcal{S}$. We check at least one superset of Q' for a failure since we will always check the initial set Q. Assume $C \supseteq Q'$ is a smallest superset of Q' which is checked. By the assumption of monotonicity, $tc|_C$ must fail, therefore we will minimize C. If $C = Q'$, then we must minimize to Q' since Q' is assumed to be minimal, violating the assumption that Q' is not returned by the algorithm. If $Q' \subset C$, then C will either minimize to Q' (again violating the original assumption that Q' is not returned by the algorithm) or to a different minimal subset P. In this case, we generate additional sets to be tested. However, both Q' and P are minimal subsets of C, therefore $Q' \not\subset P$ and $P \not\subset Q'$. Since $Q' \neq P$, we know that there must be an element $e \in P$ which is not in Q', i.e., such that $Q' \subseteq C \setminus \{e\}$. The set $C \setminus \{e\}$ is both strictly smaller than C and will be added to the sets to check by the algorithm in Line 9 and therefore violates our assumption that C was a smallest superset of Q' which is checked. $\square$

Finding Invariants of Distributed Systems: It's a Small (Enough) World After All

Travis Hance, Marijn Heule, Ruben Martins, and Bryan Parno
Carnegie Mellon University

Abstract

Today's distributed systems are increasingly complex, leading to subtle bugs that are difficult to detect with standard testing methods. Formal verification can provably rule out such bugs, but historically it has been excessively labor intensive. For distributed systems, recent work shows that, given a correct inductive invariant, nearly all other proof work can be automated; however, the *construction* of such invariants is still a difficult manual task.

In this paper, we demonstrate a new methodology for automating the construction of inductive invariants, given as input a (formal) description of the distributed system and a desired safety condition. Our system performs an exhaustive search within a given space of candidate invariants in order to find and verify inductive invariants which suffice to prove the safety condition. Central to our ability to search efficiently is our algorithm's ability to learn from counterexamples whenever a candidate fails to be invariant, allowing us to check the remaining candidates more efficiently. We hypothesize that many distributed systems, even complex ones, may have concise invariants that make this approach practical, and in support of this, we show that our system is able to identify and verify inductive invariants for the Paxos protocol, which proved too complex for previous work.

1 Introduction

The world increasingly relies on distributed computer systems, but the correctness and reliability of these systems depend on the imperfect coverage of testing. To obtain strong guarantees, developers are starting to turn to formal verification techniques, both in research [3, 21, 24, 31, 46, 54] and industry [38, 58]. These techniques can, in theory, prove that all possible execution traces of the system conform to a high-level safety specification (e.g., all nodes agree on the next input value, or no two nodes hold a lock at the same time).

However, verifying the safety of distributed systems can be extremely labor-intensive, especially when using general-purpose theorem provers [21, 45, 54]. For example, Hawblitzel et al. [21] report that the effort to build and verify two distributed systems (including their protocols and implementations) required 3.7 person-years, and their safety proofs (over 19K lines of code) account for $\sim$40% of the total codebase. To reduce this cost, some work has developed specialized languages that either restrict the kinds of systems that can be encoded [12, 13, 36, 53] (e.g., the protocol must proceed in synchronous rounds), or restrict the language used to describe the systems' properties [42]. In exchange for these restrictions, much of the safety proof can be dispatched automatically.

In all of these systems, the core of the safety proof requires identifying system *invariants*, and even with tools that can automate all other proof work, finding these invariants still relies on human labor and ingenuity. Anecdotally, this is a challenging task even for researchers [34], requiring days for toy systems and months for complex protocols like Paxos [29].

Ideally, we would automate invariant discovery, but theoretical results show that even in languages where *checking* an invariant is decidable [42], *finding* such an invariant is not decidable [40], meaning that no algorithm can guarantee that it will find an invariant for arbitrary protocols, even if they are indeed safe. Hence, we must turn to domain-specific insights to develop a methodology which can apply to the specific kinds of distributed systems developed in practice.

Recent approaches have been proposed to automatically infer invariants for distributed systems [27, 34]. For instance, the I4 [34] system observes that the invariants for some distributed systems are scale-invariant. Hence they ask the developer to specify appropriate finite-model parameters and to concretize some of the protocol variables. I4 then invokes a specialized model checker [19] that can deduce invariants on finite, fixed-size instances. It then employs various heuristics to generalize those invariants to arbitrary instances. Unfortunately, I4 cannot discover invariants that use existential quantifiers. Furthermore, since the model checker is a black box, the developer has no recourse when it fails. More recently, Koenig et al. [27] extend the IC3/PDR algorithm [6, 14] to infer invariants with existential quantifiers. However, neither they nor I4 can handle complex protocols like Paxos [29], for which the simplest known safety proofs require many invariants, including some with existential quantifiers.

To tackle complex protocols like Paxos, we explore an alternate approach based on our "small world" hypothesis: in many practical systems, the invariants should be relatively concise. After all, these protocols are designed by humans who have some (finite) intuition for why the protocol is correct. They are clearly not beyond human comprehension. If accurate, this hypothesis suggests we are faced with a finite space of possible invariants, which we can potentially search exhaustively.

Of course, finite is not the same as small. For a protocol like Paxos, there could be over 100 billion candidate invariants with just six terms. Even if it only took a millisecond to test each invariant, a brute force search of the entire space would require over three computation-years.

Hence, this paper presents the Small World Invariant Search System (SWISS), our system for automatically proving the safety of distributed systems by efficiently searching through the space of succinct invariants. At its core, SWISS learns from counterexample models obtained from failed invariant candidates to speed up future invariant checks. SWISS uses an SMT solver to perform these checks. SWISS also exploits various symmetries and parallelism to reduce search time. Further, for a class of invariants (described formally in §3.4) SWISS is guaranteed to find an invariant when one exists. SWISS also supports user-supplied guidance to make the search more efficient. Moreover, unlike prior approaches, even when SWISS does not produce a safety proof within a given time limit, the user still benefits from partial invariants that SWISS did find, as they can use those invariants as a starting point for finding complete invariants. The net effect is that SWISS is the *first approach that can automatically prove the safety of Paxos*, and it does so in around 4 hours on an 8-core machine. If the user provides some light guidance (§5.3.3), then the time decreases to 20 minutes.

We compare SWISS to I4 [34] and Koenig et al. [27] on a large variety of protocols (§5). None of the approaches fully dominates the others, neither in protocols solved nor in runtime. For instance, for protocols that only require invariants without existential quantifiers, I4 is generally fastest. However, for some complex distributed protocols with many invariants that contain existential quantifiers, SWISS outperforms the other tools, and in particular, it is the first to automatically prove the safety of Paxos and two variants of Paxos: Multi-Paxos and Flexible-Paxos [22]. There are still some variants of Paxos that SWISS cannot fully prove in a reasonable amount of time. However, even in these cases, SWISS still finds many partial invariants that may help the user complete the proof.

In summary, our key contributions are as follows.

- We propose and evaluate the *Small World Hypothesis*: that many distributed systems we care for can be proven safe using a sequence of concisely specified invariants.
- We present SWISS, a methodology for automatically proving the safety of distributed systems by efficiently searching through the space of candidate invariants, guided by knowledge learned from counterexamples encountered during the search. We report both our successful *and* unsuccessful optimizations.
- To our knowledge, SWISS is the first approach to identify and verify inductive invariants that prove the safety of Paxos in an *automated* fashion.

2 Background

We briefly present background on formalizing and verifying distributed systems.

2.1 Proving Safety Conditions Via Inductive Invariants

We aim to prove *safety conditions*. A safety condition is a desired property that ought to hold true at any point in a system's execution. For an exclusion lock, for example, the safety condition might be that no two agents hold a lock at the same time. For a consensus protocol such as Paxos, the condition would be that no two machines decide on different results. These safety conditions are in contrast with *liveness conditions*, which say that the system eventually performs a useful action. We do not currently consider liveness conditions.

To formalize a distributed system, one must formally describe the internal state of the participating nodes, the state of the network (packets in-flight between nodes), the initial conditions of the system, and the ways the system can evolve. Following standard practice, we formalize the latter as a sequence of atomic actions that update the system state [28].

Given this formal description, our goal then becomes to prove that the safety condition will hold for any reachable state in any possible execution of the system. The typical strategy for such a proof is to find an *inductive invariant*. An inductive invariant should **(i)** hold on all possible initial states of the system and **(ii)** continue to hold when the system transitions to a new state from a state where the invariant held.

If we could prove that the safety condition was inductive, we would be done; unfortunately, this is rarely the case for non-trivial systems. Instead, we typically must find an invariant which is stronger than the safety condition and then show this invariant is both inductive *and* implies the safety condition.

2.2 A Running Example: Simple Decentralized Lock

To make the verification process more concrete, we present a toy example: a Simple Decentralized Lock (SDL) protocol. SDL supports a single mutual-exclusion lock that is shared among multiple nodes. A node with the lock can send the lock to another machine via a message over the network, which, in this simple example only, does not permit packet duplication.

Figure 1 formally describes the SDL protocol. The state at a snapshot in time is represented by two relations: message and lock. The value message(src, dst) indicates a message in the network from machine *src* to machine *dst*, while lock$(node)$ indicates that *node* believes it holds the lock.

In the protocol's initial state (the **init** lines), the network is empty, and only one node (*start_node*) holds the lock.

The transitions are written in RML [42], an abstract language for describing system transitions. SDL has two transition actions: `send` and `recv`. In `send`, a node *with the lock* can atomically release the lock and send a packet to another machine. In `recv`, a node can receive a packet (removing it from the network) and accept the lock.

The safety condition (Figure 2) we wish to verify for SDL is

```
type node
relation message(src : node, dst : node): bool
relation lock(N : node): bool
init ∀src, dst. ¬message(src, dst)
init ∃startnode : node.
    has_lock(startnode)
    ∧ ∀N : node. (N ≠ startnode ⟹ ¬lock(N))
action send(src: node, dst: node) {
    require lock(src);
    message(src, dst) := true;
    lock(src) := false;
}
action recv(src: node, dst: node) {
    require message(src, dst);
    message(src, dst) := false;
    lock(dst) := true;
}
```

Figure 1: **The Simple Decentralized Lock Protocol**

SDL safety condition

$$\forall n_1, n_2 : \text{node.}\ \text{lock}(n_1) \wedge \text{lock}(n_2) \implies n_1 = n_2$$

SDL inductive invariant

$$(\forall n_1, n_2 : \text{node.}\ \text{lock}(n_1) \wedge \text{lock}(n_2) \implies n_1 = n_2) \wedge$$
$$(\forall n_1, n_2, n_3 : \text{node.}\ \neg(\text{lock}(n_1) \wedge \text{message}(n_2, n_3))) \wedge$$
$$(\forall n_1, n_2, n_3, n_4 : \text{node.}\ \text{message}(n_1, n_2) \wedge \text{message}(n_3, n_4) \implies n_1 = n_3 \wedge n_2 = n_4)$$

Figure 2: **Safety Condition and Invariants for the SDL**

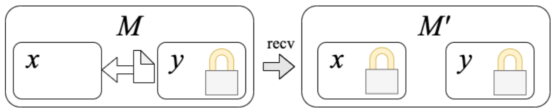

Figure 3: Two models which demonstrate that the safety condition (Figure 2) for SDL is not inductive on its own. M and M' each have a *domain* of two nodes, n_1 and n_2. In M, n_2 holds the lock, while a packet is in-flight from n_2 to n_1. M can transition to M' via the `recv` action. M does not violate the safety condition, but M' does (n_1 and n_2 both hold the lock).

that no two nodes ever hold the lock at the same time. Figure 3 shows that this condition is *not* inductive. There is a state, M, which satisfies the safety condition (only one machine holds the lock) which can transition to a state, M' (via a `recv` on y) which does not satisfy the safety condition (since two machines hold the lock). Figure 2 shows a stronger predicate which also rules out the first state. This predicate is both inductive and (trivially) implies the safety condition; thus, it completes our safety proof. It states that **(i)** no two machines hold the lock, **(ii)** no machine holds the lock while a message exists, and **(iii)** no two messages exist at the same time.

2.3 Formal Notation

To keep our subsequent discussion precise we introduce some additional notation. Formally, a *transition system* is a triple $\mathcal{T} = (\Sigma, \mathit{INIT}, \mathit{TR})$, where Σ defines the types and relations representing the state of a system, and INIT and TR are predicates describing the initial state of the system and allowed transitions of the system, respectively. In our SDL example, Σ contains the type `node` and the relations lock and message.

Since TR relates two states, we will use primes to indicate the new state, e.g., $\mathit{TR} := (x' = x + 1)$ represents a transition that increments x by one.

A *model* M represents a single possible state of the system. It contains an assignment for each variable and each possible evaluation of the system's relations. For a predicate P, we write $M \models P$ if the predicate P evaluates to *true* on model M. When P is a predicate over two states, we write $(M, M') \models P$, e.g., we write $(M, M') \models \mathit{TR}$ if M can transition to M'.

We say that M is *reachable* if there exists a sequence $M_0, \ldots, M_k$ where $M_0 \models \mathit{INIT}$, $M_k = M$, and $(M_i, M_{i+1}) \models \mathit{TR}$ for all i. A formula S is said to be *safe* if for all reachable M, we have $M \models S$.

We say that I (a formula over Σ) is *inductive* if we can prove that $\mathit{INIT} \implies I$ and $\mathit{TR} \wedge I \implies I'$ (i.e., if I is true and the system can take a transition to a new state, then I holds there as well). Here, we use I' to denote the predicate I evaluated on the second state. It is clear that any inductive invariant I will be safe. Therefore, proving that S is safe amounts to finding an inductive invariant I such that $I \implies S$; equivalently, to find a formula I such that $I \wedge S$ is an inductive invariant.

2.4 Decidability of Inductiveness

Given a candidate invariant I, we must prove that **(i)** $\mathit{INIT} \implies I$, **(ii)** $\mathit{TR} \wedge I \implies I'$, and **(iii)** $I \implies S$. We call these *verification conditions*. To check that a verification condition P holds for all possible models, we can show that $\neg P$ is unsatisfiable; i.e., there is no model M such that $M \models \neg P$.

Checking the validity of arbitrary first-order logic formulas is undecidable [52], but prior work [41, 42] shows that many distributed systems, including multiple variants of Paxos, can be encoded in RML [42], which can be translated to a restricted class of formulas where satisfiability *is* decidable. In particular, the class of *effectively propositional* (EPR) formulas, also known as the Bernays–Schönfinkel class, are the class of formulas that can be written in a form with quantifier prefix $\exists^*\forall^*$ and no function symbols. Satisfiability for this class of formulas is decidable [33, 43].

By ensuring our verification conditions lie within this class, we can always either verify the predicate $\mathit{INIT} \implies I$ or find a satisfying instance for $\mathit{INIT} \wedge \neg I$. Likewise, we can either verify the predicate $\mathit{TR} \wedge I \implies I'$ or find a pair (M, M') where $(M, M') \models \mathit{TR} \wedge I \wedge \neg I'$ (e.g., the pair in Figure 3). In either

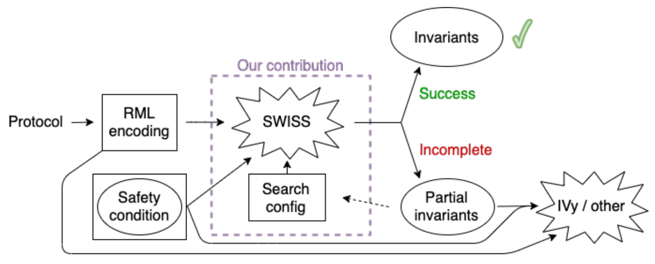

Figure 4: **SWISS Overview**. The intended workflow for using SWISS to synthesize an invariant and safety proof. A rectangle indicates a machine-readable, human-supplied input. An oval represents a collection of first-order predicates.

case, we obtain a concrete counterexample.

EPR, as stated, is a bit too restrictive; it allows only relations (not general functions), and it does not allow for invariants with quantifier alternation. However, EPR can be extended to include *stratified* function symbols—functions for which the edges from input types to output types form no cycles—while maintaining its decidability. In the same way, we can allow stratified alternation of universal and existential quantifiers in a fragment called *the extended EPR fragment* [41]. To keep our verification conditions within this class, we must impose some restrictions on the quantifier alternations which appear in I; these restrictions are determined by the shape of the protocol under consideration, in particular, the quantifier alternations which appear in $INIT$ and TR.

3 Overview: The SWISS Algorithm

SWISS is an algorithm for inferring inductive invariants of a protocol in order to prove a desired safety condition. The intended usage of SWISS is shown in Figure 4. First, the user provides an RML-encoding [42] of the protocol, a desired safety condition, and a specification of the search space (§4.1.1). SWISS either succeeds with an invariant that proves the safety condition, or it fails, with only partial invariants generated. In that case, the user may choose how to continue: they might try SWISS again with a different search configuration, or they might continue with other means, e.g., the interactive invariant-finding tool IVy [42], using the partial invariants as a starting point.

For example, suppose the user is interested in the SDL protocol (§2) and wants to prove the lock-exclusivity safety condition. They would first encode the SDL protocol into a machine-readable RML specification (Figure 1). Protocols are often concise, although in some cases it is challenging to produce a specification where the inductive invariant will be in EPR [41]. However, we consider this out of scope for SWISS.

Next, the user would write the exclusivity condition as a predicate (Figure 2). They would also choose the space of predicates to search over (§4.1.1). If the user knows nothing about the protocol, they would likely choose the most general option, to generate templates automatically. If SWISS succeeds, then they will know that the lock-exclusivity safety condition is true, and they can use the invariants from SWISS's output to validate that SWISS ran correctly.

If SWISS does not succeed, there are a few possible paths. For example, it might be that SWISS does not complete in a reasonable amount of time, in which case the user might choose to restrict the search space. For example, they might have some idea of what the invariant should look like because they have worked with similar locking protocols previously. Alternatively, if SWISS completed quickly but did not succeed, the user might choose a broader search space.

Finally, they might choose to take the incomplete invariants generated by SWISS and attempt to complete them through other means. Even though SWISS did not succeed, the user could learn useful information about the protocol from these incomplete invariants.

3.1 High-Level Algorithm

We begin with a high-level overview of our algorithm for finding the inductive invariants needed to prove safety conditions. Section 4 then explains how we make the algorithm scale to large search spaces.

SWISS takes as input **(i)** a transition system $\mathcal{T}$ encoded via RML (§2.2) **(ii)** a safety condition S, and **(iii)** a configuration of the search space (§4.1.1). In this section, we refer to search spaces with the symbols $\mathcal{B}$ and $\mathcal{F}$, which here may be viewed as arbitrary sets of first-order predicates.

SWISS is designed to exploit our hypothesis that a distributed system designed by humans will have a concise invariant, or a larger invariant composed of concise invariants. After all, the designer presumably has a finite intuition for the correctness of their system, either as a whole or as the conjunction of correct subsystems or subproperties.

Internally, SWISS uses different algorithms to target these two possible invariant styles. One algorithm, Finisher (§3.2), tries to directly find one inductive invariant that proves the safety condition. Hence any invariant it finds will necessarily complete the safety proof. Using the safety condition as a target helps Finisher search the invariant space efficiently. However, for complex protocols, searching for the entire system invariant in one shot is infeasible; e.g., a human-derived invariant for Paxos has 10 conjuncts with 34 terms, corresponding to a search space of over 10^{75} candidate invariants.

Hence, SWISS employs a second algorithm, Breadth (§3.3), that greedily searches for as many protocol invariants as possible within a finite space $\mathcal{B}$, without requiring that they directly prove the safety condition. We run Breadth multiple times so that invariants may build on each other: once Breadth finds an invariant P, the next run can then find an invariant Q that is inductive relative to P, even when Q might not be inductive on its own. More formally, we say that Q is *relatively inductive* with respect to P if $INIT \implies Q$ and $TR \wedge P \wedge Q \implies Q'$.

Algorithm 1: Solve $(\mathcal{T}, S, \mathcal{B}, \mathcal{F})$

```
invariants ⟵ {};
while true do
    newInvariants ⟵ Breadth($\mathcal{T}$, invariants, $\mathcal{B}$);
    if newInvariants imply safety then
        return newInvariants
    if newInvariants = invariants then
        break;
    invariants ⟵ newInvariants;
return Finisher($\mathcal{T}$, invariants, $S$, $\mathcal{F}$) ∪ invariants
```

The Breadth loop ultimately builds an invariant of the form $P_1 \wedge \cdots \wedge P_n$, where each P_i is relatively inductive to $P_1 \wedge \cdots \wedge P_{i-1}$. In practice (§5), without the safety condition guiding it, Breadth is slower than Finisher, but it can incrementally construct a larger invariant than Finisher can.

To benefit from the strengths of both Breadth and Finisher, SWISS's top-level Solve (Algorithm 1) combines them. It takes as input a transition system, $\mathcal{T}$, and a desired safety condition S. It also takes in two spaces of candidate invariants, $\mathcal{B}$ and $\mathcal{F}$, for Breadth and Finisher, respectively, to search. In our implementation, these spaces are defined through a combination of the protocol description and (potentially) user input (§4.1). Solve runs Breadth over $\mathcal{B}$ until no new invariants are produced, and then it runs Finisher, if necessary, to find an additional invariant needed to complete the safety proof. Section 3.4 summarizes SWISS's coverage guarantee.

3.2 The Finisher Algorithm

Finisher aims to find a single invariant P which proves a safety condition S. More formally, it tries to solve:

Task 1 (Conjecture-proving task.) *Given a transition system $\mathcal{T}$, formulas $I_1, ..., I_n$, already established (or assumed) to be invariant, and a conjectured safety condition S, find an invariant predicate P such that $P \wedge S$ is inductive relative to $I_1 \wedge \cdots \wedge I_n$.*

Evaluating a candidate invariant P requires checking the validity of the following *verification conditions* (VCs):

$$\begin{aligned} INIT &\implies S \\ INIT &\implies P \\ TR \wedge I_1 \wedge \cdots \wedge I_n \wedge S \wedge P &\implies S' \\ TR \wedge I_1 \wedge \cdots \wedge I_n \wedge S \wedge P &\implies P' \end{aligned}$$

Since the $INIT \implies S$ condition does not depend on P, we can check it once in advance of evaluating any candidat invariant.

Since we consider protocols expressed in RML (§2.4), checking the validity of these VCs is decidable, and in practice, typically quite efficient with modern SMT solvers. Hence, for a candidate invariant P, we can run a subroutine CheckVCsF to determine either that the VCs above hold, or that a finite counterexample shows they do not. As Algorithm 2 shows, rather than simply check the VCs above for each candidate predicate P in $\mathcal{F}$, Finisher accumulates a collection of counterexamples from failed candidates. As we describe in §4.2, we use these counterexamples to filter subsequent candidates, as our counterexample check is orders of magnitude faster than the VC check.

Algorithm 2: Finisher$(\mathcal{T}, \{I_1, \ldots, I_n\}, S, \mathcal{F})$

```
cexamples ⟵ {};
for $P \in \mathcal{F}$ do
    if $\forall cex \in$ cexamples . Passes($P$, $cex$) then
        $cex$ ⟵ CheckVCsF($\mathcal{T}$, $\{I_1,\ldots,I_n\}$, $S$, $P$);
        if $cex$ is None then
            return $P$;
        else
            cexamples ⟵ cexamples ∪ {$cex$};
return None
```

Algorithm 3: Breadth$(\mathcal{T}, \{I_1, \ldots, I_n\}, S, \mathcal{B})$

```
cexamples ⟵ {};
allInv ⟵ $\{I_1,\ldots,I_n\}$;
indInv ⟵ $\{I_1,\ldots,I_n\}$;
for $P \in \mathcal{B}$ do
    if $\forall I \in$ allInv . ¬FastImplies($I$, $P$) then
        if $\forall cex \in$ cexamples . Passes($P$, $cex$) then
            $cex$ ⟵ CheckVCsB($\mathcal{T}$, $\{I_1,\ldots,I_n\}$, $S$, $P$);
            if $cex$ is None then
                allInv ⟵ allInv ∪ {$P$};
                if ¬ Redundant ($P$, indInv) then
                    indInv ⟵ indInv ∪ {$P$};
            else
                cexamples ⟵ cexamples ∪ {$cex$};
return indInv;
```

3.3 The Breadth Algorithm

In the Breadth algorithm, our goal is simply to find as many invariants as possible. More formally, we wish to solve the following task.

Task 2 (Invariant-finding task.) *Given a transition system $\mathcal{T}$ and formulas $I_1, ..., I_n$, already established (or assumed) to be invariant, find any invariant predicate P which is inductive relative to $I_1 \wedge \cdots \wedge I_n$.*

The corresponding VCs are as follows.

$$\begin{aligned} INIT &\implies P \\ TR \wedge I_1 \wedge \cdots \wedge I_n \wedge P &\implies P' \end{aligned}$$

Naively, we could start with an algorithm similar to Finisher, but use the VCs above instead of Finisher's. However, this would result in a highly inefficient search since as stated, the invariant-finding task permits many tautological solutions, such as $true$ or I_i. More generally, if P is any predicate such that $I_1 \wedge \cdots \wedge I_n \implies P$, then P will be invariant, but we do not actually learn anything about the protocol by finding P: P does not rule out any states which were not ruled out by the I_i. We call such a P a *redundant invariant* with respect to $I_1 \wedge \cdots \wedge I_n$. For example, $\forall x. f(x) \vee g(x)$ is redundant with respect to $\forall x. f(x)$. As the number of terms in our search space increases, the number of redundant invariants increases exponentially. Furthermore, since any redundant invariant is, in fact, inductive, it will always pass our counterexample filters, guaranteeing an expensive VC check for each.

We devised two ways to cope with redundant invariants. First, we maintain a set *indInv* of non-redundant invariants, and whenever we find a new invariant, we explicitly check whether it is redundant with *indInv*. Second, we also track *allInv*, i.e., all invariants we find—including the redundant ones—and use these to syntactically filter future candidates by performing quick checks for logical implication using a subroutine FastImplies(I,P) described in §4.4. These checks are vastly cheaper than SMT calls.

As described thus far, Breadth works without any knowledge of the safety condition S that we aim to prove about our system. However, we observe that we will eventually need S to be an invariant of the system, so we strengthen the second VC above to assume S is true in the initial state.

$$TR \wedge I_1 \wedge \cdots \wedge I_n \wedge S \wedge P \implies P'$$

Algorithm 3 brings all of this together. This algorithm finds exactly the invariants from the space $\mathcal{B}$ which are invariant with respect to the original input invariants. More precisely, if $P \in \mathcal{B}$ is invariant with respect to the inputs, then Breadth will output a set of predicates whose conjunction implies P.

3.4 Swiss Coverage

Swiss is guaranteed to prove a safety condition S as long as the system invariant conforms to the following form.

Claim 1 Solve$(\mathcal{T},S,\mathcal{B},\mathcal{F})$ *will always succeed at proving the conjectured safety condition S provided there exist invariants* $I_1,\cdots,I_n$ *such that:*

- $I_i \in \mathcal{B}$ *for* $1 \le j \le n-1$.
- $I_n \in \mathcal{F}$.
- $I_1 \wedge \ldots \wedge I_j$ *is inductive relative to S for* $1 \le j \le n-1$.
- $I_1 \wedge \ldots \wedge I_n \wedge S$ *is inductive.*

The claim follows from inspection of Algorithms 1-3 and the fact that our counterexample and implication filters will never eliminate a valid invariant.

4 Making Invariant Exploration Scale

While the algorithms described in §3 would theoretically suffice to find invariants, implemented naively they are impractically slow. Hence, we present crucial steps we take to reduce the search space (§4.1-§4.4) and optimize the overall process (§4.5). For the sake of completeness, we also present three optimizations that our evaluation has shown *do not* improve performance in this domain (Appendix A).

4.1 Exploiting User Guidance & Candidate Symmetries

The Finisher and Breadth algorithms each take as input a space of candidate invariants to explore (§4.1.1). These spaces often contain many invariants that are identical modulo symmetries, so symmetry pruning is critical (§4.1.2).

4.1.1 Defining Candidate Spaces

Swiss searches for invariants based on *invariant templates*. Intuitively, a template defines the rough shape of a class of invariants (e.g., the number and types of the quantified variables, and a bound on the formula's size).

By default, Swiss automatically defines invariant templates based on the protocol description and the safety condition, as well as user-supplied upper bounds on the formula size. Swiss then enumerates all template spaces within these constraints, and the search space $\mathcal{B}$ or $\mathcal{F}$ is defined as the union of these spaces. Finisher prioritizes these templates in order of increasing size. Thus, if a small invariant exists, Finisher will find it without having to search the entire space.

For many protocols, this fully automatic approach suffices to produce a safety proof. For protocols where this automated search runs slower than desired, the user can specify a particular template T, rather than have Swiss enumerate all templates. As §5.3.3 demonstrates, such user guidance can dramatically speed up the search process, even if the user guesses a few incorrect templates before the right one.

More formally, every candidate invariant P that we consider is a sequence of quantifiers followed by a quantifier-free expression E. The expression E is a tree of conjunctions and disjunctions of *terms* C, expressed over values V, which is either a name and a type (e.g., $x : t$), or a function application.

$$\begin{array}{lll} V & ::= & x:t \mid f(V_1,\ldots,V_n) \\ C & ::= & V_1 = V_2 \mid \neg C \mid r(V_1,\ldots,V_n) \\ E & ::= & C \mid E_1 \wedge \cdots \wedge E_n \mid E_1 \vee \cdots \vee E_n \\ P & ::= & E \mid \forall x:t.\, P \mid \exists x:t.\, P \end{array}$$

We specify a set of candidate formulas by a triple (T,k,d). The *template* T is simply a formula P with a wildcard for the quantifier-free expression E. We define TemplateSpace(T,k,d) to be the set of formulas that match T when the wildcard is instantiated with any quantifier-free expression E that has at most k terms and a conjunction-disjunction tree of depth at most d. For instance, an expression of the form $c_1 \vee c_2 \vee c_3 \vee c_4$ has depth 1, while $(c_1 \vee c_2) \wedge (c_3 \vee c_4)$ has depth 2.

Hence, a valid candidate space might be defined by,

$$T = \forall r : \text{round}, v : \text{value}.\ \exists q : \text{quorum}.\ \forall n_1, n_2 : \text{node}.\ *$$

with $k = 3$, and $d = 1$, which would contain all invariants with the quantifiers in T and disjunctions of up to 3 terms. Swiss expects the user to specify the maximum values of k, d, m (the maximum total number of quantified variables) and q (the maximum number of *existentially* quantified variables). The user must also specify a quantifier nesting order for the types defined by the protocols: a fixed nesting order is required so that the resulting verification conditions remain in EPR.

To enumerate the formulas in TemplateSpace(T,k,d), we first enumerate a set of possible terms, $\mathcal{C}$, and then arrange them in every possible tree shape. While succinct to describe, the size of the space grows exponentially, so we take steps to prune the space as rapidly as possible.

4.1.2 Symmetry-Breaking

As defined above, a candidate space contains many logically equivalent candidates, such as:

$$\forall r_1, r_2 : \text{round} \;.\; leq(r_1,r_2) \vee geq(r_1,r_2)$$
$$\forall r_1, r_2 : \text{round} \;.\; geq(r_1,r_2) \vee leq(r_1,r_2)$$
$$\forall r_1, r_2 : \text{round} \;.\; geq(r_2,r_1) \vee leq(r_2,r_1)$$

all identical up to term reordering and variable renaming.

When enumerating candidate formulas, SWISS aims to only consider one representative from each class of identical candidates. However, checking for such logical equivalence via SMT calls would be prohibitively expensive. Hence, we use a sound set of syntactic constraints to break these symmetries far more efficiently.

Specifically, SWISS assigns an arbitrary ordering to each possible base term (e.g., *leq*) and will only produce formulas where, within any conjunction or disjunction, the terms are in increasing order. SWISS also produces formulas such that for any set of quantified variables which are interchangeable (e.g., r_1 and r_2 in the example above), their first appearances are in increasing order of quantifier nesting index.

These two steps efficiently break symmetries arising from term ordering and variable permutation. In practice, they reduce the size of the search space by over two orders of magnitude (§5).

4.2 Filtering Based on Counterexamples

As explained in §2.4, when a candidate invariant P fails a verification condition, we can extract a counterexample, specifically a concrete model where the condition failed. For example, if $INIT \implies P$ fails to hold, then we can extract a concrete model M such that $M \models INIT \wedge \neg P$; i.e., the initial conditions hold for M but P does not. Since the initial conditions hold on M, if any other formula P' fails to hold for M, then it cannot be an invariant either. SWISS exploits this observation by remembering the models from failed VC checks and using those models to quickly rule out future candidates.

More technically, we define a *counterexample filter* (*cex*) as a model or a pair of models which demonstrate that a given candidate P fails to be an inductive invariant. We consider three types of counterexample filters:

$$cex \;::=\; \mathsf{True}(M) \;\mid\; \mathsf{False}(M) \;\mid\; \mathsf{Transition}(M,M')$$

A candidate P *passes* a filter *cex* if one of the following holds.

- $cex = \mathsf{True}(M)$ and $M \models P$; i.e., all valid invariants should evaluate to true on M.
- $cex = \mathsf{False}(M)$ and $M \models \neg P$.
- $cex = \mathsf{Transition}(M,M')$ and $(M,M') \models P \implies P'$.

The last is equivalent to: P passes $\mathsf{False}(M)$ *or* $\mathsf{True}(M')$.

We construct counterexample filters based on the model(s) returned when a candidate P fails a VC check. The specific type of filter constructed depends on which type of check fails. Our construction guarantees that **(i)** P does not pass the filter *cex*, and **(ii)** any formula P' which *does* pass the same verification condition *will* pass the filter *cex*. The three possible constructions are as follows.

- A failed verification condition of the form $A \implies P$ yields a model M such that $M \models A \wedge \neg P$, so we produce a counterexample filter $\mathsf{True}(M)$. In other words, P does not evaluate to *true* on M; but any valid invariant should.
- A failed verification condition of the form $A \wedge P \implies B'$ yields models M and M' such that $(M,M') \models A \wedge P \wedge \neg B'$, which gives a counterexample filter $\mathsf{False}(M)$ (since the model represents a state M that P failed to reject and that all valid invariants ought to reject).
- A failed verification condition of the form $A \wedge P \implies P'$ yields models M and M' such that $(M,M') \models A \wedge P \wedge \neg P'$, which gives a counterexample filter $\mathsf{Transition}(M,M')$.

Essentially, these counterexample filters allow us to learn from each type of failed induction check.

Efficient Implementation. Counterexample filtering is only useful if we can apply our filters faster than executing the original VC checks. Hence, whenever we add a new model M to our set of counterexample filters, we precompute the evaluation of each term $c \in \mathcal{C}$ on M. $\mathcal{C}$ is the set of base terms (§4.1.1) produced for every possible instantiation of the quantifier variables in the template T within the model M. The evaluations are saved in a bitstring, so when we encounter a new candidate Q, the evaluation of Q on M is computed quickly with bitwise operations. As a result, counterexample filters are orders of magnitude faster than VC checks (§5).

4.3 Checking Verification Conditions

We encode our verification conditions into SMT formulas in a manner similar to prior work [42]. The encoding ensures that it is decidable to evaluate the validity of the formulas. Our encoding conforms to the standardized `smtlib2` format, although for better performance, our implementation includes the SMT solver as a library so that it can directly invoke its API rather than communicating via files.

In practice, we find that thanks to the community's large effort invested in optimizing SMT solvers, our validity queries are not just decidable, but *rapidly* decidable, typically in tens of milliseconds. However, our initial experiments found occasional outliers that consumed minutes, or more. Since a SWISS run may perform thousands of SMT calls, these outliers become an issue. After some iteration, we settled on a routine where we retry a problem instance with a different SMT solver if our first attempt exceeds a given time limit (§5.1). If the SMT instance continues to time out, we skip the invariant in question. While not a perfect solution, we found that this routine satisfactorily avoids stalling SWISS's execution.

4.4 Filtering Redundant Invariants

Since the Breadth algorithm searches rather indiscriminately for any possible invariant, it can easily waste time on redundant invariants, i.e., invariants already implied by previously established invariants.

To efficiently prune many such redundant invariants, SWISS includes a rapid FastImplies filter to see if an existing invariant Q already implies a candidate P. For correctness, FastImplies(Q,P) can return *true* only when $Q \implies P$. Our implementation of FastImplies(Q,P) always detects the case where Q and P can be written as,

$$Q = \forall^* \exists^* \dots \ (a_1 \vee \dots \vee a_j)$$
$$P = \forall^* \exists^* \dots \ (b_1 \vee \dots \vee b_k)$$

where $a_1, \dots, a_j$ is a subsequence of $b_1, \dots, b_k$ up to variable renaming. This condition certainly ensures that $Q \implies P$, meaning P is redundant if Q is already known to be invariant. Our implementation also has limited support for substituting universally-quantified variables for existential ones.

Efficient Implementation. To implement this filter efficiently, we store a set of sequences representing known invariants and query if any sequence in this set is a subsequence of a candidate sequence. We use a trie [10] for efficient queries.

4.5 Additional Optimizations

4.5.1 Minimizing Models

When extracting a counterexample from a failed VC check, we can either take the first model produced by the SMT solver, whatever it may be, or we can try to make the model as small as possible. Smaller models are faster to evaluate with our filters, but come at the cost of additional SMT queries.

In our *minimal-models* optimization, we always attempt to find a *minimal* model that satisfies a given SMT query, i.e., a model where there is no other satisfying model with a smaller domain. To bound the cost of the SMT queries made to check minimality, we apply an aggressive time limit to each query.

This is an essential optimization for complex protocols; without it, SWISS takes significantly longer (§5.3.5).

4.5.2 Parallelism

Since our algorithm is based on exhaustive search, we expect it to be parallelizable. To parallelize across n threads we do the following: for each run of either the Breadth or Finisher algorithm, we split the space ($\mathcal{B}$ or $\mathcal{F}$) into n parts, each randomly permuted. The random permutation attempts to ensure that each thread has a roughly equal amount of work. We then run our algorithm on each partition independently and combine the results. In the future, we plan to explore a more complex approach in which the threads communicate at a finer granularity, e.g., sharing counterexample filters and invariants as they are discovered.

4.6 Failed Optimizations

In the interest of full disclosure, and to save others unnecessary work, in Appendix A we briefly summarize three optimizations we implemented and evaluated, only to find that they provide little benefit or actively hurt performance.

5 Evaluation

Our evaluation seeks to answer two key questions:

- How does SWISS compare to prior work (§5.2)?
- How effective are SWISS's various optimizations (§5.3)?

5.1 Experimental Setup and Implementation Details

Benchmark Suite. To evaluate SWISS, we apply it to a test suite of well-established protocols from three sources: **(i)** the I4 benchmarks [34], **(ii)** the benchmarks from Koenig et al.'s work on first-order-logic separators [27] (henceforth, FOL), and **(iii)** six Paxos variants developed by Padon et al. [41].

Setup. All experiments are conducted on 8-core machines with Intel i9-9900K CPU processors at 3.60GHz, with 125GB of memory, running Ubuntu 19.10, and using a timeout of 6 hours. Unless specified, we run SWISS with 8 threads using automatic template generation (§4.1.1) and the following optimizations from §4: **(i)** symmetry breaking, **(ii)** cex filtering, **(iii)** hybrid SMT solvers, **(iv)** filtering redundant invariants, **(v)** model minimization, and **(vi)** parallelism. For template auto-generation, by default we use parameters (d,k,q,m) (§4.1.1) of $(1,3,1,5)$ for Breadth and $(2,6,1,6)$ for Finisher,

However, these choices were not ideal for all benchmarks. In particular, if we found that a benchmark completed in under six hours without proving the safety condition, we enlarged the $\mathcal{F}$ space by increasing k, and then increasing q. On the other hand, if a benchmark timed out after six hours without completing the breadth phase, we made the $\mathcal{B}$ space smaller by decreasing its parameters. See §5.2.1.

Implementation. We implement SWISS in approximately 14,000 lines of C++ code. To check the verification conditions, we use the Z3 SMT solver [11] version 4.8.8 with default settings. If Z3 times out after 45 seconds, then we use the CVC4 [2] SMT solver version 1.8-prerelease with the `--finite-model-find` option, an option tuned for finding finite models [44]. We found that for some satisfiable instances, Z3 would often take a very long time to return a model, whereas CVC4, *with this specific option*, was much more efficient. When applying model minimization, we set a time limit of 45 seconds; if the time limit is reached, we use the current partially minimized model.

5.2 Top-Level Protocol Results

Table 1 summarizes the results of running SWISS on our benchmark suite. It also compares SWISS's performance with that of the two most closely related systems (see §6 for details),

Table 1: **Comparison with Prior Work.** ∃? indicates that the human-written invariant uses an existential. The time for SWISS is broken down into the time for Breadth (t_B) and Finisher (t_F), with the latter omitted when synthesis succeeds during the Breadth phase. n_B denotes number of iterations of Breadth. Each SWISS result is the median of five runs. For benchmarks where SWISS times out after 6 hours, we report its partial success (§5.2.2) instead of time. Shaded boxes indicate the system did not produce any invariants. In the multi-paxos* benchmark, the user provides a correct template for SWISS as guidance. The columns m_n and m_{n-1}, discussed in §5.3.4, summarize stats related to the sizes of invariants.

namely the I4 [34] and FOL [27] tools. Below, we first discuss the comparative results, followed by SWISS-specific analysis.

5.2.1 Comparative Results

We analyze our protocol results by bucketing them into coarse-grained categories. Note that I4 can only generate invariants containing universal quantifiers, and hence cannot succeed for benchmarks that require existentially quantified invariants.

Paxos Variants. Unlike prior work, SWISS automatically finds all of the invariants for Paxos and Flexible Paxos, which were previously painstakingly constructed by hand [41]. Furthermore, it succeeds at Multi-Paxos if the user provides the correct templates; however, when we attempted to use the automatically-enumerated templates, we found that Breadth does not complete in time. All three protocols require Finisher to find an invariant with six terms and an existential.

Unfortunately, neither I4, FOL, nor SWISS can prove the safety of Fast Paxos [30], Stoppable Paxos [35], or Vertical Paxos [32]. Among the known, handwritten invariants, Fast Paxos and Vertical Paxos each have two 8-term invariants; Stoppable Paxos has three 6-term invariants. SWISS cannot currently synthesize invariants this large—indeed, as it stands, it would need several orders of magnitude more compute time to handle even a single 8-term invariant—and we did not observe it finding equivalent, smaller invariants for these protocols. However, Table 1 shows that SWISS is at least able to synthesize partial invariants equivalent to many of the handwritten ones (discussed in more detail below — §5.2.2).

Finally, we note one interesting occurrence during our preliminary testing: we initially found that SWISS succeeded on Fast Paxos far too quickly and with invariants that looked at a glance to be far too strong. This allowed us to identify a typo in the spec which caused an action to never be enabled.

Mutual-Exclusion Protocols. Protocols such as sdl, distributed-lock, lock-server-sync, lock-server-async, and sharded-kv have safety conditions asserting mutual-exclusion properties, such as those of locks. The invariants for these protocols tend to be large conjuncts of smaller, *mutually* inductive invariants. SWISS struggles with these, since it is forced to discover the entire collection at once, as none are inductive individually. For some, Finisher succeeds by inferring all of these mutually inductive invariants as a single large invariant. For sharded-kv and lock-server-async, we needed to increase the maximum value of k from our default configuration. For distributed-lock, the invariant was simply too large for SWISS to find. FOL was also unable to solve this benchmark, although I4 solves it quite handily, as it was able to infer the mutually inductive invariants on a small finite instance of the problem. Finally, for sharded-kv-no-lost-keys we needed to use $q = 2$ to allow more existentials.

Learning Switch. We have two different benchmarks called "learning-switch," one from I4 and one from FOL. We found that unlike I4 and FOL, SWISS succeeds on learning-switch-quad quite handily. In learning-switch-ternary, we found that Breadth takes far too long in the default configuration, due in part to a large number of redundant invariants not filtered by our FastImplies test and thus requiring SMT calls to identify as redundant. We reduced the size of $\mathcal{B}$ by configuring $q = 0$ (i.e., searching for universal invariants only) for this one benchmark, allowing SWISS to also be able to complete it efficiently.

5.2.2 SWISS-Specific Analysis

Invariants. In some cases, SWISS uncovered invariants that were simpler than the ones written by the original researchers. For instance, for the ring-election protocol, SWISS's Breadth algorithm identifies three 3-term invariants (9 terms total) similar to the ones from prior work [42]; however, if we run Finisher on its own rather than the full SWISS algorithm, then it instead generates a single 5-term inductive invariant. For the Paxos protocol, we initially expected that the Breadth algorithm would need to run with $k = 5$; however, we found that SWISS succeeded even with Breadth at $k = 3$. This shows that mechanized search can find simpler invariants that may be missed by trained researchers.

Partial Progress. When an execution of SWISS exceeds its time limit, it still generates many invariants which may be useful. To measure how successful this "partial progress" is, we computed how many of the handwritten invariants SWISS finds. More precisely, we count how many of these invariants are logical implications of SWISS's invariants. These results are shown in Table 1. Notice that in many cases, SWISS finds a majority of the invariants; e.g., for our largest benchmark, Vertical Paxos, SWISS finds 79%. Furthermore, for the chain benchmark, which has two safety conditions (one for linearizability and one for atomicity), SWISS solves the latter.

We do not report any partially solved invariants for the other tools in our comparison. For one, the IC3 approach does not immediately allow extraction of any inductive invariants; a partially-completed IC3 execution would provide a different kind of information: constraints on the possible states of a system after a finite number of transitions. In the case of I4, we did not find any case where it constructed a nontrivial inductive invariant for any benchmark where it did not succeed.

5.3 Understanding SWISS

To better understand SWISS, we evaluate the effectiveness of our various design choices.

5.3.1 The Utility of Combining Breadth and Finisher

In §3, we argue that Breadth and Finisher target different kinds of invariants and hence are more effective when used together. To validate this claim, we re-ran SWISS on our benchmark suite, first using only Breadth, and then using only Finisher. In both cases, we limited their execution time to that taken by the full SWISS algorithm.

Compared to the 19 benchmarks solved by the full SWISS algorithm, the Breadth algorithm alone solves only 10, while Finisher alone solves only 7.

5.3.2 Execution Times of Breadth Versus Finisher

In Table 1, Breadth is fairly quick, always less than 15 minutes, compared to Finisher which can vary from quite quick (a few seconds) to several hours. In fact, this is not an accident and follows directly from the fact that the space $\mathcal{B}$ is *chosen* to be small, whereas Finisher is designed to keep going until it finds a solution or times out. Thus, the runtime of Finisher depends on how large that solution turns out to be.

5.3.3 Impact of User Guidance

While SWISS is designed to automatically search through the space of invariant templates, users can provide more specific guidance via one or more templates. For example, for Paxos, considering the Finisher portion, the user might suggest a template like (1) or (2) in Table 2. Compared to searching the automatically generated space of templates, this guidance cuts the search space by 75% and as a result, completes in 20 minutes, a 13.4× speedup.

Of course, the user may erroneously suggest a template not containing any useful invariant. To evaluate the impact of such a mistake, we ran SWISS on a template (3) of comparable size to the "correct" templates, as well as some which are much smaller (4-6). The results suggest the user can afford to make some incorrect guesses and still outperform the full auto mode.

Finally, template (7) is the largest template generated automatically with our default configuration. It takes significantly longer, indicating the importance of exploring templates in increasing size order when using auto mode.

5.3.4 Is it a Small World?

Our Small World Hypothesis holds that many of the protocols we care about can be solved using a sequence of invariants $I_1, \ldots, I_n$, which are *individually* concise. We analyze this hypothesis by measuring the size of the invariants in each of our benchmark protocols. This, in turn, helps us understand

#	Template	Inv?	Size	Time (s)
1	$\forall r_1, r_2 : \text{round}, v_1, v_2 : \text{value}, q_1 : \text{quorum}.\ \exists n_1 : \text{node}.\ *$	✓	232,460,599,445	2036
2	$\forall r_1, r_2 : \text{round}, v_1, v_2 : \text{value}.\ \exists q_1 : \text{quorum}.\ \forall n_1 : \text{node}.\ *$	✓	232,460,599,445	4072
3	$\forall r_1, r_2 : \text{round}, v_1, v_2 : \text{value}, q_1 : \text{quorum}.\ \forall n_1 : \text{node}.\ *$		232,460,599,445	3547
4	$\forall r_1 : \text{round}, v_1, v_2, v_3 : \text{value}.\ \exists n_1 : \text{node}.\ *$		26,863,311,982	408
5	$\forall r_1 : \text{round}, v_1 : \text{value}, n_1, n_2, n_3, n_4 : \text{node}.\ *$		76,397,976,796	1015
6	$\forall r_1, r_2 : \text{round}, v_1 : \text{value}, q_1, q_2 : \text{quorum}.\ \exists n_1 : \text{node}.\ *$		39,834,946,595	557
7	$\forall r_1, r_2 : \text{round}, v_1, v_2 : \text{value}, n_1, n_2 : \text{node}.\ *$		2,621,795,213,086	47231

Table 2: **User-Provided Templates.** Experiments running Finisher on Paxos with the given template as input. Each experiment starts with many invariants provided as input, simulating the scenario that Breadth has already completed. The 'Inv?' column indicates whether the template contains an invariant that proves the safety condition. Time is given in seconds. Each experiment is run to completion, exploring the entire space, even if an invariant is found.

which protocols SWISS will likely succeed at by the degree to which they meet the Small World Hypothesis.

For a given protocol, we examine an invariant $I = I_1 \wedge \cdots \wedge I_n$ which proves the desired safety condition, chosen so that $I_1 \wedge \ldots \wedge I_j$ is inductive relative to the safety condition (as in Claim 1). The m_n column in Table 1 gives the maximum size of any invariant out of $I_1, \ldots, I_n$. Here, the "size" of a predicate is measured as its number of terms.

We do not claim that our numbers are the minimal possible—we simply use the smallest out of any I that we know of. These may be from invariants synthesized by SWISS itself; in other cases, we use human-determined invariants.

We can see that 25 out of our 27 benchmarks have $m_n \leq 8$, and 22 of them have even fewer. There were two exceptions, distributed-lock ($m_n = 12$) and vertical-paxos ($m_n = 16$). These two invariants are much bigger than any single invariant we have seen SWISS synthesize.

However, it may be worth noting that these larger invariants are conjuncts of smaller, mutually inductive invariants. For example, the 16-term invariant of vertical-paxos is actually the conjunct of two 8-term invariants (although these invariants are still on the larger side). Thus, these protocols would score much better on a weaker Small World Hypothesis, one where mutual invariants were counted separately. Other approaches may be able to take advantage of this.

To more fully understand SWISS's behavior, we also measure m_{n-1}, the maximum number of terms among $I_1, \ldots, I_{n-1}$. This statistic is interesting here because for SWISS to succeed in its current form, these $n-1$ invariants must be in $\mathcal{B}$.

To rough approximation, we see that SWISS can succeed approximately when $m_n \leq 6$ and $m_{n-1} \leq 3$. In some cases, SWISS does go beyond: some benchmarks succeed with up to $m_n = 8$, and SWISS can solve multi-paxos (where $m_{n-1} = 4$) if the search space is restricted in other ways.

5.3.5 Impact of Filtering

Table 3 shows the impact of each of our filtering stages on Paxos. Counterexample filtering drastically decreases the number of candidates which require an SMT call (i.e., those remaining after FastImplies). However, a vast number of candidates (the "Symmetries" column) must be processed by a counterexample-filter. How fast is such filtering?

	Baseline	Sym.	Cex filters	FastImpl	Inv.
$\mathcal{B}$	$820 \cdot 10^6$	$3 \cdot 10^6$	911,275	2,250	801
$\mathcal{F}$	$99 \cdot 10^{12}$	$232 \cdot 10^9$	155	155	5

Table 3: **Winnowing the Paxos Search Space**. Number of candidate predicates that remain *after* a given SWISS feature is applied. Runs are with a single thread over a single template.

To evaluate filtering efficiency, we measure the total time spent on filtering versus SMT inductivity checks in a Paxos benchmark. We find that Finisher (using Template (1) of Table 2) performs 155 inductivity checks via SMT. The average SMT call takes 96.5 ms, with a median of 7 ms and a 95th percentile of 55 ms. In contrast, filtering a single candidate takes 74 *nanoseconds* on average. Notably, both measures are important characteristics of SWISS, as some workloads are dominated by filtering and others by SMT calls (Appendix B.2).

5.3.6 Additional Analysis

See Appendix B for further analysis of SWISS's performance, e.g., the impact of optimizations, parallelism, and SMT calls.

6 Related Work

6.1 Verifying Distributed Systems

The research community has long recognized the challenges of designing correct distributed systems. Manually written proofs [25, 31] and model checking [23, 26, 56] increase assurance, but struggle with practical distributed systems [4].

Recent work applies general-purpose software-verification tools to the verification of distributed systems [21, 46, 55]. These tools offer flexibility at the price of substantial human effort. For example, verifying Raft required over 50,000 lines of Coq proof for the protocol and its 520-line implementation [55], and Hawblitzel et al. used 12,000 lines of proof for the safety and liveness proofs of their Paxos protocol [21].

These human costs motivate the search for domain-specific languages (DSLs) and tools that reduce proof effort by restricting the class of encodable systems [12, 13, 36, 53]. For example, tools based on the heard-of model [12, 13, 36] need a run-time system to bridge the gap between an asynchronous network and the synchronous semantics assumed by the verification tool, which can lead to performance bottlenecks. Similarly, pretend synchrony [53] precludes classic optimizations, e.g., request batching in Paxos implementations.

All the works above, even the DSLs, rely on the developer to intuit invariants, which can be hard even for experienced researchers [34]. Recent work tries to reduce this cost via a restricted logic (EPR – §2.4) which makes invariant checking decidable; i.e., given a correct invariant, no further human work is needed. Even within EPR, *finding* the invariant remains undecidable [40], so Padon et al.'s IVy tool [42] interactively aids the developer: IVy iteratively checks if a candidate invariant is inductive. If not, IVy presents a concrete counterexample, and the developer strengthens the candidate to eliminate it. This repeats until she derives an inductive invariant.

In contrast, Ma et al.'s I4 tool [34] aims to be fully automatic. I4 first runs a custom model checker [19] on an artificially small example of the protocol (e.g., with two nodes) to produce an invariant for the small system. I4 then attempts to generalize the invariant to the unbounded setting. When it succeeds, I4 requires no human intervention. In practice, Ma et al. report manually specifying concrete bounds for all of their benchmarks (to avoid exhaustive parameter searches) and concretizations of certain variables for several benchmarks. Ultimately, I4 is limited by the abilities of its model checker, which does not support existential quantifiers (which §5.2 shows rules out a wide swath of protocols), and is unable to scale to more complex protocols like Paxos. In such cases, the developer is left with little recourse. However, I4 is frequently faster than SWISS and able to synthesize larger invariants for protocols where universally quantified invariants exist.

In recent work, Koenig et al. (FOL) [27] develop an algorithm capable of synthesizing invariants containing existentials. Their algorithm relies on the IC3/PDR algorithm [6, 14] for constructing invariants incrementally. Like SWISS, it iteratively produces counterexamples, but it uses those counterexamples as constraints in a SAT encoding of predicates to be synthesized. SWISS verifies protocols, like Paxos, that FOL does not and verifies some faster than FOL. The reverse is also true, suggesting some complementarity of the approaches.

6.2 General-Purpose Invariant Synthesis

Extensive research [7–9, 15, 17, 18, 20, 37, 39, 49, 57] studies loop-invariant inference for proving program correctness, but this remains challenging. Most approaches are limited to single-loop programs; only a few handle multiple loops or existential invariants. Approaches include abstract interpretation [8], interpolation [37], IC3 [16, 17], templates and constraint solvers [20], counterexample-guided invariant generation (CEGIR) [18, 39, 47], trace analysis [9, 15], and machine learning [48, 49, 57].

More closely related work uses templates [7, 20] to restrict the search to invariants of a given shape. In contrast to these approaches, we automatically construct a large set of templates and search for invariants of larger sizes. CEGIR approaches [18, 39, 47] use enumeration and exploit the fact that guessing a candidate and checking if it is invariant is easier than inferring a loop invariant directly from code. They often employ dynamic analyses to infer candidates from execution traces and use a verifier to check invariant validity. The idea of learning from counterexamples has also been applied to program synthesis in the form of counterexample-guided inductive synthesis (CEGIS) [51], where the synthesizer generates a candidate program and the verifier uses the failed cases to prune the search space. SWISS's approach is inspired by techniques from search-based program synthesis [1] and the CEGIS framework. Although CEGIS is a general framework, it cannot be used as a black-box since it requires a custom synthesizer, verifier, and learner for each domain. SWISS differs from prior approaches in how it uses the counterexamples to prune the search space (§4.2) and how it applies a CEGIS-style approach to infer more complex invariants than prior work.

Program sketching [50] allows a programmer to sketch a program, i.e., write a program with "holes." A synthesizer fills the holes such that a specification is satisfied. In SWISS, the user can similarly provide templates to restrict the search, but even if such a template is not provided, SWISS can automatically generate a set of templates and search all of them.

7 Conclusions and Future Work

We explore the hypothesis that the safety of most distributed systems can be proven via relatively small invariants (or conjunctions thereof), using our system SWISS, which incorporates novel optimizations to efficiently search the space of candidate invariants. We find that in many cases our hypothesis holds, and SWISS is able to automatically prove their safety, including several, such as Paxos, beyond the reach of prior work. Our results leave open the question of inferring large, mutually inductive invariants. They also illustrate that SWISS and its most recent predecessors often have complementary coverage of the benchmarks. Exploring ways to combine the strengths of each is an intriguing direction for future work.

8 Acknowledgements

We thank Jay Lorch, Jon Howell, the NSDI reviewers, and our shepherd, Siddhartha Sen, for useful paper feedback. We also thank Jean Yang and Mickaël Laurent for many helpful conversations and early explorations. We thank the Pittsburgh Supercomputing Center for providing computation resources.

A Failed Optimizations

In the interest of full disclosure, and to save others unnecessary work, we briefly summarize three optimizations we implemented and evaluated, only to find that they provide little benefit or actively hurt performance.

A.1 Formula Synthesis

SWISS's current implementation explicitly enumerates and evaluates candidate invariants. Initially, however, we adopted a strategy from a prior system, MemSynth [5], which synthesizes memory models from a small collection of examples Instead of explicitly enumerating formulas, MemSynth encodes the desired shape of candidate formulas as constraints on its SMT queries. In our context, this means creating an SMT query that says, "Find a formula that satisfies this template and complies with our accumulated counterexamples."

However, our early experiments showed that synthesizing the formula via a solver was considerably slower than our combination of a custom enumerator and counterexample filters.

A.2 Bounded Model Checking

Prior work on finding invariants for distributed systems [42], found some benefit from using bounded model checking to try to quickly rule out candidate invariants. In our context, this means checking not just the condition $INIT \implies P$, but whether there are any violations of P in states reachable after taking a fixed number of steps from an initial state. If such a violation existed on a model M, we can use the counterexample filter True(M). Likewise, to build False filters, we consider states a fixed number of steps away from violating safety.

The hypothesis for this optimization is that it would produce more and "higher quality" filters to rule out future candidates. To pay off, these savings must offset the cost of the additional SMT calls that compute the bounded model checks. Sadly, this optimization rarely boosts performance significantly (§5.3.5).

A.3 Aggressively Accumulating Invariants

As it executes, Breadth finds predicates that are invariant with respect to the input invariants $I_1, \ldots, I_n$; these new invariants are fed into the next iteration of Breadth. This suggests an obvious improvement: treat newly found invariants as input invariants immediately in order to uncover even more invariants than the ones Breadth is guaranteed to find, leading to fewer total loops. We call this variation BreadthAccumulative.

However, this variant introduces several complications. Most critically, it interferes with the FastImplies optimization. For example, suppose we process predicates $f, g, h_1, \ldots, h_n$ in order and **(i)** g is invariant; **(ii)** f is invariant with respect to g; and **(iii)** FastImplies(f, h_i) holds for all i. BreadthAccumulative, would pass over f (not invariant), then find and add g, causing all h_i to become invariant. Since the h_i are not filtered out by the FastImplies check, BreadthAccumulative's aggressive addition of the h_i causes the number of invariants to explode. In contrast, Breadth would only add g at the end; then in the next call to Breadth, f would be added to allInv, excluding the h_i via FastImplies.

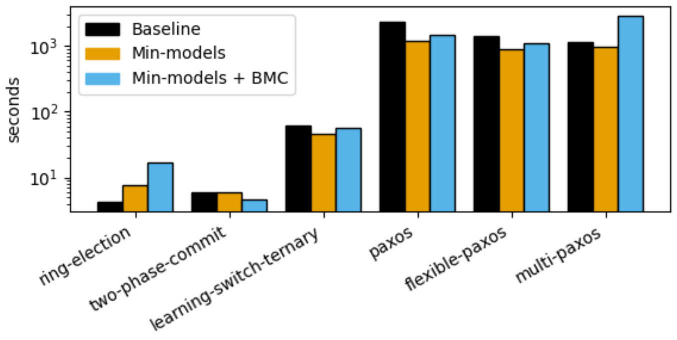

Figure 5: **Optimization Impact**. We evaluate our model-minimization and bounded-model-checking optimizations. To save time, these experiments use pre-specified templates rather than template auto-generation. Note the log scale of the y-axis.

To prevent BreadthAccumulative from adding such spurious invariants, we added a *strengthening* step, where the first h_i found would be strengthened to f. However, strengthening comes at a cost, and in the end, we found the BreadthAccumulative optimization to be unhelpful (Figure B.2).

B Additional Evaluation

In this section, we provide some additional measurements of the impact of SWISS's design decisions.

B.1 Impact of Optimizations

Model Minimization. To evaluate the effectiveness of model minimization (§A.2), we measure several benchmarks with and without it (Figure 5). While it adds some overhead for simple protocols, it helps significantly for more complex protocols; in the best case, we found that it improved the Flexible-Paxos experiment by 1.6×.

Bounded Model Checking. For our BMC variant (§A.2), we again ran several experiments with and without it (Figure 5). However, the results show that the cost of the required SMT calls was not sufficiently offset by gains from "higher quality" filters. Hence we disable it in SWISS's default configuration.

B.2 Impact of Parallelism

To evaluate our parallelism strategy (§4.5.2), we measure runtimes with varying numbers of threads, studying Breadth and Finisher independently. For each run, we break down the running time of the longest-running thread in each iteration to see which components of the algorithm parallelize well. We run our experiments on the Paxos protocol.

For the purposes of this experiment, unlike in standard runs, we do not terminate the Finisher algorithm when it finds an invariant which proves the safety condition; instead, we let it search the entire search space $\mathcal{F}$. This removes variance

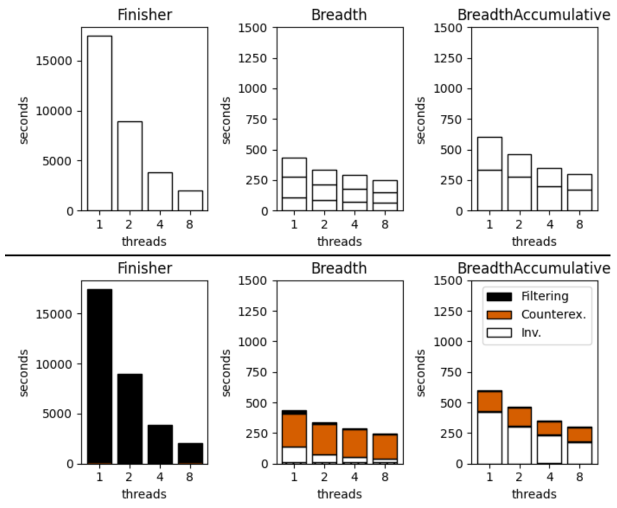

Figure 6: **Parallelism**. We measure time while varying the number of threads for Finisher, Breadth and BreadthAccumulative (§A.3) on Paxos. The top row shows the overall time, with Breadth broken down by iterations. Breadth terminates when the last (top) iteration fails to find any invariant, so it takes one less iteration than shown to find all invariants Breadth can find. In the bottom row, the runtimes are broken down into **(i)** filtering candidates with counterexamples, **(ii)** computing counterexamples of non-invariants, and **(iii)** processing candidates that are invariant.

from the random ordering of the search space, leading to more controlled experimental data.

Our results are shown in Figure 6. Finisher's runtime is dominated by enumerating and filtering, which splits fairly evenly across threads. Overall, SWISS on a single template is 2.0× faster with 2 threads than with 1 thread, and it is 8.6× faster with 8 threads than with 1.

Breadth, meanwhile, does not parallelize as well, since its runtime is dominated by time spent constructing counterexample filters via SMT calls, which is essentially a fixed cost per thread. At best, we saw a speedup of 1.7× with 8 threads.

We also evaluated BreadthAccumulative (§A.3) while varying the number of threads (Figure 6). Our hypothesis that BreadthAccumulative would require fewer iterations was confirmed: each run required only one iteration to find all invariants in $\mathcal{B}$ (plus one iteration to confirm no further invariants exist). By contrast, Breadth requires two iterations (plus one) on the same benchmark. However, BreadthAccumulative still performs worse than Breadth due its other costs (e.g., strengthening – §A.3).

B.3 Hard SMT instances

As described in §4.3, SMT queries are often rapid, but there are occasional outliers that slow down execution. To measure how problematic these outliers are, we measured the prevalence of hard instances, defined as any instance exceeding forty-five seconds and triggering our retry strategy. In particular, we measured the fraction of total computation time spent on these hard instances.

Among all protocols that SWISS was able to solve, this fraction was greatest for the paxos benchmark, which spent 10.2% of its computation time on hard instances, which accounted for 0.17% of its SMT instances.

However, among all protocols that SWISS was *not* able to solve, this fraction was greatest for the fast-paxos benchmark, which spent 98.7% of its computation time on hard instances, which accounted for 3.7% of its SMT instances. We currently do not have a good understanding of what makes this protocol's SMT instances difficult for SMT solvers, but the numbers suggest that improvement to SWISS's SMT strategy could make it much faster on harder protocols.

Avenir: Managing Data Plane Diversity with Control Plane Synthesis

Abstract

The classical conception of software-defined networking (SDN) is based on an attractive myth: a logically centralized controller manages a collection of homogeneous data planes. In reality, however, SDN control planes must deal with significant diversity in hardware, drivers, interfaces, and protocols, all of which contribute to idiosyncratic differences in forwarding behavior that must be dealt with by hand.

To manage this heterogeneity, we propose Avenir, a synthesis tool that automatically generates control-plane operations to ensure uniform behavior across a variety of data planes. Our approach uses counter-example guided inductive synthesis and sketching, adding network-specific optimizations that exploit domain insights to accelerate the search. We prove that Avenir's synthesis algorithm generates correct solutions and always finds a solution, if one exists. We have built a prototype implementation of Avenir using OCaml and Z3 and evaluated its performance on realistic scenarios for the ONOS SDN controller and on a collection of benchmarks that illustrate the cost of retargeting a control plane from one pipeline to another. Our evaluation demonstrates that Avenir can manage data plane heterogeneity with modest overheads.

1 Introduction

The network control plane plays a similar role in modern systems as a classical OS kernel. It manages resources such as end-to-end forwarding paths, maps incoming traffic onto those paths, and enforces policy such as ensuring isolation between tenants in a public cloud.

One challenge that complicates the design of the control plane is dealing with data plane heterogeneity. Much as an OS kernel manages hardware resources for a variety of peripherals, the network control plane manages hardware resources for a variety of data planes. Most network operators purchase equipment from multiple manufacturers to avoid lock-in, which results in devices with heterogeneous feature sets, and even devices manufactured by the same vendor tend to evolve over time. This heterogeneity manifests as complexity throughout the control plane, appearing in low-level drivers and SDKs, device OSes (e.g., SONiC [42], FBOSS [5], Stratum [45]), higher-level APIs (e.g., OpenFlow [23], OpenConfig [30], P4Runtime [6]), and even network applications.

As an example, switches based on Broadcom ASICs such as Trident2, Tomahawk and Qumran-MX all expose an OpenFlow-like API to SDN controllers (or more precisely, the OF-DPA [32] abstraction). However, due to differences in the chips, the API behaves in subtly different ways on various devices. For instance, the Termination MAC table, which determines whether to route packets or bridge them, appears in all three devices but behaves differently on Trident2/Tomahawk versus Qumran-MX—the former supports matching on the ingress port while the latter does not. This discrepancy has led to bugs: before a special case was added to the ONOS controller, multicast traffic on Qumran-MX devices was flooded out on all ports rather than being forwarded to the proper multicast groups [34].

This anecdote is just one example of a more pervasive problem. The OF-DPA API specification [32] is more than 150 pages of English prose. The ONOS development team took two years to validate Qumran-MX switches and certify them as production-ready. This effort included multiple iterations of testing and bug fixing to port the Tomahawk driver to Qumran-MX, even though the devices come from the same vendor, implement the same protocols, and expose the same control plane abstractions. In practice, the problem of mapping abstract specifications of forwarding behavior down to real-world targets seems too hard to solve by hand.

Control Plane Synthesis. This paper presents a different approach to managing data plane diversity. Rather than relying on careful engineers to manually craft bug-free mappings from high-level abstractions to low-level targets, we show how to automate this task using program synthesis. More precisely, we develop Avenir, a system that automatically translates control plane operations written against an abstract forwarding specification (e.g., OF-DPA), into lower-level operations for a physical target (e.g., Qumran-MX).

*Work performed at Cornell.

Our approach proceeds in two steps. First, we use the P4 language [4] to model the behavior of the abstract and target devices. Although P4 was originally designed as a domain-specific language for programming devices like Barefoot's Tofino switch, it is also being used as a specification language for fixed-function devices (e.g., at Google [47]). For our purposes, what matters is that P4 provides a precise, bit-level specification of data plane behavior that can be mechanized using an SMT solver [21]. Hence, when P4 is not sufficiently expressive to model the pipelines' behavior, our approach should still be applicable. For example, one could work with other packet-processing languages like NPL, eBPF, or vendor SDKs. Second, we use *counterexample guided inductive synthesis* (CEGIS) [41] to translate the abstract control plane operations, such as inserting entries into a match-action table, into equivalent physical operations. Our synthesis algorithm is provably *sound* (i.e., if it succeeds, the abstract and target behaviors are guaranteed to be equivalent) and *complete* (i.e., if there a translation for a given operation, Avenir finds it).

At a technical level, we exploit the insight that data plane devices are fundamentally simple. When modeled as programs, they lack complex features like pointers and loops (parser state machines and uses of recirculation can be finitely unrolled in practice). Although data planes exhibit complexity in other dimensions, such as the number of protocols or table entries they support, the amount of processing they perform on any given packet is limited. Hence, it is possible to model their behavior using simple, loop-free programs that are amenable to analysis using automated solvers. In particular, P4's match-action tables can be treated as *program sketches*—i.e., programs populated with unknown variables called *holes*. The CEGIS loop synthesizes table operations by inductively filling in the program's holes. The controller interacts with these tables incrementally: table entries are usually not changed wholesale, but in small batches. We incrementally synthesize individual control plane operations rather than full tables, which greatly improves Avenir's efficiency.

However, even if one does synthesis incrementally, scaling up to real-world programs remains a significant challenge. Program synthesis has often been used in offline settings, where performance is not a critical concern. However, a typical control plane might modify a table every few milliseconds. To enable online operation, Avenir incorporates heuristic optimizations such as ignoring existing table rules (when possible), and learning "templates" that cache repeated patterns and avoid unnecessary calls to the SMT solver.

Implementation and Evaluation. We have built an implementation of Avenir in OCaml and Z3, and evaluated its effectiveness and scalability. In particular, we used Avenir to perform a "reboot" load test from the ONOS controller with moderate overhead: ONOS takes 15 minutes to generate 40k abstract IPv6 forwarding rules while our tool translates the insertions to a Broadcom pipeline in about 12 minutes. We conducted a series of experiments in which we retarget control

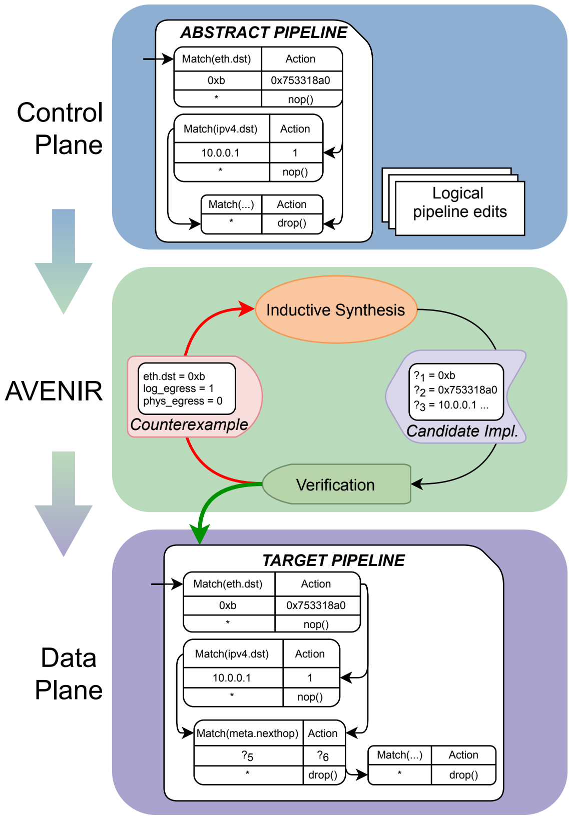

Figure 1: Avenir maps control plane operations for an abstract pipeline into corresponding operations for a target using sketch-based synthesis. The synthesis loop alternates between verifying the correctness of a candidate implementation and learning from counterexamples to generate a better one; the holes (e.g., $?_5$) in the target sketch denote missing values that are filled in using an SMT solver.

planes from one pipeline to another, and show that generated rules successfully forward packets on the Bmv2 software switch. Finally, to assess Avenir's scalability, we ran experiments on synthetic microbenchmarks.

Contributions. This paper presents Avenir, a practical control plane synthesis tool based on the following contributions:

- We present synthesis algorithm that incrementally computes changes to data plane operations, motivated by examples in real-world control planes.
- We formalize our synthesis algorithm and prove (in the appendix) that it is sound and complete.
- We present optimizations that leverage incrementality and domain insights to accelerate synthesis.
- We discuss an implementation and show through case studies and microbenchmarks that Avenir synthesizes control plane operations correctly with modest overheads.

L2_fwd

$\qquad\quad$ for every existing row r in LAG
$e \text{ otherwise} \mapsto \mathsf{Failure}$

(f) Translations from "one big table" to Pipelines 1 to 3.

Figure 2: Pipelines used in example scenario.

2 Background and Motivation

As shown in Figure 1, Avenir sits between the controller and the data plane, exposing an interface based on an abstract pipeline to the SDN control plane. It intercepts the control operations, translates them to the target pipeline, and passes results to the switch agent to install on the target device. Note that because Avenir works with an abstract notion of a pipeline, it could be used at multiple levels of abstraction—e.g., to implement a driver for a given switch, an abstraction layer like SAI, or even at higher layers of the SDN controller. Likewise, because Avenir operates on switch-by-switch granularity, it can expose different abstract pipelines for different targets. Avenir's synthesis algorithm is sound and its solutions are formally verified, which eliminates the potential for subtle bugs caused by the inherent complexity of the problem, assuming the specifications are correct. Avenir's algorithm is also complete—i.e., given sufficient time, it is guaranteed to find a correct sequence of target operations if it exists.

Status Quo: Manual Control Plane Mappings. Consider a simple running example based on ONOS that illustrates the need for a control plane synthesis tool. Suppose that each switch implements the simple L2-L3 pipeline in Figure 2a. In this pipeline, the output port is set based on the Ethernet and IPv4 destination addresses in the corresponding tables.

As the network matures, its engineers decide to add additional physical data planes—e.g., to incorporate a new generation of hardware or to avoid vendor lock-in. For instance, the pipeline, shown in Figure 2b, adds a layer of metadata indirection to the physical device to support link aggregation.

To avoid disrupting the control plane, which likely consists of hundreds of thousands of lines of code,[1] the engineers write a *driver* that translates operations written for Pipeline 1 into operations for Pipeline 2. In this case, the driver, shown in Figure 2e, is relatively simple: for each rule, it simply copies the output port into meta and inserts a row into the LAG table effectively copying the value of meta into the output port.

Now, suppose the engineers decide to support a third pipeline (Figure 2c), which sets a separate metadata field in each table. The translation (Figure 2e), is also simple, but requires some care to write—in particular, the L3 table's forwarding decision must always be preferred in the LAG table.

Finally, suppose the engineers want to migrate their original pipeline to a *one big table* abstraction (Figure 2d), similar to OpenFlow. Now, the engineers need to make code changes to all three translations (Figure 2f).

[1]ONOS has currently about 611k lines of Java code [28, 37].

Of course, the ONOS engineers could compose the translations from the one big table to the first pipeline, and on to the other pipelines. However as more and more logical and physical tables are added, managing a complex cascade of translations would become unwieldy, and hard to maintain.

Control Plane Synthesis with Avenir. Avenir improves upon the state of the art—i.e., writing manual translations—by automating the translation of rules from an abstract pipeline to a target pipeline. Of course, the programmer still needs to write programs that capture the behavior of both pipelines, and that's a non-trivial task. But we believe this should be less challenging than actually writing the translations—akin to describing source and target languages vs. writing a compiler.

To see how this is done, let's explore how Avenir translates abstract Pipeline 1 L2 insertions into Pipeline 2 insertions. First, assume, as shown in Figure 2b, that the L3 table is populated with rules that match on the IPv4 address (10.0.0.1) and set the metadata to (8), and the LAG table matches on that metadata and forwards out port 8. Consider inserting a single rule into the abstract Pipeline 1 L2 table that matches on $\mathsf{eth.dst} = \mathsf{ABB28FC}$ and sets the outport to 5. To reflect this update in Pipeline 2, we then need to solve for the unknowns, written as (?) in Figure 2b. These unknowns model the answers to questions like "Which tables need modification?" and "What should the matches/actions/action data be?"

More formally, the unknowns (?) represent a special kind of variable we instrument our program with, called a *hole*. Programs instrumented with holes are called *sketches*. We heuristically search for a valuation of these holes that makes the behaviors of the two pipelines equivalent. In this example, we could set $?_1 = \mathsf{ABB28FC}$, $?_2 = \mathsf{set\_meta}(5)$, $?_3 = 5$, and $?_4 = \mathsf{set\_out}(5)$. Since we do not need to insert a rule in the L3 table, we do not need to find values for these holes. In practice, holes can only be assigned values, not code snippets, like we are doing here for $?_2$ and $?_4$. We will see how to construct these sketches in detail in Section 3.2, and we will introduce our synthesis algorithm in Sections 3.3, 4.1 and 5.2.

As a strawman, we might consider an offline approach, where we synthesize the driver code once-and-for-all that translates any abstract operation into equivalent target operations. However, there are many cases (e.g., Figure 2f) where there is no translation that works for all abstract operations, this synthesis algorithm would fail to produce any solution in many cases where Avenir would succeed. Avenir's online solution allows for a more dynamic and flexible approach.

Incrementality and Optimizations. The key challenge in making Avenir practical is scaling up to handle real-world programs, which typically have at least dozens of tables with thousands of rules. Avenir needs to potentially compute a translation on every abstract control plane operation, so it must be responsive. As another strawman, imagine an approach that computes a full set of table rules on every control plane operation. This strategy might be workable when the tables have only a few rules, e.g., recomputing the existing match in Pipeline 2's L3 table, but it would quickly become a bottleneck if there were say, tens of thousands of rules in L3. Hence, we employ an incremental approach in which we synthesize "deltas" consisting of small batches of control plane operations rather than full tables. By only considering the most recent insertion or deletion into a table, we can often reuse previous solutions and avoid redundant recomputation.

Going a step further, we can cache "templates" derived from previous solutions to help translate future operations. For example, on the next insertion into L2, we can try to reuse the same stucture by inserting into L2_fwd and LAG, with actions set_meta and set_out, forcing the argument to set_meta to equal the LAG table match.

3 Control Plane Synthesis

Our synthesis algorithm is based on CEGIS [40]. The core of CEGIS is a loop with two main components: verification and inductive synthesis. In each iteration of the loop, a candidate implementation is run through the verification component to check correctness. If verification fails, a counterexample trace is produced, allowing the inductive synthesis component to learn from this failure to generate a better candidate. The loop terminates when verification ultimately succeeds.

In our setting, the CEGIS loop is run for each insertion into the abstract pipeline. Inductive synthesis produces candidate control plane implementations for the target pipeline, and verification checks whether the behavior of the two pipelines are equivalent. The rest of this section discusses the CEGIS components in detail. Section 4 discusses optimizations that make this approach efficient and scalable.

3.1 Basic Definitions and Verification

The *verification* component of the CEGIS loop determines whether the synthesized control plane operations implement the same packet-processing behavior on the target pipeline as on the abstract pipeline. We model packets as finite maps from a fixed set of header and metadata fields to bit vectors, and say two packets are equal and write $pkt = pkt'$ if they agree on all header fields. Packets have a direct interpretation as a boolean formula: for headers Hdr and a list $\vec{x} \subseteq \mathsf{Hdr}$, we write $pkt[\vec{x}]$ to mean $\bigwedge_{x \in \vec{x}} x = pkt.x$.

Syntax and Semantics. In Figure 3, we define the syntax of pipelines. A pipeline program is a just a command $c \in \mathsf{Cmd}$, that denotes a packet processing function, which we write $[\![c]\!] : \mathsf{Pkt} \to \mathsf{Pkt}$. Pipeline programs can contain bitvector expressions $e \in \mathsf{Expr}$ and boolean expressions $b \in \mathsf{Bool}$. Given a bitvector $[n]_s$ of length s, we use "wraparound" semantics when values n larger than $2^s - 1$ overflow. We often omit subscripts when s is clear from context or use evocative notation.

There are a few ways to compositionally build a pipeline program. First, fields f can be assigned values via the command $f := e$, which updates the packet pkt to $pkt\{f \mapsto n\}$, where e evaluates to n in pkt. Further, commands can be sequenced, $c_1; c_2$, which first executes c_1 then c_2. We can also

$$\begin{array}{rcll}
c & ::= & & (c \in \mathsf{Cmd}) \\
& | & f := e & \textit{Assignment(*)} \\
& | & c;c & \textit{Sequence(*)}\\
& | & \mathsf{if}\ \overrightarrow{b \to c}\ \mathsf{fi} & \textit{Guarded Commands(*)}\\

f & \in & \mathsf{Hdr} \cup \mathsf{Meta} & \\
x & \in & \mathsf{Name} & \\
n & \in & \mathbb{N} &
\end{array}$$

Figure 3: Pipeline syntax. Actions vary under starred variants

use conditional control flow, written if $b_1 \to c_1\ \ldots\ b_n \to c_n$ fi, which executes command c_i on the incoming packet *pkt* for the smallest-indexed b_i that evaluates to tt on *pkt*. These conditionals are similar to Dijkstra-style guarded commands [9]. Finally, table application $\mathsf{apply}(t)$ executes match-action table t. Tables are represented as records, where $t.name$ is table's name; $t.keys$ is a list of packet headers referred to by name; $t.actions$ is the list of actions (which are lexically-scoped anonymous functions $\lambda(\vec{x}).c$); and $t.default$ is the command that is executed when the table is missed. Only certain commands c may occur inside an action (denoted with a $(*)$ in Figure 3)—e.g., table application is not allowed.

Notice that tables have no way of referring to their entries. To represent entries in a table t, we maintain a *table instantiation* $\tau : \mathsf{Name} \to \mathsf{List}[\mathsf{Row}]$, alongside the syntactic pipeline, which maps table names to their row lists. We write Inst for the set of all instantiations. We refer to the pair (c,τ) as the *pipeline state*. A row $\rho \in \mathsf{Row}$ is a triple $\rho = (\vec{m}, \vec{d}, a)$, where $\vec{m}$ are matches, a is the action index and $\vec{d}$ is the action data.

We can define a source-to-source syntactic transformation $\mathsf{subst}(c,\tau)$ that replaces every occurence of $\mathsf{apply}(t)$ in c with a guarded command encoding the rows of the table $\vec{\rho} = \tau(t.name)$, as follows, where the ith row $\rho_i = (\vec{m_i}, \vec{d_i}, a_i)$:

$$\mathsf{if}\ \left(\begin{array}{ccc} t.keys = \vec{m_0} & \to & t.action[a_0](\vec{d_0}) \\ & \cdots & \\ t.keys = \vec{m_n} & \to & t.action[a_n](\vec{d_n}) \\ \mathsf{tt} & \to & t.default \end{array}\right)\ \mathsf{fi}$$

Hole	Description
$?\mathsf{Del}_{t,i} = 1$	Delete row i in table t
$?\mathsf{Add}_{t,j} = 1$	Add j rows to table t
$?\mathsf{Act}_{t,j} = i$	New Row j in table t (if added), has action i
$?\mathsf{k}_{t,j} = v$	New Row j in table t (if added), matches header k with v
$?\mathsf{d}_{t,j,i} = v$	New Row j in table t (if added with action i) has action data for parameter d set to v

Figure 4: Summary of holes used in sketching.

We say that a row $(\vec{m}, \vec{d}, a)$ is well-defined for a table t when $|\vec{m}| = |t.keys|$, $a < |t.actions|$, and for the parameters $\vec{x}$ of $t.actions[a]$, $|\vec{d}| = |\vec{x}|$. Further, an instance is well-defined when all of its rows are well-defined for their tables, and a command is well-defined when no two tables have the same name. We assume that commands and instantiations are well-defined, and that there are no bit-width mismatches: both are easy to check statically.

Finally, we have control plane edits ($\delta \in \mathsf{Edit}$), which are operations that allow the control plane to modify table instantiations. We interpret them as functions, i.e., $\delta(\tau) \in \mathsf{Inst}$. There are two kinds of edits: insertions and deletions. For a given instance τ, an insertion $\mathsf{A}_x(\rho)(\tau)$ appends ρ to the end of $\tau(x)$ (meaning it has the lowest priority). If $\tau(x)$ has a row ρ' with the same matches as ρ, the inserted row is dropped. A deletion $\mathsf{D}_x(i)(\tau)$ removes the ith element from $\tau(x)$.

Now that we know how to interpret pipelines as functions, we say $c_1 = c_2$ when they are functionally equivalent. To check this condition, we use predicate transformer semantics to generate a verification condition [13], written $c_1 \equiv c_2$, which we check using an SMT solver, by running $\mathsf{CheckSat}(c_1 \not\equiv c_2)$. If the solver returns UNSAT, we conclude the programs are equivalent. Otherwise, it returns SAT as well as a model that encodes a counterexample χ—i.e., an input and output packet pair χ that demonstrates different behavior in the abstract and physical programs, writing χ_0 and χ_1 for the input and output packets respectively. It is easy to prove that this validity check implies functional equivalence.

Theorem 1. *For every pair of pipelines* c_1, c_2*, if* $c_1 = c_2$ *then* $\mathsf{CheckSat}(c_1 \not\equiv c_2) = \mathsf{UNSAT}$*, and if* $c_1 \neq c_2$ *then* $\mathsf{CheckSat}(c_1 \not\equiv c_2) = \mathsf{Sat}\ \chi$.

Proof. By soundness of verification conditions with respect to the denotational semantics of guarded commands [9, 13]. □

3.2 Synthesizing Candidates via Sketches

To propose new candidate programs for verification, we use a technique called Sketching [41]. A *sketch* is a command containing special variables called *holes*. Aside from holes for values (i.e., ?k for match keys and ?d for action data), which we introduced in Section 2, we also need holes for table entries, corresponding to deletions (?Del), insertions (?Add) and action choice (?Act). The meaning of these holes is described in Figure 4.

$$\mathsf{fix\_cex}(p,\sigma,\chi,n,\vec{x}) \triangleq \chi_0[\vec{x}] \Rightarrow wp\,(\mathsf{instr}(p,\sigma,\cdot,n),\chi_1[\vec{x}])$$
$$\mathsf{model}(p,\sigma,X) \triangleq \mathsf{CheckSat}\left(\forall \vec{x}.\, \textstyle\bigwedge_{\chi\in X} \mathsf{fix\_cex}(p,\sigma,\chi,|X|,\vec{x})\right)$$

Figure 5: The model function. In the above, the vector $\vec{x}$ is all of the non-hole variables that occur in the formula.

To compute a candidate solution in our CEGIS loop, we first instrument the program with holes. We write $\mathsf{instr}(c,\tau,\vec{\delta},n)$ to describe the program $\vec{\delta}(\tau(c))$ with deletion holes for every row in τ, and holes for n row insertions. We do not add deletion holes for insertions in $\vec{\delta}$, which is crucial for the completeness theorem (Section 4). We lift this function from tables to programs in the obvious way.

Consider the L2 table from pipelines 1 and 2. To instrument it with holes, allowing for a single insertion, we would insert a deletion hole for the existing rule and a single row of insertion holes, yielding the following sketch:

	Match(eth.dst)	**Action**
?Del = 0	ABB28FC	set_out(5)

?Add = 1	?eth.dst	if ?Act = 0 → set_out(?p)
		?Act = 1 → drop()
		fi

A possible model for these holes that matches the destination MAC address with 00 : 00 : 00 : 00 : 00 and drops the packet, is $\{?\mathsf{Del} \mapsto 0, ?\mathsf{eth.dst} \mapsto 0, ?\mathsf{Act} \mapsto 1\}$. Note that ?p is irrelevant, so we omit it from the model.

Of course, sketches represent a vast search space of edits: every existing table row can be deleted, and up to n rows can be inserted. Blindly searching through this space would not scale in practice. Instead, we learn from counterexamples to help guide the search toward a solution.

3.3 Counterexample-Guided Search

When the solver determines that a proposed candidate pipeline is not equivalent to the abstract pipeline, it generates a counterexample χ that encodes an input-output packet pair. This pair corresponds to a behavior of the abstract switch that is not replicated in the candidate or vice versa. We can use this counterexample to guide our search. More formally, we use the weakest precondition $wp(c,\varphi)$ whose satisfying models are inputs that, after executing c, yield outputs satisfying φ.

The fix_cex function constructs the formula $\chi_0[\vec{x}] \Rightarrow wp(s,\chi_1[\vec{x}])$ for the sketch $s = \mathsf{instr}(p,\sigma,\cdot,|X|)$. The formula identifies edits that when applied to the physical pipeline state (p,σ) produce the input-output behavior indicated by χ.

The function model in Figure 5 lifts fix_cex over all counterexamples X that have been seen so far. Notice that we only instrument the physical pipeline with $|X|$ insertion holes since each counterexample hits at most one rule in each table.

3.4 Synthesis Algorithm

The full synthesis algorithm is presented in Figure 6. Given a abstract pipeline l, a target pipeline p, an abstract table instan-

```
$\mathsf{cegis}(l,p,\tau,\sigma,\vec{\delta},X) \triangleq$
  match $\mathsf{CheckSat}(\mathsf{subst}(l,\tau) \not\equiv \mathsf{subst}(p,\vec{\delta}(\sigma)))$ with
   | UNSAT $\to$ Ok $\vec{\delta}$
   | SAT $\to$
      match $\mathsf{model}(p,\vec{\delta}(\sigma),\{\chi\}\cup X)$ with
        | UNSAT $\to$ Fail
        | SAT $\vec{\delta}'$ $\to$ $\mathsf{cegis}(l,p,\tau,\sigma,\vec{\delta}',\{\chi\}\cup X)$
```

Figure 6: Simple Algorithm for Control Plane Synthesis.

tiation τ, a target table instantiation σ, a sequence of physical edits $\vec{\delta}$, and a set of counterexamples X, $\mathsf{cegis}(l,p,\tau,\sigma,\vec{\delta},X)$ produces a sequence of edits $\vec{\varepsilon}$ such that $\mathsf{subst}(l,\tau) = \mathsf{subst}(p,\vec{\varepsilon}(\sigma))$ if one exists. We initially call the algorithm with $\vec{\delta} = []$ and $X = \{\}$. First, we call the SMT solver to check for equality. If the programs are equal, we are done, and return $\vec{\delta}$. Otherwise, we get a counterexample χ and solve for new edits by augmenting X with χ, applying the edits to the target pipeline and calling model. If it returns UNSAT, there is no way to make the programs equivalent and we fail. Otherwise, we get a new sequence of edits and keep searching.

3.5 Formal Properties

Next we establish two formal properties for our synthesis algorithm: soundness and completeness. Soundness means that synthesized target operations produce equivalent behavior.

Theorem 2 (Soundness). *For every* $l,p \in \mathsf{Cmd}$, $\tau,\sigma \in \mathsf{Inst}$, $\vec{\delta} \in \mathsf{List}[\mathsf{Edit}]$, *and* $X \subseteq [\![\mathsf{subst}(l,\tau)]\!] \cap [\![\mathsf{subst}(p,\vec{\delta}(\sigma))]\!]$ *if* $\mathsf{cegis}(l,p,\tau,\sigma,\vec{\delta},X) = \mathsf{Ok}\,\vec{\varepsilon}$ *then* $\mathsf{subst}(l,\tau) = \mathsf{subst}(p,\vec{\varepsilon}(\sigma))$.

Proof. Follows from Theorem 1. ☐

Completeness says that if a solution exists, then our synthesis algorithm will (eventually) find it.

Theorem 3 (Completeness). *For every* $l,p \in \mathsf{Cmd}$, $\tau,\sigma \in \mathsf{Inst}$, $\vec{\delta} \in \mathsf{List}[\mathsf{Edit}]$, *and* $X \subseteq [\![\mathsf{subst}(l,\tau)]\!] \cap [\![\mathsf{subst}(p,\vec{\delta}(\sigma))]\!]$, *if* $\exists \vec{\delta}' \in \mathsf{List}[\mathsf{Edit}].\ \mathsf{subst}(l,\tau) = \mathsf{subst}(p,\vec{\delta}'(\sigma))$ *then* $\exists \vec{\delta}'' \in \mathsf{List}[\mathsf{Edit}].\ \mathsf{cegis}(l,p,\tau,\sigma,\vec{\delta},X) = \mathsf{Ok}\ \vec{\delta}''$ *and* $\mathsf{subst}(l,\tau) = \mathsf{subst}(p,\vec{\delta}''(\sigma))$.

Proof. By induction on the size of $\mathsf{Pkt} \setminus \pi_1(X)$. ☐

Limitations The main limitation of this first synthesis algorithm is that the number of queries is bounded by the number of counterexamples—i.e., every possible packet. Given an MTU of n, there could be as many as 2^n packets.

4 A Scalable Solution: Incremental Synthesis

To obtain a scalable synthesis algorithm, we first exploit the insight that the control plane operates in an incremental fashion—i.e., before each control plane operation, the data

	Match(eth.dst)	**Action**
$?\mathsf{Del}_0 = 0$	ABB28FC	set_out(5)

$?\mathsf{Del}_2 = 0$	10.0.0.1	set_out(8)
	8.8.8.8	set_out(47)

$?\mathsf{Add}_1 = 1$	$?\mathsf{ipv4.dst}_1$	if $?\mathsf{Act}_1 = 0 \rightarrow$ set_out($?\mathsf{p}_1$)
		$?\mathsf{Act}_1 = 1 \rightarrow$ drop()
		fi

(b) Incremental Sketch: Unsatisfiable for packets that hit L2's first row and L3's second, which triggers backtracking, remembering that the previously-synthesized edit was incorrect.

Figure 7: Examples of basic and incremental sketches for Pipeline 1.

planes are already equivalent, so we only need to handle incremental changes to the abstract program, such as adding or deleting a rule. In the common case, we do not have to resynthesize all of the previously generated rules. However, some care is needed as certain control plane operations do require deleting previously installed rules.

4.1 Single Counterexample-Guided Search

Our first enhancement to the basic synthesis algorithm is to only add insertion holes to solve for the most recent counterexample, and only add deletion holes for state that existed before synthesis began, which greatly reduces the number of holes we need to produce as we explore the space. Instead of instrumenting the program with insertion holes for every counterexample, we only do it for the most recent one.

Consider again the L2 and L3 tables from pipelines 1 with the initial state depicted in Figure 2a. We want to synthesize edits that send Ethernet packets that miss in the L2_fwd with destination DECAFBAD out on port 47. Suppose the first counterexample has input packet $\chi_0 = \{\mathsf{eth.dst} \mapsto \mathsf{DECAFBAD}, \mathsf{ipv4.dst} \mapsto 8.8.8.8\}$, and output packet $\chi_1 = \chi_0\{\mathsf{out} \mapsto 47\}$. Let's say on the first iteration we produce the (incorrect) edit to L2_fwd that maps ipv4.dst = 8.8.8.8 to set_out(47), and the verification step will provide a new counterexample.

Suppose the next counterexample has input packet $\chi_0' = \{\mathsf{eth.dst} \mapsto \mathsf{ABB28FC}, \mathsf{ipv4.dst} \mapsto 8.8.8.8\}$, and output packet $\chi_1' = \chi_0'\{\mathsf{out} \mapsto 5\}$. Now the simple algorithm will produce the sketch in Figure 7a, which can be solved by deleting the already inserted row ($?\mathsf{Del}_1 = 1$) and adding the single required row to the L2 table ($?\mathsf{Add}_0 = 1$, $?\mathsf{eth.dst}_0 =$ DECAFBAD, $?\mathsf{Act}_0 = 0$, $?\mathsf{p}_0 = 47$, and remaining Add/Del holes disabled).

In contrast, the incremental search will first create the unsatisfiable sketch shown in Figure 7b. There is no way to fill its holes to satisfy the above counterexample. We backtrack with the knowledge that $?\mathsf{ipv4.dst} \neq 8.8.8.8$ and attempt to solve the original sketch with respect to the original counterexample, and the only remaining solution is correct.

First, notice that the final simple sketch uses 21 holes, whereas each incremental sketch uses only 10. On the other hand, the incremental search sends 3 sketches to the solver as opposed to the simple search, which only sends 2. Why do we want to send *more* queries to Z3 instead of less? This is a result of the NP-completeness of SAT/SMT solving. Solving more formulae with fewer variables is often faster than solving fewer formulae with more variables. Here, the search space size for the 3 incremental sketches is approximately $3 \cdot |B|^{10}$, whereas for "simple" query it is approximately $|B|^{21}$, where $|B|$ is the size of the bitvector domain.

Further, observe that the incremental sketches we send will *always* have 10 holes, independent of the number of counterexamples, whereas the simple sketch will continue to add holes as the number of counterexamples grows.

We formalize this new incremental model-finding function model' in Figure 8. It is defined in term of a satisfiability check for a conjunction of three sub-formulas. The first conjunct uses a modified fix_cex function that instruments the program with one addition hole per table. The second conjunct, φ, limits the search by preventing models from reoccurring. The final conjunct is a search oracle HEURISTIC() that computes restrictions on the search space. The only constraints on HEURISTIC() are that it must not add covered rules or previously-deleted rules (to avoid looping), and it must not permanently preclude any solution (to ensure completeness).

$$\mathsf{fix\_cex}(p,\sigma,\vec{\delta},\vec{x},\chi) \triangleq pkt[\vec{x}] \Rightarrow wp(\mathsf{instr}(p,\sigma,\vec{\delta},1),pkt'[\vec{x}])$$

$$\mathsf{model}'(p,\sigma,\vec{\delta},\chi,\varphi) \triangleq \mathsf{SAT}\left(\begin{array}{l}\forall\vec{x}.\mathsf{fix\_cex}(p,\sigma,\vec{\delta},\vec{x},\chi))\\ \wedge\,\varphi\wedge\mathsf{HEURISTIC}()\end{array}\right)$$

Figure 8: The model' function computes edits to physical state (p,σ) to accomodate the counterexample χ. The oracle soundly restricts the search space.

```
$\mathsf{cegis}(l,p,\tau,\delta,\sigma) \triangleq \mathsf{verify}(l,p,\delta(\tau),\sigma,[\,])$
$\mathsf{verify}(l,p,\tau,\sigma,\vec{\delta}) \triangleq$
  match $\mathsf{CheckSat}(\mathsf{subst}(l,\tau) \not\equiv \mathsf{subst}(p,\vec{\delta}(\sigma)))$ with
    | $\mathsf{UNSAT} \to \mathsf{Ok}\ \vec{\delta}$
    | $\mathsf{SAT}\ \chi \to \mathsf{solve}(l,p,\tau,\sigma,\vec{\delta},\chi,\mathsf{tt})$
$\mathsf{solve}(l,p,\tau,\sigma,\vec{\delta},\chi,\varphi) \triangleq$
  match $\mathsf{model}'(p,\sigma,\vec{\delta},\chi,\varphi)$ with
    | $\mathsf{UNSAT} \to \mathsf{Fail}$
    | $\mathsf{SAT}\ \vec{\delta}' \to$
      match $\mathsf{verify}(l,p,\tau,\sigma,\vec{\delta}\circ\vec{\delta}')$ with
        | $\mathsf{Ok}\ \vec{\delta}'' \to \mathsf{Ok}\ \vec{\delta}''$
        | $\mathsf{Fail} \to \mathsf{solve}(l,p,\tau,\sigma,\vec{\delta},\chi,\varphi\wedge\neg\vec{\delta}')$
```

Figure 9: The incremental backtracking CEGIS algorithm.

4.2 Incremental Synthesis Algorithm

We present our incremental synthesis algorithm in Figure 9. It comprises two mutually recursive functions: verify, which checks the verification condition and solve, which generates new models. Both functions take the same arguments: the abstract and target programs and instantiations ((l,τ) and (p,σ) respectively), and a sequence of edits to the target program $\vec{\delta}$. They either return $\mathsf{Ok}\ \vec{\delta}'$, where $\vec{\delta}$ is the prefix of $\vec{\delta}'$ and $\mathsf{CheckSat}(\mathsf{subst}(l,\tau) \not\equiv \mathsf{subst}(p,\vec{\delta}'(\sigma))) = \mathsf{UNSAT}$, or Fail, if there is no such $\vec{\delta}'$. The cegis function is the "main" method. It takes the abstract and target pipelines (l and p) and instantiations (τ and σ) as arguments, as well as the abstract edit δ. It then applies δ to τ and invokes verify with no target edits.

The verify function resembles the cegis function of Section 3. It first checks whether the programs are equal, and if so returns $\mathsf{Ok}\ \vec{\delta}$. Otherwise it calls solve with an initial counterexample χ and an unrestricted model, which searches for an edit to make the programs equivalent.

The solve function takes the standard arguments, with the addition of a counterexample χ and the model space restriction formula φ, which keeps track of failed solutions for χ, to prevent repetition. First, model' searches for a target edit that corrects the behavior for the counterexample. If none exists, we return Fail, indicating that there is no sequence of equivalent target edits with the prefix $\vec{\delta}$. Otherwise, model' provides a model $\vec{\delta}'$. In this case we extend the running sequence of edits to $\vec{\delta}\circ\vec{\delta}'$ and call back to verify. If successful, we return the result, otherwise we preclude $\vec{\delta}'$ from the space of possible models φ (writing $\neg\vec{\delta}'$ for the negation of valuations that produce $\vec{\delta}'$.) Then we recursively call solve and continue searching within this restricted space of models.

4.3 Formal Properties

We prove that the incremental algorithm is also sound and complete. As with the simpler algorithm, the proof of soundness follows by the correctness of the verification condition.

Theorem 4 (Incremental Soundness)**.** *For every* $l,p \in \mathsf{Cmd}$, $\tau,\sigma \in \mathsf{Inst}$, $\delta \in \mathsf{Edit}$, $X \subseteq [\![\mathsf{subst}(l,\tau)]\!] \cap [\![\mathsf{subst}(p,\vec{\delta}(\sigma))]\!]$, *if* $\mathsf{cegis}(l,p,\tau,\sigma,\delta,X) = \mathsf{Ok}\ \vec{\varepsilon}$, *then* $\mathsf{subst}(l,\tau) = \mathsf{subst}(p,\vec{\varepsilon}(\sigma))$.

Proof. Again, the result follows from Theorem 1. ☐

As in the simple synthesis algorithm, incremental completeness relies on the finite domain, which here is the product of two finite domains: (1) sequences of reachable edits that do not redundantly add and delete a rule, and (2) the number of valuations for the holes introduced by the instr function.

Theorem 5 (Incremental Completeness)**.** *For every abstract program* l*, target program* p*, abstract instantiation* τ*, target instantiation* σ *and abstract edit* δ *if* $\exists\vec{\varepsilon} \in \mathsf{List}[\mathsf{Edit}]$. $\mathsf{subst}(l,\delta(\tau)) = \mathsf{subst}(p,\vec{\varepsilon}(\sigma))$ *then* $\exists\vec{\delta}' \in \mathsf{List}[\mathsf{Edit}]$. $\mathsf{cegis}(l,p,\tau,\delta,\sigma,[\,]) = \mathsf{Ok}\ \vec{\delta}'$ *and* $\mathsf{subst}(l,\delta(\tau)) = \mathsf{subst}(p,\vec{\delta}'(\sigma))$.

Proof. By strong outer induction on the size of the reachable non-deleting edit sequences, and strong inner induction on the (lexicographically ordered) size of the counterexample set and the number of models in each model space. ☐

Theorem 5 proves that Avenir translates abstract operations given unbounded resources. In practice, Avenir's effectiveness relies on heuristics and optimizations.

5 Heuristics and Optimizations

Avenir offers a number of heuristic optimizations designed to help it scale to larger networks. Interestingly, these optimizations need not be sound. We introduce a run-time check for soundness and revert the optimization if it fails. We focus on two classes of optimizations: verification and model finding.

5.1 Exploiting Incrementality

The key to scalable synthesis is to adopt an incremental approach and focus on edits, while incorporating further optimizations within the verification and synthesis steps.

Fast Counterexamples. In the incremental setting, we know that a new abstract insertion δ must be the cause of any semantic difference with the target pipeline. We symbolically compute packets that hit δ via an SMT query that gives us a potential counterexample packet *pkt*. We use the denotational semantics to check whether *pkt* is a real counterexample. If *pkt* doesn't induce different behavior we retry the query (in practice 10 times) until we either obtain a true counterexample, or resort back to the standard equivalence check.

Program Slicing. We leverage the incrementality assumption to use program slicing to verify only the part of the program that changes. This isn't always sound, so we check that the abstract edits are reachable iff the target edits are. We also have a faster and stronger constraint that checks that the abstract and target matches are disjoint from the extant rules. If both conditions fail, we run the full equivalence check. In practice, slicing composes with constant propagation and dead code elimination to normalize the queries.

Query Templates. The queries produced using program slicing are often syntactically similar. So when we see two validity queries that only differ in their specific concrete values, we try to abstract those concrete values into a universally quantified variable. We then check whether that more-general query is valid. If it is, we add it to a cache of templates, otherwise we continue in a CEGIS loop by negating the valuation of the quantified variables and trying again. Whenever we get future queries that are instances of the template, we can return VALID without having to consult the SMT solver.

Translation Templates. As with queries, we can cache translations of operations by generalizing over their concrete values to obtain a template. The template observes the way that concrete values are mapped from previously-seen abstract insertions into their equivalent target insertions, and structurally replicates that mapping on the new abstract insertion. It also observes the cache of translations for differing constants and generates unused constants for new rules which optimizes for metadata patterns like in Figures 2b and 2c. Note that before adding a solution to the cache, Avenir optionally reduces its size, by heuristically removing superfluous target edits, which improves the generality of the solution. When no template applies, Avenir relies on a heuristic-guided search.

5.2 Model-Finding Heuristics

Now we describe the implementation of the HEURISTIC() oracle, which abstracts a combination of heuristics. In our formalization, we assume that the heuristics are always complete. However in practice, many of Avenir's individual heuristics are not; when a given combination fails, we disable some and try again with a different combination. This search through the heuristics is currently hard-coded, but we plan to support user control of the search strategy and custom heuristics. We describe the heuristics useful in our experiments here.

Ternary and Optional Matching. In the previous sections, we only inserted holes to generate exact matches. We can generate ternary matches for a match key k, which allows us to represent, say, a wild-carded IPv4 source address in only a single row (rather than 2^{32} exact-match rows). To do this, we generate a pair of holes ?k and $?\mathsf{k}_{\mathtt{mask}}$ and encode the match as $\mathsf{k}\&?\mathsf{k}_{\mathtt{mask}} = ?\mathsf{k}$. To eliminate duplicate keys we also enforce the constraint $?\mathsf{k}\&?\mathsf{k}_{\mathtt{mask}} = ?\mathsf{k}$. For optional matches, we restrict the masks to be all 1s or all 0s.

Exact and Mask Hints. When a row is inserted into the abstract pipeline, the non-wildcarded keys K of that row are likely relevant in classifying packets. So, we force the relevance of matches on fields in K, either by copying the abstract match values into the target edits (which is very optimistic), or by forcing their masks (if masking is enabled) to be all 1s.

Action Hints. Given a counterexample (pkt_0, pkt_1), we can observe the variables that change in the abstract program, i.e., $\Delta = \{x \mid pkt_0.x \neq pkt_1.x\}$, and ensure that all edits have actions that can influence the value of some variable in Δ.

Other Optimizations. Our final collection of optimizations are based on intuitive heuristics that arise often in practice.

- **Reachable Adds.** We force synthesized models to be reachable using the counterexample driving the search.
- **Prefer Adds.** We try to find a solution that does not require deleting existing rules.
- **Prefer Non Zero Models.** We enforce $?\mathsf{k} \neq 0 \neq ?\mathsf{d}$ for all key and data holes, unless they are wildcarded.
- **Bounded Edits.** We restrict the search space so that backtracking is triggered beyond specified limits.
- **Previous Counterexamples.** We try to synthesize rules that do not violate previously-seen counterexamples.

6 Implementation

We implemented Avenir in approximately 11K lines [37] of OCaml code that interfaces with Z3 [8]. Our implementation accepts a description of an abstract and a target pipeline, sequences of insertions to both programs (to construct the initial state), as well as a sequence of abstract edits to synthesize. Avenir then produces a sequence of edits to the target program (or fails if no such sequence exists). All of the optimizations described in 5 are configurable as command line flags. In our implemention, we use an efficient encoding of the weakest precondition [13], which has linear size for the programs in our internal syntax.

P4 Program Encoding. The front-end of our implementation supports a large subset of P4, via an encoding from P4's control blocks into Avenir's internal syntax. This translation resembles previous work on verifying P4 programs [21]. Of course, P4 is a larger language than Avenir's syntax. We support more complex P4 language constructs by desugaring them into sequences of internal commands.

We currently assume that all of the data plane programs use the same parser and headers. Hence, in cases where a mapping only exists due to invariants enforced by the parser—e.g., that a packet cannot simultaneously have IPv4 and IPv6 headers—these assumptions must be manually encoded as annotations. We also ignore match kinds and assume all matches are either exact, ternary or optional, depending on command line flags. Finally, we manually encode certain device-specific behaviors

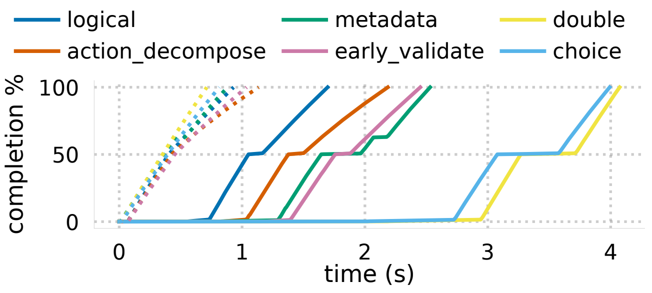

Figure 10: Retargeting case study: solid lines show cold-start completion %; dotted lines show hot-start completion %.

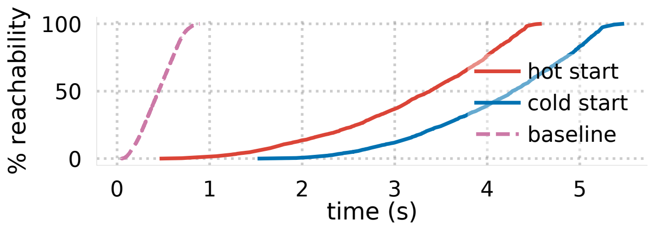

Figure 11: Proportion of all pairs of 64 hosts connected in a star topology that have completed a successful IPv4 ping.

such as the initial value fields and the drop port value. Our implementation is on GitHub[2] under an open-source license.

7 Evaluation

To evaluate Avenir, we demonstrate its functionality under a variety of synthetic and realistic scenarios, and measured its performance against hand-written baselines. First, we show how Avenir can automatically retarget a given abstract pipeline to multiple target pipelines (Section 7.1). Second, we pass packets through the Bmv2 software switch using the generated rules, which both shows they are correct and quantifies Avenir's performance when installing rules for multiple hosts (Section 7.2). Third, we present a case study consisting of a realistic workload drawn from the Trellis data center fabric, running on top of the ONOS SDN controller [2, 29] (Section 7.3). Finally, we study Avenir's scalability via a suite of microbenchmarks (Section 7.4). Our evaluation pays particular attention to the caches, as these are particularly important to obtain good performance.

Summary of Results. Overall, our evaluation shows that, in a variety of cases, Avenir can translate large numbers of rules efficiently. The retargeting, emulation, and ONOS experiments show that Avenir is effective at mapping to and from a variety of programs, and demonstrate that the caching optimizations are highly effective at reducing overheads.

7.1 Retargeting Study

Avenir allows operators to expose a single pipeline abstraction to the control plane, while implementing the forwarding logic over a myriad of physical devices. We demonstrate this use case via a retargeting study, where we retarget an initial program onto a variety of different target pipelines.

The logical program logical.p4 is a simple L2-L3 pipeline followed by a PUNT table that performs packet validation on all headers and metadata. We describe 5 additional target pipelines in terms of the changes to logical.p4:

(early_validate.p4) Replaces the PUNT table of logical.p4 with an ACL that can only match on addresses. Adds a validation table prior to the L2 table that matches on the validity of IPv4 and the TTL field and conditionally applies the rest of the pipeline.

(action_decomp.p4) Decomposes the L3 table into two tables, (1) a forward table that matches on the IPv4 destination and sets the output port, (2) a rewrite table that matches on the IPv4 destination and performs MAC rewriting.

(metadata.p4) Instead of setting the output port, the L2 and L3 tables set a metadata field. This metadata field is mapped to the output port in the nexthop table, which is applied between the L2 and L3 tables.

(double.p4) Applies all three tables in the pipeline twice.

(choice.p4) Introduces a staging table that sets a metadata variable to select between copies of the abstract pipeline.

We used Avenir to translate 1,001 logical.p4 insertions (1 into PUNT for TTL checking, 500 into L2 for Ethernet destination forwarding, and 500 into L3 for IPv4 destination forwarding and MAC rewriting). We show completion graphs for each target in Figure 10.

There are a few things to notice. Every line has an "elbow" at the 50% mark on the y-axis, after which the slope decreases. This represents the transition between parts of the workload. The L3 insertions are slower, because the L2 table is already populated with 500 rules, and slicing has to deal with larger tables. Further, these rules may cause the query template cache to miss: the second "elbow" on the metadata line indicates where the query cache's synthesis engine was able to successfully abstract.

To further demonstrate the power of our template caches, we compare our "cold-start" synthesis (solid lines), where the caches are empty, with "hot-start" synthesis (dotted lines), where the caches are fully populated. We achieve this by running Avenir on the same data twice, without resetting the caches, and logging performance for the second run. The massive performance increase is seen in Figure 10. Network operators concerned with nondeterministic runtimes associated with synthesis can manually populate their caches.

7.2 Network Emulation

We use Avenir to program the entries of a programmable software switch (bmv2) running in a network emulator (mininet). We configure 64 hosts in a star topology connected to a single

[2] Available at https://github.com/cornell-netlab/avenir

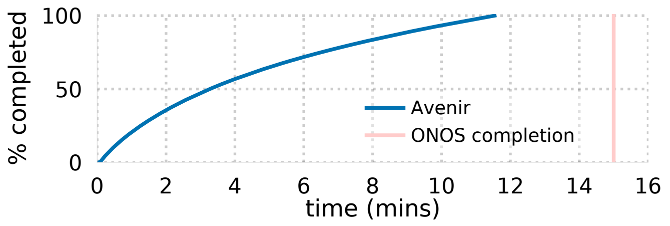

Figure 12: Completion graph for mapping 40k fabric.p4 IPv6 route insertions onto bcm.p4; ONOS takes around 15 min.

switch, and install rules to establish all-pairs ping connectivity. The P4 program running on the software switch is the simple_router.p4 program from the Bmv2 repository. The abstract program is a modified version that joins together the L3 rewriting and forwarding tables into one.

We generate rules required to establish all-pairs connectivity into the logical program and use Avenir to synthesize the equivalent edits into simple_router.p4. We then report the time of the first successful ping between each pair of hosts. We compare Avenir cold-cache run with a manually generated sequence of rule insertions and a pre-populated hot-cache, the results are depicted in Figure 11.

7.3 Case Study: Trellis & ONOS

Trellis [46] is a set of production-grade SDN apps running on ONOS [2,29] to provide control plane logic for multi-purpose L2/L3 leaf-spine fabrics of OF-DPA Broadcom switches. Internally, Trellis uses an ONOS API called FlowObjective, designed to allow portability of apps across different switches by abstracting common L2/L3 functionalities. Trellis controls switches by writing FlowObjectives, which are translated by an ONOS driver into OpenFlow messages for OF-DPA tables. Finally, OF-DPA translates OpenFlow messages to Broadcom SDK calls to populate ASIC-specific tables.

We evaluated Avenir on real-world P4 programs that represent the outermost layers of the architecture described above. The fabric.p4 [12] P4 program was created by the ONOS developers to support Trellis on programmable switches. It is designed to simplify control plane operations, and for this reason it closely resembles the FlowObjective API. Likewise, bcm.p4 [27] abstracts tables from the Broadcom SDK, and was created for Stratum [45], an open source switch agent that uses P4 to model control APIs.

We then collected 40k IPv6 route insertions into fabric.p4 corresponding to a switch reboot load test designed by ONOS engineers. Avenir synthesized insertions into bcm.p4 that equivalently process the IPv6 header and egress specification.

Since Avenir does not process the parser, we simulated its behavior by manually setting the validity bit of the IPv6 header to true, and the IPv4 and MPLS headers to false. Further, the P4 specification [7] leaves the initial values of metadata headers undefined; we manually zero-initialize the metadata fields (a behavior that can be specified for many P4

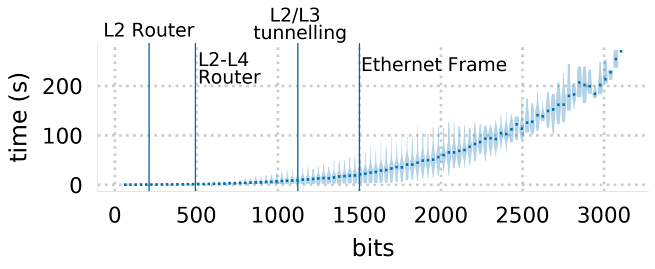

Figure 13: Program bits vs time to translate 100 edits. The vertical lines estimate the sizes of common router programs.

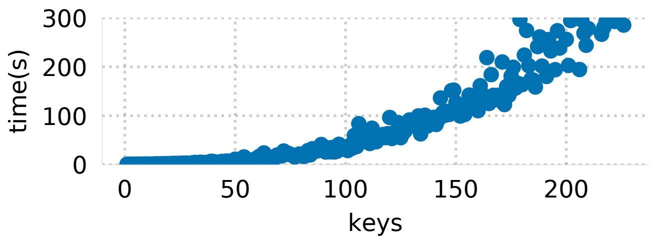

Figure 14: Classifier Scaling. We fixed the number of 32-bit output variables to 8, and varied the number of keys.

targets via a compile time flag).

Further, we modified the l3_fwd in bcm.p4 by swapping the IPv6 matches for IPv4 matches; otherwise there wouldn't have been a valid translation. Finally since Avenir works with parsed headers, we systematically renamed headers in bcm.p4 to match fabric.p4.

The results are shown in Figure 12. According to its engineers, ONOS computes and installs these 40k IPv6 routes over a period of about 15 minutes. This figure includes Trellis' route computation logic, the translation itself and the installation of rules onto the physical target devices. Figure 12 shows that Avenir translates these 40k routes into bcm.p4 pipeline in just under 12 minutes. However, it is unclear what conclusions to draw about overhead, because we don't know how ONOS' translation logic performs. In the (unlikely) best case, we would have no overhead. In the (also unlikely) worst case, we would nearly double the runtime. The real performance would likely be somewhere between these extremes.

7.4 Microbenchmarks

To assess Avenir's scalability, we procedurally generated a collection of microbenchmarks that explore two independent variables, the number of 32-bit input variables I and the number of 32-bit output variables O. For simplicity, the input and output variables sets are distinct.

The abstract pipeline has one table that matches on all of the input variables, and assigns one of the output variables. The target pipeline first matches on all output variables and assigns a metadata value m. This initial staging table is followed by a sequence of O output tables. Table i in this sequence matches solely on m and optionally assigns an output variable.

The results are shown in Figure 13. The x-axis shows the number of bits in the abstract program (i.e., $32(I+O)$) and the y axis shows the time in seconds to translate 100 random abstract edits. The violins show the timing distribution marked with median value. The variation comes from the random generation and from the variation in I and O.

Since networking programs are usually classifier-heavy, we also fixed the number of 32-bit output variables to 8, and varied the size of the classifier. The results are in Figure 14.

Of course, it's difficult to make general claims about the scalability of Avenir's approach, which incorporates numerous heuristics. Nevertheless, it does seem that the complexity increases exponentially with the number of bits, as is expected for a tool that relies on a black-box solver. Target pipelines with different structure than the regular, repeated structure in our microbenchmarks may behave differently.

8 Limitations and Future Work

We discuss two limitations to Avenir's methodology: the cost of formally specificying the abstract and target pipelines, and the run-time overheads of our heuristic search.

The biggest threat to Avenir's use is the requirement that pipelines be formally specified. The work required to develop a formal specification can be significant, and there is no guarantee that a given specification of a pipeline will accurately describe its run-time behavior. Of course, these concerns can be side-stepped if the pipelines are already programmed in P4. But more generally we would need tools for generating specifications and testing conformance. We plan to explore such tools in future work.

Another limitation is our use of heuristic search. The evaluation shows many situations in which Avenir works efficiently, but there are also situations in which it fails to terminate in a reasonable time. For example, to translate from $Pipe_1$ to *OBT* in Figure 2, Avenir maintains a cross product of L2_fwd and L3_fwd, which requires quadratic operations, and causes incremental heursitics to fail. Expanding the effective scope of Avenir's search is future work. We also plan to explore optimal notions of synthesis—e.g., finding the smallest solution.

9 Related Work

Synthesis. Avenir is based on Sketching [39], wherein the programmer is allowed to insert unknown "holes" into a program that are filled using CEGIS [40]. Sketching has been used to build a code generator for packet-processing switch pipelines [16]. NetComplete [10] allows network operators to express their intent by sketching parts of the intended configuration for refactoring or updating purposes. Our novelty is to use sketching to synthesize control plane mappings.

Another use of synthesis is to generate implementations from high-level specifications, e.g., stratified Datalog [11], regular expressions with uninterpreted functions [35], first-order logic constraints [3], and LTL [22].

P4 Verification. There are several recent projects on verifying P4 program properties. Lopes et al. developed an operational semantics for P4 and developed a verification tool based on Datalog which can check program equivalence [24]. P4K presented an operational semantics for P4 using the K framework [19]. p4pktgen uses symbolic execution to generate test cases for P4 programs [26]. ASSERT-P4 translates P4 to a C-like representation, and then symbolically executes the program [15]. Vera [43] uses SymNet [44] as a symbolic execution framework to verify P4 programs. p4v [21] uses symbolic techniques to avoid run-time source traversals.

Network Virtualization. There are many SDN controllers, such as POX [33], NOX [17], and Open Daylight [31]. A few of them specifically target the problem of flow rule composition, including the Frenetic language and controller [14] and Pyretic [25]. Other efforts have focused on network virtualization, i.e., mapping abstract specifications down to target realizations, such as ONIX [20]. FlowVisor [36], CoVisor [18] and the NetKAT compiler [38]. Among this work, Avenir is unique in developing an approach to managing heterogeneous abstract and target pipelines.

10 Conclusion

This paper presented Avenir, a tool that automatically synthesizes control plane operations to ensure uniform behavior across a variety of physical data planes. Avenir uses a counterexample guided inductive synthesis algorithm based on a novel application of sketches to data plane programs. Our evaluation demonstrates that Avenir correctly synthesizes control plane operations with modest overheads.

Acknowledgments

The authors wish to thank Andy Fingerhut for suggesting that we explore the idea of control plane synthesis, and for many helpful discussions as we developed Avenir. Thanks also to Charles Chan and Pier Luigi Ventre from ONF for the discussion on their experience supporting OF-DPA switches in ONOS and Trellis. This work is supported by NSF GRFP grant number DGE-1650441, NSF CCF-1553168, NSF FMiTF-1918396, DARPA HR001120C0107, and gifts from Alibaba, Fujitsu, Infosys, and VMware.

A Formal Details

The grammar of bit-vector expressions and boolean formulae is described in Figure 15.

$$
\begin{array}{rcll}
e & ::= & & (e \in \mathsf{Expr}) \\
 & \mid & v & \textit{Bit Vector} \\
 & \mid & f & \textit{Field} \\
 & \mid & e - e & \textit{Subtraction} \\
 & \mid & e + e & \textit{Addition} \\
 & \mid & e \,\&\, e & \textit{Bitwise And} \\
 \\
b & ::= & & (b \in \mathsf{Bool}) \\
 & \mid & \mathsf{tt} & \textit{Truth} \\
 & \mid & \mathsf{ff} & \textit{Falsehood} \\
 & \mid & e = e & \textit{Equality} \\
 & \mid & e < e & \textit{Inequality} \\
 & \mid & \neg b & \textit{Negation} \\
 & \mid & b \wedge b & \textit{Conjuction} \\
 & \mid & b \vee b & \textit{Disjunction}
\end{array}
$$

Figure 15: Syntax of BitVector expressions and boolean formulae.

The semantics of edits are defined below

$$
\begin{array}{rcl}
\mathsf{A}_x(\rho)\ \tau & \triangleq & \begin{cases} \tau\{x \mapsto \tau(x) @ [\rho]\}, & \forall \rho \in \tau(x), \\ & \pi_1(\rho) \neq \pi_1(\rho') \\ \tau, & \textit{otherwise} \end{cases} \\
\mathsf{D}_x(i)\ \tau & \triangleq & \tau\{x \mapsto \tau(x)[0:i] @ \tau(x)[i+1:]\} \\
\vec{\delta}\ \tau & \triangleq & \delta_1 \circ \cdots \circ \delta_n\ \ \tau
\end{array}
$$

Instantiations. A table is populated by rows in Row. A single row $\rho = (\vec{m}, \vec{d}, a) \in \mathsf{Row}$ is a tuple comprising a sequence of match values $\vec{m}$, a sequence of action data $\vec{d}$, and an action index i. We write $\pi_1(\rho) = \vec{m}$, $\pi_2(\rho)$ for $\vec{d}$, and $\pi_3(\rho)$ for a.

Note that our instantiations only allow exact matches on data. This does not affect the generality of our formal results, since exact matches can easily encode ternary and lpm matches (with untenable blowup, of course). Using these more compact matches is an optimization we describe in Section 5.

A row is *well-formed* for a table t if $|\vec{m}| = t.keys$, $i < |t.actions|$, and when $t.actions[i] = \lambda\vec{x}.\ c$, then $|\vec{x}| = |\vec{d}|$. In practice, there are additional typing constraints regarding the sizes of the bitvectors, but as we've abstracted bitvectors to naturals in this exposition, we can set that bookkeeping aside. We assume henceforth that all rows are well-formed for the tables into which they are being installed.

An instantiation $\tau \in \mathsf{Inst}$ is a function from table name to sequences of rows that describes the given state of the tables in a pipeline, i.e., given a table t, $\tau(t.name)$ gives us the sequence of rows in the table. We often write $\tau(t)$ as convenient shorthand. Moving forwards we will use τ to describe instantiations for abstract programs and σ to describe instances for physical programs.

An instantiation is well-formed if every row in every table is well-formed

Now that we have pipelines c and instantiations τ, we can define how to combine them via the function $\mathsf{subst}(c,\tau)$, which produces another command with no tables in it. Effectively we replace a table t with a guarded command that checks each row $(\vec{m}, \vec{d}, i)$ in sequence. A single row is translated to the guarded command: $\mathsf{encKeys}(t.keys, \vec{m}) \to t.actions[i](\vec{d})$, where the encKeys function We present this formally in Figure 16. Since instances τ are total functions, $\tau(t)$ will always be defined.

We call the command $c' = \mathsf{subst}(c,\tau)$ an *instantiated pipeline*. Note that all of the table applications have been encoded away and we have a simple loop-free command.

Interpretation. We can interpret instantiated pipelines as functions on packets. A packet comes in and then a (possibly) different packet goes out. Similar to other formalisms of packet processing functions we define packets to be valuations on the headers and metadata [1]: packets are defined as finite maps $\mathsf{Hdr} \cup \mathsf{Meta} \rightharpoonup (\mathsf{BitVec})$. Operations on packets pkt are the standard ones: the empty packet is written $\{\}$; to update or set the value of $h \in \mathsf{Hdr}$ to $[n]_s \in \mathsf{BitVec}$ with $h.size = s$, write $pkt\{h \mapsto [n]_s\}$, otherwise the update is undefined; to access the value of x, write $pkt.x$. The set of defined names x in a packet pkt is denoted $\mathrm{dom}(pkt)$. A packet is *well-formed* when it can be constructed by a series of defined updates. In what follows, we assume all updates are well-formed and all packets well-defined: specifically, that Pkt the set of well-defined elements of $\mathsf{Hdr} \rightharpoonup (\mathsf{BitVec})$.

The semantics of commands on a packet pkt are straightforward. The assignment operation $x := e$ first evaluates e to a value n in the environment defined by the packet pkt, and then returns the packet $pkt\{x \mapsto n\}$. The sequence operator $(c_1; c_2)$ is simply interpreted as functional composition: the output of $[\![c_1]\!]\ pkt$ is passed into $[\![c_2]\!]$.

The semantics of guarded commands are broken into two cases. First, if there are no rows in the selection, i.e., if fi, the command is interpreted as the identity function, otherwise, if there is at least one row in the selection (i.e., if $(b \to c)\ \overrightarrow{b \to c}$ fi), then b is evaluated in the packet environment. If it evaluates to tt, then execute c, i.e., $[\![c]\!]\ pkt$, otherwise, if b evaluates to ff, we simply check the remaining rows in the guarded command, i.e $[\![\text{if } \overrightarrow{b \to c} \text{ fi}]\!]\ pkt$.

Finally, the denotation of a table is simply its default action.

We leave the semantics of our expressions ($\mathcal{E}[\![-]\!]$) and booleans ($\mathcal{B}[\![-]\!]$) undefined, as their definitions are standard.

The logical encoding uses the predicate transformer semantics of GCL programs [9]. Our semantics are identical to Dijkstra's, with the exception of our guarded commands. Ours are definitionally mutually exclusive, his are nondeterministic. To remedy this we simply negate the preceding guards, and then apply the weakest precondition function, *wp*.

$$\begin{array}{rcl}
\Phi & \triangleq & \bigwedge\{h.name = x' \mid h \in x' \text{ fresh}\} \\
c_1 \equiv c_2 & \triangleq & wp(c_1, \Phi) \Leftrightarrow wp(c_2, \Phi) \\
\mathsf{ISVALID}(\varphi) & \triangleq & \mathsf{SAT}(\neg\varphi)
\end{array}$$

Figure 18: The verification condition for determining when two programs implement the same function

$$\begin{array}{lcl}
\mathsf{encKeys} :: \mathsf{List}[\mathsf{Hdr}] \times \mathsf{List}[\mathsf{BitVec}] \to \mathsf{Bool} & & \\
\mathsf{encKeys}(\vec{k}, \vec{m}) & \triangleq & \bigwedge_{0 \le i < |t.keys|} k_i = m_i \\
 & & \\
\mathsf{subst}(c, \tau) :: \mathsf{Cmd} & & \\
\mathsf{subst}(x := e, \tau) & \triangleq & x := e \\
\mathsf{subst}(c; c, \tau) & \triangleq & \mathsf{subst}(c, \tau); \mathsf{subst}(c, \tau) \\
\mathsf{subst}(\mathsf{if}\ \overrightarrow{b \to c}\ \mathsf{fi}, \tau) & \triangleq & \mathsf{if}\ \overrightarrow{b \to \mathsf{subst}(c, \tau)}\ \mathsf{fi} \\
\mathsf{subst}(\mathsf{apply}\ t, \tau) & \triangleq &
\end{array}$$

```
    if
      $\mathsf{encKeys}(t.keys, \vec{m}_1) \to t.actions[a_1](\vec{d}_1)$
                    $\vdots$
      $\mathsf{encKeys}(t.keys, \vec{m}_n) \to t.actions[a_n](\vec{d}_n)$
    fi

    where $(\vec{m}_1, \vec{d}_1, a_1), \ldots, (\vec{m}_n, \vec{d}_n, a_n) = \tau(t)$
```

[\![\mathsf{apply}(t)]\!]\ pkt & \triangleq & [\![t.default]\!]\ pkt
\end{array}$$

Figure 17: Semantics of programs

The verification condition is defined in Figure 18. Leveraging the connection between weakest preconditions and denotational semantics [9], we can define equivalence pipelines c_1 and c_2 by taking the weakest precondition with respect to a particular formula Φ, which equates every header variable to a fresh symbolic variable. The free variable will then capture the input value of a program, and the symbolic variable will capture the output value of the program.

As an example, consider the following command c:

```
if   $x = 1$   $\to$   $x := 5$
       tt   $\to$   $x := 9$
fi
```

Then the Φ corresponding to this command is $x = x'$. Then $wp(c, \Phi)$ is equivalent to

$$\begin{array}{l}
(x = 1 \Rightarrow 5 = x') \\
\wedge (x \neq 1 \Rightarrow 9 = x')
\end{array}$$

The variable x captures the input conditions (either $x = 1$ or not), and the x's capture the output varibles: when the input x value is one, the output will be 5; otherwise, it will be 9.

Instrumentation The instr function formalizes how to add holes to a table. We write else if to help delineate elements in the selection list.

```
instr$(t, \tau, \vec{\delta}, n)$   $\triangleq$
  if $t.keys = \vec{m}_i \wedge ?\mathtt{Del}_{t.name,i} = 0 \to t.actions[a_i](\vec{d}_i)$
                    for $(\vec{m}_i, \vec{d}_i, a_i) \in \tau(t)$ if $\mathsf{D}(t.name, i) \notin \vec{\delta}$
  else if $t.keys = \vec{m} \to t.actions[a_i](\vec{d})$
                              for $\mathsf{A}(t.name, (\vec{m}_i, \vec{d}_i, a_i)) \in \vec{\delta}$
  else if
    $\left(\begin{array}{l} \bigwedge_{k \in t.keys} k = ?\mathtt{k}_{t.name,j} \\ \wedge ?\mathtt{Add}_{t.name,j} = 1 \\ \wedge \bigwedge_{k \le j} ?\mathtt{Add}_{t.name,k} = 1 \\ \wedge ?\mathtt{ActId}_{t.name,j} = i \end{array}\right) \to t.action[i](\overrightarrow{?d_{t.name,j,i}})$
                    for $0 \le i < |t.actions|$ and $0 \le j < n$
  fi
```

Figure 19: The instr function formalizes how to add holes to a tables

B Proof of Completeness

Lemma 1 (Hits Restrict)**.** *For every program $p \in \mathsf{Cmd}$, instance $\sigma \in \mathsf{Inst}$, and set of counter examples X such that for every $(\chi_0, \chi_1) \in X$, $[\![\mathsf{subst}(p,\sigma)]\!]\ \chi_0 = \chi_1$, then there exists σ' such that $X \subseteq [\![\mathsf{subst}(p,\sigma')]\!]$ and $|\sigma'(t)| \leq |X|$ for every $t \in \mathsf{Tables}(p)$.*

Proof. Proceed by induction on the structure of p:

[$(p = x := e)$] Trivial because $\mathsf{Tables}(x := e) = \emptyset$ and for every σ, $\mathsf{subst}(x := e, \sigma) = x := e$.

[$p = (p_1; p_2)$] Assume $p = p_1; p_2$. Introduce X and σ as above.

Decompose X across p_1 and p_2 such that

$$\begin{array}{lll} X_1 & \triangleq & \{(\chi_0,\chi_1) \mid [\![\mathsf{subst}(p_1,\sigma)]\!]\ \chi_0 = \chi_1, \chi_0 \in \pi_1(X)\} \\ X_2 & \triangleq & \{(\chi_1,\chi_2) \mid [\![\mathsf{subst}(p_2,\sigma)]\!]\ \chi_1 = \chi_2, \chi_1 \in \pi_2(X_1)\} \end{array}$$

Notice that $X_2 \circ X_1 = X$.

Now by the IH on p_1, σ and X_1 we get σ_1 such that every rule is hit by a counterexample in X_1,

$$\forall(\chi_0,\chi_1) \in X_1, [\![\mathsf{subst}(p_1,\sigma_1)]\!]\ \chi_0 = \chi_1$$

and $|\sigma_1(t)| \leq |X_1|$ for all $t \in \mathsf{Tables}(p_1)$. Similarly, by the IH on p_2, σ and X_2, we get σ_2 such that every rule is hit by a counterexample in X_2.

$$\forall(\chi_1,\chi_2) \in X_2, [\![\mathsf{subst}(p_2,\sigma_2)]\!]\ \chi_1 = \chi_2$$

and $|\sigma_2(t)| \leq |X_1|$ for all $t \in \mathsf{Tables}(p_2)$.

Now we can construct σ' such that

$$\sigma'(t) = \begin{cases} \sigma_1(t), & \text{if } t \in \mathsf{Tables}(p_1) \\ \sigma_2(t), & \text{if } t \in \mathsf{Tables}(p_2) \end{cases}$$

Observe that $\sigma|_{\mathsf{Tables}(p_i)} = \sigma_i$ for $i = 1,2$. Now we show the two remaining properties.

- Since $X = X_2 \circ X_1$ is a function, we know $\forall t \in \mathsf{Tables}(p)$, $|\sigma_1(t)| \leq |X_1| \leq |X|$ and $|\sigma_2(t)| \leq |X_2| \leq |X|$, and the table names in p_1 and p_2 are disjoint. Conclude that $\forall t \in \mathsf{Tables}(p), |\sigma'(t)| \leq |X|$.
- Show $X \subseteq [\![\mathsf{subst}(p_1;p_2,\sigma')]\!]$. Our IHs give

  $$\begin{array}{l} X_1 \subseteq [\![\mathsf{subst}(p_1,\sigma_1)]\!] \\ X_2 \subseteq [\![\mathsf{subst}(p_2,\sigma_2)]\!] \end{array}$$

  By definition,

  $$\begin{array}{c} [\![\mathsf{subst}(p_1;p_2,\sigma')]\!] \\ = \\ [\![\mathsf{subst}(p_2,\sigma')]\!] \circ [\![\mathsf{subst}(p_1,\sigma')]\!] \end{array}$$

  Then,

  $$\begin{array}{c} [\![\mathsf{subst}(p_2,\sigma')]\!] \circ [\![\mathsf{subst}(p_1,\sigma')]\!] \\ = \\ [\![\mathsf{subst}(p_2,\sigma_2)]\!] \circ [\![\mathsf{subst}(p_1,\sigma_1)]\!] \end{array}$$

  by the disjointness of table names. The result follows.

[$p = \mathsf{if}\ \overrightarrow{b \to p}\ \mathsf{fi}$] Similar, but n-ary.

[$p = \mathsf{apply}(t)$] Assume that $p = \mathsf{apply}(t)$ for some table t. The corresponding rows for the table are $\sigma(t) = \vec{\rho}$. Compute a subsequence $\vec{\rho}'$ of $\vec{\rho}$ such that $\vec{\rho}'$ contains ρ_i iff there is some input packet in X that hits ρ_i. Create an instantiation $\sigma' = \sigma\{t \mapsto \vec{\rho}'\}$. Since each the rules are equality matches (and hence disjoint), $[\![\mathsf{subst}(\mathsf{apply}(t),\sigma')]\!]\ \chi_0 = \chi_1$ for every $(\chi_0,\chi_1) \in X$. Since some $\chi_0 \in \pi_1(X)$ may miss, conclude that $|\sigma'(t)| \leq |X|$. □

Lemma 2 (Model Solution)**.** *For every $p \in \mathsf{Cmd}$, every $\sigma \in \mathsf{Inst}$, and every $X \in \mathsf{Pkt}^2$, if there exists $\vec{\delta} \in \mathsf{List[Edit]}$ such that $X \subseteq [\![\mathsf{subst}(p,\vec{\delta}(\sigma))]\!]$, then*

$$\mathsf{SAT}\ \vec{\delta}' = \mathsf{model}(p,\sigma,X)$$

and

$$X \subseteq [\![\mathsf{subst}(p,\vec{\delta}'(\sigma))]\!]$$

Proof. Let $\vec{\delta}$ be such that $X \subseteq [\![\mathsf{subst}(p,\vec{\delta}(\sigma))]\!]$.

Lemma 1 gives us σ' from $\vec{\delta}(\sigma)$ such that for every table $t \in \mathrm{dom}(\sigma')$, $|\sigma'(t)| \leq |X|$, and $X \subseteq [\![\mathsf{subst}(p,\sigma')]\!]$.

Construct the following witness to the query in Figure 5

$$\left\{ \begin{array}{l|l} ?\mathtt{Del}_{x,i} \mapsto 1, & t \in \mathsf{Tables}(p), \\ ?\mathtt{Add}_{x,j} \mapsto 1, & x = t.name \\ ?\mathtt{ActId}_{x,j} \mapsto a, & 0 \leq i < |\sigma(t)|, \\ \overrightarrow{?k_{x,j} \mapsto m}, & 0 \leq j < |\sigma'(t)| \\ \overrightarrow{?d_{x,j,i} \mapsto d} & (\vec{m},\vec{d},a) = \sigma'(t)[j] \end{array} \right\}$$

which corresponds to the rules

$$\begin{array}{llll} d_{t,i} & \triangleq & \mathsf{D}(t,i), & \forall t \in \mathsf{Tables}(p), |\sigma(t)| > i \geq 0 \\ a_{t,j} & \triangleq & \mathsf{A}(t,\sigma'(t)[j]), & \forall t \in \mathsf{Tables}(p), 0 \leq j < |\sigma'(t)| \\ \vec{\delta}' & \triangleq & \vec{d} \cdot \vec{a} & \end{array}$$

Note that $\vec{d}_t$ is sorted from highest index to lowest index. Observe that $\vec{\delta}'(\sigma) = \vec{a}(\vec{d}(\sigma))\sigma = \vec{a}(\cdot) = \sigma'$, so we can conclude that $\forall(\chi_0,\chi_1) \in X, [\![\mathsf{subst}(p,\vec{\delta}'(\sigma))]\!]\ \chi_0 = \chi_1$, and we're done. □

Theorem 6 (Completeness)**.** *For every logical program $l \in$ Cmd, physical program $p \in \mathsf{Cmd}$, logical instantiation $\tau \in$ Inst, physical instantiation $\sigma \in \mathsf{Inst}$, sequence of physical edits $\vec{\delta} \in \mathsf{List[Edit]}$, and every set X s.t.*

$$X \subseteq [\![\mathsf{subst}(l,\tau)]\!] \cap [\![\mathsf{subst}(p,\vec{\delta}(\sigma))]\!],$$

if

$$\exists \vec{\varepsilon} \in \mathsf{List[Edit]}.\mathsf{subst}(l,\tau) = \mathsf{subst}(p,\vec{\varepsilon}(\sigma))$$

then

$$\mathsf{Ok}\ \vec{\delta}' = \mathsf{cegis}(l,p,\tau,\sigma,\vec{\delta},X)$$

and

$$\mathsf{subst}(l,\tau) = \mathsf{subst}(p,\vec{\delta}'(\sigma))$$

Proof. Proceed by induction on $|\mathsf{Pkt} \setminus \pi_1(X)|$.

Base Case. $(\pi_1(X) = \mathsf{Pkt})$. The definition of functional subset gives us

$$\forall(\chi_1,\chi_2) \in X.[\![\mathsf{subst}(l,\tau)]\!]\ \chi_1 = \chi_2 = [\![\mathsf{subst}(p,\delta(\vec{\sigma}))]\!]\ \chi_1$$

which reduces to

$$\forall \chi_1 \in \pi_1(X).[\![\mathsf{subst}(l,\tau)]\!]\ \chi_1 = [\![\mathsf{subst}(p,\vec{\delta}(\sigma))]\!]\ \chi_1.$$

Then by the assumption that $\pi_1(X) = \mathsf{Pkt}$, this is just

$$\forall \chi_1 \in \mathsf{Pkt}.[\![\mathsf{subst}(l,\tau)]\!]\ \chi_1 = [\![\mathsf{subst}(p,\vec{\delta}(\sigma))]\!]\ \chi_1$$

Conclude, by definition, that

$$\mathsf{subst}(l,\tau) = \mathsf{subst}(l,\vec{\delta})$$

Inductive Step. $(\pi_1(X) \subseteq \mathsf{Pkt})$. If $\mathsf{subst}(l,\tau) = \mathsf{subst}(p,\vec{\delta}(\sigma))$, then we're done, so assume instead that we have a counterexample $\chi = (\chi_0,\chi_1)$ such that

$$[\![\mathsf{subst}(l,\tau)]\!]\ \chi_0 = \chi_1 \neq [\![\mathsf{subst}(p,\vec{\delta}(\sigma))]\!]$$

which tells us that that $\chi \notin X$.

Our main assumption tells us that there is some $\vec{\varepsilon}$ such that

$$\mathsf{subst}(l,\tau) = \mathsf{subst}(p,\vec{\varepsilon}(\sigma))$$

By definition we have

$$\forall pkt \in \mathsf{Pkt}.[\![\mathsf{subst}(l,\tau)]\!]\ pkt = [\![\mathsf{subst}(p,\vec{\varepsilon}(\sigma))]\!]\ pkt.$$

which, since $\pi_1(\{\chi\} \cup X) \subseteq \mathsf{Pkt}$, means that

$$\forall pkt \in \{\chi\} \cup X.[\![\mathsf{subst}(l,\tau)]\!]\ pkt = [\![\mathsf{subst}(p,\vec{\varepsilon}(\sigma))]\!]\ pkt,$$

Then Lemma 2 gives us a model $\vec{\delta}'$ such that

$$\forall pkt \in \{\chi\} \cup X.[\![\mathsf{subst}(l,\tau)]\!]\ pkt = [\![\mathsf{subst}(p,\vec{\delta}'(\sigma))]\!]\ pkt$$

The result follows by IH on $\{\chi\} \cup X$ as $|\{\chi\} \cup X| > |X|$. □

C Proof of Completeness for Incremental Synthesis

Definition 1 (Minimal Sequence)**.** *Given an instantiation τ, a sequence of edits $\vec{\delta}$ is minimal iff for every table $t \in \mathrm{dom}(\tau)$, for every $\vec{\delta}'$ s.t. $\vec{\delta}(\sigma) = \vec{\delta}'(\sigma)$, $|\vec{\delta}| \leq |\vec{\delta}'|$.*

Definition 2 (Minimal Extension)**.** *Given a command c, an instantiation τ, and a sequence of edits $\vec{\delta}$, another sequence $\vec{\delta}'$ is called a* minimal extension *of $\vec{\delta}$ when $\vec{\delta} \circ \vec{\delta}'$ is minimal.*

Lemma 3 (Finite Minimal Sequences)**.** *Given a command c, and an instantiation τ, the set of minimal sequences is finite.*

Proof. Proceed by induction on the structure of c.

$(h := e)$ There there is one minimal instatiation: $[]$.

$(c_1; c_2)$ By IHs, the set of minimal sequences corresponding to c_1 and τ is a finite D_1, and the set of minimal sequences corresponding to c_1 and τ is a finite D_2. The set of minimal sequences corresponding to $c_1; c_2$ is the set of all interleaving of all sequences in D_1 and sequences of D_2, which is finite.

$(\mathsf{if}\ \overrightarrow{b \to c}\ \mathsf{fi})$ This is similar to the previous case except $n$ary.

$(\mathsf{apply}(t))$ First we show that the space of functions that t can represent is finite. Since $t.keys$ is finite, and each header in $t.keys$ has a finite domain of values, so the domain of matches is finite. A similar argument shows that the domain of actions is finite, and so the domain of functions is finite. Further for each of these functions, there are finitely many ways of representing them (all of the permutations of the rules).

This means that there are finitely many minimal sequences when $\tau(t) = []$, simply install each of these, with no duplicates, since removing the duplicates would result in a smaller sequence of edits.

When $\tau(t) \neq []$ there are also finitely many minimal sequences. They are those that delete as few rules in $\tau(t)$ as necessary and then install the missing rules (if any are needed): they never delete a rule and then reinstall the same rule, and then never install a rule only to delete it later. □

Lemma 4 (Finite Minimal Extensions)**.** *For a command c and an instantiation τ, and a sequence of edits $\vec{\delta}$, there are finitely many minimal extensions of $\vec{\delta}$.*

Proof. There are finitely many minimal extensions of c and τ. Some of those have $\vec{\delta}$ as a prefix; there are finitely many of them. □

Definition 3 (φ-Preclusion). *For a program c, instantiation τ, and a packet pair $\chi \notin [\![\mathsf{subst}(c,\tau)]\!]$, we say that φ precludes $\vec{\delta}$ when for every $\vec{\delta'} \models \varphi$ that is also a prefix of $\vec{\delta}$, $\chi \notin [\![\mathsf{subst}(p,\vec{\delta}(\tau))]\!]$. We say that* φ precludes a solution, *when it precludes every $\vec{\delta}$.*

Definition 4 (Zip Function). *Let* zip*($\vec{x}$, $\vec{y}$) be the function that simultaneously iterates through $\vec{x}$ and $\vec{y}$ and returns a sequence of the element-wise pairs, i.e., $\overrightarrow{(x,y)}$. The function is undefined if $|\vec{x}| \neq |\vec{y}|$.*

Lemma 5 (Model Finding). *For every logical program l, physical program p, logical instantiation τ, phsyical instantiation σ, sequence of physical edits $\vec{\delta}$, counterexample $\chi \in [\![\mathsf{subst}(l,\tau)]\!] \setminus [\![\mathsf{subst}(p,\vec{\delta}(\sigma))]\!]$, and formula $\varphi \in \mathsf{Bool}$ such that for every $\vec{\delta'} \models \neg\varphi$ st $\chi \in [\![\mathsf{subst}(p,\vec{\delta'}(\vec{\delta}(\sigma)))]\!]$, there is no extension $\vec{\delta''}$ such that $\mathsf{subst}(l,\tau) = \mathsf{subst}(l,\vec{\delta''}(\vec{\delta'}(\vec{\delta}(\sigma))))$, then if there exists $\vec{\varepsilon}$ not precluded by φ such that*

$$\mathsf{subst}(p,\tau) = \mathsf{subst}(l,\vec{\varepsilon}(\vec{\delta}(\sigma)))$$

, and $\vec{\delta} \circ \vec{\varepsilon}$ is minimal, then

$$\mathsf{Sat}\ \vec{\delta''} = \mathsf{model}'(p,\sigma,\delta,\chi,\varphi)$$

Proof. Let l, p, τ, σ, $\vec{\delta}$, χ, and φ be given. Construct the following model for the query in $\mathsf{model}'(p,\sigma,\delta,\chi,\varphi)$:

We accumulate a model for every table $t \in \mathsf{Tables}(p)$. If $\pi_1(\chi)$ in $\mathsf{subst}(p,\vec{\varepsilon}(\vec{\delta}(\sigma)))$ hits the ith row ρ_i, then there are several cases

MISS If $\pi_1(\chi)$ misses in $\mathsf{subst}(p,\vec{\delta}(\sigma))$, then add

$$\left\{\begin{array}{l} ?\mathsf{AddRowTo}_{t,1} \mapsto 1 \\ ?\mathsf{Act}_{t,1} \mapsto \rho_i.action \\ ?\vec{\mathsf{k}}_{t,1} \mapsto \rho_i.keys \\ \overrightarrow{?\mathsf{d}_{t,\rho.action,1}} \mapsto \rho_i.data \end{array}\right\}$$

HITCORRECT If $\pi_1(\chi)$ hits the jth row ρ_j of $(\vec{\delta}(\sigma))(t)$ in $\mathsf{subst}(p,\vec{\delta}(\sigma))$, and $\rho_i = \rho_j$ then do nothing.

HITWRONG If $\pi_1(\chi)$ hits the jth row of $(\vec{\delta}(\sigma))(t)$ in $\mathsf{subst}(p,\vec{\delta}(\sigma))$ and $\rho_j \neq \rho_i$,

$$\left\{\begin{array}{l} ?\mathsf{AddRowTo}_{t,1} \mapsto 1 \\ ?\mathsf{Act}_{t,1} \mapsto \rho_i.action \\ ?\vec{\mathsf{k}}_{t,1} \mapsto \rho_i.keys \\ \overrightarrow{?\mathsf{d}_{t,\rho.action,1}} \mapsto \rho_i.data \end{array}\right\}$$

From here we extract queries from the model as before, sorting the deletions by decreasing index to get $\vec{\delta''}$. Note that χ hits a syntactically equivalent rule in $\mathsf{subst}(p,\vec{\delta''}(\vec{\delta})(\sigma))$ as in $\mathsf{subst}(l,\vec{\varepsilon}(\vec{\delta}(\sigma)))$. We conclude $\chi \in [\![\mathsf{subst}(p,\vec{\delta''}(\vec{\delta}(\sigma)))]\!]$ □

Lemma 6 (Nontrivial Models). *For every physical program p, physical instance σ, sequence of edits $\vec{\delta}$, formula φ, and counterexample $\chi \in \mathsf{Pkt}^2$ such that $\chi \notin [\![\mathsf{subst}(p,\vec{\delta}(\sigma))]\!]$, if $\mathsf{Sat}\ \vec{\delta''} = \mathsf{model}'(p,\sigma,\vec{\delta},\chi,\varphi)$, then $\vec{\delta''} \neq []$.*

Proof. Let $p \in \mathsf{Cmd}$, $\sigma \in \mathsf{Inst}$, $\vec{\delta} \in \mathsf{List[Edit]}$ and φ and $\chi \in \mathsf{Pkt}^2$ be given. Assume $\mathsf{Sat}\ \vec{\delta''} = \mathsf{model}'(p,\sigma,\vec{\delta},\varphi)$.

Prove the contrapositive, that if $\vec{\delta''} = []$, then $\chi \in [\![\mathsf{subst}(p,\sigma)]\!]$. Assume $\vec{\delta''} = []$. Then the query in $\mathsf{model}(p,\sigma,\vec{\delta},\chi,\varphi)$ is satisfiable with all deletion and insertion holes set to zero. This means that the following query is also satisfiable (where $\chi = (pkt, pkt')$):

$$\mathsf{SAT}\left(\forall\vec{x}.\varphi \wedge \left(\overrightarrow{\chi_1.x = x}\right) \Rightarrow wp\left(\mathsf{subst}(p,\vec{\delta}(\sigma)), \left(\overrightarrow{pkt'.x = x}\right)\right)\right)$$

By the correspondence between wp and the denotational semantics, conclude that $\chi \in [\![\mathsf{subst}(p,\vec{\delta}(\sigma))]\!]$. □

Proposition 1 (Oracle Constraints). *For a given physical program p, edit sequence δ and instance σ,*

$$\mathsf{HEURISTIC}() \Rightarrow \bigwedge_{t \in \mathsf{Tables}(p)} ?\mathsf{Add}_{t,1} = 1 \Rightarrow \bigwedge_{(\vec{m},\vec{d},\vec{a}) \in \vec{\delta}(\sigma)(t)} \neg\left(\overrightarrow{?\mathsf{k}_{t,1}} = m\right)$$

and

$$\mathsf{HEURISTIC}() \Rightarrow \bigwedge_{\substack{t \in \mathsf{Tables}(p) \\ 0 \le i < |\sigma(t)| \\ (\vec{m},\vec{d},a) = \sigma(t)[i]}} ?\mathsf{Del}_{t,i} = 1 \Rightarrow \neg\left(\begin{array}{l} \overrightarrow{?\mathsf{k}_{t,1} = m} \\ \wedge ?\mathsf{Act}_{t,l} = a \\ \wedge \overrightarrow{?\mathsf{d}_{t,a,1} = d} \end{array}\right)$$

Lemma 7 (Reachable Edits). *For every program p, instantiation σ, edit sequence $\vec{\delta}$, counterexample χ and $\varphi \in \mathsf{Bool}$, if*

$$\mathsf{Sat}\ \vec{\delta'} = \mathsf{model}'(p,\sigma,\vec{\delta},\chi,\varphi)$$

then the insertions in $\vec{\delta}$ are reachable.

Proof. By Proposition 1. □

Lemma 8 (Deletes Not Resurrected). *For every program p, instantiation σ, edit sequence $\vec{\delta}$, counterexample χ and $\varphi \in \mathsf{Bool}$, if*

$$\mathsf{Sat}\ \vec{\delta'} = \mathsf{model}'(p,\sigma,\vec{\delta},\chi,\varphi)$$

then the insertions in $\vec{\delta}$ are reachable.

Proof. By Proposition 1. □

Lemma 9 (Minimal Models). *For every physical program p, physical instance σ, sequence of edits $\vec{\delta}$, formula φ, and counterexample $\chi \in \mathsf{Pkt}^2$ such that $\chi \notin [\![\mathsf{subst}(p,\sigma)]\!]$, if $\mathsf{Sat}\ \vec{\delta''} = \mathsf{model}'(p,\sigma,\vec{\delta},\varphi)$, then $\vec{\delta} \circ \vec{\delta''}$ is minimal.*

Proof. Let p, σ, $\vec{\delta}$, φ, χ be given. Assume $\mathsf{Sat}\ \vec{\delta}'' = \mathsf{model}'(p,\sigma,\vec{\delta},\varphi)$.

Consider another sequence of edits $\vec{\delta}'$ such that there is some σ' such that $\vec{\delta}''(\vec{\delta}(\sigma)) = \sigma' = \vec{\delta}'(\sigma)$. Show that $|\vec{\delta} \circ \vec{\delta}''| \leq |\vec{\delta}'|$.

We prove two propositions.

(ADD) Assume that there were some insertion $\delta_i = \mathsf{A}(t,\rho) \in \vec{\delta} \circ \vec{\delta}''$ that doesn't occur in $\vec{\delta}'$. If $\delta_i \in \vec{\delta}$, then $\rho \in \sigma'(t)$. By minimality of $\vec{\delta}$, and $\rho \notin \sigma'(t)$. So $\sigma' \neq \vec{\delta}(\sigma)$, which is a contradiction. If $\delta_i \in \vec{\delta}''$, then $\rho \in \sigma'(t)$, and $\rho \notin \sigma(t)$, because model' always produces reachable edits (Lemma 7). Consequently $\vec{\delta}'(\sigma) \neq \sigma'$ which is a contradiction.

So we know that δ_i has a corresponding edit $\delta'_j \in \vec{\delta}'$. Assume that there is another edit $\delta_k \in \vec{\delta} \circ \vec{\delta}$ that corresponds to δ'_j. This is impossible by Lemma 7 and by the minimality of $\vec{\delta}$.

(DEL) Assume that there were some edit $\delta_j = \mathsf{D}(t,i) \in \vec{\delta} \circ \vec{\delta}''$ deletes some row ρ that occurs in $\vec{\delta}'(\sigma)$: ie. $((\delta_{i-1} \circ \cdots \circ \delta_1)(\sigma))(t)[i] = \rho \notin \sigma'(t)$ and $\rho \in \vec{\delta}'(\sigma)$.

If $\delta_i \in \vec{\delta}''$, we know, by construction, that δ_i deletes a row in $\sigma(t)$. Further, Lemma 8 says $\vec{\delta}'(\sigma) \neq \sigma'$, which is a contradiction.

So we know that δ_i has a corresponding edit $\delta'_j \in \vec{\delta}'$. Assume that there is another edit $\delta_k \in \vec{\delta} \circ \vec{\delta}$ that corresponds to δ'_j. This is impossible because rows can only be deleted once.

Since every edit in $\vec{\delta} \circ \vec{\delta}''$ has a corresponding unique edit in δ'. Conclude that $\vec{\delta} \circ \vec{\delta}'' \subseteq \vec{\delta}'$. The result follows. ☐

Lemma 10 (Completeness)**.** *For every logical program l, every physical program p, every logical instantiation τ, every physical instantiation σ and every sequence of physical edits $\vec{\delta}$, then, the following properties hold:*

1. *if there exists a sequence of physical edits $\vec{\delta}'$ such that*
$$\mathsf{subst}(l,\tau) = \mathsf{subst}(p,\vec{\delta}'(\vec{\delta}(\sigma)))$$
then
$$\mathsf{Ok}\ \vec{\delta}'' = \mathsf{verify}(l,p,\tau,\sigma,\vec{\delta})$$
and
$$\mathsf{subst}(l,\tau) = \mathsf{subst}(p,\vec{\delta}''(\sigma))$$

2. *For every $\chi \in [\![\mathsf{subst}(l,\tau)]\!] \setminus [\![\mathsf{subst}(p,\vec{\delta}(\sigma))]\!]$, and every $\varphi \in \mathsf{Bool}$ such that if $\vec{\delta}' \models \neg\varphi$ and $[\![\mathsf{subst}(l,\tau)]\!]\ \pi_1(\chi) = \pi_2(\chi) = [\![\mathsf{subst}(p,\vec{\delta}'(\vec{\delta}(\sigma)))]\!]\ \pi_1(\chi)$, there is no extension $\vec{\delta}''$ such that $\mathsf{subst}(l,\tau) = \mathsf{subst}(l,\vec{\delta}''(\vec{\delta}'(\vec{\delta}(\sigma))))$ then if there exists a non-empty, minimal sequence of physical edits $\vec{\varepsilon}$ not precluded by φ such that*
$$\mathsf{subst}(l,\tau) = \mathsf{subst}(p,\vec{\varepsilon}(\vec{\delta}(\sigma)))$$
then
$$\mathsf{Ok}\ \vec{\delta}'' = \mathsf{solve}(l,p,\tau,\sigma,\vec{\delta},\chi,X,\varphi)$$
and
$$\mathsf{subst}(l,\tau) = \mathsf{subst}(p,\vec{\delta}''(\sigma))$$

Proof. First we justify the finiteness of our inner inductive measure. There is a finite number of models to every model' query, simply because there are finitely many holes, each of which has finite domain. Since φ is composed of the same set of variables, it is also finite.

Let l, p, τ and σ be given. Proceed by induction on the number of nonempty minimal extensions of $\vec{\delta}$. Lemma 4 shows this measure is well-formed.

BASE CASE There are no nonempty minimal extensions of $\vec{\delta}$. Consider each proposition separately

1. Let $\vec{\varepsilon}$ be a nonempty sequence of edits such that $\mathsf{subst}(l,\tau) = \mathsf{subst}(l,\vec{\varepsilon}(\sigma))$. However, $\vec{\delta}$ has no nonempty minimal extensions, so $\mathsf{subst}(l,\tau) = \mathsf{subst}(l,\vec{\delta}(\sigma)))$. Entering the verify function, observe that by Theorem 1 $\mathsf{CheckSat}(\mathsf{subst}(l,\tau) \not\equiv \mathsf{subst}(l,\vec{\delta}(\sigma)))$ will be UNSAT, and we're done by Theorem 4.
2. Vacuous, there is no such $\vec{\varepsilon}$.

INDUCTIVE STEP There are nonempty minimal extensions of $\vec{\delta}$.

First we prove proposition 2 by strong induction on the number of models for φ.

BASE CASE There are no models for φ, i.e., φ is unsatisfiable. Consequently, the call to model' fails to produce a model. This is a contradiction by Lemma 5.

INDUCTIVE STEP There are n models for φ Let X and χ be given. Assume $\vec{\varepsilon}$ exists such that $\mathsf{subst}(l,\tau) = \mathsf{subst}(p,\vec{\varepsilon}(\vec{\delta}(\sigma)))$.

Now, we get a model by calling $\mathsf{model}'(p,\sigma,\vec{\delta},\chi,\varphi)$, and there are two cases.

i. Assume the result is UNSAT. This is a contradiction by Lemma 5.
ii. Assume the result is $\mathsf{Sat}\ \vec{\delta}''$. By Lemma 6, $|\vec{\delta}''|$ is nonempty. Consider two cases:
Case 1. Assume there exists some extension of $\vec{\delta} \circ \vec{\delta}''$ that is a solution. Then the outer IH proves that the verify call produces a solution.
Case 2. Assume there is no extension of $\vec{\delta} \circ \vec{\delta}''$ that is a solution. Then $\mathsf{verify}(l,p,\tau,\sigma,\vec{\delta} \circ \vec{\delta}'')$

returns Fail. Then, since $\vec{\delta}'' \models \varphi$, and $\vec{\delta} \not\models \neg\vec{\delta}$, the number of models for $\varphi \wedge \neg\vec{\delta}''$ is strictly less than n. Further, we know that there is an way to extend $\vec{\delta}$ that is a solution, namely $\vec{\varepsilon}$. We also know that $\vec{\varepsilon}$ isn't precluded by φ, by assumption, finally we also know that $\vec{\varepsilon}$ isn't precluded by $\neg\vec{\delta}''$, because of our assumption that $\vec{\delta} \circ \vec{\delta}''$ cannot be extended to a solution. These final conditions witness the preconditions of the inner IH, which proves the result.

✓

Now prove proposition 1. Let $\vec{\varepsilon}$ be such that

$$\mathsf{subst}(l, \tau) = \mathsf{subst}(l, \vec{\varepsilon}(\vec{\delta}(\sigma)))$$

There are two cases, either $\mathsf{subst}(l, \tau) = \mathsf{subst}(l, \vec{\delta}\sigma)$ or not. In the former case, we are done by Theorem 1. In the latter, we will get a counterexample χ (by Theorem 1), such that

$$\chi \notin \mathsf{subst}(l, \tau) \cap \mathsf{subst}(l, \vec{\delta}(\sigma))$$

Then the result follows as a special case of the preceeding proof of proposition 2. □

Don't Yank My Chain: Auditable NF Service Chaining

Guyue Liu, Hugo Sadok, Anne Kohlbrenner,[*] *Bryan Parno, Vyas Sekar, Justine Sherry*
Carnegie Mellon University [*]*Princeton University*

Abstract

Auditing is a crucial component of network security practices in organizations with sensitive information, such as banks and hospitals. Unfortunately, network function virtualization (NFV) is viewed as incompatible with auditing practices which verify that security functions operate correctly. In this paper, we bring the benefits of NFV to security-sensitive environments with the design and implementation of AuditBox.

AuditBox not only makes NFV compatible with auditing, but also provides stronger guarantees than traditional auditing procedures. In traditional auditing, administrators test the system for correctness on a schedule, e.g., once per month. In contrast, AuditBox continuously self-monitors for correct behavior, proving runtime guarantees that the system remains in compliance with policy goals. Furthermore, AuditBox remains compatible with traditional auditing practices by providing sampled logs which still allow auditors to inspect system behavior manually. AuditBox achieves its goals by combining trusted execution environments with a lightweight verified routing protocol (VRP). Despite the complexity of routing policies for service-function chains relative to traditional routing, AuditBox's protocol introduces 72-80% fewer bytes of overhead per packet (in a 5-hop service chain) and provides 61-67% higher goodput than prior work on VRPs designed for the Internet.

1 Introduction

Modern networks contain a myriad of *network functions* (NFs) such as firewalls, intrusion detection systems, normalizers, exfiltration detectors, and proxies. Beyond security and performance benefits, a key driving factor for NFs is that they are mandated by legal and policy requirements; *e.g.,* HIPAA [8], FERPA [7], and PCI [13], among others.

While *network functions virtualization* (NFV) promises potential benefits in cost, elasticity, and richer policies [32, 58, 63], there is significant resistance to adoption of NFV [6] for such regulatory use cases. Conversations with industry experts suggest that this reluctance stems from the inability to audit NFV deployments to demonstrate *compliance* as mandated by standards [15, 41]; *i.e.,* show that the service function chains (SFC) are correctly implemented and packets traverse the intended sequences of NFs in the right order.

With legacy hardware NF deployments, administrators and auditors can simply look at static wiring and hardware placement to intuitively verify ('what you see is what you get') if the network meets intended requirements.[1] In contrast, NFV introduces new dimensions of dynamism, virtualization, and multiplexing in the environment. For instance, VMs running NFs may be ephemeral, virtual switches may multiplex several services, and servers may host multiple services. Enhanced dynamism and a larger attack surface make NFV systems harder to reason about and as such, regulators do not have suitable tools for auditing. This lack of auditing is a fundamental stumbling block for NFV adoption.

To this end, we propose (1) *formal models* of correct SFC routing which clarify 'correctness' in the context of dynamic NF scheduling and routing; and (2) a protocol which *provably* provides *continuous* assurance that packets follow the (formally specified) policy-mandated paths.

Realizing this vision in a practical system, however, is challenging. To see why, consider traditional *verified routing protocols* [46, 55] (VRPs). At a high level, VPRs cryptographically ensure that packets are not modified in flight and do not deviate from a traversal of a prespecified sequence of routers. Unfortunately, VRPs fail to provide the required capabilities for our setting. First, VRPs assume that packets will traverse their path unmodified, but NFs can legitimately modify packets. Second, VRPs assume that the correct route for packets is fixed and known a priori, but in SFC the correct route for a packet may only be revealed mid-flight. Third, these approaches focus on per-packet behavior, whereas NFV often involves stateful NFs whose semantics depend on cross-packet state. Furthermore, VRPs have prohibitively high performance overhead; *e.g.,* OPT [46] increases min-sized packets by 3× for a 4-NF chain, and even the most recent work EPIC [47] incurs 1.69× overhead for a strong attack model.

In this paper, we present the design and implementation of AuditBox, which (1) re-enables status-quo 'what you see is what you get' auditing practices, and (2) raises the bar by enforcing *at runtime* that the system operates correctly. AuditBox builds on four key ideas:

- *Using secure enclaves:* To ensure that the correct NF software is running, AuditBox runs them atop hardware enclaves (*e.g.,* Intel's SGX [25]). By changing the trust model, we reformulate verified routing to audit actions between *trusted* NFs, with an untrusted network in between.
- *Trusted PacketIDs:* To tackle dynamic packet modifications, *immutable packetIDs* are carried by an AuditBox packet trailer. This enables us to logically bind modified packets to incoming packets when creating audit trails.
- *NF-hop-by-hop protocols:* Given trusted NFs, we devise a simplified path attestation protocol that focuses on the packets at individual "NF hops". This hop-by-hop attestation has the dual benefit of addressing dynamic paths and reducing the size of attestation headers.

[1]As we argue later, this is indeed a weak guarantee, but today's NFV deployments lack tools even for this weak property.

- *Lightweight simplified operations:* The use of trusted NFs inside enclaves enables a number of simple-yet-effective cryptographic optimizations such as the use of symmetric keys and *updatable MAC* computations to significantly improve data plane performance.

To realize these ideas with minimal modifications to NF implementations, AuditBox embeds a trusted SFC routing shim in the enclave alongside the NF. The shim receives inbound/outbound packets to/from the NF and is simultaneously responsible for generating *audit trails* for traditional auditing practices and for our new goal of enforcing *runtime checks* that the untrusted components of the system behave as expected. Relative to verified routing protocols for the Internet, AuditBox introduces 72-80% less per-packet header overhead (assuming a 5-hop service chain) and offers 62-67% higher goodput in the dataplane.

Nonetheless, auditability in AuditBox (or any such framework) does come at a cost relative to an uninstrumented NFV cluster (*e.g.,* 3%-38% overhead for s single NF as shown in Figure 16). That said, for security-sensitive settings, regulatory compliance is a fundamental requirement for NFV deployment. Hence, AuditBox's essential advantage is in bringing the benefits of ease of management, lower-cost equipment, faster upgrades and security patches, and flexibility that are associated with NFV to new markets where it would not have been viable previously. Indeed, we estimate that AuditBox, despite its overheads relative to uninstrumented NFV, can still result in capital savings of 1.9-60× (depending on the appliance) relative to traditional hardware middlebox solutions.

2 Background and Motivation

We begin by discussing network compliance today (§2.1), our problem statement (§2.2) and threat model (§2.3), and finally discuss why compliance for NFV is challenging (§2.4).

2.1 Tussle Between Compliance and NFV

Modern organizations need to satisfy a number of security standards for compliance with government and industrial regulations (*e.g.,* HIPAA, FERPA, FISMA, GDPR, and PCI, among others) [66]. In this paper, we focus on requirements or *controls* related to network security under NIST 800-53 [41] in the United States:[2]

- *Middleboxes must be deployed to protect sensitive data and systems:* Control SC-7 mandates the need for protection devices (*e.g.,* proxies, gateways, firewalls, guards, encrypted tunnels) arranged in an effective architecture.
- *Administrators must periodically test that security infrastructure is running properly:* Control SI-6 demands that these inspections be performed periodically, with 'once a month' as an example acceptable frequency.
- *Systems must provide logs of anomalies and past behavior:* Control AU-2 requires systems to keep such records for later analysis for auditing.

[2]ISO 270001 [15] has similar international standards.

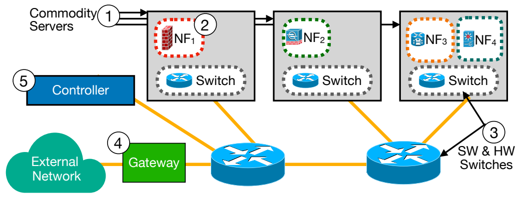

Figure 1: Components of a basic NFV cluster.

- *Independent 'auditors' must certify that security mechanisms are in place and running correctly:* Control CA-7 mandates that organizations be 'certified' by outside auditors (*e.g.,* third-party IT consulting companies) that the above requirements (among others) are being met.

Reluctance to adopt NFV: To meet the above compliance requirements, there is a large regulatory technology ('RegTech') industry [66] (expected to surpass \$55.28B by 2025). One might expect then that this RegTech market would be an early adopter of NFV to reduce capital and operating expenses. However, our conversations with representatives from NIST and a RegTech firm revealed that this industry is *hesitant* to adopt NFV. The key reason is that while NFV lowers the bar for some aspects of compliance (*e.g.,* SC-7), it makes other requirements such as SI-6, AU-2, and CA-7 difficult, if not impossible.

In hindsight, this reluctance is not surprising. NFV introduces new dimensions of dynamism and multiplexing (*e.g.,* shared hosts running VMs, dynamic overlay routing, dynamic load balancing). This makes it harder to reason about the deployment and introduces an increased attack surface for threats (and misconfigurations). In contrast, a simple statically-wired NF deployment with hardware boxes seems intuitively easy to test, audit, and demonstrate compliance to external auditors.

2.2 Problem Setup

We consider an NFV cluster managed by a framework such as E2 [58], AT&T Domain 2.0 [2], or Blue Planet [3]. At a high level, NFV clusters consist of five basic components (Figure 1): (1) *Commodity servers* on which containerized or virtualized NFs run; (2) *Network Functions* such as firewall, proxy, or IDS; (3) *Software and Hardware Switches* that steer traffic between a sequence of NFs; (4) *Gateways* where cluster traffic enters; and (5) a *Controller* responsible for provisioning NFs on the servers and defining routes through them. NF instances are composed to create *service function chains* (SFC) policies for specific traffic classes (*e.g.,* Gateway → Firewall → Proxy → IDS → Gateway).

To make these systems *auditable*, we need to verify that: (1) the correct and untampered NFs are running correctly and (2) packets traverse these NFs according to policy. We formally define what it means for traffic to traverse NFs 'according to policy' in §4. Furthermore, to meet the compliance requirements, operators must be able to inspect and demonstrate that the correct behavior is happening; *e.g.,* trigger tests to observe that packets follow policies (SI-6) and

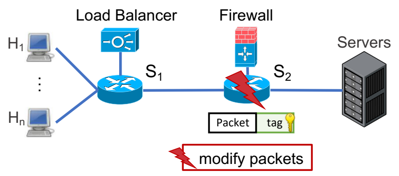

Figure 2: MACs for integrity are invalidated by rewritten packets.

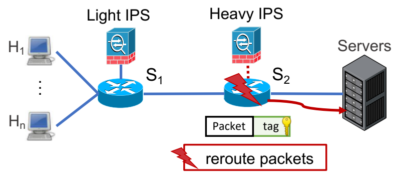

Figure 3: Rerouting traffic and bypassing the heavy IPS.

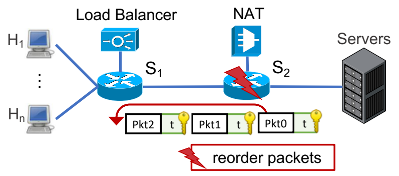

Figure 4: Reordering packets effects NF state and future packets.

produce *audit trails* for external inspectors.

To 'raise the bar' for auditability, we add two additional requirements. First, rather than merely enabling administrators to test on demand or post-facto whether or not the system is or was running correctly, we also want to enable the system to *audit itself, continuously, at runtime* for deviations from correct behavior, and to alert administrators if such a deviation is detected. Second, we also want to support rich *dynamic* SFC policies as opposed to traditional static service-chain policies; *e.g.,* steering packets tagged as suspicious by earlier NFs for deeper inspection [32].

In this context, we note that while auditability may seem related to *network verification* (*e.g.,* [44, 45, 60, 74], the requirements are fundamentally different on two fronts. First, most existing network verification efforts simply look at the configurations of the network elements such as NFs/switches and formally verify if the configuration meets intended policies. It does not typically provide any runtime guarantees about data plane actions. Second, network verification *can* be used to provide evidence of correct operation [45] but it does not provide 'what you see is what you get' audit trails; in this regard, verification could be coupled with audit trails to provide additional evidence of compliance.

2.3 Threat Model

Although most operators are primarily concerned with cluster misconfiguration rather than outright attacks, we target a stronger threat model as follows. First, what is trusted: the controller is the arbiter of correct policy and how NFs should be scheduled; we assume that the controller is trusted, and we do not consider attacks where a 'lead' administrator (that is, an administrator charged with configuring policies at the controller) provides invalid or malicious policies to the controller. In the case of the gateway and the NFs, we assume there exists vendor-certified code which is digitally signed. This code is privileged to drop or rewrite packets, and we exclude NFs that can inject packets.

Most other components of the network are untrusted. An attacker may attempt to corrupt server software (including the operating system and/or VMM), NF and gateway software, and the software and hardware of the switches. The attacker can cause one or more corrupted components to inject, drop, or rewrite packets.

Our solution builds on the 'abstract enclave assumption' defined by prior research [17, 18, 61]: the attacker cannot observe or modify any data or program code running within an enclave, and the enclave is trusted to attest to the integrity of the code running therein. While existing enclave solutions – such as SGX, which we build on – fall short of meeting the abstract enclave assumption perfectly [22, 24, 36, 54, 73], fixing the shortcomings of current enclave solutions is out of scope for this work, as such fixes are an active area of research in their own right [26, 34].

2.4 Challenges

At first glance, it would appear that we can borrow from prior work on *verified routing protocols* (VRPs) that cryptographically guarantee that a packet takes a pre-specified intended path and is not modified in flight (*e.g.,* [46, 49, 55, 77, 80–83]). We use OPT [46] as an exemplar state-of-art solution from this class. Specifically, OPT extends each packet with: (a) a cryptographic hash of the packet contents and (b) its expected switch-level path. Every router along the path verifies that the packet's current hash matches the header and also adds attestations to ensure the packet has matched the expected sequence. As we will see next, our NFV auditability problem introduces new dimensions outside the scope of these prior efforts.

Mutable Packets: Figure 2 shows two NFs: a load balancer that modifies the destination IP to distribute the load across multiple backend servers and a firewall configured to block packets from malicious IPs. Consider the scenario where switch S_2 (either adversarially or via misconfigurations) modifies the IP header to bypass the firewall. Because NFs can legitimately modify packet headers, it is difficult to distinguish whether this action was malicious or an intended NF action. OPT-like VRPs assume that most packet fields are immutable and perform crypto operations by excluding a few mutable packet fields (*e.g.,* TTL), and hence would generate a large number of false positives by flagging all legitimate NF modifications.

Dynamic Paths: Consider a dynamic SFC scenario in Figure 3, where a lightweight IPS performs basic detections and then routes suspicious packets to the heavy IPS for further processing. Again, an adversarial or misconfigured device could reroute all suspicious packets to bypass the heavy IPS, and it is hard to tell whether this was the result of the light IPS's action or a malicious switch. Because the intended path cannot be determined until the light IPS finishes processing, OPT-like VRPs – which must pre-specify the end-to-end route of the packet – are not applicable to this network.

Stateful Behavior: NFs' stateful semantics mean that per-packet auditability may not be sufficient. We may also need to ensure that all packets in a given flow follow the same path and that they arrive in order if we wish to ensure the stateful semantics are not compromised. To see why, consider Figure 4, which shows two stateful NFs: a layer 4 load balancer to distribute packets based on source IP and port and a NAT that maps public ports to private ports. Consider an adversary (or misconfiguration) that reorders packets and sends the `FIN` packet before the data packets. This could cause all following data packets to be discarded by the load balancer. This highlights a fundamental limitation of VRPs: because they reason about correctness of each packet independent of the others, there may be cross-packet policy violations which they cannot capture.

3 AuditBox Overview

Our goal in designing AuditBox is to provide auditing capabilities for NFV deployments. In practice, we also want: R1) *minimal modifications* to existing NFs and R2) *low overhead* on the data/control paths. In this section, we discuss some of the key ideas in AuditBox and its overall architecture.

3.1 Key Ideas

We first discuss the main ideas that enable AuditBox to tackle the challenges of packet modifications (C1), dynamic paths (C2), and stateful actions (C3) while meeting the practical requirements of minimal NF modifications (R1) and low overhead (R2).

A) Running NFs in enclaves atop a shim: Inspired by the trust guarantees provided by prior work [39,61,70], AuditBox runs NFs in trusted enclaves. This enables AuditBox to trust those modifications that are validly introduced by NFs (C1). To avoid modifying existing NFs (R1), we introduce a trusted shim in each enclave to perform auditing (§5.4). This shim also ensures that the next-hop NFs are chosen based on the intended policy (C2).

B) Trusted Packet ID: Mutable packets (C1) make it hard to generate audit trails as we cannot causally relate NF-modified packets to their inputs (§4). To tackle this, we introduce an *immutable packet ID*, carried by the packet header (§5). We envision a *trusted gateway* (running in an enclave) that generates and assigns this ID when the packet first arrives in the NFV cluster; the packet ID is carried through NFs even if the packet itself is modified or rewritten by NFs.

C) NF-Hop-by-hop updated attestations: We leverage the trusted shim in each enclave to develop a hop-by-hop attestation protocol in which each *pair* of shims attest that the packet was delivered, without improper modification between an NF and its policy-compliant successor. Compared to the end-to-end approach taken by traditional VRPs, hop-by-hop attestation has the dual benefit of supporting *dynamic paths* and also *reducing packet overheads*.

D) Efficient crypto mechanisms: By using trusted enclaves, we can use *one symmetric key* for all NFs in the same policy pipelet (§3.3), to simplify the cryptographic operations and also introduce new opportunities for efficiency. For example, we implement an efficient *updatable MAC* algorithm to improve the performance of repeated attestations to the packet at each hop (§6.1).

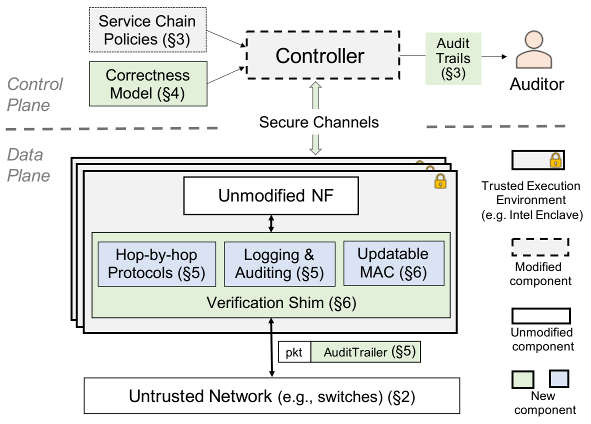

Figure 5: AuditBox Architecture.

3.2 AuditBox Architecture: Data Plane

The key components of the AuditBox architecture are illustrated in Figure 5.

In the data plane, AuditBox runs unmodified NFs in trusted execution environments (TEEs) to isolate them from other untrusted network components (*e.g.,* switches, OSes). Although our current implementation (§6) uses Intel SGX enclaves, our design in principle can be realized using other TEE technologies such as Arm TrustZone [1]. The key capabilities we leverage are attested memory isolation and integrity during program execution. In each enclave, we add a shim which intercepts the traffic entering/exiting the NF to serve three purposes. (1) The shim determines the correct next-hop NF according to a policy it received from the controller; this is no different than any other NFV policy manager such as FlowTags [32] or E2 [58].

The second two tasks for the shim are novel to AuditBox and form the entirety of sections 4, 5, and 6 and so we only introduce them briefly here. (2) The shim checks each incoming packet to verify that the packet has not been improperly routed or modified while traversing the untrusted network between enclaves; on egress the shim attaches a custom trailer (called AuditTrailer) along with a MAC attesting to the contents of the packet and trailer so that the next-hop NF can similarly verify the packet was routed correctly. (3) The shim logs any packets to local storage which *either* appear to violate policy, *or* are tagged via a secret 'log bit' for recording.

3.3 AuditBox Architecture: Control Plane

The controller serves two key purposes: NF deployment and management, and serving as an interface for an administrator to inspect logs and audit trails.

NF Deployment: NF deployment includes scheduling NFs

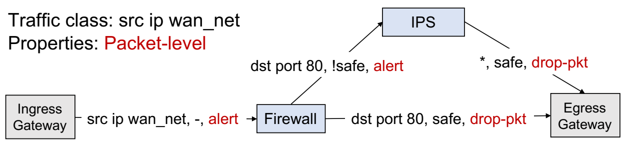

Figure 6: An annotated policy graph.

on servers, verifying enclave attestations that the correct NF software is running at each NF, distributing and updating the global symmetric key used for dataplane verification, and installing the correct *next-hop policies* at each enclave.

Policies are roughly similar to other DAG-based policy languages [31, 32, 58]: network operators specify *policy pipelets* where nodes represent NFs and edges are annotated with traffic classes and where they should be routed according to policy (illustrated in Figure 6). AuditBox augments this traditional policy with two new parameters: a *correctness model* which defines what behavior in the network constitutes a violation (presented in §4) and *violation annotations* on each edge to determine whether packets which violate the correctness model should be dropped or raise an alert. From this policy, the operator can define a function which, for a given packet egressing an NF, can determine what the correct next-hop NF to deliver the packet to is; this function is installed in the shim at each enclave along with the assigned violation action to take in case, *e.g.,* a packet is corrupted inflight between enclaves.

Logging and Audit Trails: Auditors and administrators can use the controller to query for *logs* (records of any anomalies or policy violations) and *audit trails* (the end to end path a packet takes through the cluster, and all intermediate rewritten states of the packet between NFs). By default, each enclave stores logs and audit trail records to local storage, encrypted with a symmetric key that is local to that NF; the controller sets up pairwise keys with each NF for log and audit storage. Because it is infeasible to log every packet through the system, the administrator configures a sampling policy; we discuss the sampling policy, the logging mechanism, and the security of the logs in §5.4.

4 Formalizing Correctness

We begin by formally defining what it means for a system to **(a)** obey correct routing, and **(b)** support auditing.

Correct Routing: Since networked forwarding elements are untrusted, we rely on a trusted shim in each SGX enclave to verify at runtime that the network has not deviated from correct behavior. §4.2 defines 'correctness' with regard to network forwarding behaviors, *i.e.,* those verified by the shim.

Auditability: Our verified routing approach operates on a hop-by-hop basis; as we discuss in §5 this simplifies our protocol and limits its size overhead. However, auditors expect *end-to-end* evidence (upon inspection) that the system is operating correctly. An 'audit trail' consists of a recorded sequence of *causally connected* operations across devices – *e.g.,* packet p entered at the gateway, was processed by NF_i resulting in p', which was processed by NF_j, and resulted in p'', which was released through the gateway. Due to space constraints, we defer our formal definition of an 'audit trail' to §B.2.

Prior to introducing our formal definitions (§4.2), we define our model of the network (§4.1). We make a few assumptions for the sake of simplifying our presentation. All can be relaxed at the cost of additional notational complexity. First, we assume that the cluster has a single ingress/egress 'gateway' where packets transit to/from the primary network. We similarly assume that each NF has only one ingress/egress port. Finally, we assume that forwarding within the cluster is performed at L2, and hence it is not necessary for network switches to update any TTL values or checksums, *i.e.,* there is no need for the network to modify packets.

4.1 Definitions

Time: We model time as an ordered sequence E, the set of all *events* in the system. E is initialized to $[]$, that is, empty.

As the (modeled) system runs, NFs in the system populate E with 4-tuples containing the following named values:

- $\mathbf{pkt}_{\mathrm{in}}$: a packet received ($\in P$, defined below).
- $\mathbf{pkt}_{\mathrm{out}}$: a packet sent ($\in P$).
- **NF**: the network function ($\in F$, defined below).
- **t**: the logical 'time' the packet was received or sent (*i.e.,* the index in E); represented as a positive integer ($\in \mathbb{N}$).

We may refer to members of $e \in E$ as $e.\mathrm{pkt}_{\mathrm{in}}$, $e.\mathrm{pkt}_{\mathrm{out}}$, $e.\mathrm{NF}$, or $e.\mathrm{t}$. We *index* E using array notation *e.g.,* $\mathrm{E}[43] = (*,*,*,43)$. We may also search E for events matching the specified value at a specified field using the function $\text{get-event}_E(\text{field, value}) \rightarrow [\mathrm{E}]$, for example, $\text{get-event}_E(\mathrm{pkt}_{\mathrm{in}}, p_i)$ returns the sequence of all events in E where p_i was received as input at an NF.

Note that, although AuditBox provides some logging mechanisms, *there is no globally ordered event log in the system implementation* – the event sequence defined here is merely an abstraction to help reason about time while modeling.

Packets: P is the set of all 64-9000 byte binary strings, that is, P is the set of all (up to jumbo framed) Ethernet packets. Each packet p contains an Ethernet header and an IP header. Depending upon the NFV framework, the packet may also contain a collection of 'metadata' fields such as FlowTags [32] or a Network Service Header (NSH) [64]. If the packet represents a TCP or UDP packet, we represent the classic flow 5-tuple (source IP address, destination IP address, source port, destination port, protocol) through the function $\textsc{flow}(p)$.

As a packet p traverses the network, it may be transformed into some p' or p'' through modifications to the payload or metadata fields. If the data *anywhere* in the packet – that is, the 64-9000 byte binary string it represents – has been changed, then $p \neq p'$. In the event log, $e.\mathrm{pkt}_{\mathrm{in}}, e.\mathrm{pkt}_{\mathrm{out}} \in P$.

NFs: There is a set of Network Functions F. Each $\mathrm{NF}_i \in F$ is a function,[3] $\mathrm{NF}_i : P \rightarrow P \cup \{\perp\}$. That is, it takes in a packet and produces another packet (or null).

[3]Called a 'transfer function' elsewhere in the literature [44, 60].

In our model, we assume NF_i encloses some NF_i-specific function $f_i : P \to P \cup \{\perp\}$, which may keep state, modify packet contents, etc. When NF_i takes in a packet and f_i returns null, this represents a drop. We exclude NFs that could inject new packets.

With respect to the event log E, we log each operation at NF_i as follows:

Algorithm 1 NF Model

```
1: function NF_i(input)
2:     output ← $f_i$(input)
3:     if output $\neq \perp \vee$ input $\neq \perp$ then
4:         $E$.append(input, output, NF_i, $E$.length + 1)
5:     return output
```

Switches: Like prior work in SDN and formal modeling [44], we consider the network as 'one big switch' or a 'fabric' and we model its behavior with a single function $\Phi : P \cup \{\perp\} \to P \cup \{\perp\}$. In our threat model, Φ is the untrusted part of the system. Φ is not considered an NF ($\Phi \notin F$), and Φ does not append to E.

Gateway: Packets enter and exit the cluster – and hence enter and exit the model – via a dedicated NF, GW which, like other NFs, also appends to the event sequence. We model the Gateway as GW_{in} when a packet enters the cluster via the gateway as follows:

Algorithm 2 Model of Packets Entering the Cluster

```
1: function $GW_{\text{IN}}$(input)
2:     if input $\neq \perp$ then
3:         $E$.append($\perp$, input, $\mathrm{GW}_{\text{in}}$, $E$.length + 1)
4:     return $f_{in}(input)$
```

Like normal NFs, the gateway applies a gateway-specific function f_{in} to the packet before transmitting it. We define GW_{out}, for when a packet exits the cluster similarly (§B.1).

Path: Packet processing occurs via traversal of a sequence of NFs and switches. Whenever an NF sends a packet, it is passed to the network which is expected to steer the packet to the next NF specified by the service-chain policy. When a new packet arrives at GW_{in}, we model traversal of the network via a nested function of Φ and elements of F, for example: $\mathrm{GW}_{\text{out}} \circ \Phi \circ \mathrm{NF}_i \circ \Phi \circ \mathrm{NF}_j \circ \Phi \circ \ldots \circ \Phi \circ \mathrm{GW}_{\text{in}}$.

Policy: There are many languages [32, 58] and services for specifying service-chain policy. Here we assume that for a packet and an NF which just produced that packet, that there exists some *policy function* ($\text{policy} : P \times F \to F$) that can determine the NF that should next process the packet. Importantly, we assume that the information necessary to determine the right next hop relies only in the packet fields (*e.g.,* IP header, metadata) and the departing NF.

4.2 Correctness

We give two possible definitions of "correct" forwarding below, based on properties of the modeled event log E.

4.2.1 Packet Correctness

Our first definition, packet correctness, is based on the UDP service model of packet delivery. Under the packet-correctness definition, the system is 'correct' even if packets are reordered, dropped, or duplicated between NFs. The behaviors which are incorrect under this model are limited to **(a)** injecting packets which were not sent by an end host, or **(b)** modifying/corrupting packets between sender and receiver.

Packet correctness holds iff Property 1 holds over E.

$$\forall e_b \in E \text{ s.t.}: e_b.\text{pkt}_{\text{in}} \neq \perp, \tag{1}$$
$$\exists e_a \in E \text{ s.t.}: e_a.\text{t} < e_b.\text{t} \wedge e_a.\text{pkt}_{\text{out}} = e_b.\text{pkt}_{\text{in}} \tag{2}$$
$$\wedge \text{policy}(e_a.\text{pkt}_{\text{out}}, e_a.\text{NF}) = e_b.\text{NF} \tag{3}$$

Property 1: No Injection or Modification

To summarize the above: for all events e_b in which an NF e_b.NF receives and processes a packet, there exists a prior event e_a in which e_a.NF sends the same packet to e_b.NF.

4.2.2 Flow Correctness

Flow correctness is based on the TCP service model. Like packet correctness, a network where packets are injected or corrupted by the network is not correct. To meet flow correctness, the network also must not drop packets, reorder packets within a flow, or duplicate them. Hence, the network obeys Flow Correctness iff it respects Property 1 and the following three properties.

The first additional property aims to verify that the network has not dropped any packets in flight. An absolute guarantee that no packets are dropped is impossible, as the NFs cannot force hostile network elements to deliver packets. Hence, we instead define our 'no drops' property to state that packets in a given flow that *do arrive* at their own destination may only be accepted if all packets previously transmitted from that flow to that destination have already arrived. To achieve this, Property 2 ('No Drops') says in English that if a packet $e_{a2}.\text{pkt}_{\text{in}}$ is sent by e_{a2}.NF and received at e_{b2}.NF, then any other earlier packet $e_{a1}.\text{pkt}_{\text{out}}$ belonging to the same flow and also destined for e_{b2}.NF should have already been received by e_{b2}.NF prior to $e_{b2}.\text{pkt}_{\text{in}}$.

$$\forall \mathrm{NF}_a, \mathrm{NF}_b \in F, \forall e_{a1}, e_{a2}, e_{b2} \in E \text{ s.t.}: \tag{4}$$
$$(e_{a1}.\text{t} < e_{a2}.\text{t} \wedge e_{a1}.\text{pkt}_{\text{out}} \neq \perp \wedge e_{a2}.\text{pkt}_{\text{out}} \neq \perp \tag{5}$$
$$\wedge e_{a2}.\text{pkt}_{\text{out}} = e_{b2}.\text{pkt}_{\text{in}} \tag{6}$$
$$\wedge \text{policy}(e_{a1}.\text{pkt}, e_{a1}.\text{NF}) = \text{policy}(e_{a2}.\text{pkt}, e_{a2}.\text{NF}) \tag{7}$$
$$\wedge e_{a1}.\text{NF} = e_{a2}.\text{NF} = \mathrm{NF}_a \wedge e_{b2}.\text{NF} = \mathrm{NF}_b \tag{8}$$
$$\wedge \text{flow}(e_{a1}) = \text{flow}(e_{a2})) \implies \tag{9}$$
$$(\exists e_{b1} \in E \text{ s.t.}: \tag{10}$$
$$(e_{b1}.\text{t} < e_{b2}.\text{t} \wedge e_{b1}.\text{NF} = \mathrm{NF}_b \wedge e_{b1}.\text{pkt}_{\text{in}} = e_{a1}.\text{pkt}_{\text{out}})) \tag{11}$$

Property 2: No Drops

Property 3 ensures that packets within a flow are not reordered between NFs. In English, the property specifies that if an NF_a transmits a packet $e_{a1}.\text{pkt}_{\text{out}}$ before a packet

e_{a2}.pkt$_{\text{out}}$ to the same NF$_b$, then e_{a1}.pkt$_{\text{out}}$ should also *be received* by NF$_b$ before e_{a2}.pkt$_{\text{out}}$.

$$\forall \text{NF}_a, \text{NF}_b \in F, \tag{12}$$
$$\forall e_{a1}, e_{b1}, e_{a2}, e_{b2} \in E \text{ s.t. :} \tag{13}$$
$$(e_{a1}.\text{pkt}_{\text{out}} = e_{b1}.\text{pkt}_{\text{in}} \wedge e_{a2}.\text{pkt}_{\text{out}} = e_{b2}.\text{pkt}_{\text{in}} \tag{14}$$
$$\wedge e_{a1}.\text{pkt}_{\text{out}} \neq \perp \wedge e_{a2}.\text{pkt}_{\text{out}} \neq \perp \tag{15}$$
$$\wedge e_{a1}.\text{NF} = e_{a2}.\text{NF} = \text{NF}_a \wedge e_{b1}.\text{NF} = e_{b2}.\text{NF} = \text{NF}_b \tag{16}$$
$$\wedge \text{flow}(e_{a1}) = \text{flow}(e_{a2})) \implies (e_{a1}.\text{t} < e_{a2}.\text{t} \iff e_{b1}.\text{t} < e_{b2}.\text{t}) \tag{17}$$

Property 3: No Reordering Within the Same Flow

$$\forall e_a \in E, \nexists e_b \in E \setminus \{e_a\} \text{ s.t. : } e_a.\text{pkt}_{\text{in}} = e_b.\text{pkt}_{\text{in}} \tag{18}$$

Property 4: No Duplication

Finally, we ensure that packets are not duplicated in the networks ('replay attacks') with Property 4. We note that the Property 4 formalization assumes that the same packet is never sent by any NF more than once. This seems to be a reasonable assumption. As we are forwarding under L2, an NF$_A$ and an NF$_B$ will always have different Ethernet headers even if the IP, TCP/UDP, and payload are identical. And it seems reasonable to assume that an NF$_A$ will never transmit the same packet twice either – even a re-transmitted TCP packet will come with a different IPID value. However, we discuss how to revise this formalism to allow NFs to duplicate packets in §A.

5 AuditBox Protocol

In this section, we focus on the dataplane protocol. We begin by providing a high-level view of the actions that each AuditBox-enabled node performs at each hop (§5.1). Then we discuss the detailed construction of the attestation check and update logic we use for packet- (§5.2) and flow-level (§5.3) correctness. We envision different NFV deployments can flexibly choose one of these levels of correctness as desired. Finally, in §5.4 we describe the secure logging mechanisms which allow auditors to observe audit trails demonstrating that the system is operating correctly.

5.1 High-level workflow

AuditTrailer: AuditBox adds an AuditTrailer, carried by the packet, to verify integrity. We discuss the contents of AuditTrailer in packet-level and flow-level form in detail in §5.2 and §5.3 respectively; here we briefly present the two foundational fields for auditing and runtime correctness. These fields are present in both the packet-level and flow-level versions of the AuditTrailer.

pktID is a unique, immutable ID assigned to a packet; when a packet enters an NF and is modified or rewritten, the *pktID* allows us to identify for each input packet which output packet (if any) is a result of its processing. This tracing is the key mechanism which enables us to generate audit trails – the causal sequence of events we present in §B.2.

tag is a message authentication code (MAC) which allows us to identify if a packet has been improperly modified while in flight between two (trusted) shims. Operationally, the tag is a Galois Message Authentication Code (GMAC), computed using a symmetric key over various packet fields (discussed below in §5.2 and §5.3). The *tag* field enables us to perform runtime correctness checks while running with untrusted operating systems, switches, *etc.*.

Data Plane Actions (Shim and Gateway): The AuditBox dataplane protocol is implemented at the gateway to/from the cluster and at the shims inserted into each NF enclave.

At the Gateway: For each incoming packet, the ingress gateway generates an AuditTrailer (including a unique pktID field) and appends it to the packet, and then forwards it to the next NF. At the end of the service chain, as packets leave the cluster, the egress gateway validates the AuditTrailer (assuming the validation passes), and then removes the AuditTrailer and forwards the packet out of the cluster.

At the Shim: At each hop, the shim receives the incoming packet and performs the following four operations: Check, Process, Update, and Log. *Check* validates the received packet, including verifying the MAC stored in the *tag* field, to verify that the received packet was not incorrectly modified by the network. *Process* hands the packet to the actual NF code; when the packet is returned from the NF, the shim then *Updates* the AuditTrailer (*e.g.,* computing the new *attestation* field). Finally, in certain cases the shim *Logs* the packet and certain metadata to produce an audit trail; the packet is then released to its next hop in the service chain.

5.2 Packet Correctness Protocol

As presented in §4.2.1, the goal of our packet correctness protocol is to ensure that packets are not injected or modified by the network, *i.e.,* that all packets received and processed by an NF were transmitted *to* that NF by another NF or the ingress gateway.

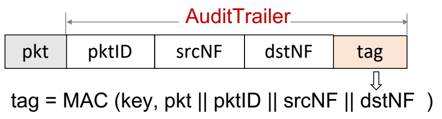

Figure 7: The AuditTrailer for packet-level integrity.

For packet correctness, the AuditTrailer (Figure 7) contains the following fields: pktID (6 bytes), tag (16 bytes), srcNF (2 bytes), dstNF (2 bytes). As discussed above, the pktID is required for generating audit trails so we do not discuss it further here other than to require that it be transmitted alongside other packet fields (IP header, payloads, *etc.*) uncorrupted by the network. Naïvely, one might simply compute the MAC over the packet and pktID to compute the tag. However, this would only meet a portion of the clauses from Property 1 – that there exists *some* valid NF which transmitted this packet. If a malicious or misconfigured switch delivers a valid packet, intended for some NF A, to NF B, the packet would appear to have a valid tag.

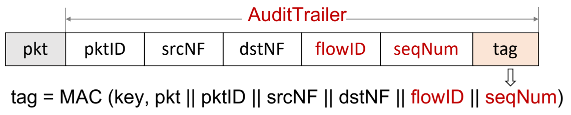
Adding the srcNF and dstNF fields explicitly to the header bind the packet to the *policy-compliant route*, meeting the final clause of Property 1. The sender explicitly encodes its own NF ID and the intended destination NF ID into the packet and computes the MAC over the packet, pktID, srcNF, and dstNF fields. The receiver, by validating the MAC stored in the tag, can be sure that the sending NF intended to send the packet to the receiver; the receiver can also (redundantly, as a sanity-check) re-compute the policy compliant next-hop NF for the received packet and the source NF to further verify that it is indeed the correct recipient.

We specify this protocol in Algorithm 5 and prove that it meets the requirements of Property 1 in Appendix D.

Theorem 1 (Packet Correctness) *Consider the game described in §D.3 with adversary $\mathcal{A}$ and instantiated with the AuditBox packet-correctness protocol. Specifically, looking at Algorithm 5, we instantiate f_{in} with the function* GENERATE *and f_i with* PROCESS$_i$*. The probability that the game outputs an event log E that violates Property 1 is negligible.*

5.3 Flow Correctness Protocol

We now discuss the implementation of the Flow Correctness Protocol, which in addition to Property 1 also meets Properties 2, 3, 4. We envision that networks that use only stateless or order-insensitive NFs will prefer the lighter packet-correct protocol, but those with stateful NFs whose operations are sensitive to packet ordering may use the stronger flow-correctness protocol.



AuditTrailer
pkt
pktID
srcNF
dstNF
flowID
seqNum
tag
tag = MAC (key, pkt || pktID || srcNF || dstNF || flowID || seqNum)

Figure 8: The AuditTrailer for flow-level integrity.

As shown in Figure 8, to extend the AuditTrailer for flow-level semantics, we add two additional fields over the packet-level version: a flowID field (4 bytes), and a seqNum field (4 bytes). The tag is now computed over the packet and all fields including flowID and seqNum.

When packets enter the cluster through the gateway, the gateway hashes the classic '5-tuple' and looks this up in a flow table mapping 5-tuples to flowIDs. If a flowID already exists for this flow, the gateway appends the existing flowID to the AuditTrailer. If a flowID does not exist for this flow, the gateway assigns an unallocated ID number to the flow and inserts this into the flow table and the packet. For non-TCP and non-UDP packets, the flowID is simply set to 0. Like the pktID, the flowID is unmodified as packets flow through the network – even if header values and port numbers are rewritten, the flowID remains the same across NFs; as we will show, this is important for the creation of audit trails (§5.4).

seqNum values are maintained per-hop and represent the ordering of packets between a sending NF$_A$ and a receiving NF$_B$ for a given flow. The sending NF maintains an incrementing per-flow counter, and, for each packet from the same flow, appends the sequence number to the seqNum field in the AuditTrailer. At the receiver, there is a corresponding table of per-flow counters with the next sequence number expected. In our implementation, there is no reason for in-network reordering within a flow and hence the receiver raises an alert for any out-of-order packets; we could configure the receiver to maintain a small buffer to wait for reordered packets and put them back in order for processing in a cluster (and to only raise an alert after multiple out of order arrivals) where reordering were for some reason possible. Thus, packets are discarded at the receiver if they *either* fail the tag verification *or* fail the expected-next-sequence number test.

Because the protocol rejects out-of-order packets, it easily meets Property 3. Since duplicate packets will have the same sequence number, they are detected. Thus, the protocol also meets Property 4. Finally, if a packet is dropped, the arrival of subsequent packets will induce alerts due to out-of-order sequence numbers, meeting Property 2.[4] We specify this protocol in Algorithm 6 and formally prove its security in Appendix D.

Theorem 2 (Flow Correctness) *Consider the game described in §D.2 with adversary $\mathcal{A}$ and instantiated with the AuditBox flow-correctness protocol. Specifically, looking at Algorithm 6, we instantiate f_{in} with the function* GENERATE *and f_i with* PROCESS$_i$*. The probability that the game outputs an event log E that violates Properties 1-4 is negligible.*

Why not use existing TCP sequence numbers? Rather than embedding an additional sequence number, one might attempt to naïvely re-use the sequence number already embedded in TCP flows to save additional bytes in the header. However, packets may *already be missing* when they enter the cluster (leading to sequence number gaps which are not the result of misbehavior within the cluster) and NFs may choose to drop packets (also creating legitimate sequence number gaps). Hence we need a new sequence number whose role is only to detect gaps that are the result of drops *between NFs* in our cluster.

Why not one sequence number per pair of NFs, rather than per-flow? At first glance, it may seem simpler to keep a sequence number across all flows rather than a sequence number per-flow. However, many NF implementations use receive side scaling (RSS) at the receive NIC to fan out packets across multiple cores; in such an architecture a unified sequence number becomes a performance bottleneck; per-flow counters are more parallelizable and hence more scalable.

5.4 Logging & Auditing

Traditional logging (as mandated by AU-2 in §2) focuses on recording packets which resulted in alerts, policy violations,

[4]However, an attacker who blocks *all* packets from a flow may go undetected – to avoid this noncompliance, a receiver detecting a flow with over a minute without transmissions will query the sender for its sequence number to detect any dropping behavior.

and anomalies. At each shim, any packet which results in a violation is logged in its entirety, including all fields of the AuditTrailer; the log is written to local storage and encrypted with an NF-local symmetric logging key provided by the controller.

AuditBox also records additional logged events to produce an 'audit trail', which restores 'what you see is what you get' confidence in the correctness of the underlying system. As defined in §B.2, an audit trail consists of a hop-by-hop trace of a packet (or all packets in a flow) through a sequence of NFs as well as their intermediary rewritten states.

The basic idea is as follows. The gateway probabilistically samples incoming packets and tags them with a 'log bit' which follows the packet through the cluster along with the AuditTrailer. Any packet whose log bit is set to true is logged at each shim, including all metadata or AuditTrailer fields. The administrator or inspector specifies three parameters to define which packets are sampled: (1) a Berkeley Packet Filter (BPF) to match for selected packets, (2) a sampling rate (*e.g.,* 0.001%), and (3) whether to log at the packet- or flow- granularity. Logging at the flow granularity is only permitted if the policy is in flow-correctness mode.

Upon querying, the administrator can then inspect manually (or via an automated script) the path of packets or flows throughout the entire system. Even if packet headers or fields are changed, the packetID or flowID are preserved between NFs; even in traditional service chain deployments such tracing is not possible today when NFs modify packets in a way that they cannot be connected to their corresponding inputs.

There is only one 'trick' to this very simple design: in a truly malicious environment, the network could selectively treat logged packets according to correct policy and only manipulate unlogged packets. Although we would still expect our runtime checks at each shim to detect the error, auditors would no longer be able to retrieve an audit trail associated with the violation. Hence, it is important that we *hide* the logging bit at the gateway so that that the attacker cannot mount such an attack. In the following section, as we discuss our implementation, we describe how the logging bit is stored virtually in a way that is cryptographically secure while consuming 0 bits of overhead in the AuditTrailer.

6 AuditBox Implementation

We now discuss two performance optimizations to our protocol (§6.1) and our end-to-end prototype (§6.2).

6.1 Optimizing Verification

Updatable GMAC: To support mutable packets and dynamic paths, AuditBox computes the MAC twice for each packet at each hop: first to verify the packet when receiving it, and second to authenticate the packet before sending it out (§5). In our implementation, we use the GMAC algorithm [53]. While GMAC is one of the fastest authentication algorithms (thanks in part to acceleration from Intel's AES-NI instructions [40]), it still adds non-trivial overhead to packet processing.

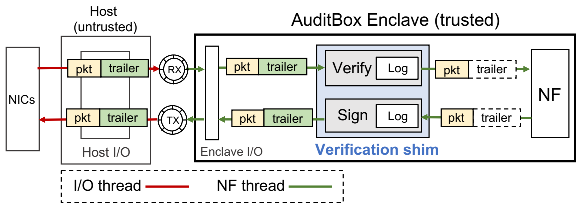


Figure 9: AuditBox software architecture (white boxes denote existing Safebricks components).

To reduce AuditBox's overhead, we implement a proven secure [52] *updatable* version of GMAC on top of EverCrypt [62], a formally verified cryptographic library. We use EverCrypt because it is easy to port into SGX and it is fast; its verified properties are a pleasant bonus. We defer to future work the extension of EverCrypt's formal verification to our updatable API.

The key optimization of updatable GMAC is to take advantage of GMAC's algebraic structure to securely *reuse* the first MAC when computing the second MAC [52]. With this optimization, the second MAC's cost is proportional to the number of modified data blocks, rather than the total packet length. In practice, this improves performance for NFs that only read the packet or that modify a small portion of it (§7).

In addition to a key and a message, GMAC requires as input an initialization vector (IV) that must be unique for each MAC invocation with a given key. For this we use the concatenation of the srcNF and pktID fields. This leads to a bound on how long we can use the same key K_σ. At 100Gbps, we would expect to overflow the pktID once every 22 days and hence we use we use a 14 day key rotation which ensures that the same IV is never used twice. When the pktID wraps around, one can use timestamps to differentiate entries in audit trails.

Secret Logging: In §5.4 we discussed that we must encrypt the bit used to mark which packets should be logged for auditing; we now describe how we introduce 0 bits of overhead and 0 computational overhead for unsampled packets. Our idea is to embed a *virtual logging bit* in the AuditTrailer. When the ingress gateway generates the *tag*, it appends this virtual logging bit as the last field when computing the MAC. For example, $tag = \text{MAC}_{K_\sigma}(pkt||pktID||srcNF||dstNF||\ 1)$ for a packet that should be logged. When the packet arrives at the verification shim, it verifies the MAC by appending a 0 (assuming most packets will not be logged). If the verification fails, the NF then appends 1 and performs a second MAC verification. The success of the second verification means the NF should log the packet, while failure indicates a malicious/mangled packet. We formally prove this approach is secure in §D.

Theorem 3 (Secret Logging Security) *Consider the game described in §D.5 with adversary $\mathcal{A}$. When the MAC algorithm is GMAC, the adversary's advantage is negligible.*

6.2 Prototype Details

We implement an end-to-end prototype using Safebricks [61]. Safebricks is an NFV framework that builds on top of DPDK [5] and runs NFs in Intel Enclaves [25]. While the idea of AuditBox could be applied to other NFV frameworks [48, 58, 59, 79], we choose Safebricks mainly to leverage its I/O optimization to avoid expensive enclave transitions. We modified approximately 4k lines of Rust to implement our protocols, and added 2.5k lines of C and 100 lines of x86 assembly to implement and test the updatable GMAC implementation. Here, we focus on the implementation of the verification shim and the AuditTrailer, which are the key enablers to avoid any NF changes.

Verification Shim: As shown in Figure 9, AuditBox inserts a verification shim that sits between the enclave I/O interface and the NF in each enclave. The shim implements our custom verification protocol using two modules: one verifies the incoming packets by checking the AuditTrailer, and the other updates the AuditTrailer on outgoing packets. Both modules use our *updatable* GMAC algorithm, and both modules have access to the logging function to save logs for offline auditing.

Packet Trailer: Typically, to carry a wrapper or metadata header through unmodified NFs, one incurs two overheads. First, one must *strip* the header from the packet and copy the packet (starting from the IP or Ethernet header) to the first byte of the packet buffer; the packet can then enter the NF as if it had come in off the wire. Second, one must *restore* the header to the packet; when packets have been modified by the NF this step may require complex algorithms to infer the correct mapping from original input packet to final output packet [32].

By using a trailer, AuditBox sidesteps these challenges in many cases. Before passing the pointer to the packet buffer into the NF, the shim adjusts the packet length to the end of the encapsulated packet, leaving the trailer at the bottom of the buffer and invisible to the NF code. Even if the packet has been modified or shortened, when the packet egresses the NF, the shim can simply restore the trailer sitting at the bottom of the allocated memory. When NFs extend the length of the packet, this overwrites the trailer and so the trailer must be restored similarly to the header operations above, however, we find for most NFs leaving the trailer at the base of the buffer is an effective way to improve performance (§7.3).

7 AuditBox Evaluation

AuditBox aims to enable real-time auditing for NFV deployments with low overhead. In this section, we evaluate its overhead using a testbed and traces and show that:

- AuditBox correctly detects a broad class of practical policy violations (§7.1).
- AuditBox enables auditing for unmodified NFs while adding less overhead than existing verification protocols (§7.2). We discuss our optimizations in §7.3.

Setup: Our testbed has four severs: three SGX servers (4-core 3.80 GHz Intel Xeon E3-1270 v6 CPUs, 64 GB RAM, Intel XL710 40Gb NICs) run AuditBox, and one server (dual-socketed Intel Xeon E5-2680 v2 GHz Xeon CPUs, with

	Blue Team Policies	Attacks	AuditBox		OPT
			Packet	Flow	
1	Mutable packets (Fig. 2): Load balancer modifies packets	-	no	no	yes
2	Mutable packets (Fig. 2): Load balancer modifies packets	modify	yes	yes	yes
3	Dynamic paths (Fig. 3): Light IPS reroutes packets	-	no	no	yes
4	Dynamic paths (Fig. 3): Light IPS reroutes packets	reroute	yes	yes	yes
5	Stateful NFs (Fig. 4): NAT tracks flow states	reorder	-	yes	no
6	Stateful NFs (Fig. 4): NAT tracks flow states	drop	-	yes	no

Table 1: Example scenarios that use AuditBox and OPT [46] to verify whether policy violations happen; "yes"/"no" indicate whether the system reports a violation. Shaded cells are correct auditing results.

10 cores, 128 GB RAM, Intel XL710 40Gb NICs) is used as a traffic generator. Each server runs Ubuntu 18.04 with Linux kernel 4.4.186. We use Moongen (DPDK-based) [30] to generate synthetic test traffic, as well as replay empirical traces [10] of varying packet sizes. We enable jumbo frames to allow the trailer to be added to large packets (which makes them larger than the default 1500 byte MTU). For each experiment, we report the median value of 20 tests, error bars represent one standard deviation (which in some cases are too small to see).

Sample NFs: AuditBox supports all existing NFs in Safebricks without any NF changes. To evaluate the performance of AuditBox, we choose three sample NFs with varying complexity: (1) *NAT* rewrites IP and TCP headers, representing NFs that modify packets (Figure 2); (2) *Stateful Firewall* which tracks connection states (Figure 4), configured with a campus ruleset (643 rules); and (3) *DPI*, which represents the most computationally expensive NF in Safebricks, configured with the Snort Community ruleset [14].

7.1 Functionality Evaluation

To validate the end-to-end effectiveness of AuditBox, we run different red-blue team exercises. In each scenario, the blue team (operator) chooses a service chain policy and the protocol (AuditBox packet, AuditBox flow, or OPT). The red team (attacker) randomly picks an attack vector. Then, we emulate this scenario with generated traffic. Finally, we reveal the ground truth and the audit trails to check if the protocol helped the blue team correctly identify/diagnose the attack.

We run these scenarios in a combination of a real testbed and a custom simulator. For the testbed we use one server to generate traffic, and three to run NFs. We introduce attacks (*e.g.,* modifying packets) using the I/O thread (Figure 9), and apply them when packets arrive at the NF. We built a custom simulator, where all NFs are connected via "one big switch" and this switch executes one or more adversarial actions (*e.g.,* rerouting) when forwarding packets between NFs.

Table 1 shows a subset of the scenarios, including the motivating examples from §2. In all scenarios, with AuditBox, the blue team successfully detects the policy violations and has correct auditing trails for doing so. OPT [46] detects some

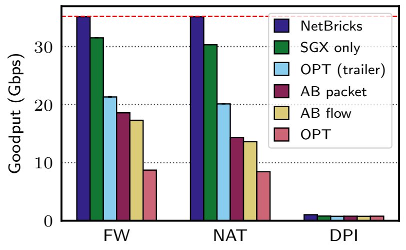

Figure 10: Cost of auditing for a single NF using empirical packet traces (AB represents AuditBox).

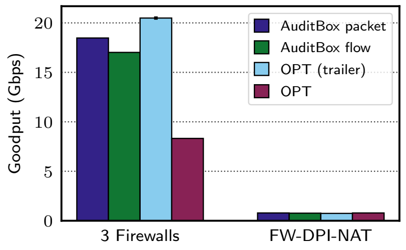

Figure 11: Cost of auditing for different chains of NFs using empirical packet traces.

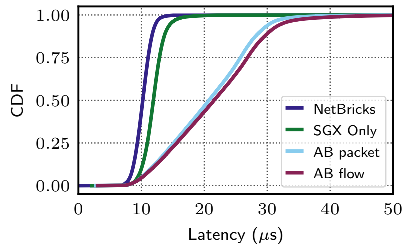

Figure 12: RTT at 80% load using empirical packet traces.

scenarios (scenarios 2 and 4), but has both false positives (1 and 3) and false negatives (5 and 6). Note that this is not unique to OPT; other VRPs [55] have the same issues as well.

7.2 Performance Evaluation

We first measure the performance of AuditBox for a single NF and a chain of NFs using empirical traffic [10]. For all tests, we run the NF using one core, and we report the goodput by excluding extra bytes used for verification. In these experiments, we compare against three alternative baselines, none of which are an apples-to-apples comparison with AuditBox (in that each was designed for a different purpose) but nonetheless we believe the comparison helps to put our results in context.

The first baseline is 'NetBricks' [59], which is a Rust-based NFV framework and does not use SGX. The second baseline is 'SGX-only', which runs NFs in enclaves but does not use any special protocol for verified routing. Our third and final baseline is OPT, which, as we have discussed (§2.4) is most closely related to AuditBox's use case but nonetheless cannot provide correct routing in the presence of dynamic routing and packet modifications.

Single NF: Figure 10 shows the goodput for running a single NF. The red dotted line shows the maximum rate of our traffic generator. NetBricks is able to process packets at the packet generator rate for both firewall and NAT. Compared to running NFs outside the enclave, the SGX baseline ('SGX only') incurs up to 15% overhead. Relative to running NFs in the enclave alone, AuditBox incurs 19% overhead for the firewall, 38% for the NAT, and 3% overhead for the DPI. The flow-level incurs slightly more overhead than the packet-level as it involves flow-table updates to track flow states.

AuditBox achieves up to two times higher goodput than the strawman OPT due to our reduced packet overhead (24B for AuditBox-pkt, 32B for AuditBox-flow vs. 84B for OPT) and our use of a trailer, instead of a header. We hypothesize that OPT's high overhead stems from its need to strip and restore large headers at each hop. To test this hypothesis, we implement OPT using our trailer optimization ('OPT-trailer'). The optimized OPT achieves a higher throughput than AuditBox, which is expected as it requires fewer MAC computations.

NF Chains: We also ran experiments to evaluate the performance of AuditBox under different NF chains across multiple nodes, similar to prior work [61]. As shown in Figure 11, for a chain of 3 firewalls AuditBox has 67% better goodput than OPT. Unlike AuditBox, which has a constant packet-size overhead regardless of chain length, OPT's header grows with chain length (116B for 3 NFs and 148B for 5 NFs), which contributes to the drop in goodput. Our optimized version, 'OPT-trailer,' gets better goodput after eliminating the header stripping and restoring overhead. We also evaluated a chain with a Firewall, followed by a DPI and a NAT. For this chain, both AuditBox and OPT achieve similar performance since the entire chain is bottlenecked by the heavy DPI.

Cost Analysis: It is worth putting the performance numbers in context to see the effective "cost" of auditability. Consider an organization deploying specialized hardware appliances for regulatory compliance. Today, this costs roughly \$600-\$3500 per-Gbps for firewalls and \$6000-\$12000 per-Gbps for IPS (*e.g.,* Cisco FirePOWER 8140 [4], Juniper Networks SRX345 [9]). If this organization shifts to NFV on commodity servers because of the auditability offered by AuditBox, we estimate the cost will be 12X-60X lower for the firewall, and 1.9X-9X lower for the IPS.While we acknowledge that any such cost analysis is fraught with uncertainties (e.g., cost at scale, reliability, service contracts, power), this rough estimate suggests that RegTech customers can still achieve financial gains through NFV.

Latency Overhead: Figure 12 shows the latency overhead of AuditBox using empirical packet traces. For each test, we measure the RTT at 80% of the maximum throughput of the system under test as a metric for latency. Compared to the SGX baseline, AuditBox-pkt adds around 18μs for 99^{th} percentile latency, and AuditBox-flow adds another 6μs.

Sweep packet size and NF type: Figure 16 (Appendix E) shows the overhead of AuditBox for varying packet sizes and NF types. Across all NFs, the overhead of AuditBox decreases as packet sizes increase. Since NAT modifies the packet, we do not use our updatable GMAC, making the overhead of AuditBox more noticeable.

7.3 Impact of Our Optimizations

Header vs Trailer: Figure 13 shows the benefit of implementing AuditTrailer as a trailer instead of a header. Unlike our trailer which can be made invisible inside the NF (shown in Figure 9), the shim needs to strip off the added header

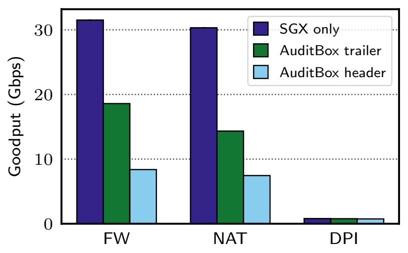

Figure 13: Effect of using trailer vs. header to carry verification data.

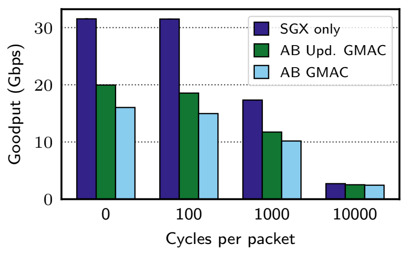

Figure 14: Effect of using updatable GMAC as NF complexity scales.

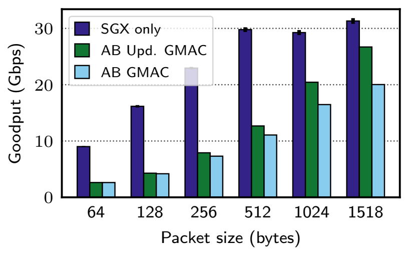

Figure 15: Effect of using updatable GMAC for varying packet sizes.

before delivering the packet to the NF to avoid modifying the NF. After the packet is processed, the shim needs to prepend the header before sending it to the next NF. These header manipulations slow down packet processing and verification, resulting in decreases of goodput by up 2×.

Regular GMAC vs Updatable GMAC: In Figures 14 and 15, we compare the performance of AuditBox when using our implementation of the updatable GMAC with the regular GMAC that is used by popular cryptographic libraries (*e.g.,* OpenSSL [12], NSS [11]). When varying the NF complexity (cycles/pkt), using updatable GMAC improves goodput by up to 23%. When varying the packet sizes, our updatable GMAC outperforms the regular GMAC by up to 25% for large packets. These improvements can largely be attributed to reusing the first MAC to compute the second MAC, which avoids the recomputing overhead for non-modified data blocks.

Dedicated log bit vs Virtual log bit: We compared our virtual logging bit with an approach with a real encrypted bit. On average, using a virtual log bit improves goodput by 4-5%.

8 Related Work

We have already discussed existing VRPs (*e.g.,* [46, 55]), service chaining policies and mechanisms (*e.g.,* [32, 58]), and how auditing is different from network verification (*e.g.,* [44, 45, 50, 60]). Here, we focus on other classes of related work.

Traditional NFV Frameworks: Prior NFV [6] frameworks focus on management [35, 42, 58, 65, 67], performance [28, 43, 51, 79], and programability [23, 48, 59]. We argue auditability should be added as a first-order feature of the NFV framework, which would relieve enterprises' concerns about deploying the NFV for security-critical services or outsourcing them to a third-party provider [33, 68].

Securing NFs: Prior work has proposed the use of SGX to protect an NF's source code [61, 72], an NF's state [69], traffic metadata [29], and to support end-to-end encryption [39, 56]. While these enhance security for NFs, they only focus on individual NFs on a single server, and they do not provide mechanisms to audit the entire service chain.

NF Verification: NF verification [27, 75, 76, 78] guarantees that a certain NF implementation is correct (memory-safe, crash-free, *etc.*). AuditBox assumes that vendors have 'certified' NF implementations as secure, and we expect this class of work would strengthen trust in such vendor certifications.

Verifiable fault localization and measurements: In addition to VRPs, auditing is also related to prior work on secure fault localization (*e.g.,* [81, 82]), robust sampling algorithms (*e.g.,* [57]), verifiable performance measurements (*e.g.,* [16]), and secure network provenance (SNP) (*e.g.,* [37, 84]). Some of our building blocks share conceptual similarity with these efforts. However, they focus on different goals. For example, SNP leverages tamper-evident logging [38] to identify misbehavior offline, unlike the runtime guarantees we provide.

9 Conclusions

In this paper, we have presented AuditBox, a framework that brings NFV to security-critical environments that require auditing. By leveraging enclaves to run NFs and continuously verifying the traffic between NFs, AuditBox provides a strong run-time guarantee that the NFV system remains in compliance with policy goals. AuditBox also supports traditional offline auditing by generating audit trails for manual inspection.

We see AuditBox as a first step in a conversation with regulators. Would our audit trails be more trustworthy if they included additional data? Should we combine our SGX protection with formal verification of the NF code [27]? In practice, should AuditBox be combined with formal verification of operator policies [60]? We expect, and hope, to see considerable evolution in supporting the RegTech space beyond AuditBox's current capabilities.

In the long run, adoption only comes when human auditors *feel comfortable* trusting the guarantees provided by any particular system. Our hope is that by not only replicating the capabilities that auditors have today, but also strengthening SFCs with runtime correctness guarantees, AuditBox will merit the trust of auditors and hence hasten the adoption of NFV in security-sensitive networks.

A Modeling Duplicate Packets

The formalization of Property 4 assumes that the same packet is never sent twice. This seems to be a reasonable assumption. As we are forwarding under L2, an NF_A and an NF_B will always have different Ethernet headers even if the IP, TCP/UDP, and Payload are identical. And it seems reasonable to assume that an NF_A will never transmit the same packet twice either – even a re-transmitted TCP packet will come with a different IPID value.

Nonetheless, we could remove these requirements and allow NFs to transmit the same packet repeatedly by defining correctness as follows:

Let $\text{SEND-TO}_{F,P}(E) \to \{0,1\}$ be defined:

```
function $\text{SEND-TO}_{\text{NF}_i,p_i}(e)$
    if $e.\text{op} = \text{SEND} \wedge e.\text{pkt} = p_i \wedge \text{policy}(p_i, e.\text{NF}) = \text{NF}_i$
then
        return 1
    else
        return 0
```

Let $\text{RECV-PKT}_{F,P}(E) \to \{0,1\}$ be defined:

```
function $\text{RECV-PKT}_{\text{NF}_i,p_i}(e)$
    if $e.\text{op} = \text{RECV} \wedge e.\text{pkt} = p_i \wedge e.\text{NF} = \text{NF}_i$ then
        return 1
    else
        return 0
```

To allow identical packets, we could then say the system was correct under packet correctness iff:

$$\forall e \in E \text{ s.t. } e.\text{op} = \text{RECV}:$$
$$\sum_{i=1}^{e.\text{t}} \text{SEND-TO}_{e.\text{NF},e.\text{pkt}}(E[i]) = \sum_{i=1}^{e.\text{t}} \text{RECV-PKT}_{e.\text{NF},e.\text{pkt}}(E[i])$$

B Additional Definitions

B.1 Modeling Packet Exit

We define GW_{out} for when a packet exits the cluster as follows:

Algorithm 3 Model of Packets Exiting the Cluster

```
1: function $GW_{\text{OUT}}(\text{input})$
2:     input $\leftarrow f_{in}(input)$
3:     if input $\neq \perp$ then
4:         $E$.append(input, $\perp$, $\text{GW}_{\text{out}}$, $E$.length + 1)
5:     return input
```

B.2 Audit Trail Definition

While our routing protocol provides hop-by-hop guarantees, auditors are familiar with end to end 'what you see is what you get' *evidence* that packets are indeed following the correct route. To provide auditors the confidence of proven correctness with empirical evidence, AuditBox provides empirical evidence in the form of audit trails. Following the model of our event log E, one can take a packet in any of its states (prior to entry, between two NFs, post exit) and compute the forms the packet took on and all NFs it traversed across its entire traversal of the system. While 5.4 describes how this works in practice, we describe audit trails in the context of our model with Algorithm 4.

Algorithm 4 Audit Trail Definition

```
function CAUSED-BY(event)
    if event.pkt$_{in}$ = $\perp$ then
        return [(event.NF, event.pkt$_{out}$)]
    trail ← (event.pkt$_{in}$, event.NF, event.pkt$_{out}$)
    prev ← get-event$_E$(event.pkt$_{in}$, pkt$_{out}$)
    return caused-by(prev) + trail
function LEADS-TO(event)
    if event.pkt$_{out}$ = $\perp$ then
        return [(event.pkt$_{in}$, event.NF)]
    prev ← get-event$_E$(event.pkt$_{out}$, pkt$_{in}$)
    prev_trail ← (prev.pkt$_{in}$, prev.NF, prev.pkt$_{out}$)
    return prev_trail + leads-to(prev)
function AUDIT-TRAIL(event)
    return CAUSED-BY(event) + LEADS-TO(event)
```

Note that the definition assumes that all transmitted packets are unique.

C Pseudocode

In the algorithms below, we expand the notion of a packet to also include the AuditBox trailer.

In the flow-verification algorithm (Algorithm 6), we assume each NF, including the gateway, maintains a flow-counter table FC which maps a flow ID and destination NF to a counter value:

$$ctr \leftarrow FC[flowID, NF]$$

Performing a lookup with a new $flowID, NF$ pair implicitly initializes the counter to zero. Comments highlight differences relative to the packet-verification algorithm (Algorithm 5).

Algorithm 5 Packet Verification Protocol

```
Input: The shared symmetric key $K_\sigma$ for the current epoch $\sigma$.
 1: ▷ Generate an AuditTrailer for each packet at the gateway GW$_{in}$
 2: function GENERATE(pkt)
 3:     $out.pkt = pkt$
 4:     $out.pktID = genPktID(pkt)$
 5:     $out.srcNF = \mathrm{GW}_{in}$
 6:     $out.dstNF = Policy(pkt, \mathrm{GW}_{in})$
 7:     $out.tag = \mathrm{MAC}_{K_\sigma}(out.pkt|out.pktID|out.srcNF|out.dstNF)$
 8:     return $out$
 9:
10: ▷ Process a packet $in$ at NF$_i$
11: function PROCESS$_i$(in)
12:     ok ← $in.dstNF = \mathrm{NF}_i$   $\wedge$
13:             Verify$_{K_\sigma}(in.pkt|in.pktID|in.srcNF|in.dstNF, in.tag)$
14:     if ok then:
15:         $out.pkt = f_i(in.pkt)$
16:         $out.pktID = in.pktID$
17:         $out.srcNF = \mathrm{NF}_i$
18:         $out.dstNF = Policy(out.pkt, \mathrm{NF}_i)$
19:         $out.tag = \mathrm{MAC}_{K_\sigma}(out.pkt|out.pktID|out.srcNF|out.dstNF)$
20:     else
21:         $out \leftarrow \perp$       ▷ Drop packet and raise alert
    return $out$
```

Algorithm 6 Flow Verification Protocol

```
Input: The shared symmetric key $K_\sigma$ for the current epoch $\sigma$.
 1: ▷ Generate a flow AuditTrailer for each packet at the gateway GW$_{in}$
 2: function GENERATE(pkt)
 3:     ▷ Same as Packet Verification
 4:     $out.pkt = pkt$
 5:     $out.pktID = genPktID(pkt)$
 6:     $out.srcNF = \mathrm{GW}_{in}$
 7:     $out.dstNF = Policy(pkt, \mathrm{GW}_{in})$
 8:     ▷ New for Flow Verification
 9:     $out.flowID = computeFlowID(pkt)$
10:     $out.seqNum = FC[out.flowID, out.dstNF]{+}{+}$
11:     $out.tag = \mathrm{MAC}_{K_\sigma}(out.pkt|out.pktID|out.srcNF|out.dstNF$
            $|out.flowID|out.seqNum)$
12:     return $out$
13:
14: ▷ Process a packet $in$ at NF$_i$
15: function PROCESS$_i$(in)
16:     ok ← $in.dstNF = \mathrm{NF}_i$
17:         $\wedge$  Verify$_{K_\sigma}(in.pkt|in.pktID|in.srcNF|in.dstNF|in.flowID$
                $|in.seqNum, in.tag)$
18:         $\wedge$  $in.seqNum = FC[in.flowID, in.srcNF]$    ▷ New
19:     if ok then:
20:         $FC[in.flowID, in.srcNF]{+}{+}$    ▷ New
21:         $out.pkt = f_i(in.pkt)$
22:         $out.pktID = in.pktID$
23:         $out.srcNF = \mathrm{NF}_i$
24:         $out.dstNF = Policy(out.pkt, \mathrm{NF}_i)$
25:         ▷ New for Flow Verification
26:         $out.flowID = in.flowID$
27:         $out.seqNum = FC[out.flowID, out.dstNF]{+}{+}$

```

D Security Proofs

D.1 Cryptographic Assumptions

We introduce the standard notation we use and the standard cryptographic assumptions we make.

We write $x|y$ for the uniquely delimited (either via tags or fixed widths) concatenation of x and y. Hence, $x_0|y_0 == x_1|y_1$ implies $x_0 == x_1$ and $y_0 == y_1$.

Our scheme relies on a Message Authentication Code (MAC) scheme, which consists of three algorithms. A symmetric key K is generated by the KeyGen() algorithm. We write $\tau \leftarrow \text{MAC}_K(m)$ to indicate using key K to compute a MAC *tag* τ on message m, and $\text{Verify}_K(m,\tau)$ for the algorithm that uses key K to check the validity of tag τ for message m.

We assume that the MAC scheme is existentially unforgeable under chosen-message attacks (EUF-CMA) [21]. Intuitively, the definition says that an adversary who can request validly computed tags for n adaptively chosen messages cannot produce a new pair $(m,\tau) \notin \{(m_1,\tau_1),\ldots,(m_n,\tau_n)\}$ which passes $\text{Verify}_K(m,\tau)$. Standard algorithms, such as HMAC [20] and GMAC [53], are EUF-CMA secure.

D.2 Security Definition

To formalize AuditBox's security, we take the standard approach of defining our desired security property via a cryptographic *game* involving a challenger $\mathcal{C}$, and a probabilistic, polynomial-time adversary $\mathcal{A}$, which intuitively corresponds to the untrusted network, Φ. The game can be instantiated with an *audit protocol* that supplies NF functions f_i.

The challenger begins the game by creating an empty event log E and calling KeyGen() to produce key K. The adversary is then allowed to run and can call the following oracles which represent the various NFs in the system.

1. $p_{out} \leftarrow \text{Oracle-GW}_{IN}(p_{in})$ allows the adversary to introduce a new packet p_{in} to the gateway and obtain the packet p_{out} produced by the gateway.
2. $p_{out} \leftarrow \text{Oracle-NF}_i(p_{in})$ invokes NF_i on the adversarially supplied input packet p_{in} and gives the adversary the resulting packet p_{out}.

The challenger instantiates these oracles using the models described in §4.1. Specifically, $\text{Oracle-GW}_{IN}(p_{in})$ runs Algorithm 2 using the protocol-supplied function f_{in}, and $\text{Oracle-NF}_i(p_{in})$ runs Algorithm 1 using the protocol-supplied function f_i. Note that both oracles append to the event log E

When the adversary terminates, the game ends and outputs E.

D.3 Security Proof of Packet Correctness

Theorem 1 (Packet Correctness) *Consider the game described above with adversary $\mathcal{A}$ and instantiated with the AuditBox packet correctness protocol (§5.2). Specifically, looking at Algorithm 5, we instantiate f_{in} with the function* GENERATE *and f_i with* PROCESS$_i$*. The probability that the game outputs an event log E that violates Property 1 is negligible.*

Proof of Theorem 1: We prove security by reducing the security of our protocol to the EUF-CMA security of our MAC algorithm though a series of cryptographic games [19, 71]. The initial game matches the game defined in §D.2, and each subsequent game idealizes a portion of the protocol. At each step, we calculate the adversary's success in distinguishing between the two games.

Game 0 is defined as in §D.2 with an adversary $\mathcal{A}$ which queries its oracles a total of α times.

Game 1 is the same as above, except that the NF oracle, when given an input packet p_{in}, computes

$$m \leftarrow p_{in}.pkt|p_{in}.pktID|p_{in}.srcNF|p_{in}.dstNF$$

and immediately rejects the packet if m was not previously passed as an argument to $\text{MAC}_K(\cdot)$ (*i.e.,* $\mathcal{C}$ keeps a list $\mathcal{L}$ of all values passed to $\text{MAC}_K(\cdot)$, and upon receiving a packet p_{in} on which it would normally call $\text{Verify}_K(m,\tau)$, it looks up m in $\mathcal{L}$ and accepts/rejects based on the lookup, without looking at τ).

The adversary can distinguish Game 1 from Game 0 only if it can forge a valid tag τ for m. This happens with probability at most $\texttt{EUF-CMA}(\alpha)$, the probability of breaking our unforgability assumption given at most α chosen-message tags.

From Game 1, we show that Property 1 perfectly holds, which means that the probability that an adversary can break Property 1 is at most $\texttt{EUF-CMA}(\alpha)$, which is, by definition, negligible when we employ a secure MAC scheme.

In Game 1, consider any $e_b \in E$ such that $e_b.pkt_{in} \neq \perp$. By the construction of the *NF* model (Algorithm 1) an event e_b is only added to E after the NF runs f_i, which we instantiated with PROCESS$_i$. PROCESS$_i$ ensures $e_b.pkt_{in}.dstNF == e_b.NF$ (Line 12 of Algorithm 5). In Game 1, instead of running the MAC's verification algorithm on Line 13, it checks that the computed m is on the list $\mathcal{L}$ of previously MAC'ed messages. For this check to succeed, there must have been a logically earlier MAC call, which must have occurred during a previous invocation of Oracle-GW_{IN} or Oracle-NF_i, which each compute a tag on their outbound packet. For the verification lookup in $\mathcal{L}$ to succeed, that MAC call must have computed an m' for its output packet, where $m' == m$. This earlier oracle invocation would have produced event $e_a = (p, e_b.pkt_{in}, e_b.pkt_{in}.srcNF, i)$ for some other input packet p and index i, with $i < e_b.t$, since this was an earlier invocation, and the log E was necessarily shorter. Hence, the equality of m and m' implies that we have $e_a.pkt_{out} = e_b.pkt_{in}$, and $policy(e_a.pkt_{out}, e_a.NF) = e_b.NF$ (note Lines 6 and 18 of Algorithm 5), satisfying Property 1. ■

D.4 Security Proof of Flow Correctness

Theorem 2 (Flow Correctness) *Consider the game described in §D.2 with adversary $\mathcal{A}$ and instantiated with the AuditBox flow-correctness protocol (§5.3). Specifically, looking at Algorithm 6, we instantiate f_{in} with the function* GENERATE *and f_i with* PROCESS$_i$*. The probability that the game outputs an event log E that violates Properties 1-4 is negligible.*

Proof of Theorem 2:

We prove Theorem 2 by considering each property in turn.

Proof of Property 1 We begin by observing that compared with the packet-verification protocol, the flow-verification protocol

1. Includes in its AuditTrailer a superset of the packet-verification fields.
2. Computes the values the packet-verification fields in an identical manner.
3. Computes MACs over a superset of the packet-verification fields. algor
4. Performs a superset of the validation checks (compare Lines 16-18 of Algorithm 6 with Lines 12-13 of Algorithm 5).

Hence, we can apply an identical set of arguments as we did in our proof of Theorem 1 to show that Property 1 still holds when we employ a secure MAC. In the discussion, Property 1 allows us to assume that all packets in E originated from an NF, and hence we no longer need worry about adversarially mangled or injected packets.

Proof of Property 2 To show that Property 2 (*i.e.,* no packet injection or modification) holds, choose an arbitrary $\text{NF}_a, \text{NF}_b \in F$, and $e_{a1}, e_{a2}, e_{b2} \in E$ such that Lines 5-9 of Property 2 hold. We will show that there must exist $e_{b1} \in E$ such that

$$e_{b1}.\text{t} < e_{b2}.\text{t} \wedge e_{b1}.\text{NF} = \text{NF}_b \wedge e_{b1}.\text{pkt}_{\text{in}} = e_{a1}.\text{pkt}_{\text{out}}$$

When $e_{a1}.\text{pkt}_{\text{out}}$ was produced by $\textsc{Process}_a$, it was assigned a flow sequence number $FC_a[e_{a1}.\text{pkt}_{\text{out}}.\mathit{flowID},\ e_{a1}.\text{pkt}_{\text{out}}.\mathit{srcNF}]$ (Line 27 of Algorithm 6), and NF_a immediately increments the counter.

When we subsequently call $\textsc{Process}_a$ to produce $e_{a2}.\text{pkt}_{\text{out}}$ (we know this is a subsequent invocation of $\textsc{Process}_a$ because $e_{a1}.\text{t} < e_{a2}.\text{t}$), we can show that it will read the same counter from FC_a, which by observation always increases monotonically. Hence, it must be that $e_{a2}.\text{pkt}_{\text{out}}.\mathit{seqNum} > e_{a1}.\text{pkt}_{\text{out}}.\mathit{seqNum}$.

We can show that $\textsc{Process}_a$ accesses the same counter by showing that $e_{a1}.\text{pkt}_{\text{out}}.\mathit{flowID} = e_{a2}.\text{pkt}_{\text{out}}.\mathit{flowID} \wedge e_{a1}.\text{pkt}_{\text{out}}.\mathit{srcNF} = e_{a2}.\text{pkt}_{\text{out}}.\mathit{srcNF}$. The first is straightforward, since $e_{a1}.\text{pkt}_{\text{out}} = e_{a2}.\text{pkt}_{\text{out}} \implies \mathit{flow}(e_{a1}) = \mathit{flow}(e_{a2})$, and the second follows from Line 7 of Property 2.

For $e_{a2}.\text{pkt}_{\text{out}}$ to have passed the "ok" check in $\textsc{Process}_b$, and hence to have generated e_{b2}, it must have passed the check on Line 18, which means that at the time, $e_{a2}.\text{pkt}_{\text{out}}.\mathit{seqNum} = FC_b[e_{a2}.\text{pkt}_{\text{out}}.\mathit{flowID},\ e_{a2}.\text{pkt}_{\text{out}}.\mathit{srcNF}]$. Now consider the set $E_{b1} \subseteq E$ of all e_{b1} such that $e_{b1}.\text{t} < e_{b2}.\text{t} \wedge e_{b1}.\text{NF} = \text{NF}_b \wedge e_{b1}.\text{pkt}_{\text{in}}.\mathit{srcNF} = NF_a \wedge \mathit{flow}(e_{b1}) = \mathit{flow}(e_{a1})$; *i.e.,* all previous events generated by NF_b that came from NF_a and are part of the same flow as e_{a1} (and hence e_{a2} and e_{b2}). The crucial observation is that each such e_{b1} increments $FC_b[e_{b1}.\text{pkt}_{\text{in}}.\mathit{flowID},\ e_{b1}.\text{pkt}_{\text{in}}.\mathit{srcNF}]$, and these are the *only* events that do so prior to $e_{b2}.\text{t}$. Hence, it must be the case that $|E_{b1}| = e_{b2}.\text{pkt}_{\text{in}}.\mathit{seq}$, and each $e_{b1} \in E_{b1}$ has a unique sequence number (as guaranteed by the monotonically increasing counter value). Since we know that $0 \leq e_{a1}.\text{pkt}_{\text{out}}.\mathit{seqNum} < e_{a2}.\text{pkt}_{\text{out}}.\mathit{seqNum} = e_{b2}.\text{pkt}_{\text{in}}.\mathit{seqNum}$, there must be an $e_{b1} \in E_{b1}$ with $e_{b1}.\text{pkt}_{\text{in}}.\mathit{seqNum} = e_{a1}.\text{pkt}_{\text{out}}.\mathit{seqNum}$. Furthermore, the monotonic counter on the sending side (NF_a) guarantees that NF_a must have only assigned the sequence number $e_{a1}.\text{pkt}_{\text{out}}.\mathit{seqNum}$ to a single packet, namely $e_{a1}.\text{pkt}_{\text{in}}$. Since we have proven Property 1 holds (*i.e.,* the attacker cannot inject or modify packets), if NF_b received a packet $e_{b1}.\text{pkt}_{\text{in}}$ with sequence number $e_{a1}.\text{pkt}_{\text{out}}.\mathit{seqNum}$ from NF_a, it must be the case that $e_{a1}.\text{pkt}_{\text{out}} = e_{b1}.\text{pkt}_{\text{in}}$. Hence, we have identified an e_{b1} such that $e_{b1}.\text{t} < e_{b2}.\text{t} \wedge e_{b1}.\text{NF} = \text{NF}_b \wedge e_{b1}.\text{pkt}_{\text{in}} = e_{a1}.\text{pkt}_{\text{out}}$, proving that Property 2 holds.

Proof of Property 3 To show that Property 3 (no packet reordering) holds, choose an arbitrary $\text{NF}_a, \text{NF}_b \in F$ and $e_{a1}, e_{b1}, e_{a2}, e_{b2} \in E$ such that Lines 14-17 of Property 3 hold. Suppose for the sake of contradiction that $e_{a1}.\text{t} < e_{a2}.\text{t}$ but $e_{b1}.\text{t} \geq e_{b2}.\text{t}$ (*i.e.,* NF_b received the packets in reverse order). Since each NF increments its flow counter after sending a packet (Lines 10 and 27 in Algorithm 6), and we know that $\text{flow}(e_{a1}) = \text{flow}(e_{a2})$, it must be the case that $e_{a1}.\text{pkt}_{\text{in}}.\mathit{seqNum} < e_{a2}.\text{pkt}_{\text{in}}.\mathit{seqNum}$. Since we supposed $e_{b1}.\text{t} \geq e_{b2}.\text{t}$ (and $e_{b1}.\text{t} \neq e_{b2}.\text{t}$ because each entry in E has a unique position) it must be the case that $\textsc{Process}_b$ was called on $e_{a2}.\text{pkt}_{\text{out}}$ before it was called on $e_{a1}.\text{pkt}_{\text{out}}$. For $e_{a2}.\text{pkt}_{\text{out}}$ to have passed the "ok" check in $\textsc{Process}_b$, it must have passed the check on Line 18, which means that at the time, $e_{a2}.\text{pkt}_{\text{out}}.\mathit{seqNum} = FC_b[e_{a2}.\text{pkt}_{\text{out}}.\mathit{flowID},\ e_{a2}.\text{pkt}_{\text{out}}.\mathit{srcNF}]$. The counter is then incremented on Line 20, and continues to increase monotonically on subsequent invocations. Hence, when $\textsc{Process}_b$ was later called on $e_{a1}.\text{pkt}_{\text{out}}$, to have passed the "ok" check, it must be the case that $e_{a1}.\text{pkt}_{\text{out}}.\mathit{seqNum} > e_{a2}.\text{pkt}_{\text{out}}.\mathit{seqNum}$. This contradicts our starting point that $e_{a1}.\text{pkt}_{\text{out}}.\mathit{seqNum} < e_{a2}.\text{pkt}_{\text{out}}.\mathit{seqNum}$. Hence we can conclude that if $e_{a1}.\text{t} < e_{a2}.\text{t}$ then $e_{b1}.\text{t} < e_{b2}.\text{t}$.

To prove the other direction of the implication, namely that if $e_{a1}.\text{t} \geq e_{a2}.\text{t}$ then $e_{b1}.\text{t} \geq e_{b2}.\text{t}$. we can apply the same argument as above, swapping $a2$ for $a1$ and $b2$ for $b1$.

Proof of Property 4 To show that Property 4 (no packet replay) holds, choose an arbitrary $e_a \in E$. Suppose for the sake of contradiction that $\exists e_b \in E$ such that $e_a.\text{pkt}_{\text{in}} = e_b.\text{pkt}_{\text{in}}$. Since each entry in E has a unique position, we know $e_a.\text{t} \neq e_b.\text{t}$, so without loss of generality, assume $e_a.\text{t} < e_b.\text{t}$. Since we know that $e_a.\text{pkt}_{\text{in}}.\mathit{dstNF} = e_b.\text{pkt}_{in}.\mathit{dstNF}$, both entries must have been produced by invocations of $\textsc{Process}_{e_a.\text{pkt}_{\text{in}}.\mathit{dstNF}}$, and it was invoked on $e_a.\text{pkt}_{\text{in}}$ before

e_b.pkt$_{\text{in}}$ (because e_a.t$<e_b$.t). Since PROCESS did not raise an alert on e_a.pkt$_{\text{in}}$, it must be the case that it passed the check on Line 18, which means that at the time, e_a.pkt$_{\text{in}}$.$seqNum=FC_b[e_a$.pkt$_{\text{in}}$.$flowID$, e_a.pkt$_{\text{in}}$.$srcNF]$. The counter is then incremented on Line 20, and continues to increase monotonically on subsequent invocations. Hence, when PROCESS was later called on $e_b.pkt$, to have passed the "ok" check, it must be the case that e_b.pkt$_{\text{in}}$.$seqNum > e_a$.pkt$_{\text{in}}$.$seqNum$. But we supposed that e_a.pkt$_{\text{in}}$ = e_b.pkt$_{\text{in}}$, which means e_b.pkt$_{\text{in}}$.$seqNum = e_a$.pkt$_{\text{in}}$.$seqNum$. This contradiction show that e_b.pkt$_{\text{in}}$.$seqNum \neq e_a$.pkt$_{\text{in}}$.$seqNum$. ■

D.5 Security of Secret Logging

As described in §6.1, AuditBox implements secret logging via a *virtual* bit that is appended to the real data carried in the AuditTrailer when computing a MAC. For this approach to effectively sample packets even in the presence of an adversary, it should be computationally difficult to distinguish packets with the virtual bit set to one (indicating a packet that should be logged) from those with the virtual bit set to zero.

Security Definition We capture this security notion with the following game involving a challenger $\mathcal{C}$, and a probabilistic, polynomial-time adversary $\mathcal{A}$. When the game begins, $\mathcal{C}$ chooses a random bit b and then runs KeyGen() to produce key K. The adversary is then allowed to run and given access to Oracle-MAC($\cdot$), which when given a message m, returns MAC$_K(m|b)$. $\mathcal{A}$ eventually terminates and outputs its guess b'. The game returns 1 if $b{=}{=}b'$ and 0 otherwise.

We define $\mathcal{A}$'s advantage after making α queries to its oracle as $2\left|P-\frac{1}{2}\right|$, where P is the probability that the game returns 1.

Security Proof The game above is not secure for arbitrary MACs. In other words, given a EUF-CMA secure MAC scheme $\mathcal{M}$, we can construct a new scheme $\mathcal{N}$ that is also EUF-CMA secure, but where an adversary can achieve advantage 1 in the game above. For example, we could define $\mathcal{N}$.MAC$_K(m) = \mathcal{M}$.MAC$_K(m)|m$. This is EUF-CMA secure (since the adversary still cannot produce a forgery against $\mathcal{M}$), but message secrecy is entirely broken.

Fortunately, we *can* prove security for specific MAC algorithms, including HMAC and, crucially for our implementation, GMAC. In particular, we leverage the fact that

GMAC is defined (simplifying slightly) as:

$$\text{GMAC}_K(IV,m) = \text{PRF}_K(IV) \oplus \text{GHASH}(m)$$

Theorem 3 (Secret Logging Security) *Consider the game described above with adversary $\mathcal{A}$. When the MAC algorithm is GMAC, the adversary's advantage is negligible.*

Proof of Theorem 3: We prove security via the following two games.
Game 0 is defined as described above with an adversary $\mathcal{A}$ which queries its oracle a total of α times.
Game 1 is the same as above, except that Oracle-MAC(m) returns

$$\text{GMAC}_K(IV,m) = R \oplus \text{GHASH}(m)$$

where R is a randomly sampled value.

The adversary can distinguish Game 1 from Game 0 only if it can distinguish the output of the PRF from the output of a truly randomly selected function. This happens with probability at most $\texttt{PRF}(\alpha)$, the probability of breaking the security of GMAC's PRF given at most α queries.

From Game 1, we show that the adversary has no information about the underlying message (and hence about the value of b), which means that the adversary's advantage in the security game is at most $\texttt{PRF}(\alpha)$, which is, by definition, negligible when we employ a secure PRF, which is also necessary for the standard EUF-CMA security of GMAC to hold.

In Game 1, the output of GHASH (which is the only information derived from m) is XOR'ed with a randomly chosen value of the same length. In other words, the output is the result of applying a one-time pad to GHASH(m), which is an informationally secure encryption scheme. Hence the adversary learns nothing about m from the output of its oracle. ■

Contracting Wide-area Network Topologies to Solve Flow Problems Quickly

Firas Abuzaid[†*], *Srikanth Kandula*[†], *Behnaz Arzani*[†], *Ishai Menache*[†], *Matei Zaharia*[*], *Peter Bailis*[*]
Microsoft Research[†] *and Stanford University*[*]

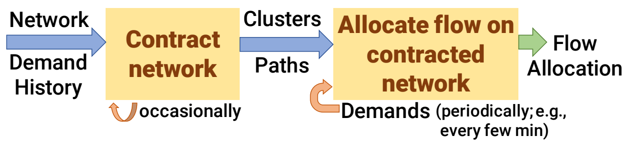
Abstract– Many enterprises today manage traffic on their wide-area networks using software-defined traffic engineering schemes, which scale poorly with network size; the solver runtimes and number of forwarding entries needed at switches increase to untenable levels. We describe a novel method, which, instead of solving a multi-commodity flow problem on the network, solves (1) a simpler problem on a contraction of the network, and (2) a set of sub-problems in parallel on disjoint clusters within the network. Our results on the topology and demands from a large enterprise, as well as on publicly available topologies, show that, in the median case, our method nearly matches the solution quality of currently deployed solutions, but is 8× faster and requires 6× fewer FIB entries. We also show the value-add from using a faster solver to track changing demands and to react to faults.

1 Introduction

Wide-area networks (WANs), which connect locations across the globe with high-capacity optical fiber, are an expensive resource [7, 35, 36, 38]. Hence, enterprises seek to carefully manage the traffic on their WANs to offer low latency and jitter for customer-facing applications [28, 62, 69] and fast response times for bulk data transfers [46, 56].

The state-of-the-art approach used in several enterprises today [35, 36, 38] is to compute optimal routing schemes for the current demand by solving global multi-commodity flow problems [7,35,36,38]; the global flow problems are re-solved periodically, since demands may change or links may fail, and the computed routes are encoded into switch forwarding tables using software-defined networking techniques [7].

As network sizes grow, solving multi-commodity flow problems on the entire network becomes practically intractable. As noted in [36], the "algorithm run time increased super-linearly with the site count," which led to "extended periods of traffic blackholing during data plane failures, ultimately violating our availability targets," as well as "scaling pressure on limited space in switch forwarding tables." This problem is unlikely to go away: anecdotal reports indicate that WAN



Network
Demand History
Contract network
occasionally
Clusters

Allocate flow on contracted network
Demands (periodically; e.g., every few min)
Flow Allocation

Figure 1: NCFlow's workflow.

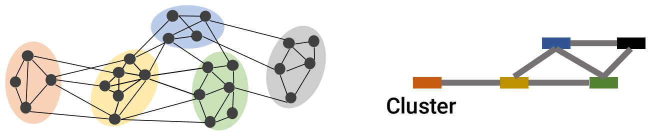

Figure 2: The original network on the left is divided into clusters, shown with different background colors. The contracted network is on the right.

footprints today are already over 10× larger than the few tens of sites that were considered in prior work [35, 36], since enterprises have built more sites to move closer to users.

In this paper, we seek to retain the benefits of global traffic management for large WAN networks without requiring excessively many forwarding entries at switches or prohibitively long solver runtimes. Also, by using a faster solver, WAN operators can reduce loss when faults occur and carry more traffic on the network by tracking demand changes.

Our solution is motivated by the observation that WAN topologies and demands are *concentrated*: the topology typically has well-connected portions separated by a few, lower-capacity edges, and more demand is between nearby datacenters. This is likely due to multiple operational considerations: (1) submarine cables have become shared choke points for connectivity between continents (see Figure 3), (2) the connectivity over land follows the road or rail networks along which fiber is typically laid out, and (3) enterprises build datacenters close to users, then steer traffic to nearby datacenters [12, 62, 69]. Therefore, more capacity and demand are available between *nearby* nodes; an analysis of data from a large enterprise WAN in §2 supports this observation.

We leverage this concentration of capacity and demand to decompose the global flow problem into several smaller problems, many of which can be solved in parallel. As shown

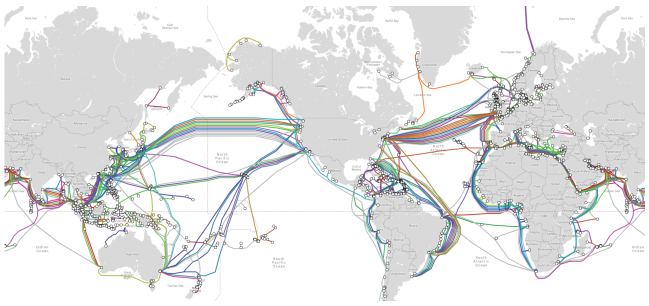

Figure 3: Submarine cables serve as choke points in WAN topologies; figure is excerpted from [63].

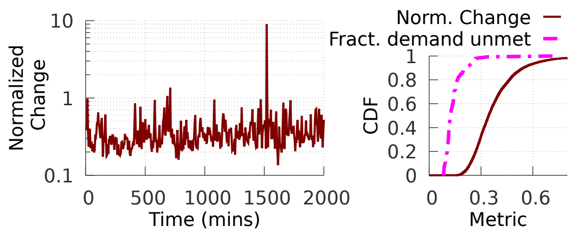

Figure 4: On the left, we plot the L2 norm of the change in the demands between successive 5-minute periods divided by the L2 norm of the traffic matrix at a time. On the right, we show the CDF of this change ratio. We also show a CDF of the fraction of demand that is unsatisfied if using the allocation computed for the previous period.

in Figure 2, we divide the network into multiple connected components, which we refer to as *clusters*. We then solve modified flow problems on each cluster, as well as on the *contracted network*, where nodes are clusters and edges connect clusters that have connected nodes. Prior work [4, 9, 15] notes that Google and other map providers use different contractions to compute shortest paths on road network graphs. Our goal is to closely match the multi-commodity max flow solution in quality (i.e., carry nearly as much total flow), while reducing the solver runtime and number of required forwarding entries. We discuss related work in §7; to our knowledge, we are the first to demonstrate a practical technique for multi-commodity flow problems on large WAN topologies.

Solving flow problems on the contracted network poses two key challenges:

1. How to partition the network into clusters? More clusters leads to greater parallelism, but maximizing the inter-cluster flow requires careful coordination between the sub-problems at multiple clusters.
2. How to design the sub-problems for each cluster to improve speed while reducing inconsistencies in allocation? The sub-problem for a cluster has fewer nodes and edges to consider, but it will not be be faster if it must consider all node pairs whose traffic can pass through the cluster.

Our solution NCFlow[1] achieves a high-quality flow allocation with a low runtime and space complexity by addressing each of these challenges in turn. First, we contract the network using well-studied algorithms such as modularity-based clustering [25] and spectral clustering [53], which are designed to identify the choke-point edges in a network. Second, we *bundle* demands whose sources and/or targets are in the same cluster, treating them as a single demand. In Figure 2 for example, the yellow cluster considers as one bundled demand all traffic from source nodes in the red cluster to target nodes in the green cluster. Doing so can lead to inconsistent flow allocations between clusters (which we explain in §3.1.1) and we devise careful heuristics to provably avoid them (§3.2). Finally, we reduce the forwarding entries needed at switches by reusing pathlets within clusters and traffic splitting rules across multiple demands (§3.5).

Figure 1 shows the workflow for NCFlow. First, we choose appropriate clusters and paths using an offline procedure over historical traffic—these choices are pushed into the switch forwarding entries. This step happens infrequently, such as when the topology and/or traffic changes substantially. Then, online (e.g., once every few minutes), NCFlow computes how best to route the traffic over the clusters and paths, similar to deployed solutions [35, 36, 38].

Overall, our key contributions are:

- We propose NCFlow, a decomposition of the multi-commodity max flow problem into an offline clustering step and an online, provably feasible, algorithm that solves a set of smaller sub-problems in parallel.
- We evaluate NCFlow using real traffic on a large enterprise WAN, as well as synthetic traffic on eleven topologies from the Internet Topology Zoo [6]. Our results show that, for multi-commodity max flow, NCFlow is within 2% of the total flow allocated by state-of-the-art path-based LP solvers [35, 36, 38] in 50% of cases; NCFlow is within 20% in 97% of cases. Furthermore, NCFlow is at least $8\times$ faster than path-based LP solvers in the median case; in 20% of cases, NCFlow is over $30\times$ faster. Lastly, NCFlow requires 2.7–16.7$\times$ fewer forwarding entries in the evaluated topologies. NCFlow also compares favorably to state-of-the-art approximation algorithms [27,41] and oblivious techniques [44,57].
- We show that, as a fast approximate solver, NCFlow can be used to react quickly to demand changes and link failures. Specifically, in comparison to TEAVAR [19], NCFlow carries more flow when no faults occur and suffers about the same amount of total loss during failures.

We have open-sourced an anonymous version of NCFlow [2], and are in the early stages of integrating NCFlow into production use at a large enterprise.

2 Background and Motivation

We analyze the changes in topology and traffic on a large enterprise WAN over a several-month period. As Figure 4

[1] short for **N**etwork **C**ontractions for **Flow** problems

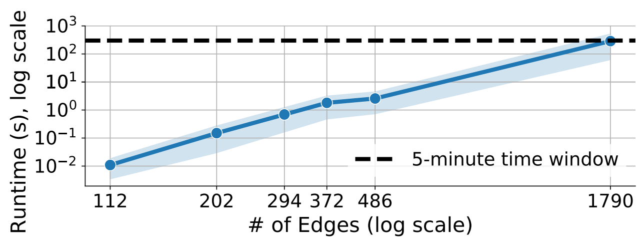

Figure 5: Runtimes of a state-of-the-art solver on topologies from Internet Topology Zoo [6]. Both axes are in log scale and the band represents standard deviation. In production WANs, new traffic demands arrive every few minutes [35, 38].

shows, the change in traffic demand from one 5-minute window to the next is substantial; the average change is 35%; in 20% of the cases, the traffic change is over 45%. The enterprise solves a global flow allocation problem every few minutes. The figure on the right shows the fraction of traffic that will remain unsatisfied if the flow allocation from the previous window were to be used instead of computing a new allocation. We see that the median loss is 13%; in 20% of the cases, over 20% of the demand remains unsatisfied. We verify that computing a new allocation will satisfy all of the demand; using the previous window's allocation causes loss because some datacenter pairs may receive more flow in the previous allocation than their current demand while other datacenter pairs go unsatisfied.

Given the above data, computing a new allocation in each time window is needed to carry more traffic on the WAN. However, solver runtime increases super-linearly with the size of the topology, as shown in Figure 5. For several public topologies and on a variety of traffic matrices, we benchmark the multi-commodity max-flow problem (specifically PF_4, as will be described in §5.1). The runtimes were measured on a server-grade machine using a production-grade optimization library [33]. As the figure shows, when the topology size exceeds a thousand edges, the time to compute a flow allocation can exceed the allotted time window.

A fast solver would not only ensure that new allocations complete in time—it could also enable more frequent allocations, e.g., every minute. Doing so would enable allocations to track changing demands at a finer granularity. Moreover, as we show in §5, a fast solver can help when reacting to link and switch failures.

Our observation that demand and capacity are concentrated among *nearby* nodes is grounded on the following measurements from a production WAN:

Demand properties:

- On average, 7% (or 16%) of the node pairs account for half (or 75%) of the total demand.
- When nodes are divided into a few tens of clusters, 47% of the total traffic stays within clusters. If the demands were distributed uniformly across node pairs, only 8% of the traffic would stay within clusters; thus the demand within clusters is about 6× larger than would be expected from a uniform distribution.

WAN topology properties:

- When nodes are divided into tens of clusters, 76% of all edges and 87% of total capacity is within clusters.
- The skew in capacity is small: the ratio between the largest edge capacity and the mean is 10.4.
- The skew in node degree is also small: the average node degree is 3.9, with $\sigma = 2.6$; the max is 16.
- Relative to the network size (hundreds of nodes), the average network diameter (=11) and the average shortest-path length (= 5.3) are very small.

Motivated by the above analyses, NCFlow seeks to be a fast solver for large WAN topologies by leveraging the concentration of traffic demands and capacity.

Background: Before we describe NCFlow's design, we give some background on multi-commodity flow problems. Given a set of nodes, capacitated edges, and demands between nodes, a flow allocation is feasible if it satisfies demand and capacity constraints. The goal of a multi-commodity flow problem is to find a feasible flow which optimizes a given objective; Table 1 lists some common flavors.

The fastest algorithms [27, 41] are approximate; i.e., given a parameter ε, they achieve at least $(1-\varepsilon)\times$ the optimal value. And, their runtime complexity is at least quadratic (Table 1).

Moreover, these solutions allow demands to travel on any edge, thus requiring millions of forwarding table entries at each switch for thousand-node topologies. Instead, production systems [35, 38] restrict flow to a small number of pre-configured paths per demand, which reduces the required forwarding table entries by 10–100×.

Using notation from Table 2, the feasible flow over a pre-configured set of paths can be defined as:

$$
\begin{aligned}
&\mathsf{FeasibleFlow}(\mathcal{V},\mathcal{E},\mathcal{D},\mathcal{P}) \triangleq \{f_k \mid \forall k \in \mathcal{D} \text{ and} && (1)\\
&\qquad f_k = \sum_{p \in \mathcal{P}_k} f_k^p, && \forall k \in \mathcal{D} \quad \text{(flow for demand } k\text{)}\\
&\qquad f_k \le d_k, && \forall k \in \mathcal{D} \quad \text{(flow below volume)}\\
&\qquad \sum_{\forall k, p \in \mathcal{P}_k, e \in p} f_k^p \le c_e, && \forall e \in \mathcal{E} \quad \text{(flow below capacity)}\\
&\qquad f_k^p \ge 0 && \forall p \in \mathcal{P}, k \in \mathcal{D} \quad \text{(non-negative flow)} \}
\end{aligned}
$$

Production systems use linear optimization-based solvers [35, 36, 38]. On WANs with thousands of nodes, the optimization problem could have millions of variables and equations just to verify that a flow allocation is feasible.

In this paper, we consider the problem of maximizing the total flow across all demands:

$$
\begin{aligned}
&\mathsf{MaxFlow}(\mathcal{V},\mathcal{E},\mathcal{D},\mathcal{P}) \triangleq \arg\max_{\mathbf{f}} \sum_{k \in \mathcal{D}} f_k && (2)\\
&\qquad \text{s.t.} \quad \mathbf{f} \in \mathsf{FeasibleFlow}(\mathcal{V},\mathcal{E},\mathcal{D},\mathcal{P})
\end{aligned}
$$

	Maximization term	**Additional Constraints**	**Used in**	**Known best complexity**
MaxFlow	$\sum_{k\in\mathcal{D}} f_k$	none	[35, 38]	$O(M^2\epsilon^{-2}\log^{O(1)} M)$ [27]
MaxFlow with Cost Budget	$\sum_{k\in\mathcal{D}} f_k$	$\sum_k \sum_{p\in\mathcal{P}_k} \sum_{e\in p} f_k^p \mathsf{Cost}_e \le \mathsf{Budget}$		$O(\epsilon^{-2} M \log M(M + N\log N)\log^{O(1)} M)$ [27]
Max Concurrent Flow	α	$d_k\alpha \le f_k, \forall k \in \mathcal{D}$	[19, 39, 40]	$O(\epsilon^{-2}(M^2 + KN)\log^{O(1)} M)$ [41]

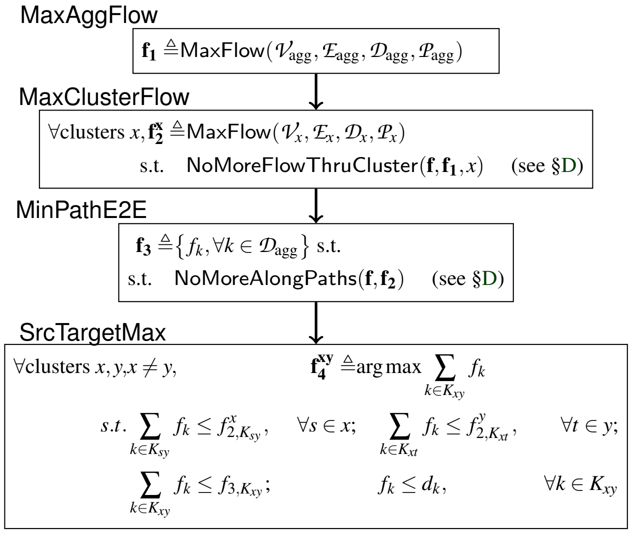
Table 1: We illustrate a few different multi-commodity flow problems all of which find feasible flows but optimize for different objectives and can have additional constraints; see notation in Table 2. Equation 6 fleshes out the problem completely for the case of maximizing flow. More problems are discussed in [11].

Term	**Meaning**
$\mathcal{V}, \mathcal{E}, \mathcal{D}, \mathcal{P}$	Sets of nodes, edges, demands, and paths
N, M, K	The numbers of nodes, edges, and demands, i.e., $N = \lvert\mathcal{V}\rvert, M = \lvert\mathcal{E}\rvert, K = \lvert\mathcal{D}\rvert$
e, c_e, p	Edge e has capacity c_e; path p is a set of connected edges
(s_k, t_k, d_k)	Each demand k in $\mathcal{D}$ has source and target nodes ($s_k, t_k \in \mathcal{V}$) and a non-negative volume (d_k).
$\mathbf{f}, f_k^p$	Flow assignment vector for a set of demands and the flow for demand k on path p.

Table 2: Notation for framing multi-commodity flow problems.

$\mathcal{V}_{\text{agg}}$, $\mathcal{E}_{\text{agg}}$, $\mathcal{D}_{\text{agg}}$, $\mathcal{P}_{\text{agg}}$	Nodes, edges, demands, and paths in the aggregated graph
$\mathcal{V}_x, \mathcal{E}_x, \mathcal{D}_x, \mathcal{P}_x$	Subscript denotes entities in the restricted graph for cluster x
x, η	Each cluster x is a strongly connected set of nodes and η is the number of clusters
$k, K_{xy}, K_{sy}, K_{xt}$	An actual demand (k); the rest are bundled demands from one source (s) or all nodes in a cluster (x) to a target (t) or to all nodes in a cluster (y)

Table 3: Additional notation specific to NCFlow.



MaxAggFlow
$\mathbf{f_1} \triangleq \mathsf{MaxFlow}(\mathcal{V}_{\text{agg}}, \mathcal{E}_{\text{agg}}, \mathcal{D}_{\text{agg}}, \mathcal{P}_{\text{agg}})$
MaxClusterFlow
$\forall$clusters $x, \mathbf{f_2^x} \triangleq \mathsf{MaxFlow}(\mathcal{V}_x, \mathcal{E}_x, \mathcal{D}_x, \mathcal{P}_x)$
s.t. $\mathsf{NoMoreFlowThruCluster}(\mathbf{f}, \mathbf{f_1}, x)$ (see §D)
MinPathE2E
$\mathbf{f_3} \triangleq \{f_k, \forall k \in \mathcal{D}_{\text{agg}}\}$ s.t.
s.t. $\mathsf{NoMoreAlongPaths}(\mathbf{f}, \mathbf{f_2})$ (see §D)
SrcTargetMax
$\forall$clusters $x, y, x \neq y$, $\mathbf{f_4^{xy}} \triangleq \arg\max \sum_{k\in K_{xy}} f_k$
$s.t. \sum_{k\in K_{sy}} f_k \le f^x_{2,K_{sy}}, \quad \forall s \in x; \quad \sum_{k\in K_{xt}} f_k \le f^y_{2,K_{xt}}, \quad \forall t \in y;$
$\sum_{k\in K_{xy}} f_k \le f_{3,K_{xy}}; \quad f_k \le d_k, \quad \forall k \in K_{xy}$

Figure 6: The basic flow allocation algorithm used by NCFlow; notation used here is defined in Table 3.

SDN-based traffic engineering schemes [35, 38], in addition to repeatedly solving global optimizations, must maintain an up-to-date view of the topology, gather desired volumes for demands and update traffic splits at switches based on the result of the optimization. Our production experience is that most of these repetitive steps have a latency of a few RTTs (round trip times) and so solving the optimization dominates, especially on large topologies. Moreover, demands are limited to their allocated rates in software at the source servers and thus allocating less than the full desired rate need not result in packet loss [35]. Finally, applications that contribute a large fraction of the bytes moving between datacenters are elastic in short timescales; e.g., large dataset transfers for data analytics. That is, these apps seek a fast completion time but do not need a large rate in every optimization epoch. Some other applications have a decreasing marginal utility as their rate allocation increases such as video streams of varying quality [43]. Today's SDN-based TE solutions [35, 38] use multiple priority classes to maximize allocations for elastic traffic without affecting the latency-sensitive traffic.

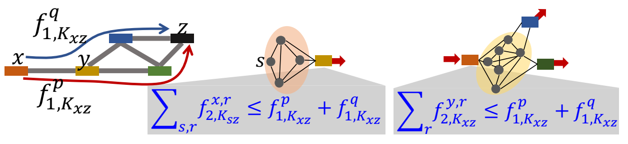
3 NCFlow

In this section, we describe NCFlow. Our steps are as shown in Figure 1. Offline, based on historical demands, we divide the network into clusters and determine paths. Further details are in §3.4. Online, we allocate flow to the current demands by solving a carefully constructed set of simpler sub-problems, some of which can be solved independently and in parallel. We describe these sub-problems in §3.1. Although they can be solved quickly, disagreements between independent solutions can lead to infeasible allocations; we present a simple heuristic in §3.2 that provably leads to feasible flow allocations. In §3.3, we discuss extensions that increase the total flow allocated by NCFlow. We also show sufficient conditions under which NCFlow is optimal and matches the flow allocated by MaxFlow. Finally, in §3.5, we discuss how NCFlow uses fewer forwarding entries by reusing pathlets within clusters and splitting rules for different demands.

3.1 Basic Flow Allocation

We begin by describing a simple (but incomplete) version of NCFlow's flow allocation algorithm; the pseudocode is in Figure 6. We continue using Figure 2 as a running example. The basic algorithm proceeds in four steps.

In the first step, we allocate flow on the aggregated graph; as shown in MaxAggFlow in Figure 6. In the aggregated graph, an example of which is in Figure 2 (right), nodes are clusters and the edges are bundled edges from the original graph—the edge between the red and yellow clusters corresponds to the five edges between these clusters on the actual graph. Similarly, we bundle demands on the aggregated graph: the demand K_{xy} between the clusters x and y corresponds to all of the demands whose sources are in cluster x and targets are



$f^q_{1,K_{xz}}$
z
x
y
$f^p_{1,K_{xz}}$
s
$\sum_{s,r} f^{x,r}_{2,K_{sz}} \le f^p_{1,K_{xz}} + f^q_{1,K_{xz}}$
$\sum_{r} f^{y,r}_{2,K_{xz}} \le f^p_{1,K_{xz}} + f^q_{1,K_{xz}}$

Figure 7: An example illustrating how the flow allocated in MaxAggFlow translates to constraints on the flow to be allocated in MaxClusterFlow.

in cluster y. The resulting flow allocation ($\mathbf{f_1}$) accounts for bottlenecks on the edges between clusters. However, this flow may not be feasible, since there may be bottlenecks *within* the clusters.

In the second step, we refine the allocation from step 1 to account for intra-cluster demands and constraints. Specifically, we allocate flow for the demands whose sources and targets are within the cluster. We also allocate no more flow than was allocated in $\mathbf{f_1}$ for the inter-cluster flows. MaxClusterFlow in Figure 6 shows code for this step. We note a few details:

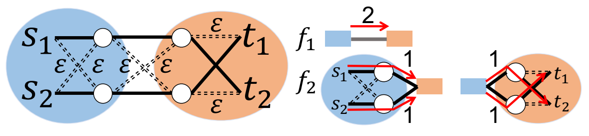
- We use virtual nodes to act as the sources and targets for the inter-cluster flows; the flow allocated in $\mathbf{f_1}$ determines which virtual node (i.e., which neighboring cluster) is the sender or the receiver for an inter-cluster demand.
- Figure 7 shows two examples on the right where the virtual nodes are drawn using squares.
- Figure 7 also shows the NoMoreFlowThruCluster constraints for demands from sources in the red cluster to targets in the black cluster (depicted as x and z respectively). On the aggregated graph, the flow for this demand takes the two paths shown. In the red cluster, as shown in the equation, the traffic from all sources (s), along multiple paths (r) to the virtual node, is restricted to be no more than what was allocated in $\mathbf{f_1}$.
- Figure 7 on the right also shows a more complex case that happens in the yellow cluster. Here, the traffic arrives at one virtual node but can leave to multiple virtual nodes. In MaxClusterFlow, we set up paths between all pairs of virtual nodes. As shown in the equation, the traffic leaving the red virtual node on paths (r) to either of the other virtual nodes must be no more than the total flow on paths p and q from $\mathbf{f_1}$.
- Observe that bundling demands ensures fewer variables and constraints for MaxClusterFlow. The demand from red to black clusters comprises twenty node pairs in the actual graph in Figure 2 (left); four sources in the red cluster and five targets in the black cluster. However, the MaxClusterFlow for the red cluster only has four bundled demands, from each source to the virtual node, and the yellow cluster has just one bundled demand from and to virtual nodes.

In the third step, we reconcile end-to-end; that is, we find the largest flow that can be carried along each path on the aggregate graph. As shown by MinPathE2E in Figure 6, for each bundle of demands and each path, we take the minimum flow allocated ($\mathbf{f_2^x}$) at each cluster on the path.

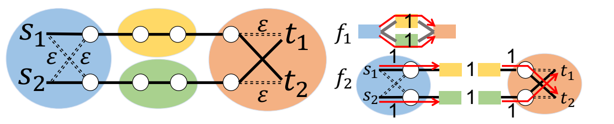
The flow allocation for the demands in a cluster x can be read directly from the $\mathbf{f_2^x}$ solution of MaxClusterFlow. For demands that span clusters, however, more work remains because the steps thus far do not directly compute their flow. In particular, $\mathbf{f_3}$ allocates flow for cluster bundles; such as say for all the demands whose sources are in cluster x and targets are in cluster y. The corresponding per-cluster flow allocations, $\mathbf{f_2^x}$ and $\mathbf{f_2^y}$, allocate flow from a source node and to a given target respectively. Thus, in the final step, SrcTargetMax, we assign the maximal flow to each inter-cluster demand that respects all previous allocations.

Problem	# of Nodes	# of Edges	# of Demands
MaxFlow	N	M	K
MaxAggFlow	η	$\le \min(M, \eta^2)$	$\le \min(K, \eta^2)$
MaxClusterFlow	$\sim \frac{N}{\eta} + \eta$	$\sim \frac{M}{\eta} + 2\eta$	$\sim \frac{K}{\eta^2} + 2\frac{N}{\eta} + \eta^2$

Table 4: Sizes of the problems in Figure 6 using notation from Tables 2 and 3. Just verifying that flow is feasible (i.e., FeasibleFlow in Eq. 1) uses $O(\#\text{ nodes} * \#\text{ edges})$ number of equations and variables. NCFlow has one instance of MaxAggFlow and executes the η instances of MaxClusterFlow in parallel. MinPathE2E and SrcTargetMax, are relatively insignificant.



(a) Disagreement arising from bundling edges: As shown on the right, the algorithm in Figure 6 will allocate 2 units of flow but only 5ε units can be carried.



(b) Disagreement arising from bundling demands: As shown on the right, the algorithm in Figure 6 will allocate 2 units of flow, but only 2ε units can be carried.

Figure 8: Illustrating how disagreements in flow allocation can occur in the basic flow allocation algorithm; see §3.1.1.

3.1.1 Properties of Basic Flow Allocation

Solver runtime: The numbers of equations and variables in the sub-problems are shown in Table 4. If the number of clusters η is 1, note that there is exactly one per-cluster problem, MaxClusterFlow, which matches the original problem from Eqn. 2. When using a few tens of clusters, we will show in §5 that all of the sub-problems are substantially smaller than the original problem (MaxFlow).

Feasibility: The flow allocated by Figure 6 satisfies demand and capacity constraints; we will prove this formally in §B.1. For demands whose source and target are in different clusters, however, disagreements may ensue since the different problem instances assign flow to different bundles of edges and demands. We illustrate two such examples in Figure 8; both have 1 unit of demand from s_1 to t_1 and from s_2 to t_2. The dashed edges have a capacity of $\varepsilon \ll 1$ and all of the other edges have a very large capacity.

- The example in Figure 8a illustrates an issue with bundling edges. The actual graph on the left can only

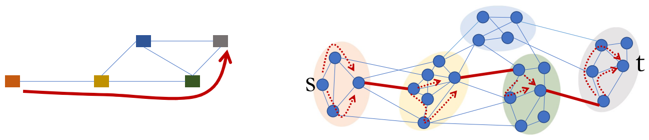


Figure 9: To guarantee feasibility, each cluster bundle is allocated flow on only one path on the aggregated graph (left) and on only one edge between each pair of clusters (right); the usable path and edges are shown in dark red. Note that multiple paths can still be used within clusters.

carry 5ε units of flow for each demand. However, as the figures on the right show, MaxAggFlow allocates two units of flow since the four edges between these two clusters can together carry all of the two units of demand. The MaxClusterFlow instances also allocate two units of flow as shown. The discrepancy arises because the problems in Figure 6 do not know that the *top* egress of the left cluster can take in all of the demand of s_1 but has only a low capacity to t_1.

- The example in Figure 8b illustrates an issue with bundling demands. Here too, observing the actual network on the left will show that 2ε units can be carried for each demand split evenly between the top and the bottom path. Again, as the figures on the right show, the basic flow allocation algorithm will conclude that both units of demand can be carried. Here, the discrepancy arises from the bundling of demands, the problems in Figure 6 cannot discern that the MaxClusterFlow instance of the left cluster sends the first demand to the brown cluster while the MaxClusterFlow of the right cluster wants to receive the second demand from the brown cluster.

3.2 A feasible heuristic

To avoid end-to-end disagreements, we make two simple changes to the basic flow allocation in §3.1.

First, when solving MaxAggFlow, only one path on the aggregated graph can be used for all of the demands between a given pair of clusters; we call such groups of demands to be cluster bundles. Next, between a pair of connected clusters, only one edge can carry the flow for a cluster bundle. Figure 9 shows in dark red an example path for a cluster bundle and the allowed edges between clusters; we also show the intra-cluster paths that can carry flow for this bundle.

There are multiple ways to avoid disagreements while keeping the problem sizes small via bundling. We discuss the above changes here because they are simple and sufficient. Specifically, we show that:

Theorem 1. *The algorithm in Figure 6, when constrained as discussed above, will always output a feasible flow.*

Proof. The proof is in §B.2. Intuitively, these changes suffice because the independent decisions made by different problems in Figure 6 cannot disagree; per cluster bundle, all problem instances allocate flow to the same edge and path. □

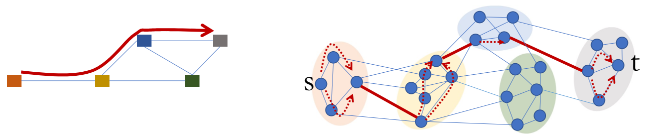

Figure 10: Contrasting with Figure 9, for the same cluster bundle, in a subsequent iteration, NCFlow allocates flow on a different path on the aggregate graph and on different inter-cluster edges. The chosen paths and edges are again shown in red.

3.3 Stepping towards optimality

The flow allocation algorithm described thus far is fast but not optimal; that is, it may allocate less total flow over all demands than the flow allocated by solving the larger global problem (MaxFlow from Eqn. 2). There are a few reasons why this happens. The MaxAggFlow in Figure 6 allocates flow on paths through clusters without knowing how much flow the clusters can carry. Switching the order, i.e., solving MaxClusterFlow before MaxAggFlow, could be worse because each cluster must allocate flow without knowing how much flow can be carried end-to-end. Furthermore, the heuristic in §3.2 constrains each cluster bundle to use only one edge between clusters and one path on the aggregated graph. We now discuss a few extensions to increase the flow allocation.

First, we re-solve the problems in Figure 6 multiple times. A simple way to do this would be to deduct the allocated flow and use the residual capacity on edges in the next iteration. Also, we pick different edges between clusters and/or different paths on the aggregated graph in different iterations (see Figure 10 for an example). The number of iterations is configurable; we continue as long as the total flow increases in each iteration by at least a pre-specified amount (say 5%). One could apply other policies such as a timeout. We show in §5 that a small number of iterations suffice for a sizable increase in the total flow. We will also show that later iterations finish faster than the first iteration perhaps because fewer demands remain to satisfy.

Next, we empirically observe that the choice of clusters and edges/paths to use in different iterations has an effect on flow allocation. For instance, the disagreements in Figure 8 *go away* by using a different choice of clusters—specifically, see Figure 31d and Figure 31e. We discuss how NCFlow precomputes cluster and edge/path choice in §3.4.

To sum up, we prove that flow allocation will be optimal when a few sufficient conditions hold:

Theorem 2. *The method in Figure 6 leads to the optimal flow allocation when any path can be used within each optimization and the number of clusters is* 1 *or equal to the number of nodes or all of the following conditions hold:*

- *the aggregated graph $\mathcal{G}_{agg}$ is a tree,*
- *only one edge connects any pair of clusters,*
- *all demands are satisfiable.*

Proof. By optimal, we mean that the total allocated flow must be as large as an instance of Equation 6 wherein any path can be used. The proof is in §B.3. Intuitively, when the number of clusters is 1 and any paths can be used, a single instance of MaxClusterFlow is identical to the optimal problem in Equation 6. Similarly, when the number of clusters equals the number of nodes, MaxAggFlow is identical to the optimal problem. Furthermore, the conditions listed lead to optimality because the optimal flow allocation can be transformed into an allocation that can be outputted by Figure 6. □

Even though the listed conditions appear restrictive, note that the topology within clusters can be arbitrary. We will show in §5 that NCFlow offers nearly optimal flow allocations even when the above conditions do not hold.

3.4 Choosing clusters and paths

The choice of clusters and paths affects both the solution quality and runtime of NCFlow. We cast cluster choice as a graph partitioning problem [5, 21, 65] with these objectives:

- **Concentrated with a low cut:** NCFlow can output better flow allocations when much of the total demand and the total edge capacity is between nodes in the same cluster.
- **Balanced cut:** Intuitively, NCFlow will have a smaller runtime when the complexity of MaxAggFlow balances with that of MaxClusterFlow. Recall from Table 4 that the former depends on the number of clusters whereas the latter depends on the size of the largest cluster.

We empirically observe, based on experiments with many WANs and different types of demands, that:

- On a graph with N nodes, about $\sqrt{N}$ clusters, irrespective of the clustering technique, leads to the best result, i.e., smallest runtime and fewest forwarding entries while allocating nearly the largest amount of flow possible; see Figure 13.
- When choosing the same number of clusters, one of the three considered clustering techniques (described below) generally performs better than the others but not in all cases; see Figure 21.

Thus, the *optimal* clustering choice for a WAN is unclear; it is possible that hand-tuning or using a learning technique may lead to better-performing clusters. Nevertheless, any of the three simple clustering schemes discussed below already suffice for NCFlow to improve substantially over baselines.

We consider the following clustering choices because they are simple and fast; unless otherwise noted, results in this paper use FMPartitioning.

- FMPartitioning [18, 25] divides nodes into clusters so as to maximize a "modularity" score which prefers more edges to lie within than between clusters. In NCFlow, we apply modularity-based clustering with edge weights set to their capacity.
- Spectral clustering [53] computes eigenvectors of the weighted adjacency matrix and chooses a desired number of the top eigenvectors as *cluster heads*; each node is assigned to the cluster of their closest eigenvector (e.g., using k-means).
- Leader Election picks a desired number of nodes at random as leaders and assigns each other node to the closest leader; wherein, distance is measured as the path length using invcap edge weights.

Some other clustering techniques [5, 42, 65] can balance cluster sizes or trade-off between concentration and balance but are more complex computationally; it is possible that using such schemes can further improve NCFlow.

Path choice in NCFlow: On the aggregated graph and on each cluster graph, we pre-compute offline a small number of paths between every pair of nodes. We consider the following different path choices and pick paths that lead to the largest flow allocation on historical demands:

- k-shortest paths [70] with edge weight of 1 or $\frac{1}{c_e}$ where c_e is the capacity of edge e and $k = 4, 8$ or 16.
- As above, but with the additional requirement that the paths for a node pair are edge-disjoint [52].

NCFlow also pre-computes offline (1) a pseudo-random choice of which edges to use between a pair of connected clusters in each iteration and (2) which path on the aggregated graph to use for each cluster bundled demand in each iteration.

3.5 Setting up switch forwarding entries

NCFlow uses many fewer switch forwarding entries than prior works due to the following reasons.

First, the paths along which NCFlow allocates flow can be thought of as a sequence of pathlets [32, 47, 68] in each cluster connected by crossing edges between clusters. Figures 9 and 10 illustrate such paths on the right. This observation is crucial because a pathlet can be reused by multiple demands. For example, in Figure 9, the flow from any source in the red cluster to any target in the grey cluster would use the same pathlets shown in the yellow, green, and blue clusters. Prior work [35, 36], on the other hand, establishes paths for each demand. Using pathlets has two advantages. The number of pathlets used by NCFlow is about η times less than the number of paths used by prior works[2]. Furthermore, a typical pathlet has fewer hops than a typical end-to-end path. Thus, NCFlow uses many fewer rules to encode paths in switches.

[2]More precisely, the number reduces from $PN(N-1)$ to $\sum_x P(N_x)(N_x-1)$ where P is the number of paths per node pair, the N nodes are divided into η clusters, and cluster x has N_x nodes. If clusters are evenly sized, $N_x = N/\eta$, and the ratio of these terms is $\sim \eta$.

Next, whenever NCFlow allocates flow at the granularity of cluster bundles, all of the demands in a bundle take the same paths and are split in the same way across paths. Hence, NCFlow uses one traffic splitting rule for all demands in such bundles. For instance, the demands from source s in the red cluster in Figure 9 to any target in the grey cluster are split with the same ratio across the same pathlets in all clusters (except the grey cluster where they take different pathlets to reach their different targets). Thus, with NCFlow, the number of splitting rules at a source decreases by a factor of $\sqrt{N}/2$[3].

The paths and splitting rules to push into switch forwarding tables are determined by the offline component of NCFlow and only change occasionally. After each allocation, only the splitting ratios change. More details on the data-plane of NCFlow such as how to compute the total flow that can be sent by each demand and the splitting ratios as well as how to move packets from one pathlet to the next are in Appendix C. In §5, we measure the numbers of rules used by NCFlow.

4 Implementing NCFlow

Our current prototype of NCFlow is about 5K lines of Python code, which invokes Gurobi [33] v8.1.1 to solve all of the optimization problems. For clustering WAN topologies, we adapt [26] to find clusters that maximize modularity; we also use our own implementation of NJW spectral clustering [53]. We use a grid search over the number of clusters (η) and the above clustering techniques to identify the best performing choice for each topology on a set of historical traffic matrices. To compare with state-of-the-art techniques, we customize the public implementations of SMORE [44, 45] and TEAVAR [19]. We have also implemented Fleischer's algorithm [27]; our implementation is about 10× faster than public implementations [8, 37] since we carefully optimize a key bottleneck in Fleischer's algorithm. All of these code artefacts are available on GitHub [2].

5 Evaluation

We evaluate NCFlow on several WAN topologies, traffic matrices, and failure scenarios to answer the following questions:

- Compared to state-of-the-art LP solvers and approximate combinatorial algorithms, does NCFlow offer a good trade-off between runtime and total flow allocation? Is it substantially faster, with only a small decrease in total flow?
- For real-world TE scenarios, in which flow solvers must adapt to changing demands and faults, how much benefit does NCFlow offer relative to the state-of-art?

[3]A source uses $N-1$ splitting rules in prior works but with NCFlow only requires $N_x+\eta-2$ rules when the source's cluster has N_x nodes; if clusters are evenly sized and $\eta \sim \sqrt{N}$, the ratio of these terms is $\sqrt{N}/2$.

- How do our various design choices in NCFlow impact its performance?

5.1 Methodology

Here, we describe our methodology—the topologies, traffic, baselines, and metrics used in our evaluation.

Topologies: We use two real topologies from a large enterprise—PrivateSmall is a production internet-facing WAN with hundreds of sites, and PrivateLarge is a larger WAN that contains many more sites. We also use several topologies from the Internet Topology Zoo [6] and reuse topologies used by prior works [19, 38]. Table 5 shows details for some of the used topologies; note that the topologies shown are 10× to 100× larger than those considered by prior work [19, 35, 38, 44, 49].

Traffic Matrices (TMs): We benchmark NCFlow on traffic traces from PrivateSmall, which contain the total traffic between node pairs at 5-minute intervals. We also generate the following kinds of synthetic traffic matrices for all topologies:

- **Poisson**(λ, δ) models demands with varying concentration; the demand between nodes s and t is a Poisson random variable with mean $\lambda\delta^{\mathrm{d}_{st}}$, where d_{st} is the hop length of the shortest path between s and t and $\delta \in [0,1)$ is a *decay factor*. We choose δ close to 0 or to 1 to model strongly and weakly concentrated demands, respectively.
- **Gravity**(v) [14, 60]: The total traffic leaving a node is proportional to the total capacity on the node's outgoing links (parameterized by v); this traffic is divided among other nodes proportional to the total capacity on their incoming links.
- **Uniform**$([0,a))$: The traffic between any pair of nodes is chosen uniformly at random, between 0 and a.
- **Bimodal**$([0,a),[b,c),p)$ [14]: A p fraction of the node pairs, chosen uniformly at random, receive demands from **Uniform**$([b,c))$ while the rest receive demands from **Uniform**$([0,a))$. We use $p = 0.2$.

For each above model, we select parameters such that fully satisfying the traffic matrix leads to a maximum link utilization of about 10% in each topology. Then, we scale all entries in the TM by a constant $\alpha \in \{1,2,4,8,16,32,64,128\}$. Doing so creates demands that range from easily satisfiable to only partially satisfiable; with $\alpha = 128$, the satisfiable portion of the demand varies between 25-70%. We generate five samples for each traffic model and scale factor for each topology.

Baselines: We compare NCFlow with these techniques:

Path Formulation (PF_4) solves the multi-commodity max-flow problem shown in Equation 2 using k-shortest paths between node pairs where $k = 4$. Results for other path choices are in §G.4.

PF *Warm Start* (PF_{4w}) matches PF_4 except that it allows the LP solver to "warm start"; that is, over a sequence of traffic matrices, the flow allocated to the previous TM is used as a starting point to compute allocation for the next TM. When traffic changes are small, warm start leads to faster solutions.

Approximate Combinatorial Algorithms: Fleischer's algorithm [27] is the best-known approximation for MaxFlow. We use two variants: Fleischer-Path where flow is restricted to a path set and Fleischer-Edge without any path restrictions. We show results here for an approximation guarantee of 0.5; that is, the techniques must achieve at least half of the optimal flow allocation. Results for other approximation guarantee values are in [10].

SMORE [44] allocates flow dynamically on paths that are pre-computed using Räcke's Randomized Routing Trees (RRTs). We use the code from [45] to compute paths. Since the LP in [45] requires demands to be fully satisfiable, we implement a variant, SMORE*, that maximizes the total flow on the computed paths, regardless of demand satisfiability.

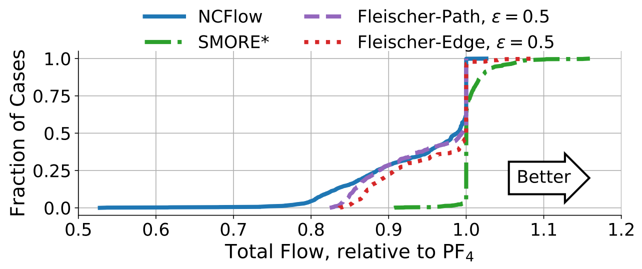
TEAVAR [3, 19] models link failure probabilities and computes flow allocations given an availability target. We implement a variant, TEAVAR*, that maximizes the total flow[4]; further details are in Appendix F.

Clusters, Paths, and # of Iterations: Table 5 shows the number of clusters used by NCFlow per topology. Here, we report results on edge-disjoint paths, chosen using inverse capacity as the edge length; results for other path choices are qualitatively similar (see §G.4). All schemes that use paths (i.e., PF_4, Fleischer-Path, TEAVAR*, and NCFlow) use the same method to compute paths. For each iteration up to $I = 6$, we also pre-compute offline the path to use on the aggregated graph, and the edge to use between connected clusters for each cluster bundle.

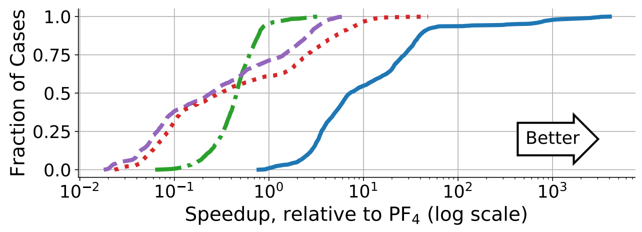
Metrics: We compare the schemes on the following metrics:

- **Relative total flow** is the total flow achieved by a scheme relative to PF_4.
- **Speedup ratio** is the runtime of each scheme relative to PF_4. For LP-based methods, we report the Gurobi solver runtimes, since models can be constructed once offline in practice. For combinatorial methods, we report algorithm execution time. All runtimes are measured on an Intel Xeon 2.3GHz CPU (E52673v4) with 16 cores and 112 GB of RAM.
- **FIB Entries:** We measure the number of switch forwarding entries used.

[4]TEAVAR [3, 19] maximizes the *concurrent* flow; see Table 1



(a) CDF of total flow relative to PF_4



(b) CDF of speedup relative to PF_4

Figure 11: CDFs comparing NCFlow with state-of-the-art methods. With only a modest decrease in total flow, NCFlow offers a substantial runtime speedup.

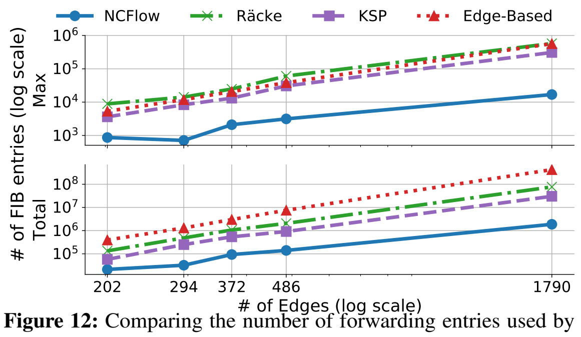


Figure 12: Comparing the number of forwarding entries used by various methods for the experiments from Figure 11.

5.2 Comparing NCFlow to the State of the Art

Figures 11a and 11b show cumulative density functions (CDFs) of the relative total flow and speedup ratio for NCFlow and several baselines. These results consist of 2,600 traffic matrices and 13 topologies. If a scheme matches the baseline PF_4, its CDF will be a pulse at $x = 1$ in both figures; the fraction of cases to the left (or right) of $x = 1$ indicate how often a scheme is worse (or better) than PF_4. Note that the x-axis for the speedup ratio is in log scale.

We see that SMORE*, shown using green dashed lines in the figures, modestly improves the flow allocation (in 25% of the cases) while almost always taking longer to run than PF_4.

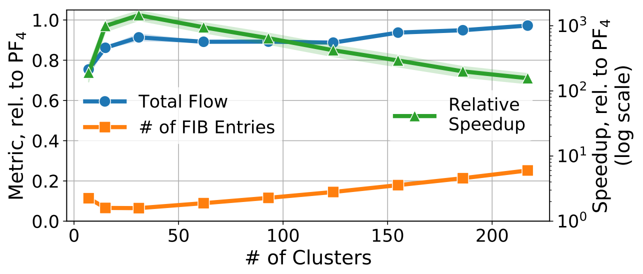

Figure 13: NCFlow's performance when using different numbers of clusters on PrivateLarge. The speedup ratio is plotted on the right y-axis in log scale; the other metrics use the left y-axis.

Both effects are because SMORE* allocates flow on Räcke's RRTs instead of k-shortest paths.

The edge and path variants of Fleischer's, shown using purple and red lines in the figures, perform similarly; since they are approximate algorithms, they allocate less flow than PF_4 in roughly 50% of cases, but are also faster than PF_4 in slightly less than 50% of cases. We conclude that these approximate algorithms are not practically better than PF_4.

In contrast, NCFlow, shown with dark blue lines in the figures, almost always allocates at least 80% of PF_4's total flow, while achieving large speedups. In the median case, NCFlow achieves 98% of the flow and is over 8× faster. These improvements accrue from NCFlow solving smaller optimization problems than PF_4.

Figures 18 and 19 tease apart the above results by load, traffic type and topology. Figures 23–27 show results for alternate path choices. Taken together, these results indicate that NCFlow's improvements hold across a variety of scenarios.

For the same experiments considered above, Figure 12 shows the number of switch forwarding entries used in different topologies. (A full set of results is in Table 6.) The bottom plot is the total number of forwarding entries across all switches, while the top shows the maximum for any switch. Note that both the x and y axes are in log scale. NCFlow consistently uses fewer forwarding entries; using NCFlow offers a greater amount of relative savings than switching from all edges to just a handful of paths per demand. The savings from NCFlow also increase with topology size. The reason, as noted in §3.5, is that NCFlow reuses pathlets and traffic splitting rules for many different demands.

5.3 Effect of Design Choices

Figure 13 shows how NCFlow's performance varies with the numbers of clusters used on PrivateLarge. While NCFlow allocates roughly the same amount of total flow, using about 30 clusters improves runtime and reduces forwarding entries. Figure 21 compares NCFlow's performance when using different clustering techniques; more details are in §G.2.

Recall from §3.3 that NCFlow uses multiple iterations of Figure 6. In the above experiments, the first iteration alone accounts for 75% of the runtime and for roughly 90% of the

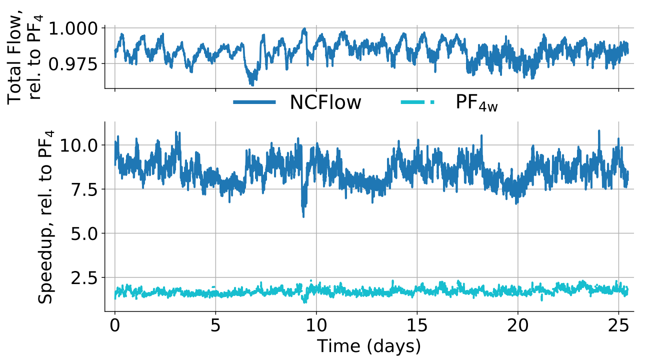

Figure 14: Allocated flow and speedup relative to PF_4 on a sequence of production TMs from PrivateSmall. In half of the cases, NCFlow allocates at least 98.5% of the flow and is at least 8.5× faster.

flow that is allocated by NCFlow. Later iterations are faster perhaps because they have less traffic to consider.

Breaking down the runtime by the steps in Figure 6, we see cases where MaxClusterFlow accounts for over 70% of NCFlow's runtime perhaps because the largest cluster contains a large fraction of the nodes. Better cluster choice or recursively dividing the largest clusters can further lower runtime.

5.4 NCFlow on Real-World Traffic

Here, we experiment with a sequence of traffic traces collected on the PrivateSmall WAN. Figure 14 plots the moving average (over 5 windows) of the total flow and speedup relative to PF_4 for two schemes—NCFlow in blue and PF_{4w} in light blue. The figure shows that PF_{4w}'s warm start yields a median speedup of 1.66×. NCFlow achieves a consistently higher speedup (8.5× in the median case), and the flow allocation is nearly optimal: the median total relative flow is 98.5%, and NCFlow always allocates more than 93%.

5.5 Tracking Changing Demands

Here, we evaluate the impact of a technique's runtime on its ability to stay on track with changing demands. Specifically, on the PrivateLarge topology, we use a time-series of traffic matrices, wherein a new TM arrives every five minutes and the change from one TM to the next is consistent with the findings in Figure 4 (more details are in Figure 20). At each time-step, all techniques have the opportunity to compute a new allocation for the current TM or to continue computing the allocation for an earlier TM if they have not yet finished; in the latter case, their most recently computed allocation will be used for the current TM. For example, a technique that requires five minutes to compute a new allocation will be always *one window behind*, i.e., each TM will receive the allocation that was computed for the previous TM.

Figure 15 shows the fraction of demand that is satisfied by three different schemes; we also show the value for an instantaneous scheme which is not penalized for its runtime.

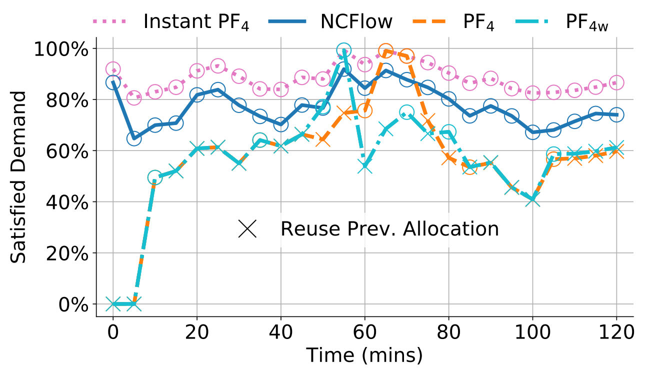

Figure 15: When demands change, how solver runtimes affect flow allocation on PrivateLarge: Due to the slow runtime, PF$_4$ and PF$_{4w}$ carry only 62% of the traffic that can be satisfied by Instant PF$_4$, a (hypothetical) scheme which has zero runtime. NCFlow carries 87% of the traffic since its faster runtime compensates for its sub-optimality.

PF$_4$'s average runtime here is over 15 minutes; hence, as the orange dashed line shows, PF$_4$ is able to compute a new allocation only for every third or fourth TM. This leads to substantial demand being unsatisfied: for node pairs whose current demand is larger than before, PF$_4$ will not allocate enough flow. On the other hand, node pairs whose current demand is less than their earlier demand will be unable to fully use PF$_4$'s allocation. As the figure shows, PF$_4$ only satisfies 53% of the changing demand on average, whereas Instant PF$_4$ satisfies 87% of the demand.

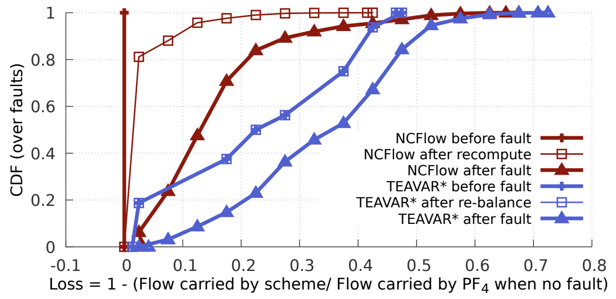
PF$_{4w}$ (the dash-dot light blue line), where the solver warm starts using the previous allocation, is modestly faster than PF$_4$ on average. As the figure shows, the average demand satisfied by PF$_{4w}$ is only slightly larger than PF$_4$ (about 54%).

In contrast, NCFlow (the solid dark blue line) finishes well within five minutes which allows allocations to change along with the changing demands. We find that on average NCFlow satisfies 75% of the demands; its smaller runtime more than makes up for sub-optimality, allowing NCFlow to carry more flow than PF$_4$ when demands change.

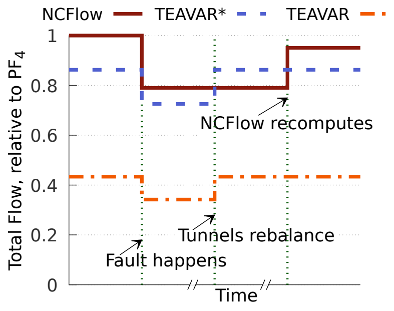
5.6 Handling Failures with NCFlow

Here, we evaluate the effect of link failures. As we note in §F, TEAVAR* did not finish within several days on any of the topologies listed in Table 5 because when all possible 2-link failure scenarios are considered, the number of equations and variables in the optimization problem increase from $O(N^2)$ for MaxFlow to $O(M^2N^2)$ for TEAVAR [19], where N and M are the numbers of nodes and edges, respectively. Hence, we report results on the 12-node, 38-edge WAN topology from B4 [38]. We generate synthetic traffic matrices as noted in §5.1. Using link failure probabilities from TEAVAR [3], we generate several hundred failure scenarios and, for each TM, we measure the flow carried by NCFlow and TEAVAR* before the fault, immediately after the fault, and after recovery.

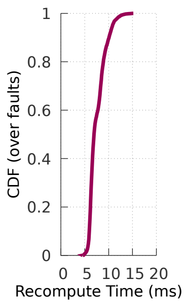
A key difference in fault recovery between NCFlow and TEAVAR* is that TEAVAR* requires sources to rebalance the traffic splits when a failure happens; doing so takes about one RTT on the WAN. Given a parameter β, TEAVAR* guarantees that there will be no flow loss after the tunnels re-balance with a probability of $1-\beta$. See §F for more details. We use $\beta = 0.99$, as recommended in [19]. NCFlow, on the other hand, recomputes flow allocations taking into account the links that have failed; doing so takes one execution of NCFlow and some RTTs to change the traffic splits at switches; more details are in §E. Figure 16c shows that the recomputation time is well within one RTT on the WAN.



(a) CDFs of the flow *loss* before faults, immediately after faults and after recovery (B4 topology, many traffic matrices and faults; see §5.6).



(b) Timelapse of when a fault occurs (B4 topology, Uniform traffic matrix, $\beta = 0.99$)



(c) NCFlow's time to recompute after fault.

Figure 16: Comparing failure response of NCFlow with prior work.

Figure 16b shows a timelapse of the flow carried on the network before the fault, immediately after the fault, and after recovery. As the figure shows, TEAVAR* can have a smaller loss and for a shorter duration; i.e., until sources rebalance traffic while NCFlow can carry more flow before fault and after recovery; moreover, the fast solver time can reduce the duration of loss.

Figure 16a shows CDFs over many faults and traffic matrices for NCFlow and TEAVAR*. We record the flow loss at three stages: before the fault, immediately after the fault, and after recovery. As the figure shows, NCFlow's ability to carry more flow before the fault and after recovery more than compensates for the slightly larger loss it may accrue in between.

6 Discussion

Extending beyond MaxFlow: FeasibleFlow is a common constraint for many objectives beyond MaxFlow (see Table 1). Since the algorithm in §3.1 and the heuristic in §3.2 guarantee feasibility, NCFlow can apply to objectives beyond MaxFlow;

however, we believe that more work is needed to improve the solution quality for different objectives.

Optimality guarantee: In §I, we show that constraining by clusters and paths, as done by NCFlow, does not necessarily reduce the flow allocation; that is, nearly the maximum amount of flow can be carried while respecting clustering and path constraints. This is promising because a better heuristic (than Figure 6) may allocate more flow without losing the benefits of solving smaller per-cluster problems. Furthermore, although NCFlow achieves sizable speedups by using simple clustering methods, the optimal cluster choice is uncertain; we show examples in §H to illustrate the challenges.

Recursive (or multiple levels of) clusters: For large topologies or when the largest cluster has a disproportionate number of nodes, we can further divide a cluster into sub-clusters. Doing so is an extension of the algorithm in Figure 6 where, in the iterative step, the MaxClusterFlow problem at a cluster is replaced with a new instance of all of the steps in Figure 6 along with the additional constraints that arise from the current level (e.g., NoMoreFlowThruCluster constraints). We leave further details to future work.

7 Related Work

NCFlow builds upon a few themes in prior work. We discuss and evaluate against some prior works already. To recap: (1) Some large enterprises use path-based global optimization problems similar to MaxFlow to manage traffic on their WANs [35, 36, 38]. We saw in §5 that doing so does not scale to the WAN topologies of today or the future, which consist of thousands of sites; (2) We saw that approximate algorithms for multi-commodity max flow, such as [27], require a large number of switch forwarding entries since they can send flow along any edge. Also, NCFlow allocates more flow and is faster compared to path-based versions of these algorithms. (3) Probabilistic fault protection schemes such as TEAVAR [19] take infeasibly long to run on large topologies when considering multiple link failures; they also allocate less flow to reserve capacity to deal with possible failures. Other oblivious techniques [13,14,19,44,49,66] have a similar tradeoff. Quickly recomputing using NCFlow trades off slightly more loss after a fault to carry much more traffic before the fault and after recomputation; hence, we believe that NCFlow is better suited to enterprise WANs, which target very high link utilization and have traffic that is elastic to short-term loss (e.g., scavenger-class traffic, such as replicating large datasets [35, 38, 49]). Here, we discuss other related work.

TE on WANs: Typically, a WAN node is not a single switch, but rather a group of switches connected in a specific way such as a full mesh. Similarly, a WAN edge is a systematic collection of links between many switches. [36] discusses how to hide the intra-node connectivity from the global TE solution. NCFlow complements this technique; it can use a similar intra-node scheme and can support WANs that are 10× larger than were considered in [36]. The specific contraction used by NCFlow—node clusters with large capacity and/or demand between themselves—also differs from the contractions used in route planning [4, 9, 15]. Some BGP-based TE schemes [24, 62, 69], which address how best to move traffic between different (BGP) domains, are also complementary to NCFlow which considers the WAN of a single enterprise (domain). Other TE schemes use different protocols, such as OSPF, or work over longer timescales (e.g., hours to days) [29, 39, 46, 51].

Multi-Commodity Flow Solutions: Both the edge- and path-based LP formulations are well-studied [16, 67]. Some works consider the case of a single commodity, i.e., one source and target, and do not directly extend to the case of multiple commodities [34,48,55]. The best-known approximate algorithms for multi-commodity flow problems incrementally allocate flow on the shortest path and increase the length of all edges on that path [17, 27, 30, 41]. For the problem sizes considered here, LP solvers such as Gurobi are faster in practice, perhaps because they take larger steps towards the optimal allocation. A few works customize LP solvers to improve performance on flow problems [23, 50]. NCFlow is agnostic to the solver used and can use any solver for the sub-problems in Figure 6.

Decompositions: Using standard decomposition techniques for large optimization problems, such as Dantzig-Wolfe and Benders [16,20], for multi-commodity flow problems has lead to inconclusive results [31,54]; i.e., not consistently faster than MaxFlow. NCFlow can be thought of as a problem-specific decomposition that leverages the observation that both capacity and demands are concentrated in today's WANs.

8 Conclusion

We present a fast and practical solution for allocating flow on large WANs. We leverage the concentrated nature of demands and topologies to divide nodes into clusters and solve sub-problems per cluster and on the aggregated graph. Our heuristics guarantee feasibility and empirically achieve close-to-optimal flow allocations. By reusing pathlets and splitting rules across demands, we require fewer forwarding entries in switches. Empirically, on topologies that are over 10× larger than were considered in prior work and many traffic matrices, our solution NCFlow is 8.2× faster than the state of the art, while allocating 98.8% of the total flow and using 6× fewer forwarding entries in the median case. We demonstrate that NCFlow offers sizable benefits when tracking changing demands and reacting to failures. As enterprise WANs continue to grow, we believe techniques such as NCFlow can enable improved traffic orchestration and higher link utilization.

A More Discussion

NCFlow is **agnostic to the underlying solver** used for the problems in Figure 6 and can benefit from future improvements to LP solvers and approximate methods [27, 30, 41].

Further use cases: Beyond serving as a drop-in replacement for today's production WAN traffic controllers, NCFlow can be used whenever fast and close-to-optimal solutions are desirable such as: when allocating flow for future timesteps [39, 40] or to compare topology changes [1, 22] or to accelerate the training of ML-based routing systems [64].

B Properties of NCFlow's flow allocation algorithm

B.1 Proof that the algorithm in §3.1 meets demand and capacity constraints

Satisfying demand constraints: Demands whose source and target are in the same cluster are considered by only one instance of MaxClusterFlow; hence, they do not receive more flow than their demands. Specifically, MaxClusterFlow in Figure 6 invokes MaxFlow which in turn imposes the demand constraints listed in FeasibleFlow; Equation 1.

Demands whose source and target are in different clusters receive no more flow than their demand due to SrcTargetMax; observe in Figure 6 that one of the four constraints in SrcTargetMax explicitly controls the flow for such demands.

Satisfying edge capacity constraints: We say an edge is local to a cluster if both its incident nodes are within the same cluster. Flow is assigned to a local edge only by the MaxClusterFlow instance of the cluster that contains that edge. Since MaxClusterFlow ultimately invokes FeasibleFlow; by Equation 1 a local edge is allocated no more than its capacity.

Edges that are not local receive flow allocation in MaxAggFlow where, as noted in §3.1, all of the edges that lie between a pair of clusters are treated as a single edge whose capacity equals the sum of the capacity of the underlying edges. Thus, the flow assigned to a bundle of edges by MaxAggFlow is no more than the total capacity of the edges in the bundle. Subsequently, MaxClusterFlow instances behave similarly; that is, the flow allocated for a bundle of edges is no more than the capacity of that bundle. For example, Figure 17 shows the four edges between the yellow and green clusters in Figure 2 as well as the bundles considered by MaxAggFlow (in the middle) and the two instances of MaxClusterFlow corresponding to the yellow and green clusters on the right. The later steps in Figure 6 do not increase flow and so we conclude that capacity constraints are satisfiable for all non-local edges.

B.2 Proof that the heuristic in §3.2 leads to feasible flow allocations

Here, we prove Theorem 1. First, note that the heuristic in §3.2 which only restricts the edges between clusters and paths on the aggregate graph that can be used by some demands does not affect the proof in §B.1; that is, edges still receive flow less than their capacity and demand constraints hold.

We now prove that the heuristic will satisfy flow conservation; that is, at any node in the network, for any demand which neither originates nor ends at this node, the net flow is zero, i.e., incoming flow to the node equals the flow leaving that node.

It is easy to see that flow conservation holds for demands whose source and target are in the same cluster even without the heuristic in §3.2 because: (1) Only the instance of MaxClusterFlow for that cluster assigns flow to such a demand. (2) Since MaxClusterFlow invokes FeasibleFlow in Equation 1, the flow is allocated along paths which start and end at the source and target of that demand respectively. (3) Thus, every node that is neither the source or target will have incoming flow equal to the outgoing flow.

We now consider the remaining demands, that is, whose source and target are in different clusters.

It is easy to see that for such demands, flow conservation holds at all nodes that do not have edges to or from other clusters by logic that is similar to the above. The MaxClusterFlow instance of the cluster containing such a node would allocate flow to some bundle of demands on paths in this cluster that neither start nor end at such a node.

The only case left is nodes which have edges to and from other clusters. Suppose by contradiction that some demand k violates flow conservation at such a node u. The heuristic in §3.2 allocates flow for demand k along only one path in the aggregated graph and on only one edge between connected clusters. If the cluster containing u is not on the chosen path or none of the chosen edges are incident on u, then the net flow allocated for k over all edges incident on u will be zero. Let e be that one chosen crossing edge incident on u which can receive non-zero flow for demand k. Observe that all of the other demands whose source and target are in the same clusters as k would also be allocated flow on the same path and edges as k. Thus, all the flow allocated for these demands entering or leaving node u as the case may be would be on edge e. Two instances of MaxClusterFlow, one corresponding to the cluster that contains u and another corresponding to the other side of edge e, will assign possibly different flow values for this bundle of demands on edge e. To conclude our proof, note that MinPathE2E takes the minimum flow assigned along all such crossing edges e on the chosen path through the aggregated graph and that SrcTargetMax further breaks open the bundle to assign feasible flow for each actual demand contained in the bundle.

If more than one crossing edge or more than one path on the aggregate graph are used for a demand, it is easy to see how the above proof will break. The two instances of MaxClusterFlow that correspond to the clusters on either side of a crossing edge will be forced by MinPathE2E to only agree on the total volume for the cluster bundle of demands for all edges between the pair of clusters; that is, these instances may allocate different flow on different edges or allocate different flow to individual demands in the bundle. Figure 8 shows simple examples of such disagreement.

B.3 Proof of optimality for algorithm in §3.1 given some sufficient conditions

Here, we prove Theorem 2. We already discussed in §3.3 the case where the number of clusters, η, is 1 or N, the number of nodes in the graph. To prove optimality for the other sufficient conditions, we posit a helper theorem.

Theorem 3. *Given a set of paths $\mathcal{P}$ that can be used by flows, there exists a clustering of nodes into clusters such that any flow allocated on a set of paths $\mathcal{P}$ can also be allocated by the method in Figure 6 over those clusters.*

Proof. The claim is trivially true by using N clusters, where each node is in a cluster by itself. We show that it is possible to use fewer clusters next. Let $\mathcal{S}$ be a set of nodes such that every path in $\mathcal{P}$ contains at most one contiguous sequence of the nodes in $\mathcal{S}$. For example, the set $\{u, v\}$ satisfies this property if every path in $\mathcal{P}$ has neither u nor v, just u but not v (no repetitions allowed), just v but not u, $u \to v$ (no repetitions of u or v anywhere else in the path) or $v \to u$. Coalescing each such set $\mathcal{S}$ into a cluster would allow the method in Figure 6 to allocate the same flow as MaxFlow using the paths in $\mathcal{P}$. □

If G_{agg} is a tree and there is at most one edge between any pair of clusters, any set of paths $\mathcal{P}$ on the actual graph would consist of contiguous segments that are contained within each cluster. Thus, per the above theorem, any flow allocated by MaxEdgeFlow (Equation 6) can also be allocated by the method in Figure 6. The only difference then between the global optimization and the method in Figure 6 is that whereas the former is a single optimization call, the latter is a sequence of optimizations. Since demands are satisfiable, however, all of the steps in Figure 6 will allocate the entirety of demand and hence will allocate the maximum amount of flow.

Note, in particular, that for the sufficient conditions listed in Theorem 2 a single iteration of the steps in Figure 6 suffice.

In §H, we show some counter-examples where NCFlow can lead to sub-optimal allocations when any of these sufficient conditions do not hold.

C Data-plane details for NCFlow

C.1 Actions at the NCFlow controller, after each allocation

The SDN controller for NCFlow computes total flow per demand and some splitting ratios after each allocation.

Total Flow: The flow assigned to a demand whose source and target are in different clusters is read off SrcTargetMax, i.e., $f_{4,k}$. For intra-cluster demands, their flow is read off MaxClusterFlow, i.e., $f^x_{2,k}$ at the cluster x that contains the source and target of demand k. These flow values are summed up over all the iterations used by NCFlow.

Splitting ratios at sources: At source s of cluster x, we have two cases depending on whether the target of the demand is within the cluster x or in some other cluster y.

For the former case, let $\mathcal{P}_{st}$ be the path set to target t for demand k; the splitting ratio for each path p in the set is $f^{x,p}_{2,k}$ summed up over all iterations, divided by the total flow assigned to demand k above. Here, $f^{x,p}_{2,k}$ is the flow assigned to demand k on path p by the MaxClusterFlow instance for cluster x.

For the latter case, let z_i be the next cluster on the one path that can receive flow in iteration i for all traffic going to targets in cluster y. The splitting ratio for path p in the path set $\bigcup_i \mathcal{P}_{sz_i}$ is the value of $\sum_{r\in K_{sy}} f^{x,p}_{2,r}$ summed up over all iterations where K_{sy} is the set of all demands from source s to targets in cluster y divided by the total value for all such paths.

Uniquely, note that each source s has a splitting ratio per target t within the same cluster or per target cluster y.

We call a subset of nodes as ingresses if they have at least one edge to a node in another cluster that is chosen by the offline component of NCFlow in §3.4 as a crossing edge

Splitting ratios at ingresses are computed in a similar way to the splitting ratios at sources. At each ingress node w of cluster y for traffic from cluster x, there are two cases depending on whether the target is some node t in the same cluster as the ingress (y) or in some other cluster z.

For the former case, in iteration i, the splitting ratio for path p in the set $\mathcal{P}_{wt}$ is the value of $\sum_{r\in K_{xt}} f^{y,p}_{2,r}$ in iteration i divided by the total over all such paths. As above, K_{xt} is the set of demands from sources in cluster x to target t.

For the latter case, in iteration i, let z_i be the next cluster on the path to targets in z; the splitting ratio for path p in the set $\mathcal{P}_{wz_i}$ is the value of $\sum_{r\in K_{xz}} f^{y,p}_{2,r}$ divided by the total value over all such paths. As above, K_{xz} is the set of all demands from sources in cluster x to targets in cluster z.

Note that an ingress node w has splitting ratios only for demands whose chosen path at an iteration contains w's cluster (y) and whose chosen edge enters y at w.

C.2 Details on switch forwarding entries

Pathlets: NCFlow sets up label-switched paths (LSPs) between each pair of nodes in each cluster. Which paths to setup is pre-determined by the offline component in §3.4.

Splitting rules: A source s in cluster x has a splitting rule for each other node in the same cluster and for each other cluster. The splitting ratios are as computed in §C.1.

In each iteration, at each cluster, at most one ingress node is active per pair of other clusters. This is because the bundle of demands for a given pair of clusters has at most one crossing edge entering a cluster.

The active ingress node at a cluster x for the bundle of demands from cluster y to cluster z has one splitting rule when $z \neq x$ and one splitting rule per target in cluster x when $z = x$.

Packet content: The LSP (which pathlet to use) is encoded in the L2 header [59]. Additionally, NCFlow has the following tuple in each packet: (x, y, i, e) where x and y are the source and target cluster ids, i is the iteration number of the flow allocation that the packets have been assigned to and e is the edge to leave the current cluster on. The bits needed are $2\ln\eta + \ln I + \ln \text{node degree}$.[5] We note that 16 bits of header space suffice for all the WAN topologies and experiments considered in this paper; that is $\eta \leq 64$ clusters, $I \leq 8$ iterations and up to 2 edges to nodes in other clusters being used per egress node by NCFlow.

Data path actions:

- At source s in cluster x:
  - The host or middleware adds the cluster-ids x and y into the packet.
  - Source switch uses the appropriate splitting rule to pick a (p, i, e) tuple; the values e and i are placed in the packet and the L2 header gets the identifier for path p. To avoid reordering packets in the same TCP flow, traffic can be split using flow hashes or flowlets [61].
- Each cluster egress removes e from the packet header and forwards packets to the next-hop of the edge e.
- Each cluster ingress uses the appropriate splitting rule to pick a (p, e) tuple; the value e is put into the packet header and p determines the identifier in the L2 header.

D Definitions of NoMoreFlow

In the flow vector computed by MaxClusterFlow at a cluster x, $\mathbf{f}^{\mathbf{x}}_{\mathbf{2}}$, we use the subscript k to denote a bundle that may include (1) transit demands through cluster x (i.e., from all sources in some other cluster w to targets in some other cluster z), (2) leaving demands (i.e., from a source in cluster x to

[5]The edge id must suffice to distinguish at an egress node between the edges to a particular next cluster; so node degree is an overestimate.

all targets in some other cluster z) or (3) entering demands (i.e., to a target in cluster x from all sources in some other cluster z). Furthermore, we use the subscript y_{out} to denote the flow allocated for the bundle k on paths to the virtual node that corresponds to the cluster y. Thus, $f^x_{2,k,y_{\text{out}}}$ is the flow allocated at cluster x for all demands in the per-cluster bundle k on paths to the virtual node corresponding to a neighboring cluster y.

With this background, Equation 3 ensures that the flows allocated in MinPathE2E for an inter-cluster bundle K in $\mathcal{D}_{\text{agg}}$ on all paths in $\mathcal{P}_{\text{agg}}$ that contain a cluster edge (x,y) is no more than the flow that is allocated at either cluster x or cluster y for their respective per-cluster bundles that are contained in K to and from each other respectively.

$$\boxed{\begin{aligned}&\mathsf{NoMoreAlongPaths}(\mathbf{f},\mathbf{f_2}) \triangleq \forall K \in \mathcal{D}_{\text{agg}},\ \forall x,y \in \mathcal{V}_{\text{agg}}, x \neq y,\\ &\sum_{p\in\mathcal{P}_{\text{agg}},(x,y)\in p} f^p_K \leq \min\left(\sum_{k\in K} f^x_{2,k,y_{\text{out}}}, \sum_{k'\in K} f^y_{2,k',x_{\text{in}}}\right) \qquad (3)\end{aligned}}$$

Equation 4 is logically similar to Equation 3 except that the constraints are specific to a cluster x and the constants and variables have been flipped; that is, here, the flows on the paths in the aggregate graph are given ($f^p_{1,K}$) and the flow on paths within the cluster are to be computed by MaxClusterFlow. In particular, note that $\sum_{p'\in\mathcal{P}_{x,*y_{\text{out}}}} f^{p'}_k \triangleq f^x_{2,k,y_{\text{out}}}$; that is, the flow assigned in MaxClusterFlow of cluster x on all paths leading to the virtual node corresponding to a neighbor cluster y is precisely the value on the right that is used above in Equation 3.

$$\boxed{\begin{aligned}&\mathsf{NoMoreFlowThruCluster}(\mathbf{f},\mathbf{f_1},x) \triangleq \forall K \in \mathcal{D}_{\text{agg}},\ \forall y \in \mathcal{V}_{\text{agg}} : y \neq x,\\ &\sum_{p\in\mathcal{P}_{\text{agg}}:(y,x)\in p} f^p_{1,K} \geq \sum_{k\in K,\ p'\in\mathcal{P}_{x,y_{\text{in}}*}} f^{p'}_k, \text{ and}\\ &\sum_{p\in\mathcal{P}_{\text{agg}}:(x,y)\in p} f^p_{1,K} \geq \sum_{k\in K,\ p'\in\mathcal{P}_{x,*y_{\text{out}}}} f^{p'}_k \qquad (4)\end{aligned}}$$

E Fault Model

When failures happen, prior works [19, 49] assume that the sources of the label switched paths (LSPs) will proportionally shift traffic. That is, a source that splits traffic in the ratio of $(0.3, 0.5, 0.2)$ between three paths will change to a splitting ratio of $(0.6, 0, 0.4)$ when the middle LSP fails. Doing so can cause congestion on either of the remaining LSPs.

The key idea in prior works [19, 49] is to proactively allocate flow such that the maximal load on any link remains under capacity—FFC [49] protects against up to k simultaneous link failures, whereas TEAVAR [19] ensures that the flow at risk is below a given fraction (e.g., 99.9% of flow can be carried by the network on average over all possible failure scenarios).

The cost of such congestion protection is two-fold: (1) proactive schemes substantially increase the solution runtime, and (2) they under-allocate flow, since capacity must be set aside to help with possible failures. Instead, NCFlow uses a *reactive* strategy, and recomputes a new flow allocation after the fault occurs. This enables NCFlow to carry more flow before the fault, and potentially carry more flow after recovery. Furthermore, since NCFlow uses fewer FIB entries for the same number of paths, it is naturally easier to spread flow onto more paths with NCFlow. Thus, the key trade-off is slightly longer and more lossy episodes immediately after a fault when using NCFlow versus longer solver runtimes and flow under-allocation with proactive schemes [19, 49].

F Benchmarking TEAVAR and TEAVAR*

F.1 Formulation for TEAVAR*

Here, we discuss our adaptation of TEAVAR to maximize total multi-commodity flow. The TEAVAR [19] paper considers a different objective – maximizing the *concurrent* multi-commodity flow (see Table 2). When all demands are satisfiable, both objectives allocate the same flow; however, when not enough capacity is available to meet the desired failure assurance, maximizing total flow leads to a strictly larger allocation. We describe TEAVAR* from first principles here.

In addition to the inputs of MaxFlow (see Equation 2), TEAVAR* has the following inputs:

- A value $\beta \in [0,1]$; larger values of β correspond to greater fault assurance.
- A set of fault scenarios, $\mathcal{S}$; each scenario i has a probability of occurrence β_i and a set of failed edges $\mathcal{E}_i$.

In a fault scenario i, the edges in $\mathcal{E}_i$ will fail and so the flow allocated to paths that contain any edge in $\mathcal{E}_i$ will be *lost*. The number of possible fault scenarios is exponential in the number of edges in the network. Thus, to keep the optimization tractable, we consider only a subset of scenarios.

Let $\mathcal{L}(i)$ denote the total flow lost in fault scenario i. Per Proposition 8 in [58], minimizing the potential function, $\alpha + \frac{1}{1-\beta}\mathbb{E}[\mathcal{L}_i - \alpha]^+$, would minimize the conditional value at risk. Here, the expectation is over all possible fault scenarios. Since we only consider a subset of fault scenarios to keep optimization tractable, we minimize: $\alpha + \frac{1}{1-\beta}\left(\sum_{i\in\mathcal{S}} \beta_i[\mathcal{L}_i - \alpha]^+ + (1 - \sum_{i\in\mathcal{S}} \beta_i)(1-\alpha)\right)$. The last term accounts for the unconsidered scenarios for which we must assume the worst possible loss. Note that we can simplify this expression by dropping the constant $\frac{1-\sum_{i\in\mathcal{S}}\beta_i}{1-\beta}$.

$$\begin{aligned}
&\textsf{TEAVAR}^*(\mathcal{V},\mathcal{E},\mathcal{D},\mathcal{P},\beta,\mathcal{S}) && && (5)\\
&\triangleq \arg\min_{\mathbf{f}} \left(\alpha + \tfrac{1}{1-\beta}\left(\textstyle\sum_{i\in\mathcal{S}} \beta_i \textsf{Excess}_i - (1-\textstyle\sum_{i\in\mathcal{S}}\beta_i)\alpha\right)\right)\\
&\text{s.t. } \mathbf{f}\in \quad \textsf{FeasibleFlow}(\mathcal{V},\mathcal{E},\mathcal{D},\mathcal{P}), && && \text{(Eqn. 1)}\\
&\quad \mathcal{L}_{i,k}\ge 0, && \forall i,k && \text{(loss is non-negative)}\\
&\quad \mathcal{L}_{i,k}\ge d_k - \sum_{p\in\mathcal{P}_k} f_k^p \textsf{Active}_{p,i}, && \forall i,k && \text{(loss)}\\
&\quad \alpha \ge 0 && && \text{(loss } \textit{cutoff}\text{)}\\
&\quad \textsf{Excess}_i \ge 0 && \forall i && \text{(excess loss in scenario } i\text{)}\\
&\quad \textsf{Excess}_i \ge \sum_{k\in\mathcal{D}} \mathcal{L}_{i,k} - \alpha, && \forall i && \text{(excess loss)}
\end{aligned}$$

The formulation for TEAVAR* is in Equation 5. Recall that f_k^p is the flow assigned to demand k on path p. Active$_{p,i}$ is an indicator denoting whether path p is active in fault scenario i. Thus, the allocation for demand k in scenario i will be $\sum_{p\in\mathcal{P}_k} f_k^p \textsf{Active}_{p,i}$. When the allocation is below the required volume d_k, the demand will suffer loss; we use $\mathcal{L}_{i,k}$ to denote the flow loss for demand k in scenario i.

The flow allocation resulting from the above formulation cannot be promised to the demands; in particular, more flow will be assigned on some paths to account for possible failures on other paths. After solving the above LP, we compute the flow allocation for a demand k as follows: (1) sort the per-scenario losses $\mathcal{L}_{i,k}$ in ascending order; (2) starting at index 0, add up the probability of each scenario until the running sum is at least β—let i_β be the unique crossing index; (3) Set demand k's flow to be $d_k - \mathcal{L}_{i_\beta,k}$, the demand minus the loss at the crossing index.

Choosing the fault scenarios to use in TEAVAR*:

- Intuitively, achieving a greater amount of fault assurance requires considering more fault scenarios. Specifically, if the total probability of considered scenarios is below β, the above LP as well as the LP used by TEAVAR become unbounded. To see why, the coefficient of α in Eqn. 5 is $\frac{(\sum_{i\in\mathcal{S}}\beta_i)-\beta}{1-\beta}$. If the probability of considered scenarios is less than β, this coefficient becomes negative, and the objective value reaches $-\infty$ by setting α to ∞.
- Intuitively, if the total probability of considered scenarios is just larger than β, the flow allocated to demands is very small. To see why, the smaller the value of $\sum_{i\in\mathcal{S}}\beta_i - \beta$, the smaller the positive coefficient of α in the objective of Eqn 5. Thus, the solution of Eqn 5 will have a large value of α and a very small amount of allocatable flow.
- In light of these two points, in our experiments, we choose all scenarios that are individually more likely to occur than a cutoff ρ and multiplicatively reduce ρ until the total probability of considered scenarios exceeds $1-\frac{1-\beta}{2}$.

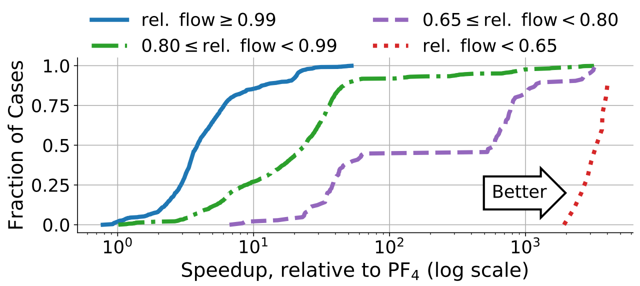

Figure 18: Breaking down the NCFlow results from Figure 11b into four separate CDFs based on relative total flow.

F.2 Comments on benchmarking TEAVAR

Observe that the number of scenarios affects the complexity of the TEAVAR* optimization; specifically, the number of equations and variables increases by $|\mathcal{S}| * |\mathcal{P}|$. The path set is at least as large as the node pairs, i.e., $|\mathcal{P}| > N^2$ where N is the number of nodes. The appropriate choice of fault scenarios to consider, as discussed above, depends on the size of the topology, the failure probability of edges, and the required assurance level β. Suppose one considers all 2-edge failure scenarios; then $|\mathcal{S}| \sim M^2$ where M is the number of edges. Hence, the increase in equations and variables exceeds N^2M^2. Note that MaxFlow is substantially simpler, having at most $O(N^2)$ variables and constraints (Equation 1).

On the topologies listed in Table 5, our implementation of TEAVAR* never ran to completion even after several days. We ran with $\beta = 0.99$ and link failure probability set to 0.004; both of these are the default values used in [3]. The reason is that the optimization problem becomes intractably large. TEAVAR behaves similarly [19]. We conclude that probabilistic fault protection using this methodology is infeasible on large topologies and for non-trivial fault assurance levels such as when considering multiple link failures.

We also note that we are unable to simultaneously achieve the solution quality and the runtimes that are reported in TEAVAR [19] using their code [3]. Specifically, achieving the assurance levels reported in their experiments requires many scenarios to be considered. The runtimes reported in [19] appear to have been measured when considering only single link failures.

G Additional Experiments

G.1 Breakdown of NCFlow's Performance

To further understand the performance of NCFlow, Figure 18 breaks down the results in Figure 11 into four ranges based on total relative flow. We plot CDFs of the speedup ratio per range. The solid blue and green dashed line, which correspond to relative flow above 0.99 and in $[0.8, 0.99)$ respectively, account for 49% and 46% of all experiments. The figure shows that NCFlow achieves sizable speedups while allocating large

Table 6: Number of FIB entries for NCFlow vs. edge-based formulations (e.g., Fleischer-Edge), path-based formulations using Räcke Randomized Routing Trees (SMORE*), and path-based formulations using *k*-shortest paths (PF_4, Fleischer-Path, TEAVAR*) on every topology.

amounts of flow.

Figure 19 further breaks down the aggregate results from Figure 11 across various aspects of interest. In the two left-most columns, we break down the results by different settings of α, which illustrates how NCFlow performs on both under-subscribed ($\alpha = \{1,8\}$) and over-subscribed ($\alpha = \{32,64,128\}$) traffic matrices. In the former case, NCFlow is typically able to fully satisfy the TM's requested demand, thereby matching the total flow allocated by the other methods. At the same time, NCFlow is strictly faster on all TMs, except for those belonging to smaller topologies (e.g., Uninett2010), which we discuss later on. As α increases, so, too, does NCFlow's runtime advantage; however, this does come at the cost of the total flow allocated. For example, when $\alpha = 32$, we see many instances where NCFlow is $> 100\times$ faster than PF_4, but allocates 75% of PF_4's total flow in the worst case. This effect becomes more evident for the largest settings of α: here, the speedups are $> 1000\times$, but more flow is sacrificed for some TMs. This behavior occurs perhaps because, as the traffic volume increases and the topology becomes more congested, paths that are not allowed by NCFlow's scheme become more critical for maximizing the total flow.

In the middle two columns, we break down the results by traffic model. NCFlow tends to perform best when demands are highly concentrated within clusters. In the bottom middle plot (Poisson, $\delta \to 0$), we see that NCFlow allocates $> 90\%$ of PF_4's total flow for almost every TM, while still achieving speedups $> 100\times$. Recall that as $\delta \to 0$ in the Poisson traffic model, the traffic volume *between* clusters decreases, thus generating concentrated demands. In contrast, when $\delta \to 1$, demands are less concentrated, which leads to worse performance for NCFlow in terms of total flow, but not in terms of runtime.

Finally, in the two right-most columns, we break down the results by topology size. On Uninett2010, the smallest topology in our evaluation set, NCFlow's trade-off between total flow and runtime is not much better than the other baselines, particularly Fleischer-Edge.

As the topology size increases, NCFlow's advantage becomes more apparent. On Colt, NCFlow offers faster runtimes and sacrifices little flow, no more than 10% less than PF_4. On PrivateSmall and Kdl, NCFlow's speedup increases even more: $> 100\times$ faster than PF_4 on the majority of cases on Kdl. But flow is sacrificed, particularly for large values of α. However, NCFlow's trade-off is still favorable compared to other methods: for Kdl, we see multiple instances where NCFlow achieves $1{,}000\times$ speedups at only a 20% reduction in flow. For PrivateLarge, we see both the biggest speedups and the smallest fraction of total flow relative to PF_4. As previously discussed, the outlier coincides with a highly oversubscribed TM ($\alpha = 128$). When we move to other regimes on PrivateLarge, NCFlow's performance improves: on 31 of the 400 TMs with $\alpha \in \{32,64\}$, NCFlow is $> 1{,}000\times$ faster than PF_4 while achieving $> 80\%$ of PF_4's total flow.

In summary, we can see in this panel of CDF plots where NCFlow's strengths lie: on (1) large topologies, and (2) TMs with moderate demand volumes that are highly concentrated within the topology.

G.2 Alternate clustering methods

For each topology, we evaluate the three different clustering techniques mentioned in §3.4; on each topology we ask each technique to compute the number of clusters listed in Table 5. Figure 21 shows CDFs of the ratio of total flow and latency speed-up of a clustering technique relative to that achieved by using FMPartitioning; thus values to the left of $x = 1$ indicate worse performance compared to FMPartitioning while those on the right indicate better performance. The figure shows that clusters discovered by FM partitioning almost always let NCFlow carry more flow (red lines); using either spectral clustering or leader election leads to a noticeably smaller allocation in about 20% and 40% of the cases. The figure shows a less clear-cut separation on latency speed-up; clusters discovered by leader election offer more speedup in over 30% of the experiments. Overall, we see that FMPartitioning performs better on average but not in all cases.

G.3 Effect on path latency

Figure 22 shows a CDF of the *normalized path latency* for de-

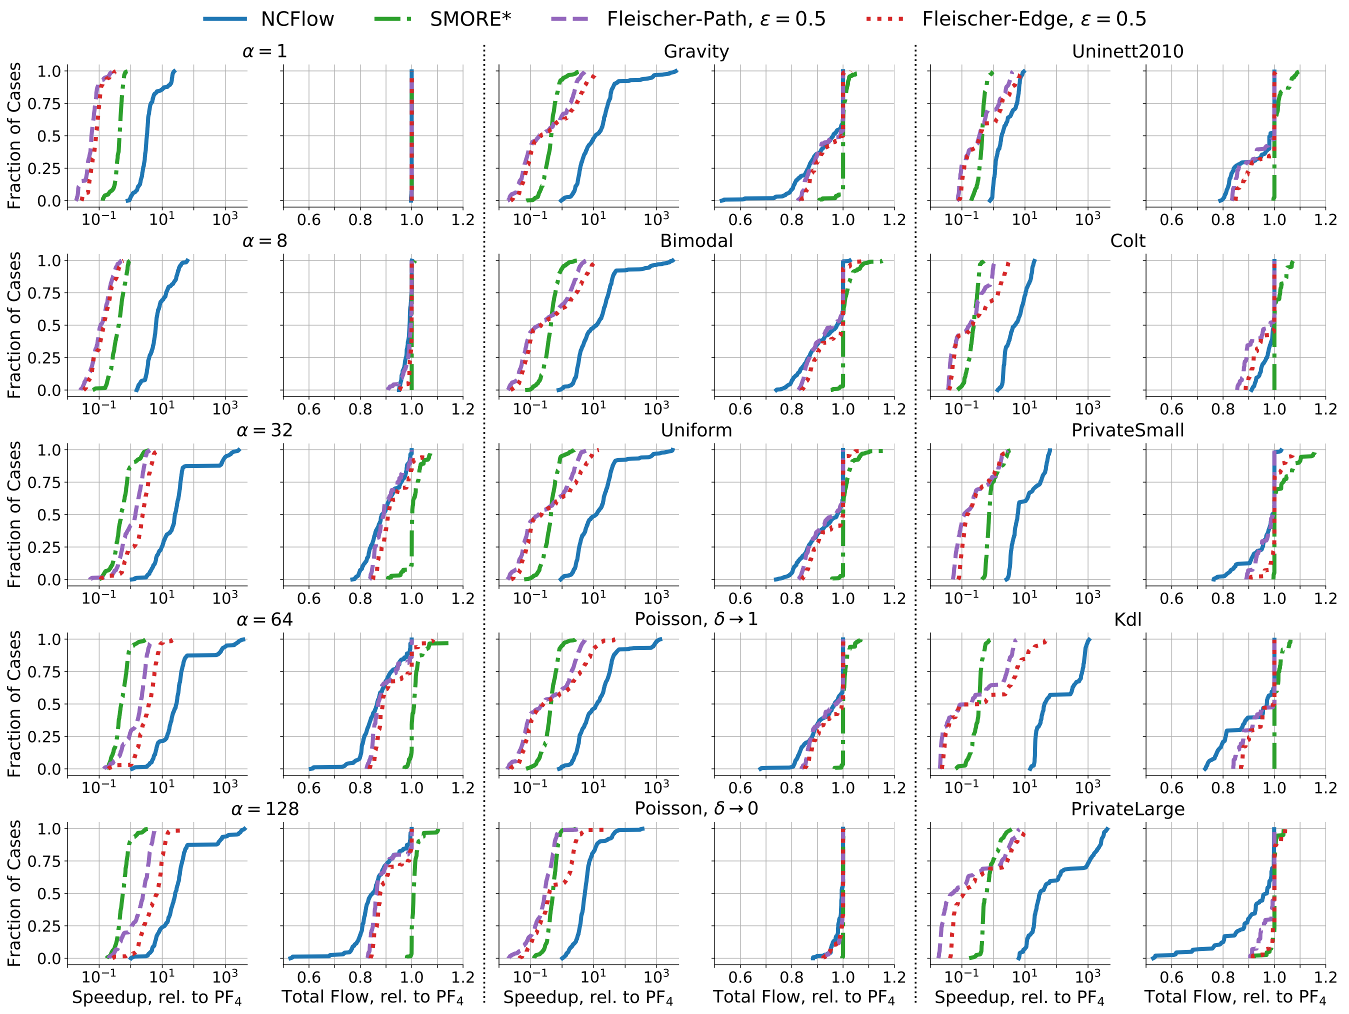

Figure 19: A breakdown of the experimental results from Figure 11 along various dimensions of interest: scale factor, traffic model, and topology size. NCFlow excels on large topologies with TMs that have highly concentrated demands.

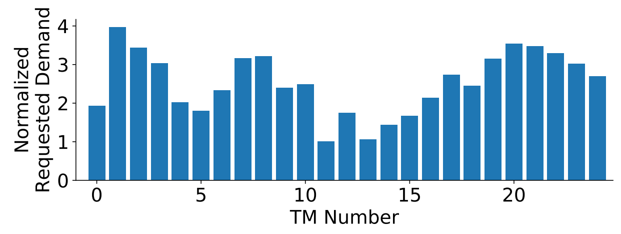

Figure 20: Traffic demand for each traffic matrix used in the demand tracking experiment (see Figure 15) on PrivateLarge. The exact values are not shown for confidentiality reasons.

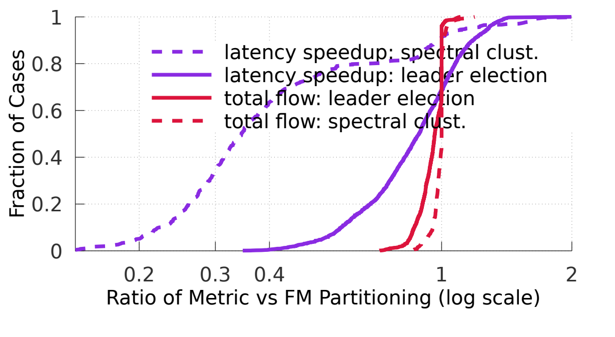

Figure 21: Comparing the total flow allocated and the speedup in computing allocations when clusters are chosen using the three techniques mentioned in §3.4–FM partitioning, spectral clustering and leader election. The default technique used in our evaluation, FM partitioning, generally performs better but not in all cases.

mands[6] under different flow allocations. The figure on the top shows CDFs of the actual normalized path latency. Observe that these distributions are nearly identical. The figure on the bottom shows a CDF of the ratio of normalized latency; we see that roughly 70% of the demands are carried by NCFlow on paths that are at most as long as the paths used by PF_4 (i.e., to the left of x=1). Most of the cases where NCFlow uses

[6]The latency of the paths along which each demand is routed weighted by the fraction of the demand routed along each path. That is, if a demand is divided equally between two paths, the normalized latency will be the average of the path latencies.

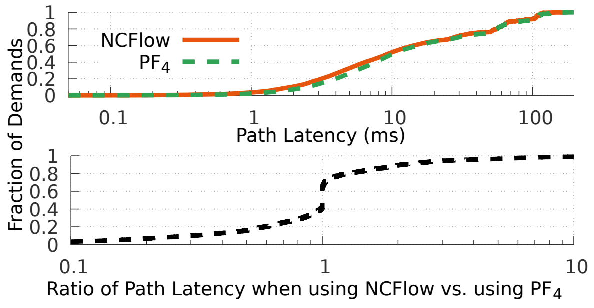

Figure 22: Effect of NCFlow on path latency

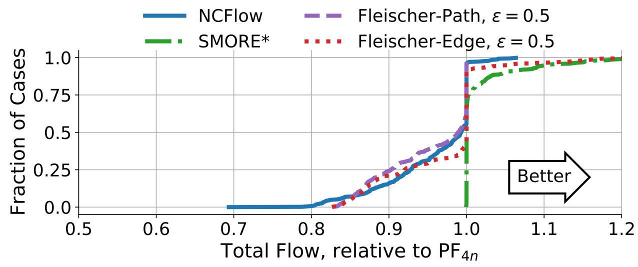
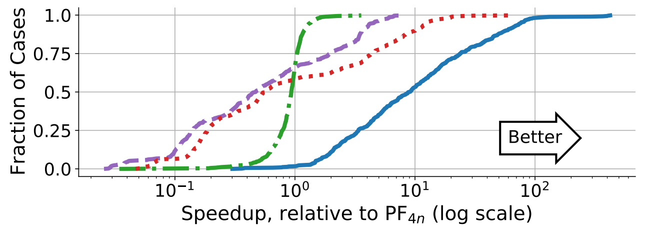


(a) CDF of total flow relative to PF$_{4n}$



(b) CDF of speedup relative to PF$_{4n}$

Figure 23: Similarly to Figure 11 all schemes use up to $k = 4$ shortest paths between each pair of nodes except that the paths are chosen *without* ensuring edge disjointness. The figure shows no qualitative difference relative to Figure 11.

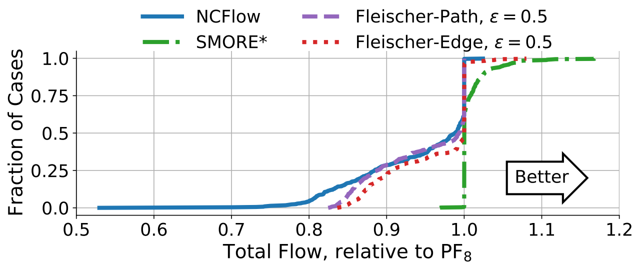
relatively longer paths are for demands that have very small latency paths as illustrated by the top figure.

Note that path latency can be further explicitly controlled in NCFlow by determining which paths can be used or by weighting the objective to prefer shorter paths in the various steps of Figure 6.

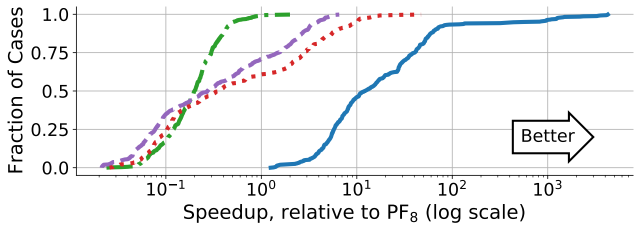
G.4 Alternate path choices

With Figure 23, Figure 24, Figure 25, Figure 26, Figure 27 we evaluate different numbers of paths between node pairs chosen with or without edge disjointness. PF$_k$ refers to path formulation with k shortest paths chosen using edge disjointness and PF$_{kn}$ indicates paths chosen without edge disjointness. Comparing these figures with Figure 11, we note that NCFlow's improvements over baselines hold across different path choices.

Note that Figure 26 and Figure 27 are missing some of the larger topologies listed in Table 5 for some of the baseline schemes because the baselines ran out of memory (we used a server with up to 3TB of memory) or raised some other exception.

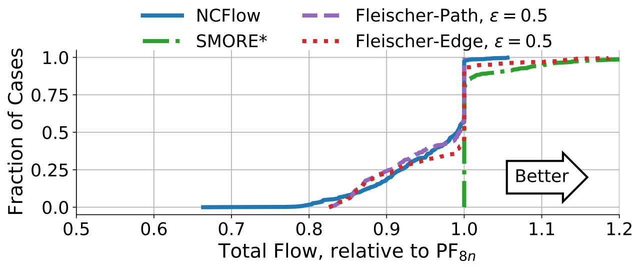


(a) CDF of total flow relative to PF$_8$

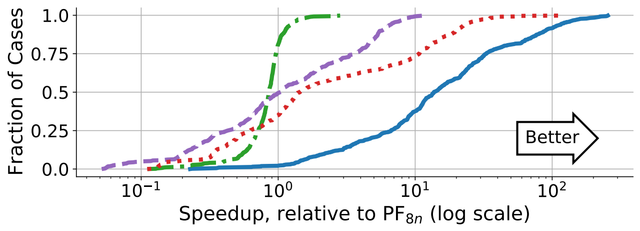


(b) CDF of speedup relative to PF$_8$

Figure 24: Similar to Figure 11 except all schemes use up to $k = 8$ shortest paths between each pair of nodes; paths chosen *with* edge disjointness. The figure shows no qualitative difference relative to Figure 11.



(a) CDF of total flow relative to PF$_{8n}$



(b) CDF of speedup relative to PF$_{8n}$

Figure 25: Similar to Figure 11 except all schemes use up to $k = 8$ shortest paths between each pair of nodes; paths chosen *without* ensuring edge disjointness. The figure shows no qualitative difference relative to Figure 11.

H Illustrative examples

Here, we show some illustrative examples where applying NCFlow using adversarially chosen clusters can lead to sub-optimal flow allocation.

Figure 28 shows a case wherein NCFlow is sub-optimal because the aggregate graph (wherein nodes are clusters) is

not a tree. The network topology and optimal allocations are shown in the graph on the left; assume each link has a unit capacity. With NCFlow, as shown in the figures on the right, MaxAggFlow can route the flow from s_1 to t_1 on either the top or the bottom path or divide between the two paths in some proportion; note that MaxAggFlow is not aware of demands that are local to a cluster (such as the flow from s_2 to t_2). Whenever MaxAggFlow assigns non-zero flow for the $s_1 \to t_1$ demand on the top path, NCFlow will be sub-optimal because then the other demand cannot be fully satisfied when MaxClusterFlow executes later on the yellow cluster. Any unsatisfied volume for $s_1 \to t_1$ can be routed on the bottom path in a later iteration but the flow for $s_2 \to t_2$ will not increase since the links that demand can use are fully utilized in the first iteration. The root of the problem here is that MaxAggFlow allocates traffic over multiple paths without being aware of the demands within clusters.

Figure 29 shows a case wherein NCFlow is sub-optimal when demands cannot be fully satisfied. As above, the topology and optimal allocations are shown on the left. Also, as above, the root of the issue here is that MaxAggFlow allocates the cross-cluster flow on the aggregate graph without being aware of the demands within clusters. As shown, subsequently, MaxClusterFlow will under-allocate flow for the local demands even though total flow would be larger if the local demands are fully satisfied.

Reordering the sub-problems, i.e., executing MaxClusterFlow before MaxAggFlow, may appear promising based on these examples but simple counter-examples exist even for such a reordered solution. The underlying cause of sub-optimality is not the order in which the global and local solutions are computed but rather that the optimal flow allocation requires *jointly solving* these problems.

Figure 30 shows a case wherein NCFlow can be sub-optimal when multiple edges connect clusters. As above, each unmarked link has unit capacity and the optimal allocations are shown in blue. Recall that NCFlow uses exactly one edge between each pair of clusters per iteration to avoid disagreements. There are two edges between each cluster but among the four possible crossing edge choices in an iteration, exactly one choice can carry non-trivial amount of flow (the top edge for each cluster pair). If that choice is somehow not picked, as shown marked in red on the right in Figure 30, NCFlow will not satisfy the demand. Simply increasing the number of iterations may not suffice either since the number of edge choices can be large, depending on the path lengths on the aggregate graph and on the number of edges between clusters.

As noted previously, the above examples are in part due to poor cluster choices; Figure 31 shows different cluster choices for these examples under which NCFlow will lead to optimal flow allocation.

I Optimality gap

$u_e, v_e \in \mathcal{V}$	Edge $e \in \mathcal{E}$ goes from node u_e to node v_e
$m_u, \forall u \in \mathcal{V}$	m_u denotes the cluster containing node u. Note that $m_u \in \mathcal{V}_{\text{agg}}$ (i.e., the cluster is a node on the aggregate graph) and $u \in \mathcal{V}_{m_u}$ (i.e., the node u belongs in the restricted graph for the m_u'th cluster)
$\forall k \in \mathcal{D}, m_{s_k} \neq m_{t_k}, x \in \mathcal{V}_{\text{agg}}$	
OutNodes(x,k)	The nodes in cluster x that can carry flow of demand k *out to* some other cluster, i.e., $\{u \mid m_u = x, \exists v \in \mathcal{V}, p \in \mathcal{P}_{\text{agg},K_{s_k t_k}}$ s. t. $m_v = y, (x,y) \in p, (u,v) \in \mathcal{E}\}$
InNodes(x,k)	The nodes in cluster x that can carry flow of demand k *into* cluster x, i.e., $\{u \mid m_u = x, \exists v \in \mathcal{V}, p \in \mathcal{P}_{\text{agg},K_{s_k t_k}}$ s. t. $m_v = y, (y,x) \in p, (v,u) \in \mathcal{E}\}$

Table 7: Additional notation for optimality gap; builds on top of notation from Table 2 and Table 3.

\end{aligned}$$

I.1 Optimal MaxEdgeFlow

The optimal flow allocation algorithm, in terms of carrying the maximum amount of flow possible on a network, is as shown in Equation 6. We will call this the EF, short for Max**E**dge**F**low. Some additional notation is in Table 7. Observe that, in this formulation, any demand can be allocated on any edge (the variable f_{ke}) as long as flow conservation holds (the longer equation at the bottom). As noted in §2, this *edge-form* of the problem carries the maximal amount of flow but has a high computation time and requires a large number of forwarding entries at switches (one rule per nodepair at each node).

I.2 Edge flow with cluster constraints

Relative to the optimal MaxEdgeFlow, we first ask how much flow will be lost by using clusters. To compute this value, we add to MaxEdgeFlow the constraint shown in Equation 7. Specifically, demands whose source and target are in the same cluster can only use edges within the cluster. However, as above, paths remain otherwise unconstrained.

$$f_{ke} = 0 \;\; \forall e, u_e \notin \mathcal{V}_x \text{ or } v_e \notin \mathcal{V}_x, \text{ if } m_{s_k} = m_{t_k} = x. \qquad (7)$$

We will call this optimization problem EF with cluster constraints.

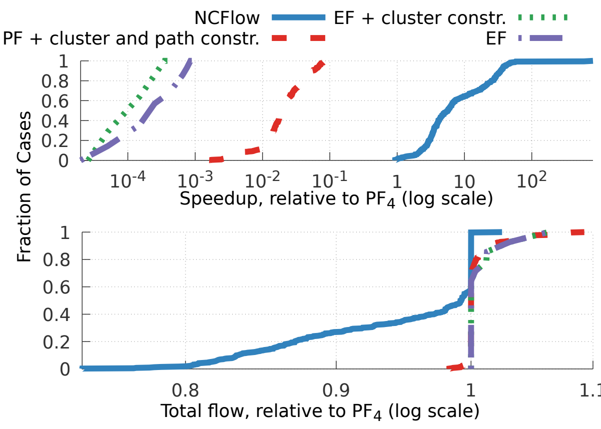

Figure 32: Comparing flow allocated by NCFlow with the best possible flows

I.3 Path form with cluster and path constraints

Next, we ask how much flow will be lost when using the clusters as well as the given set of paths within and between clusters? Computing this value is somewhat more complex because we have to stitch together the flow carried on paths within each cluster with the flow on the edges between clusters while also ensuring that flow follow the chosen paths on the aggregate graph (where clusters are nodes). For reference, we write this out in Equation 8.

In more detail, this optimization problem, as shown in Equation 8, has three classes of decision variables – f^p_K, f^p_k, f_{ke} – which respectively are the flow allocated to a bundled demand on a path on the aggregate graph, the flow allocated to a demand on a path within a cluster and the flow allocated to a demand on a crossing edge between clusters.

Equation 9 computes the net flow for each demand k which for the case of a demand whose source and target are in the same cluster is the sum of flow carried on all intra-cluster paths. For demands whose source and target are in different clusters, the net flow is the flow from the demand's source to all of the nodes in the source's cluster that connect with other clusters as well as the flow to the demand's target from all of the nodes in the target's cluster that connect with other clusters.

For flow conservation, consider Equation 11 which ensures that all of the flow leaving at a node u for a demand k on crossing edges to other clusters equals the flow that comes into the node u either from the source of the demand (if the source is within its cluster) or from all of the nodes in u's cluster that can receive flow for demand k from other clusters–$\mathsf{InNodes}(m_u, k)$. Equation 12 considers the converse case for demands that leave at a node. Finally, Equation 13 relates the total flow between a pair of clusters x, y on the crossing edges between these clusters with the flow along paths on the aggregate graph that contain the edge (x, y). We will call this optimization problem PF with cluster and path constraints.

Note that the above constraints naturally lead to a reduction in forwarding table size as discussed in §3.5. However, it is not clear how much less flow these constraints allow for relative to the optimal EF. Moreover, since this optimization has more variables (and constraints) than PF_4 (see Equation 2), it can take longer to compute and may not be practically useful. We use this optimization problem to discern how much flow is lost by the constraints used in NCFlow (restricting to clusters and paths) relative to the flow that is lost due to the heuristic allocation process described in §3.

I.4 Experimental results

Our results are in Figure 32; the baseline is PF_4 and the figures plot CDFs of total flow and latency speedup for many topologies and traffic demands. Note that using the edge formulation (purple dash-dots) often leads to substantially more flow being allocated compared to PF_4; however, as the figure on the top shows, edge formulation is a more complex problem that takes longer to run (over 1000× longer).

Adding the clustering constraint to edge formulation has an un-noticeable effect on the flow allocation (green dashes). Note that we use clusters computed using FMPartitioning for all topologies.

Constraining the path formulation using both the given clusters and the given paths (between clusters and within each cluster), as shown with the red dash line, allocates much more flow than PF_4 and not much less than is allocated in edge formulation. Thus, empirically, constraining flow allocation to traverse the chosen clusters and paths does not limit the flow that can be allocated. The figure also shows that computing the optimal flow given clusters and paths takes longer than PF_4 (roughly 10× – 100× longer). Thus, NCFlow offers a heuristic which finishes substantially faster than PF_4.

To sum up, our two main contributions are: (1) constraining flow allocations to use specific clusters and paths which reduces the number of forwarding table entries needed without affecting the flow that can be allocated and (2) a heuristic that computes flow allocations quickly given this constraint but can under-allocate flow. We believe that future work can improve the heuristic to reduce the flow loss further.

$$\text{MaxClusterPathFlow}(\mathcal{V},\mathcal{E},\mathcal{D},\mathcal{P}) \triangleq \arg\max_{\mathbf{f}} \sum_{k\in\mathcal{D}} f_k \qquad \text{s.t.} \tag{8}$$

Cost-Effective Cloud Edge Traffic Engineering with CASCARA

Rachee Singh Sharad Agarwal Matt Calder Paramvir Bahl
Microsoft

Abstract

Inter-domain bandwidth costs comprise a significant amount of the operating expenditure of cloud providers. Traffic engineering systems at the cloud edge must strike a fine balance between minimizing costs and maintaining the latency expected by clients. The nature of this tradeoff is complex due to *non-linear* pricing schemes prevalent in the market for inter-domain bandwidth. We quantify this tradeoff and uncover several key insights from the link-utilization between a large cloud provider and Internet service providers. Based on these insights, we propose CASCARA, a cloud edge traffic engineering framework to optimize inter-domain bandwidth allocations with non-linear pricing schemes. CASCARA leverages the abundance of *latency-equivalent* peer links on the cloud edge to minimize costs without impacting latency significantly. Extensive evaluation on production traffic demands of a commercial cloud provider shows that CASCARA saves 11–50% in bandwidth costs per cloud PoP, while bounding the increase in client latency by 3 milliseconds[1].

1 Introduction

Cloud wide-area networks (WANs) play a key role in enabling high performance applications on the Internet. The rapid rise in traffic demands from cloud networks has led to widespread adoption of centralized, software-defined traffic engineering (TE) systems by Google [19] and Microsoft [17] to maximize traffic flow *within* the cloud network.

In the quest to overcome BGP's shortcomings, recent efforts have focused on engineering *inter*-domain traffic, which is exchanged between the cloud WAN and other networks on the Internet [27, 33]. These systems can override BGP's best-path selection, to steer egress traffic to better performing next-hops. However, this focus on performance overlooks a crucial operating expenditure of cloud providers: the *cost* of inter-domain traffic determined by complex pricing schemes. While the prices of inter-domain bandwidth have declined in the past decade, the decrease has been outpaced by exponential growth in demand [29] from cloud networks serving high-definition video, music and gaming content. In fact, the inter-domain bandwidth costs incurred by the cloud provider we analyze increased by 40% in the March 2020 billing cycle as a consequence of the increase in demand fueled by work from home guidelines in various parts of the world. [2]

[1]Code and experiments at: http://cascara-network.github.io.

[2]We do not disclose the fraction of total cloud operation expenditure contributed by inter-domain bandwidth costs due to confidentiality reasons.

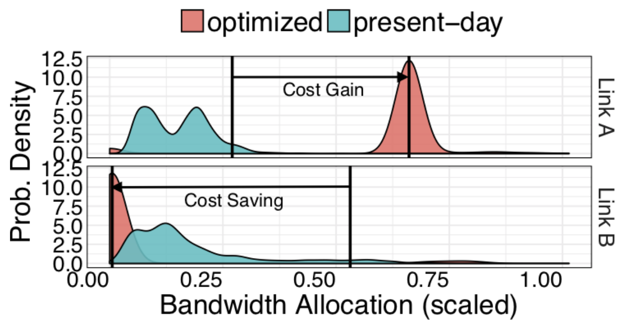

Figure 1: Present-day and CASCARA-optimized bandwidth allocation distributions for one week, across a pair of links between a large cloud provider and tier-1 North American ISPs. Costs depend on the 95th-percentile of the allocation distributions (vertical lines). CASCARA-optimized allocations reduce total costs by 35% over the present-day allocations while satisfying the same demand.

In this work, we show that recent increases in interconnection and infrastructure scale enable significant potential to reduce the costs of inter-domain traffic. These advances include the deployment of several new cloud points of presence (PoP) near clients and direct peering with an increasing fraction of the Internet's autonomous systems [5]. As a result, most clients are reachable over several short and *latency-equivalent* paths from the cloud provider [26]. We illustrate the cost saving potential due to latency-equivalent links with an example in Figure 1. We plot the distributions of bandwidth allocated over one week to links A and B, which connect a large cloud provider to tier-1 North American ISPs. Both links are located at inter-connection points within 30 km of each other, and offer comparable latency due to their geographical proximity. In this example, the bandwidth price per Mbps of Link B is 33% higher than that of Link A. Link costs are a function of the 95th percentile of the bandwidth allocations to each link. The *present-day* allocations (in blue) represent the current bandwidth assigned to the links by the cloud provider under study. In contrast, the CASCARA-*optimized* allocations (in red) meet the same or higher demand as the present-day allocations, while reducing total bandwidth costs by 35%.

Bandwidth allocations at the cloud edge impact both the client latency and inter-domain bandwidth costs to the cloud provider. At one extreme, traffic allocations may disregard the latency impact to drive bandwidth costs to near-zero while at the other extreme, allocations may incur very high bandwidth costs by greedily assigning traffic to the lowest latency peers. Balancing this *cost-latency tradeoff* is central to our work. However, it is made challenging by industry-standard pricing schemes that use 95th percentile of the bandwidth distribution over monthly time-periods. Complex relationships between bandwidth allocations, costs and client latency lead to computationally hard optimization problems.

We tackle these challenges by first analyzing the utilization of edge links from a large commercial cloud provider. We find that the majority of traffic from the cloud is exchanged with transit ISPs, with outbound traffic being twice in volume compared to inbound traffic. Thus, outbound traffic to transit ISPs dominates the inter-domain bandwidth costs of the cloud. Three such North American ISPs incur a majority of the total expenditure on inter-domain bandwidth in the continent (§3). Using these insights, we make three main contributions:

1. Quantify the opportunity of saving bandwidth cost. We formulate cloud edge TE as an optimization with the goal of minimizing percentile bandwidth costs. Despite the non-convex nature of the objective, the optimization is tractable in engineering outbound traffic to peer links with only the small number of ISPs that contribute majority of the costs. We show that cost-optimal allocations can **save up to 65% of the cloud provider's inter-domain bandwidth costs**, quantifying the upper bound on savings (§3) and offering a significant improvement over related approaches in [12, 20, 35].

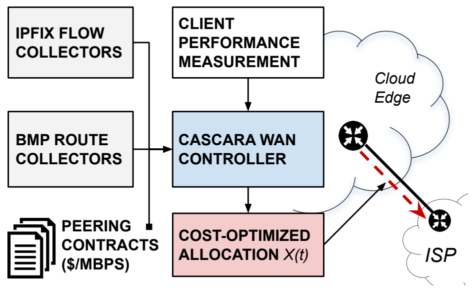
2. Practical and cost-efficient online edge TE. Since optimizing percentile costs is NP-Hard [20], finding optimal solutions can take several hours. We leverage insights from the offline optimal solution to design an efficient, heuristic-based online TE framework, CASCARA. CASCARA leverages the cloud provider's rich diversity of latency-equivalent BGP peers to offer cheaper options to outbound traffic. Through extensive experiments we demonstrate that CASCARA provides near-optimal cost saving in practice and can be deployed **safely** and **incrementally** in cloud WANs (§4).

3. Flexibility to balance the cost-latency tradeoff. CASCARA incorporates the latency of primary and alternate peer paths from the cloud [4, 27] to strike a balance between bandwidth cost savings and client latency. CASCARA provides the flexibility to pick the operating point on this tradeoff and finds allocations that bound the increase in client latency by 3 ms while saving 11-50% of bandwidth costs per cloud PoP (§5).

Client latency requirements vary based on the types of application traffic, *e.g.,* software updates and large file transfers are more delay tolerant than live video. In fact, majority of all outbound traffic from the cloud provider is marked as best-effort, making it tolerant to small changes in latency. We conclude this study by discussing the generalizability of our results, the implications of CASCARA on peering contracts and bandwidth pricing models on the Internet (§6).

2 CASCARA controller overview

CASCARA's goal is to engineer outbound traffic allocations from the cloud edge to achieve near-optimal saving in inter-domain bandwidth costs. It does so by providing operational safety knobs to the operator: configurable variation in the traffic allocations to peer links, incremental deployability and bounded impact on client latency. Figure 2 shows the different components of CASCARA. At the core is the CASCARA WAN controller that allocates cost-optimized flow to outbound peer links of the cloud network.



IPFIX FLOW COLLECTORS
CLIENT PERFORMANCE MEASUREMENT
Cloud Edge
BMP ROUTE COLLECTORS
CASCARA WAN CONTROLLER
PEERING CONTRACTS ($/MBPS)
COST-OPTIMIZED ALLOCATION X(t)
ISP

Figure 2: The design of CASCARA.

IPFIX Flow Collectors. We feed IP Flow Information Export (IPFIX) [31] logs to CASCARA to infer the utilization of edge links of the cloud network in five minute intervals of the billing cycle. These allocations to peer links are used both for offline cost analysis (§3) and online allocation to meet demands by CASCARA (§4 and §5).

BMP Route Collectors. We gather route announcements made by BGP peers at points of presence (PoP) of the cloud provider using BGP Monitoring Protocol (BMP) collectors. These routes inform CASCARA of the choices of peer links for outbound demand towards clients.

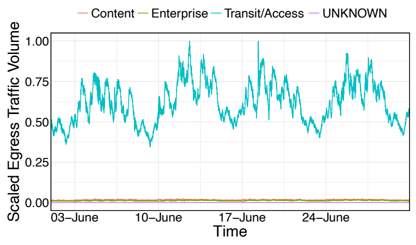
Peering Contracts. We feed the billing models and peering rates for all BGP peers of the cloud provider to CASCARA. Since peering rates remain stable over short durations of time, we use snapshot of this information from June 2019.

Client latency measurements. CASCARA makes latency-aware decisions limiting the impact of outbound traffic allocation on client latency. We feed CASCARA the median latency to all clients of the cloud provider over both the primary and alternate BGP paths at the PoPs.

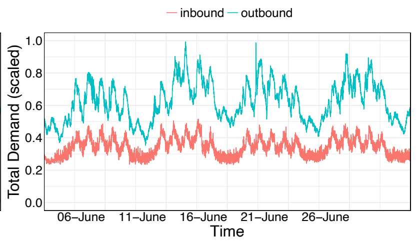
Cloud providers have developed software-defined edges for fine-grained control of outbound path selection from their networks [27, 33]. These systems provide the infrastructure to steer outbound traffic to desired peer paths. The CASCARA controller allocates flow to peer links in every 5 minute interval and can leverage the software-defined edge to optimize the inter-domain bandwidth costs. We first quantify the potential of bandwidth cost saving in a large cloud provider (§3), then develop an efficient, online and near-optimal algorithm for CASCARA to realize the saving potential (§4). Finally, we put CASCARA to test with realistic client performance and route availability constraints in §5.

3 Quantifying the Opportunity

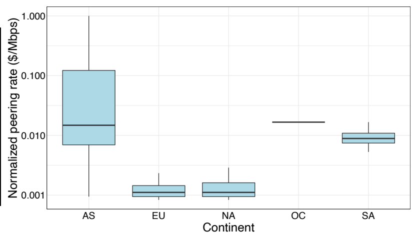
Cloud networks occupy a central position in the Internet ecosystem due to the large volume and variety of popular content they serve to users. To make this possible, cloud providers



(a) Outbound traffic types.



(b) Inbound vs. Outbound traffic.



(c) Norm. peering rates by continent.

Figure 3: (a) Outbound traffic from a large cloud provider towards BGP peers of different types; majority of outbound traffic is towards transit/access networks. (b) The distribution of inbound vs. outbound traffic volume from the cloud network. (c) Large differences in the cost per unit bandwidth in different parts of the world *e.g.,* the median peering cost in Asia is over 10X the median peering cost in North America.

peer with a large number of networks or Autonomous Systems (ASes) on the Internet, including transit ISPs and eyeball networks. The cloud provider we analyze has over 7,000 BGP peers, including transit networks, access networks, content providers and Internet Exchange Points (IXPs). These links span over one hundred geographical locations, collectively carrying terabits of traffic per second. We analyze the utilization and bandwidth costs incurred at the peering edge of the commercial cloud provider using IPFIX flow records collected from June 2018 to July 2019. Aggregated across all edge links, Figure 3a shows the outbound traffic volume per five minute interval from the cloud towards transit/access networks, cloud providers and enterprise networks, categorized by CAIDA's AS types classification [3].

3.1 Dominant contributors to bandwidth cost

A BGP peer of the cloud network charges for the traffic exchanged between them according to the billing model negotiated in their *peering contract*. There are three billing models for inter-domain traffic prevalent on the Internet today: (1) Settlement-free (2) Per-port and (3) Per-Megabit [9]. Settlement-free peers (SFP) agree to exchange traffic with each other at no cost (*e.g.,* between cloud providers). In per-port peering, a peer bills another for each network port used at their facility (*e.g.,* connections at IXPs). Per-Megabit is a utilization-based model where a network charges its peer based on the utilization of the link between them over monthly billing cycles. There can be a commit clause in this contract *i.e.,* regardless of the actual usage, the customer *commits* to pay at least some pre-arranged amount to the provider.

Utilization-based, per-megabit billing is the industry standard for paid peer and transit ISP contracts and it is the focus of our work. Our goal is to minimize bandwidth costs accrued on peering links billed by their utilization. To translate network utilization into the corresponding inter-domain bandwidth cost, ISPs measure the average utilization of peering links in five minute intervals in both inbound and outbound directions. Let the edge link from peer p_1 to peer p_2 have average outbound utilizations of $B = \{B_1, B_2, .., B_n\}$ megabits in 5-minute intervals of a given month. Let B_{out} be the 95^{th} percentile of the outbound utilizations, B. Similarly, B_{in} is the 95^{th} percentile of average inbound utilizations of the $p_1 - p_2$ link. The link cost for a billing cycle is given by, $B = c_i \cdot \text{MAX}\{B_{out}, B_{in}\}$, where c_i is the peering rate negotiated by p_1 and p_2 as part of their peering agreement. This model of billing bandwidth, also called *burstable billing*, has evolved as an industry standard on the Internet [9].

Bulk of the traffic is exchanged with Transit/Access ISPs. The large majority of traffic at the cloud edge is outbound to Transit/Access networks (Figure 3a). Therefore, traffic exchanged with transit ISPs is the main contributor to bandwidth costs incurred by the cloud provider.

Outbound traffic is twice the inbound. For the cloud WAN, outbound traffic volume is nearly twice the inbound (Figure 3b), highlighting that the cost computation based on link utilizations can be simplified to $c_i \cdot B_{out}$ for clouds networks.

Links with only three ISPs contribute majority of costs. Due to the large variance in peering rates (seen in Figure 3c) and skewed distribution of traffic towards a few large ISPs in the North American region of the cloud, edge links to three large networks incur a majority of the total spend on inter-domain bandwidth in North America.

3.2 Optimal inter-domain bandwidth costs

In this section we formalize the task of optimizing inter-domain bandwidth costs of a cloud network. As outbound traffic to paid peers is significantly higher than inbound (Figure 3b), we focus on engineering outbound traffic to minimize the overall inter-domain bandwidth cost. To quantify the potential cost savings, we formulate the offline version of the problem where traffic demands are known in advance.

Let $L = \{l_1, l_2, ..l_m\}$ be the set of all edge links from the WAN. Edge links to the same peer at different points of presence (PoP) are billed individually according to their percentile utilization. Let a five-minute interval in the monthly billing period be t_j where $j \in \{1, 2, .., n\}$. For instance, the month of January has $8,928$ five-minute intervals.

Decision variables. The traffic allocation scheme assigns network flow to peering links in L, for every time slot $t_j, j \in [1,..,n]$. Let x_{ij} be the decision variable, where x_{ij} is the flow assigned to peering link l_i in time slot t_j.

Objective function. The goal of our allocation scheme is to find a traffic assignment to edge links over the entire billing period such that the total inter-domain bandwidth cost is minimized. The cost incurred on peering link l_i is the product of the peering rate (c_i) and the 95th percentile utilization of that link (denoted by z_i). The goal is to minimize the total cost incurred across all links in the WAN:

$$\text{minimize } Z = \sum_{i=1}^{m} c_i \cdot z_i$$

Constraints. The traffic allocations are subject to constraints on link capacities. Since, the offline setting assumes knowledge of traffic demands, the traffic scheme must allocate flow in a way that the egress traffic demand is met in all time slots.

Formulating percentile cost as k-max. The cost function consisting of the sum of 95th percentile utilization of links is non-convex. Previous work has shown that optimizing percentile cost functions is NP-HARD [20]. We later show that techniques from previous work are not effective in saving bandwidth costs of edge links (§4.3). We formulate the exact 95th percentile of traffic allocations as part of the objective function. We note that the 95th percentile of a distribution of n numbers is the same as their **k-max** where $k = n/20$.

Key insight. The key insight of our formulation is that link utilization during 5% of time slots do not contribute to its 95th percentile cost. This means that 5% of time in any billing month is *free* regardless of the traffic it carries. We capture this insight in the optimization formulation using binary integer variables λ_{ij} for each decision variable x_{ij}. λ_{ij}s are also decision variables of the optimization which reflect whether their corresponding x_{ij}s contribute to the link cost. This is expressed with the indicator constraint:

$$(\lambda_{ij} == 0) \implies z_i \geq x_{ij}, \forall i, j \tag{1}$$

We note that only 5% of all $\{x_{i1}, x_{i2}, .., x_{in}\}$ can have their corresponding $\lambda_{ij} = 0$ since we can get away with considering 5% of allocations as *free*. This is expressed using Big-M constraints in the formulation [14]. The minimization objective ensures that of all λ_{ij}s, the ones corresponding to the top $k-1$ of the allocations (x_{ij}) at a link do not contribute to its cost.

Implementation details. Algorithm 1 formulates the traffic cost optimization problem as a Mixed Integer Linear Program (MILP), which is computationally hard to solve. We implement the formulation using the CVX [8] framework and solve it with the commercial optimization solver, GUROBI [15] on a machine with 12 cores and 48 Gb RAM. Our choice of solver is motivated by the computational complexity of Algorithm 1. Commercial solvers like GNU LPK [11] and CPLEX [18] were orders of magnitude slower than GUROBI in solving our formulation.

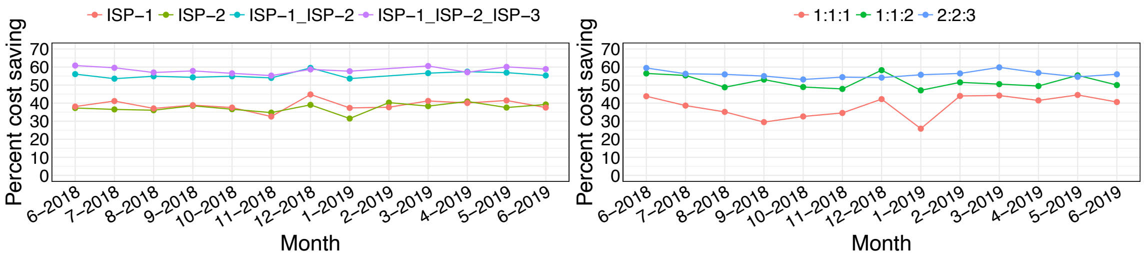
```
Algorithm 1: WAN Egress Traffic Allocation
  Inputs:
        $n$: number of five-minute time slots in a month
        $m$: number of peering links in the WAN
        $l_i$: Peering link $i$
        $C_i$: capacity of peering link $l_i$
        $c_i$: peering rate (USD/Mbps) for link $l_i$
        $d_j$: egress demand from the WAN in time slot $t_j$
        $k = \frac{n}{20}$
        $M$: large integer constant
  Outputs:
        $x_{ij}$: traffic allocation to link $l_i$ in time slot $t_j$
        $\lambda_{ij}$: binary variables that discount top-k $x_{ij}$s
        $z_i$: billable bandwidth on link $l_i$
  Minimize: $\sum_i z_i \cdot c_i$
  subject to:
        $0 \leq x_{ij} \leq C_i, \quad \forall i, \forall j$
        $\sum_i x_{ij} = d_j, \quad \forall j$
        $\sum_j \lambda_{ij} = k - 1, \quad \forall i$
        $z_i > x_{ij} - M \cdot \lambda_{ij}, \quad \forall i, \forall j$
```

3.3 Generalizable and large saving potential

Using the set of peering links (L), peering rates (c_i), link capacities (C_i) and real egress traffic demands (d_j) from a large commercial cloud network, we formulate instances of Alg. 1. The egress traffic demands (d_j) are collected from June 2018 to June 2019 and consist of flow (megabits) that traversed the BGP peering links in each 5-minute interval. Peering rates remain constant during the course of our study. This provides 12 instances of Alg. 1, one for each 1-month billing period. We discuss the implementation details and assumptions in §3.4 and offer a preview of the results here. We compare the cost of allocations computed by Alg. 1 with the real allocation cost incurred by the cloud provider and find that Algorithm 1 reduces the combined cost of the three ISPs that contribute a majority of the bandwidth cost (ISP-1, ISP-2 and ISP-3 peer links) by 65% on average (Figure 4a).

Impact of participating links. When the input to the optimization is a *single* peer's links and traffic matrix, we observe lesser, yet significant, cost savings. This can be seen in the trends for ISP-1 and ISP-2 in Figure 4a. This shows that our cost optimization techniques can be deployed incrementally in the cloud WAN by engineering the traffic flow to a few ISPs at first. The fraction of savings increase as more outbound links are included in the optimization.

Impact of peering rates. We show the impact of relative peering rates of the three participating ISPs in the cost optimization. For the optimization instances demonstrated in



(a) Cost savings with different sets of participating links.

(b) Impact of peering rates on cost saving.

Figure 4: (a) Cost savings for 12 billing cycles using traffic matrices of ISP-1, ISP-2, ISP-3 and their combinations. (b) Cost saving with ISP-1, ISP-2 and ISP-3 for different peering rate ratios.

Figure 4a, the ratio of peering rates of the ISPs is 2:2:3. While the exact peering rates are confidential, their ratio shows that links belonging to two ISPs cost less than the third ISP. To ensure that the cost savings are not simply a function of this specific cost ratio, we compare the savings from the optimization when the peering rates are in 1:1:1 and 1:1:2 ratios and demands are the same as before. Figure 4b shows that savings are significant ($\approx$ 40%) even when all links have the same peering rate. Significant cost savings with different peering ratios demonstrate the generality of our results.

Impact of engineered traffic volume It may not be desirable to allow all traffic from edge links to be engineered for saving network costs. For instance, it may be important to egress some portion of the traffic on the same edge link where the client request entered the cloud for performance or geo-political reasons. We find the impact of the fraction of traffic that can be engineered on a per-link basis by computing the cost gains for the month of June 2018 when the fraction of engineered outbound traffic on the edge links of ISP-1, ISP-2 and ISP-3 is 50%. We find that the resulting cost savings are 37.5%. We note that the solution took longer than our time limit for the solver and therefore the LP gap was higher than 15%. Similarly, when the fraction of traffic engineered on a link is reduced to 40%, the overall cost saving is 28.6%.

3.4 Computing optimal traffic allocations

We now discuss the details of our implementation of Alg. 1.

Managing the scale of the problem. Due to the non-convex nature of the problem, even state-of-the art optimization solvers can take an impractical amount of time to approximately solve Algorithm 1. We take advantage of our findings from §3.1 and only engineer peer links to the three North American ISPs (ISP-1, ISP-2 and ISP-3, anonymized for confidentiality) which incur a majority of the inter-domain bandwidth costs to the cloud. Each of the 3 ISPs peers with the cloud provider at tens of locations in North America, contributing 56 peer links between the cloud network and the three ISPs. We solve Algorithm 1 for different sets of peering links: first considering links with ISP-1 and the egress demand (d_j) that gets served over links with ISP-1. Similarly, we solve problem instances with links and demands of ISP-2, ISP-3, ISP-1 and ISP-2 and ISP-1, ISP-2 and ISP-3 as input.

Efficient computation of the lower-bound. Cutting-edge optimization solvers use a combination of techniques to solve general Mixed Integer Programs (MIPs). At a high level, the first step is *relaxing* the MIP to an efficiently solvable Linear Program (LP) by removing the integral constraints. If a feasible solution to the LP is not found, the MIP, in turn, is also infeasible. If a feasible solution is found, the solution of the LP is a lower bound to the solution of the original MIP. Therefore, in a minimization problem like Algorithm 1, the LP solution provides the lower bound on bandwidth cost without having to solve the MILP.

Running time of the optimization solver. We note that Algorithm 1 has $O(mn)$ Real decision variables and just as many binary variables. Predicting the difficulty of Integer programs in terms of the number of variables and constraints is hard. Indeed, *increasing* the number of links (size of set L) *reduces* the algorithm's running time. The rationale behind this counter-intuitive behavior is that higher number of peering links make it easier for the optimization to meet demands without raising the 95^{th} percentile utilization of the links.

Once the LP relaxation has been solved, MIP solvers use a branch-and-bound strategy to find feasible solutions to the MIP from an exponential number of possibilities. As a result, some instances of the optimization can take several hours to solve. We use two techniques to bound the time of the solver. First, using the efficiently computable LP relaxation, we compute the proximity of the MIP solution to the theoretical lower bound. Second, we configure the branch-and-bound algorithm to return the current-best feasible solution after a fixed amount of time has elapsed. We configure the solver to stop if the current best feasible solution to the MIP is within 15% of the LP optimal or if the solver has run for 15 hours.

Some instances of the optimization problem took 1-2 hours to find solutions while for others, the solution space had to be explored for 15 hours. On average, instances of Algorithm 1 took 6 hours to finish. The variance in run-time is due to differences in traffic demands of months. One strategy that was effective in speeding the optimization involved using the values of decision variables from the previous month as initial values of the corresponding decision variables for next month's model. We found that using this *warm-start* strategy reduced the running time by 3X with instances taking 2 hours to solve on average. We describe other approaches that did not reduce the running time in Appendix (§A.1).

Gap from LP optimal. While the optimal solution to the LP relaxation provides a lower bound on the minimum cost of allocations, this lower bound is not always feasible. To improve the run time, we set a break condition while solving the problem instances to either reach within 15% of the LP optimal or spend 15 hours in solving the MIP using branch-and-bound. For the instances we solved, the average gap of the final MIP solution from the LP optimal is 9% *i.e.,* the solutions are very close to the theoretical lower bound.

4 Online cost-optimization with CASCARA

Results of the offline allocation scheme (3.2) show that there is significant potential for optimizing bandwidth cost at the cloud edge. There are two caveats to the scheme's use: first, it assumes knowledge of outbound demand for every time slot of the billing cycle. In practice, an online algorithm that can allocate network flow to peer links without the knowledge of future demands is required. Second, the optimization formulation (Algorithm 1) takes two hours on average to provide optimal traffic allocations for the entire month. However, state-of-the-art TE controllers compute traffic allocations every 5-10 minutes, making it crucial to have an online solution that is efficient and effective. In this section we develop a heuristic-based online traffic allocation framework that uses insights from the offline optimal solutions to Algorithm 1. Despite the complexity of the cost optimization problem, we show that a simple and efficient algorithm with few hyperparameters governs the closeness of the heuristic solution to the offline optimal. The heuristic allocations achieve bandwidth costs savings within 5% of the optimal.

Consider the set of edge links from the cloud, L = $\{l_1, l_2, ..l_m\}$. Let L_i be a subset of L, such that links in L_i are each priced at p_i per Mbps. For example, the setup in (3.2) has two such subsets, L_1 and L_2 where links in L_1 are priced at p_1 and those in L_2 are priced at p_2. Since the peering rates of links to ISP-1, ISP-2 and ISP-3 are in the ratio 3:2:2, $p_1 = \frac{3}{2}p_2$. From the results of Section 3.4, we derive three key insights about the optimal traffic allocations:

Lower utilization of expensive links. When $p_2 < p_1$, the optimal traffic allocations use links in L_1 minimally. This means that barring capacity considerations, it is always cheaper to use links in L_2 to meet the demand and only use links in L_1 for their *free* 5% time slots.

Maximize the utilization of free slots. Figure 5 shows the density distribution of optimal allocations on an edge link by Algorithm 1. We note that the optimal allocations reduce the link's 95th percentile utilization to ≈ 15% of its capacity.

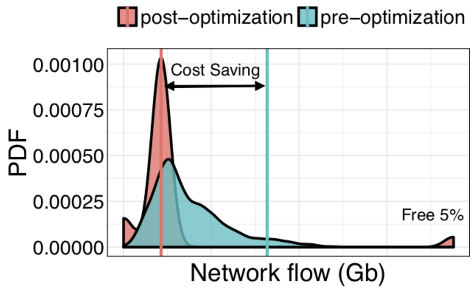


Figure 5: Optimized allocations on an edge link for a month. The vertical lines show the pre- and post-optimization 95th percentile utilization on the link. (X-axis labels removed.)

However, during 5% of time slots the link is utilized nearly at full capacity without contributing to the billable-bandwidth. Optimal allocation on all links show similar patterns.

Link utilization below the 95th percentile is uneconomical. Let u_j be the 95th percentile utilization of an egress link l_j. Assigning less than u_j flow to link l_j in any time slot is wasteful, *i.e.,* the link will get billed for u_j even if its utilization in other time slots is lower (Appendix Figure 13a).

4.1 Online traffic allocation

Using insights derived from the optimal allocations, we propose an online traffic allocation scheme, CASCARA, for the cloud edge. CASCARA *pre-decides* the fraction of the total network capacity that will be the billable bandwidth for the month (C_f). Given the billable bandwidth, finding the optimal pre-decided 95th percentile utilization of link l_j (u_j) is a special case of the bin-packing problem. Thus, greedy assignment of C_f to links in the increasing order of their peering rates minimizes the total bandwidth cost of the network. Since subsets of links ($L_i \subset L$) have the same peering rate, we assign u_j to links in the same subset using the progressive filling algorithm to ensure max-min fairness [2] within link subsets.

When a billing period begins, every link has a 95th percentile utilization (u_i) assigned to it. As new outbound demands arrive, if they can be met with $\sum u_i = C_f$ capacity, CASCARA allocates corresponding flows to the links. However, if the outbound demand exceeds C_f, CASCARA chooses to utilize one or more links at near full capacity to meet the demand. Since 5% of billing slots do not contribute to the links' costs, CASCARA ensures it only runs a link at near capacity for 5% or fewer billing time slots.

Parameters to the online algorithm. It is crucial to select C_f such that all demands in the billing period are met within C_f or by augmenting C_f with the extra capacity of links in their 5% free time slots. Once a link's 95th percentile utilization has been chosen to be u_i, using it for any lesser makes no difference to its final cost. The choice of C_f is critical to making a feasible allocation. If C_f is too low, the allocation may be infeasible or if it is too high, the bandwidth cost can be sub-optimally high. We discuss the choice of initial C_f and how CASCARA improvises when the chosen C_f is too small to meet the demand during the billing cycle.

Order of choosing peer links. CASCARA decides the order of links to be augmented above their allocation u_i to meet 5-minute demands higher than C_f. Using a configurable parameter, CASCARA can allocate how close the augmented allocation is to the link's capacity to prevent sudden link performance degradation. The time slots in which CASCARA augments the allocation to a link are called *augmented* slots. The augmented slots are limited to 5% for each link, making the order in which links are augmented relevant to the feasibility of an allocation. CASCARA uses a priority queue of all edge links where a link's priority is a combination of the time since it was last augmented and its capacity. If a link was augmented in the previous slot, it must also be augmented in the following slot, if required, so that the allocations do not change sharply. By prioritizing links with lesser capacity for augmentation, CASCARA ensures that free slots of links with higher capacity are not used pre-maturely.

Link augmentation order does not impact feasibility. If CASCARA's assignment of u_is and the order of link augmentation leads to an infeasible allocation problem, any change to the order of link augmentation does not render the allocation feasible (Proof in Appendix A.2). Since u_is are derived from C_f, the key input parameter to CASCARA is C_f. Algorithm 2 shows the online traffic allocation scheme of CASCARA in brief (details in Appendix Algorithm 3).

Insufficient C_f and infeasible allocation. If the initial capacity fraction assigned by CASCARA ends up being insufficient to meet the demand in a time slot, despite augmenting the allocations to all edge links that have free slots remaining, we consider the allocation infeasible. This means that it is no longer possible to limit the billable bandwidth of this month to C_f and the C_f value must be increased. CASCARA increases the value of C_f by step size (β) to meet the demand. Until it becomes necessary to increase C_f in a billing cycle, CASCARA has under-utilized the links stay under C_f. Increasing C_f to $C_f + \beta$ renders the past efforts to keep C_f low, futile. Indeed these efforts may have wasted the augmentation slots of links before C_f is incremented. However, there is no choice but to increase C_f as traffic demands must always be met. In the ideal case, initial value of C_f is just enough to meet demands in the entire billing period using augmentation slots when needed. On the other hand, starting the billing cycle with a C_f that is higher than required leads to sub-optimally high bandwidth costs. We show that the *ideal* C_f value is sufficient in ensuring that CASCARA finds optimal cost allocations.

Improvising billable bandwidth preemptively. When CASCARA finds that the demand is too high to accommodate in the current C_f, it increases C_f by β. Increasing the billable bandwidth estimate, C_f is a tradeoff – increasing too late in the billing cycle leads to wasteful use of links' free slots until the increase and increasing it too early reduces the cost saving potential. We capture this tradeoff by introducing the third and final parameter of CASCARA: α. α is the increase in C_f during the monthly billing cycle before an infeasible allocation is encountered. The goal is to preemptively increase C_f if such an increase is inevitable later in the month.

Algorithm 2: Online Traffic Allocation Per-Timestep

```
Function allocate_timestep($d, f$):
    if $d \le C_f$ then
        allocate $C_f$ to links in $L$
        return true
    else
        $d = d - C_f$
        while linkqueue do
            $l$ = pop(linkqueue)
            augment $l$
            decrement $l$'s priority and free slots
            decrement $d$ by $l$'s augmented capacity
            if $d \le 0$ then
                return true
        return false
```

4.2 Finding CASCARA's hyperparameters

We show that by setting C_f effectively, CASCARA's online traffic allocation (Algorithm 2) can be nearly as effective as the offline solutions of Algorithm 1. We set C_f to different fractions of the total network capacity, ranging from 0 to 1, in steps of 0.01. We compare the cost saving from the feasible allocation using the smallest C_f with the optimal cost saving[3] and find that on average, CASCARA with the optimal initial C_f achieves savings within 2% of the offline optimal allocation.

Setting C_f. CASCARA with the optimal C_f is called CASCARA-offline since it has prior knowledge of the lowest C_f for feasible allocations. CASCARA-online assumes no such knowledge and uses the optimal C_f of the previous billing cycle as the current month's initial C_f. This choice is motivated by strong daily, weekly and monthly seasonality in the outbound traffic demands. Previous month's C_f is the optimal value for the next month 64% of the time. For the rest, the average difference between optimal C_f and its initial setting is of the network capacity. When the initial C_f is not optimal, the allocation becomes infeasible and CASCARA has to increase the C_f to meet the traffic demands.

Finding α and β with grid search. Increase in C_f is a definite increase in the bandwidth cost for the billing cycle. The step size by with C_f is increased (β) is also important: too high and it would wastefully increase the cost, too low and it would mean having to increase C_f again in the future. Once increased, there is no cost saving advantage to reducing C_f. Incrementing C_f later is worse than having started with the

[3]For confidentiality reasons, we cannot not share the capacity fractions.

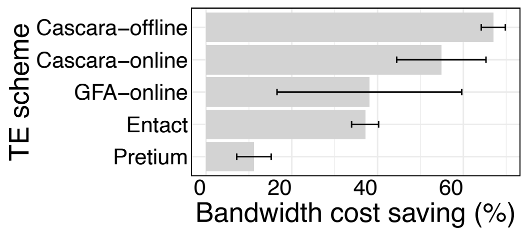

Figure 6: Costs savings from Cascara and related approaches. Bars show the mean and wiskers show the standard deviation.

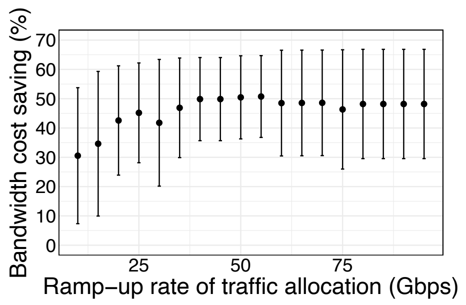

Figure 7: The impact of ramp-up rate on cost saving potential (mean and std. deviation calculated over 12 billing cycles).

optimal C_f since links' augmentation slots are wasted before the increment is made. Thus, preemptively increasing C_f by α during the billing cycle mitigates the issue of wasteful use of link augmentation slots. The hyperparameters, α and β are important to select. We perform a grid search to find the ones best suited for the cloud network. Details of the grid search are in Appendix A.5. The best values of α and β are used to for the following discussion.

4.3 Comparison with previous work

We now discuss the cost savings enabled by Cascara-online over twelve billing months from June 2018 to June 2019 (Figure 6). As before, we use the production network's traffic demands, topology and peering rates to measure the cost savings that Cascara-online would provide. We first show that Cascara-online achieves 55% cost saving, within 10% of the savings from Cascara-offline which knows the optimal C_f in advance. Then, we evaluate existing approaches that have focused on similar objective functions as Cascara. We exclude approaches that delay traffic to future time slots [13, 21] as these are not viable for the cloud provider we study (§7). The three main systems from related work are:

Pretium for dynamic file transfers in the WAN [20]. Pretium focuses on optimizing percentile costs of internal WAN links for dynamic transfers within the WAN [20]. They proposed to use the average of top 10% utilizations as a proxy for 95^{th} percentile cost of links. We find that Pretium offers modest cost saving of 11% on average compared to Cascara's 55% savings for egress WAN traffic. Pretium assumes that the 95^{th} percentile of a link's utilization is linearly correlated with the *average of top k utilizations* [20]. We evaluate this assumption using the utilizations of over 50 peering links from the cloud WAN to large ISPs in N. America. Figure 13b shows the Pearson correlation coefficient to measure the extent to which the average of top 10% utilizations can be used as a proxy for 95^{th} percentile utilization of inter-domain links. We find that the correlation coefficient for over 25% of the links is less than 0.5. Since previous work's hypothesis was derived from the data of a *single* WAN link measured a few years ago, the correlation between average of top 10% and 95^{th} percentile utilization may exist for some links but not all. Ever-changing traffic patterns from WANs due to new services like gaming also explain this difference.

Entact for cost minimization in clouds [35]. Entact shares a lot of the goals with Cascara, including finding cost optimal traffic allocations constrained by client latency. However, Entact chose to optimize *linear bandwidth prices* since percentile pricing is hard to optimize [35]. In a linear pricing scheme, greedy traffic allocation to cheapest links is optimal. However, the greedy algorithm does not fare well in percentile pricing schemes, as show in Figure 6's comparison between Cascara and Entact. The reason is that allocations in *every* time slot contribute towards the billable bandwidth in linear pricing schemes (*e.g.,* average and sum of allocations) but in percentile pricing, some percent of the allocations are *free*. Greedy allocations fail to take advantage of this phenomenon.

Global Fractional Allocation (GFA) for multihoming [12]. Finally, authors of [12] analyzed cost optimizations in the setting of multi-homed users. GFA comes closest in its approach to Cascara and this is also reflected in the cost saving comparison in Figure 6. However, Cascara outperforms GFA by 17% in the average case. There are two main reasons for this: GFA assumes a much smaller scale of the problem where the options for allocations are 3 to 4 upstream ISPs. This makes their naive estimation of cost lower bound ineffective: by using *only* 5% of the timeslots of peer links to meet demands was a viable option, traffic allocation would be *free*. Secondly, when GFA runs into an infeasible allocation, it assigns *all* remaining flow to a single link. This is often impractical at the cloud scale where the demand is too high for one peer link to handle the slack.

And finally, there are several realistic factors that need careful consideration: latency from peer links to clients and existence of routes at the peering router to engineer traffic. Cascara not only performs better in idealized environments by achieving higher cost saving that existing systems, it also takes real-world constraints of a large production WAN into account. We describe these in further details in §5.

4.4 Operational safety checks in Cascara

We discuss the safety checks built into the Cascara algorithm to ease the process of operating it in production.

Stable traffic allocation. One concern with algorithms as-

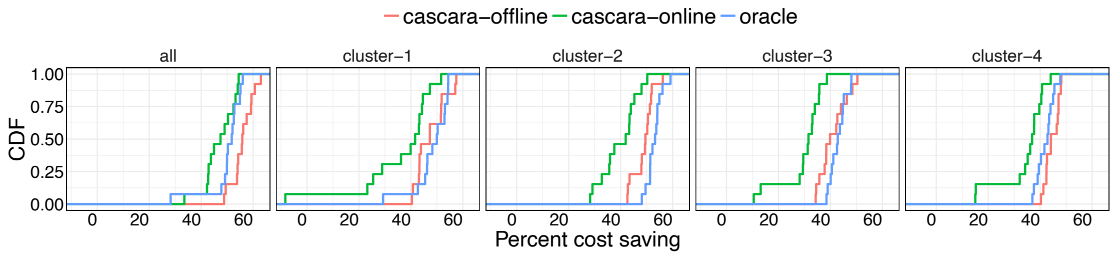

Figure 8: shows distributions of percent cost saving by CASCARA-offline, CASCARA-online and the oracle (Algorithm 1) over 12 billing cycles. CASCARA-online achieves near-optimal saving with different sets of links and corresponding demands as input.

signing traffic flows on peer links is that the allocation must be mindful of the performance impact on the inter-domain paths. CASCARA ensures that allocation to backup BGP paths does not change too rapidly by using a *maximum ramp-up* rate parameter that controls the maximum increase in the allocation to any peer link in the network. This ramp-up rate paces traffic allocation to links and allows CASCARA to incorporate path performance feedback into its decision making. We discuss how CASCARA incorporates performance metrics in its control loop in the next section. Figure 7 shows the cost saving potential of CASCARA as a function of the ramp-up rate. Very slow shifts which use a maximum ramp-up rate of 10 Gbps restrict the cost savings of CASCARA. However, at 30 Gbps ramp-up rate, CASCARA has reached its full saving potential and more rapid shifts of traffic do not offer much improvement in cost savings percentage.

Predictable traffic allocations on edge links. CASCARA's traffic allocation to edge links are more stable than present-day allocations which are driven by user-facing demands. There are two reasons for this. First, CASCARA selects a pre-decided fraction of a link's capacity as the utilization on the link for 95% of billing slots and changes are made to this fraction only when it is essential for meeting demand over C_f. Secondly, even when the allocation to a link has to be augmented, CASCARA ensures that a link, once augmented, is used until its free slots have been exhausted. Predictable allocations on edge links allow network peers to provision capacity appropriately in place of being prepared for arbitrary spikes in traffic demands.

Incremental deployability. CASCARA can be incrementally deployed across edge link groups in the cloud. To show this, we divide the peer links of ISP-1, ISP-2 and ISP-3 into four geographical clusters based on their PoP. These four clusters correspond to links at PoPs in north-central, south-central, East Coast and West Coast regions of North America. We compute the cost savings within each cluster by engineering the demands of the cluster onto its links. Figure 8 shows that CASCARA-online can achieve near-optimal cost (CASCARA-offline) savings across all peer links (cluster *all*) and also within the 4 geographical clusters. We note that in some cases CASCARA-offline achieves higher cost saving than the oracle (Alg. 1) due to the LP gap in the solution of the MILP (§3.4).

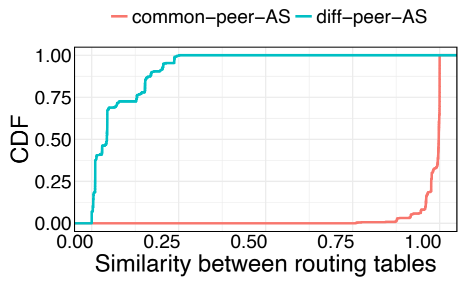

Figure 9: shows the distribution of address space similarity between peer links of ISP-1, ISP-2 and ISP-3 at different PoPs of the cloud. Each ISP announces nearly the same address space at different PoPs but the overlap in address space across ISPs is very small.

5 Performance-aware cost saving

We have demonstrated that there is significant potential of saving inter-domain bandwidth costs in a cloud network (§3) and CASCARA's efficient online algorithm can realize this potential by achieving near-optimal cost saving (§4). In this section we discuss practical aspects of achieving cost savings, namely, feasibility of engineering egress traffic in a WAN and the impact of CASCARA on client latency.

5.1 Availability of client routes at peer links

CASCARA engineers outbound traffic demand to peer links to achieve cost optimality over the billing cycle. However, it must ensure that peer links have the routes required for traffic shifted onto them. Otherwise, traffic to clients could get black-holed at the peering edge router. Using the routes announced by the three ISPs we focus on, we measure the address space overlap between peer links and find that ISPs announce the same address space across different peering locations (*e.g.,* Dallas vs. Seattle) but the overlap of address space across peers (*e.g.,* ISP-1 vs. ISP-2), even at the same PoP is minimal (Figure 9). Thus, CASCARA needs a mechanism to track the existence of relevant routes at peer links.

Tracking prefix route announcements by ISPs at different cloud PoPs in CASCARA leads to an explosion of the problem size since there are over 600,000 prefixes on the Internet. Aggregating clients to their corresponding geographic metropolitan area (metro) and autonomous system (AS) pair

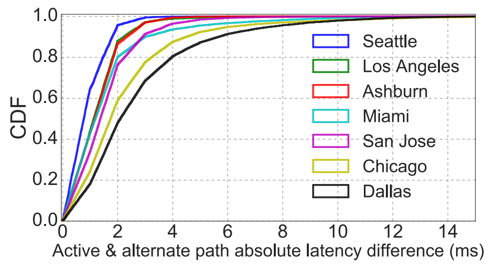

Figure 10: The difference in median latencies between primary and alternate BGP paths calculated from client measurements. The difference between latencies of primary and alternate paths is small.

significantly reduces the scale of the problem. This grouping of client prefixes within the same AS and small geographical locality has been used effectively in previous work [4]. We find that the points of presence where the cloud provider peers with ISP-1, ISP-2 and ISP-3 serve approximately 40,000 (metro, AS) pairs, reducing the scale of the mapping required to capture the existence of relevant BGP routes at peer links. Thus, we construct a bi-partite mapping between clients and peer links *i.e.,* an edge between client c to peer link p implies p has the relevant routes to c. We then constrain the traffic allocation in each timestep by the client to peer link mapping. We compute this allocation efficiently with a linear program (LP) within Alg. 2 that maps clients demands to peer links.

5.2 Bounded impact on client performance

Next, we tackle the challenge of limiting the performance impact of CASCARA's cost optimization. For this, we continuously measure the performance of alternate BGP egress paths to destination prefixes by directing a small amount of traffic over alternate peer links at eight PoPs [26,27,35]. We selected these PoPs as they carry high traffic volume – approximately 47% of all the cloud provider's North American traffic, and have high capacity alternate links.

Links at the same PoP have equivalent client latency. We analyze over 300 million measurements to the cloud PoPs for the month of August 2020, spanning 40,000 client metro and AS pairs, each with thousands of latency measurements towards the cloud on any given day. We first show the existence of latency equivalent peer links at the same PoP. Borrowing from existing methodology [26], we measure the difference in median latency between the BGP best path (*primary*) and the alternate BGP path for all clients that are served by the PoPs over 15 minute time buckets. Figure 10 shows that 80% of the time the difference in the latency is less than 3 ms. This implies that shifting client traffic to links at the same PoP, impacts the client latency by 3 ms or less.

Shifting traffic to peer links at a PoP different than the one where it ingressed introduces two challenges. First, it can inflate latency as the traffic would traverse the cloud backbone to reach the second PoP. The second PoP could be further from the client than the original, also inflating PoP to client latency. Second, traversal of the cloud backbone can congest backbone links but cloud providers often overprovision backbone capacity [6] and manage intra-WAN link utilizations with centralized controllers like SWAN [17] and B4 [19] to mitigate hot spots. Thus, we focus on the latency impact of CASCARA in this work. We find the *primary* PoP and peer ISP which historically has been the preferred egress for a client. This primary link defines the baseline for our experiments – any changes in client latency are measured in comparison with the primary peer and PoP.

Bound the latency impact in egress link selection. To limit the degradation to client latency, we inform CASCARA's allocation (Algorithm 2) of the most recent latency from a peer link to the client. In every timestep, while fulfilling demands to a client, CASCARA enforces that traffic is allocated along the primary and other sets of links. We select the set of links to empirically construct the relationship between latency impact and saving of CASCARA. We consider the set of links for each client to include ISPs with route towards the client – including a transit ISP, at the client's primary PoP. This means that along with the links to its primary ISP, the client's demand could be carried over the transit ISP link at the same PoP. This can increase the set of outbound link options for a client by two links in the best case. Since, links at the same PoP have equivalent latency, this configuration of CASCARA does not cause significant latency degradation (Figure 10).

We use CASCARA to engineer traffic at each PoP and compute the offline cost optimal solutions (Figure 11) for comparison. At some PoPs (PoPs 0, 2 and 13), there are up to five latency-equivalent peer links to most clients. *e.g.,* two interconnections with ISP-1, one with ISP-2 and two with the transit ISP. CASCARA-offline shows the potential to save up to 50% of bandwidth costs at such PoPs. At other PoPs (PoPs 4, 5, 11), there are only 2 latency-equivalent peer links to most clients *e.g.,* one interconnection with ISP-1 and one with the transit ISP. Moreover, high diversity in demands across PoPs due to client population density leads to differing opportunities of cost savings across PoPs. We use CASCARA-online to engineer traffic in an online manner with route and latency constraints. In each five minute timeslot, CASCARA allocated traffic to clients on latency equivalent links at the client's primary PoP. On average, each iteration of CASCARA takes approximately 3 seconds to compute traffic allocations, including the construction of the LP and extraction of traffic allocations on links. We note that our implementation uses Python 2.7 and could be further optimized for running time. However, TE systems typically perform allocations once every 5-10 minutes, thus CASCARA's runtime of 3 seconds is reasonable. Across all PoPs, CASCARA achieves the overall cost saving of 21% while ensuring that client latency remains unaffected. The per-PoP configuration we have evaluated enforces the strictest possible latency bound on CASCARA. CASCARA allows cloud providers to configure the acceptable

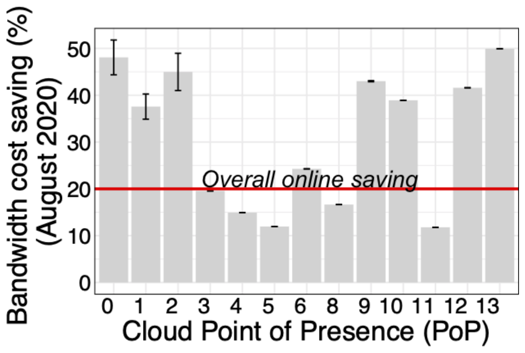

Figure 11: shows cost savings with CASCARA when engineering traffic on a per-PoP basis while limiting the impact on client latency to 3 ms in the worst case (mean and standard deviation computed over three runs of CASCARA).

worst-case latency degradation while saving bandwidth costs.

6 Discussion

In this section, we investigate the source of CASCARA's cost savings. We discuss implications of our findings on peering contracts with ISPs and bandwidth pricing on the Internet.

6.1 Where do the cost savings come from?

Network operators have historically used heuristics to limit their bandwidth costs. These include, load balancing traffic over equivalent links and preferring cheaper peer links in the BGP best path selection by setting localpref appropriately.

Localpref based cost saving is sub-optimal. We illustrate the cost savings from CASCARA with a small example using 2 links and 3 billing slots. There are two egress links from a network (Link 1 and Link 2), each of capacity 5 traffic units and unit peering rate. The traffic demand is assigned to Link 1 and 2 in any time slot (Figure 12). Traffic must not be dropped if there is enough capacity on the outbound links. For simplicity, the links are billed using the median (50^{th} percentile) utilization over three time slots. Since the peering rate of both links is the same, localpref-based cost minimization will simply balance traffic on the two links. Under this scheme, the link utilizations are : $1, 2.5, 1.5$ in time slots 1, 2 and 3 respectively (shown in red in Figure 12) for both links. The median utilization is 1.5 for both, the total cost of the links is 3 units. An alternate traffic assignment to the links is shown in blue in Figure 12, where the utilizations of link 1 and 2 are $\{1, 5, 0\}$ and $\{1, 0, 3\}$ respectively. The median cost in this case is 1 for both links, total cost being 2 units. This scheme saves one third of the traffic cost while meeting the same demand. We note that by extension, sending all traffic to a link that is cheaper would also be sub-optimal.

Free time slots for saving cost. The example shows that in case of median billing, one of the three time slots does not contribute towards the final cost of the link. Each link has one free slot that can absorb peaks in demands to reduce

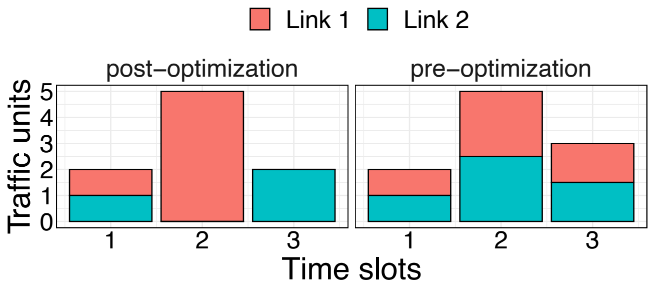

Figure 12: A toy example comparing CASCARA's cost-optimized allocations vs. load-balanced allocations.

costs. Similarly, bandwidth on the Internet is billed using 95^{th} percentile billing, meaning that 5% of 5-minute time slots in a month are *free* for each link. This implies that for roughly 36 hours in a month, traffic allocation on any link does not contribute to the final billed cost. While it may seem that the free slots provide little wriggle room for saving cost, cloud providers have a rich diversity of network peers in several PoPs. These peer links provide free slots in the billing context and enable multiple latency-equivalent ways to reach clients.

6.2 Do the findings generalize?

We believe our results generalize to any large global cloud, content provider, or content delivery network. The first reason is that the cloud provider network is not unique. These networks all share several critical properties in common with each other: **(1)** presence in hundreds of PoPs around the world to deliver traffic very close to users and **(2)** extensive peering and short AS paths [5, 32]. The second reason is that other large networks have shown that given such large deployments and peering, many of the alternate paths to users have similar latency [1, 26]; also allowing these networks to optimize bandwidth costs with stable performance.

Cost optimization is not a one-time effort. Traffic patterns across billing slots change – demands have been rising steadily at 30-40% per year. The surge in demand [7] from the COVID-19 pandemic has made traffic patterns more dynamic. We have evaluated CASCARA using over a year worth of demands, including evaluation in August 2020 to capture the post-pandemic traffic growth. Our findings show small month-to-month variation in saving but overall, the savings are significant and consistent. We note that cost savings compound over time as demand continues to rise exponentially.

6.3 How practical is CASCARA?

While CASCARA benefits from large sets of latency-equivalent peer links, it can be deployed incrementally over peer links (§5), allowing cloud operators to choose to expand CASCARA's purview over time. CASCARA can bound the amount by which allocations to links can change across time slots to prevent sudden changes in traffic (§4.4). Moreover, we foresee CASCARA as a component of a larger software-defined edge [27, 33] that already prioritizes successful traffic delivery based on the capacity and availability of the downstream path. During demand surges or outages, the high priority components of the TE system may take action to mitigate customer impact, putting CASCARA on hold for some types of traffic for short periods of time. Automated network build-out alerts limit the duration of persistent capacity crunches, enabling cost savings from CASCARA in the long term. Where cost-optimization falls among second-order priorities will vary across cloud providers and their business needs.

6.4 Implications for existing peering contracts

An important concern in optimizing the cost of inter-domain traffic is the long-term impact it may have on peering contracts. For instance, if free peers observe higher traffic volume from the cloud, they may reconsider their peering agreement or lean towards paid exchange of traffic [22]. Due to these factors, we evaluated CASCARA only on links with paid North American peers. We argue that the peering rate captures the value of the interconnection to both networks involved and thus optimizing the outbound allocations for cost, not exceeding the peering port capacity at the edge, is a reasonable strategy. Additionally, peering rates in certain regions of the world are disproportionately high due to monopolistic transit ISPs and complicated socio-political factors, making high bandwidth rates the cost of operating in the market.

6.5 Implications for bandwidth pricing

CASCARA shows that the abundance of latency-equivalent peer links has enabled networks to significantly reduce their expenditure on inter-domain bandwidth. With the findings of CASCARA, we encourage the community to revisit the classic problem of pricing inter-domain traffic effectively. A subject studied since the dawn of the Internet [24], inter-domain bandwidth pricing models and rates determine paths taken by traffic and subsequently the end-user performance. With the emergence of cloud and content providers as the source of disproportionately large volume of Internet traffic, current pricing models may not suffice in ensuring the harmonious existence of networks on the Internet [10, 30]. Today, a handful of networks (cloud and content providers) can take advantage of their rich connectivity to save inter-domain bandwidth costs, potentially taking a portion from the profits of ISPs. Some recent proposals suggest ways to better align the cost of Internet transit and the revenue gained by networks [16, 34].

7 Related Work

In this section, we discuss important pieces of work related to CASCARA and set them in the context of our contributions.

Intra-WAN traffic engineering. Large cloud providers have embraced software-defined, centralized traffic engineering controllers to assign flow within their private WAN to maximize their utilization, guarantee fairness and prevent congestion [17,19,23]. Bandwidth costs in the context of WANs were considered in Pretium [20] (comparison with CASCARA in Section 3.4). Stanojevic *et al.* used Shapley values to quantify the value of individual flows under percentile pricing [28].

Engineering the WAN egress. Recent work has proposed a software-defined edge to manage outbound flows from their networks [27, 33]. The goal of these efforts has been to react to poor client performance by switching to better performing BGP next hops. The allocation decisions made by CASCARA can be implemented using a software defined edge like Espresso or EdgeFabric. The subject of TE in multi-hoped networks has been studied [12, 25] and we compare CASCARA with a representative set of work from this space (§3.4).

Engineering delay tolerant traffic. Previous work has explored the potential of delaying traffic across timeslots to save bandwidth costs at the end of the billing cycle [21]. However, the cloud provider we analyze does not consider delaying client traffic by several minutes as a viable option.

Performance-based routing on the Internet. Google's Espresso [33] implements performance-based routing on the Internet to improve client performance. Recently, other large global networks have shown limited potential in optimizing latency by routing [1, 26]. Our work effectively exploits this realization by optimizing cost while keeping latency stable.

Bandwidth pricing schemes. In the early years of the Internet, economists studied potential mechanisms to price bandwidth [24]. Congestion pricing was proposed to bill based on the use of network resources at times when they are scarce. These pricing schemes incentivize users to reduce consumption of network resources during peak utilization by pricing bandwidth higher when the network is congested.

8 Conclusion

In this work, we quantify the potential of saving inter-domain bandwidth costs in a large commercial cloud provider and find that optimal allocations can save up to 60% of current inter-domain bandwidth costs while meeting all traffic demands as they arrive. Inspired by this, we develop an efficient online TE framework, CASCARA, that achieves cost savings within 10% of the optimal. CASCARA's cost savings are robust to changes in traffic patterns and peering rates. Finally, we show that CASCARA can balance the cost-performance tradeoff by achieving 11-50% cost savings per cloud PoP without degrading client latency significantly.

A Appendix

A.1 Speeding the MIP solution

In this section we briefly describe the intuitive but ineffective methods we employed to speed the execution of the MILP. The methods did not yield a reduction in running time but we document these for completeness.

Solving the MILP in smaller time slices. Since link utilizations at the edge exhibit strong daily and weekly seasonality, we hypothesized that solving the cost optimization in smaller chunks of time, say, one week at a time, and then stitching together the resulting solutions would find the entire month's optimal allocations. While the smaller problems of weekly allocations could be solved in approximately ten minutes, when stitched together, the overall solution is very far from optimal. In fact, the allocations obtained via this process did not show any significant reduction in inter-domain bandwidth cost over the present-day traffic allocations. On investigating the reason why this approach does not work, we found that while there are regular trends in the traffic demand, bursts of traffic are not spread uniformly across all weeks of a month. Accommodating these bursts with a local, week-long view leads to overall poor cost saving from the stitched allocations.

Automated parameter tuning. The commercial solver we used (Gurobi), provides a tool for automatically tuning the parameters of the solver for a given optimization model. We attempted to use this tool to find parameters which gave the best performance in terms of running time and closeness to the optimal. However, our model was too large for the autotune to deliver any results. Thus, we selected the appropriate parameter values manually by several runs of the optimization. These parameters are documented in the code repository we have released.

A.2 CASCARA's link augmentation order

We show that changing the order of links that CASCARA augments during the billing cycle does not make an unfeasible allocation, feasible. We take the example of an unfeasible ordering, $O_{unfeasible}$ where the demand in timeslot k cannot be met even after augmenting the capacity of all links. Consider the following change in the position of link l_i in the ordering: if l_i is picked for augmenting in timestamp k in place of timestamp j where $j \leq k$. If this were possible, then CAPACITY(l_i) would be available for use in timestamp k. However, this is not possible since l_i had to be the *smallest* capacity link that met the excess demand of timeslot j, any other link that takes its place has to have a higher capacity. This means that by using another link in place of l_i, we would reduce the available capacity in timeslot k. Thus, a change in ordering of links for augmentation would not make a problem instance feasible. □

A.3 Traffic allocation with CASCARA

In this section we discuss details of the CASCARA allocation algorithm which were omitted in Section 4 for brevity. The complete algorithm, Algorithm 3, expands on Algorithm 2. L is the set of links in the network in the increasing order of thei peering rate. The algorithm shows how CASCARA allocates flow to links in every timestamp of the billing period. The solution to this algorithm are link allocations in all time steps. CASCARA maintains a priority queue of links and the priority of a link is decided based on two factors:

- Initial priority: all links have their initial priority set to the number of free time slots they have in the current billing cycle. We update the priority after augmenting the link. In any subsequent billing timeslots, if the demand is higher than C_f, links with lower priority *i.e.,* ones which were used in the previous slots are re-used again. This ensures that the link augmentation is not spread across many links.
- Link capacity: We prefer to augment lower capacity links to save the higher capacity links for the remaining billing cycle. If the demand is too high, high capacity links are more likely to absorb it with augmentation.

We also kep track of the remaining free slots for each link. When all links have exhausted their free slots, allocation in that timestep fails and we have to increment C_f. Let O be the order in which links got augmented. An example ordering of augmented links, O is like so:

$$O = \{[l_1, l_2, l_3], [l_1, l_2,], ..[l_k, l_{k+1}, l_{k+2,..}]\}$$

In timestamp 1, CASCARA augmented allocations to links l_1, l_2 and l_3. The starting priority of links is the same, so the priority queue returns links in ascending order of their capacity. In the next timeslot, CASCARA attempts to meet the demand by augmenting the same set of links to keep allocations stable.

CASCARA initializes C_f to the minimum value that produced a feasible traffic allocation for the previous month. If C_f is too low for the current month's demands, despite augmenting allocation to links, the traffic demand would not be met and C_f will be incremented by β. The augmented link ordering of an infeasible allocation would be like so:

$$O_{unfeasible} = \{[l_1, l_2..], ..., [l_k, l_{k+1}, .., l_m]\}$$

where $\sum_k^m \text{CAPACITY}(l_i) \leq demand - C_f$.

Additionally, CASCARA has a provision to proactively increment C_f by α (not shown in the algorithm). The goal is to proactively perform an inevitable increase in C_f to avoid wasting free slots of links. To do this, CASCARA checks if the number of links with free slots remaining is proportional to the amount of time left in the billing cycle. If the number of burstable links are too few,, C_f is incremented proactively.

Algorithm 3: Online Traffic Allocation (long version)

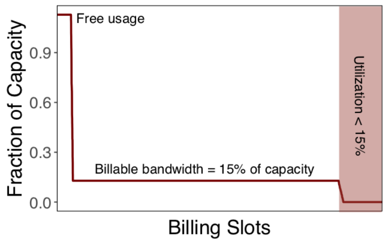
```
Result: Allocation of demand $d$ in every timestamp $t$
Input: $L, n, k, f,$ CAPACITY, $C, \alpha, \beta$
Initialization:
freeslots = $\frac{k}{100} * n$
$prio$ = freeslots          ▷ Initial priority of all links
$linkq$ = PRIORITYQUEUE()
for link ∈ $L$ do
    linkq.insert(link, CAPACITY(link), freeslots, $prio$)

Function allocate_timestep($d, f$):
    link_alloc = {}
    augmented_links = []
    $C_f = f * C$          ▷ Fraction $f$ of total capacity $C$
    if $d \leq C_f$ then
        link_alloc = bin_pack($L, C_f$)
    else
        $d = d - C_f$
        while $d \geq 0$ do
            b_link = linkq.pop()
            if !b_link then
                return {}
            augmented_links.add(b_link)
            if b_link ∈ $L_1$ then
                $d = d -$ (1 - f) $*$ CAPACITY(b_link)
            else
                $d = d -$ CAPACITY(b_link)
            link_alloc [b_link]= CAPACITY(b_link)

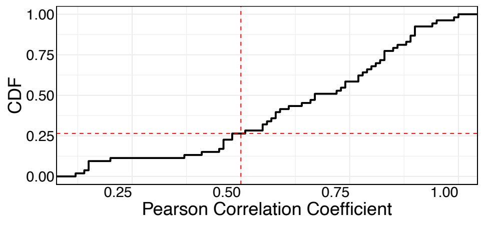
        for link ∈ augmented_links do
            link.prio = link.prio $-1$
            link.free_slots = link.free_slots $-1$
    return link_alloc
End Function
while not allocate_timestep($d, f$) do
    $f = f + \delta$
```

A.3.1 Link utilization below the billable bandwidth

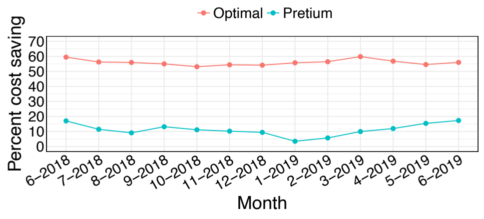
CASCARA chooses the *target* billable bandwidth (C_f) for a month. Given the billable bandwidth, it can be packed on to links by greedily assigning traffic ot cheaper links. [4] Given the minimum feasible C_f, this strategy is optimal. In fact, utilizing any link below its 95th percentile utilization is uneconomical – the link gets charged at the 95th percentile anyway. Figure 13a shows that while the utilization in some billing slots was below the 95th percentile (shaded red), yet, the link was billed for 15% of its capacity, making the period of utilization below 15%, wasteful.



(a) Link utilizations.



(b) Pearson's correlation.



(c) Pretium vs. Optimal saving

Figure 13: (a) Utilization of a link as fraction of its capacity, sorted from high to low across billing slots in a month. (b) 95th %-ile and avg. of top 10% correlation.(c) Cost saving by CASCARA vs. Pretium [20] on a month-by-month basis.

A.4 Details on the implementation of previous systems

We implement the optimization formulation from previous work using top 10% of utilizations in a month as the bandwidth cost of a link. We use CVXPY's implementation of sum of largest decision variables for this purpose. Since this formulation is a linear program, GUROBI solves it in less than a minute. While fast to compute, the allocations from this formulation are ineffective in saving the 95th percentile cost. Figure 13c compares the cost savings per-month between our solutions from Algorithm 1 and previous work. We note that the cost saving from the sum of top-k formulation are modest, 11% on average for all instances. We believe this is because of two assumptions made by previous work:

Assumption 1: 95th percentile of a link's utilization is linearly correlated with the *average of top k utilizations* [20]. We evaluate this assumption using the utilizations of over 50 peering links in a cloud WAN. These links connect the cloud WAN to large ISPs in N. America. We compute the Pearson correlation coefficient to measure the extent to which the average of top 10% utilizations can be used as a proxy for 95th percentile utilization of inter-domain links. We find that the correlation coefficient for over 25% of the links is less than 0.5. Since previous work's hypothesis was derived from the data of a *single* WAN link measured a few years ago, the correlation between average of top 10% and 95th percentile utilization may exist for some links but not all. Ever-changing traffic patterns from WANs due to the advent of new services like gaming also explain this difference.

Assumption 2: The correlation between average of top-k and 95th percentile of a link's utilization holds even after a new traffic allocation scheme replaces the current one. There is no guarantee that assumptions about allocation distributions hold in a newly proposed traffic engineering scheme. In fact, traffic engineering schemes *change* the allocation of flow along network links, modifying how links are utilized.

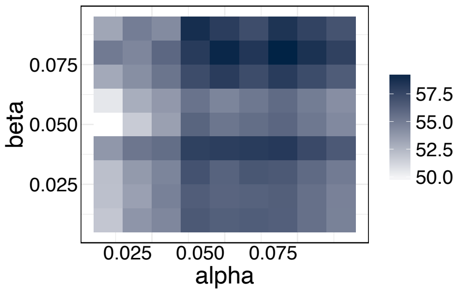


Figure 14: Average monthly bandwidth cost saving with CASCARA as a function of the parameters α and β. We choose the best values of α and β for the evaluation in §5.

A.5 Selecting CASCARA's hyperparameters

We sweep through potential values of α and β to find the ones that fit CASCARA the best. The range of values for α and β is $[0,1]$ since they represent increments to fraction of total network capacity. We sweep the space in steps of 0.01 to find the parameters that lead to the highest cost savings in the average case across all billing cycles (Figure 14).

[4]We have discussed the additional routing and client latency constraints on CASCARA in §5.

A Social Network Under Social Distancing: Risk-Driven Backbone Management During COVID-19 and Beyond

Abstract

As the COVID-19 pandemic reshapes our social landscape, its lessons have far-reaching implications on how online service providers manage their infrastructure to mitigate risks. This paper presents Facebook's risk-driven backbone management strategy to ensure high service performance throughout the COVID-19 pandemic. We describe Risk Simulation System (RSS), a production system that identifies possible failures and quantifies their potential severity with a set of metrics for network risk. With a year-long risk measurement from RSS we show that our backbone resiliently withstood the COVID-19 stress test, achieving high service availability and low route dilation while efficiently handling traffic surges. We also share our operational practices to mitigate risk throughout the pandemic.

Our findings give insights to further improve risk-driven network management. We argue for incorporating short-term failure statistics in modeling failures. Common failure prediction models based on long-term modeling achieve stable output at the cost of assigning low significance to unique short-term events of extreme importance such as COVID-19. Furthermore, we advocate augmenting network management techniques with non-networking signals. We support this by identifying and analyzing the correlation between network traffic and human mobility.

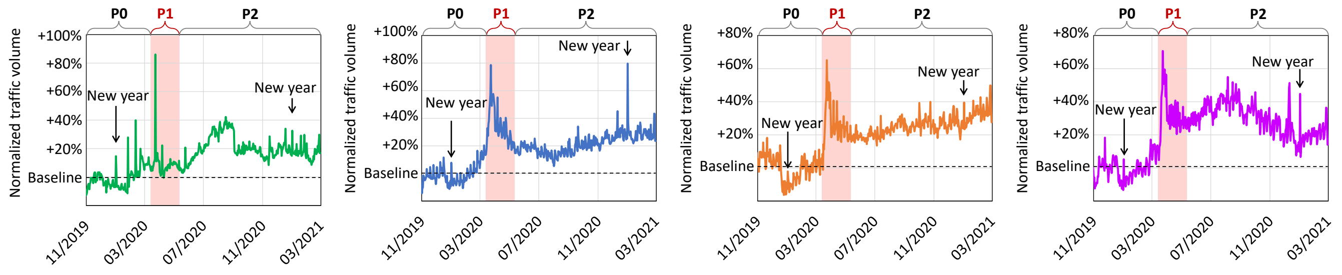
1 Introduction

COVID-19 fundamentally reshaped societal norms and human interactions by forcing most social activities to move online. The global network infrastructure was subjected to an unprecedented stress test as work, entertainment and education all had to be conducted via digital connections [37]. Over the past year, the networking community aimed to answer two fundamental questions about the impact of COVID-19 on different network environments [7,15,28]. First, how well has the current network infrastructure withstood the COVID-19 stress test? Second, how should the network infrastructure evolve to support a post-pandemic era likely to be permanently remodeled by the social distancing experience?

This paper supplements the recent COVID-19-centric research by sharing Facebook's experience emerging from the risk-driven backbone management strategy. Our work has two unique angles: the focus on the backbone network of a global online service provider and the use of network risk to quantify the robustness of the network infrastructure under adverse conditions. This study enriches previous observations made in different network environments, including the Internet [15], edge networks [7], and mobile networks [28]. Furthermore, it is a significant departure from prior work which uses only traffic measurement to quantify the impact of social events on the network infrastructure.

Our risk-driven backbone management is based on the fact that failures and disasters happen frequently and the backbone network should be equipped with sufficient protection capacity to mitigate the effects. Particularly, Facebook's backbone connects hundreds of Point-of-Presence (PoP) sites and tens of Data Center (DC) regions. At this scale, failures such as fiber cuts, router misconfigurations, and power outages happen on a daily basis [20], causing traffic congestion, packet loss, and latency increase which, in turn, negatively impact the network's availability and service-level agreements [8,21,27]. *Network risk* is an effective means to capture the impacts of potential failures in the network, before they actually occur, which is critical for identifying operational pain-points for long-term deployment planning, mid-term capacity augmentation, and short-term health monitoring.

This paper describes our Risk Simulation System (RSS), which performs comprehensive "what-if" analyses of network risk through traffic simulations under plausible failure scenarios. RSS has been in production for years. We introduce RSS in detail, showing key design decisions and engineering efforts to optimize the system over time. Specifically, we propose a set of risk metrics (demand loss, availability, latency stretch) to quantify impacts of potential failures from different aspects. Further, we introduce a high-fidelity failure model based on failure records from different data sources



(a) Asia (b) Europe (c) North America (d) South America

Figure 1: User-facing (DC-to-PoP) traffic traversing the global backbone.

and failure types. To scale our system, we provide different simulation granularities that trade failure count for simulation accuracy. Moreover, we discuss several techniques to accelerate computation such as system parallelization, routing simplification, and reduction of failure scenarios.

We conduct a year-long analysis of network risk using RSS, and in what follows, we share our operational experience of keeping risk at bay during the COVID-19 pandemic. Our risk analysis demonstrates our backbone network remained robust under the COVID-19 traffic surges. Although risk increased with traffic, even the most heavily affected class of service still achieved four 9s of availability and its flows only experienced 2.12% longer paths on average. We further discuss capacity enhancement and quality of service downgrade as two effective measures to reduce network risk.

Finally, we use case studies to show unusual network conditions caused by social distancing have challenged fundamental assumptions of the traditional network design, and we share our insights on future directions of risk-driven backbone management. We observe a large variation of optical and IP-layer failures triggered by changes of human activities. We thus suggest failure modeling to be more responsive to short-term failure statistics and discuss the tradeoff between model stability and agility for accurate failure predictions. We also identify the limitation of standard network management that only considers in-network signals and is blind to social impacts to the network. We find a negative correlation between traffic volume and population mobility rate during social distancing, and use it as an example to show opportunities for improving network management with external non-networking signals.

Our risk metrics, failure model and risk simulation approach generalize beyond the initially envisioned backbone network scenario and are readily applicable to other network environments. We believe that risk-driven network management has the potential to become the standard approach to disaster prevention, monitoring and recovery. Towards this goal, we hope that our experience can inspire future solutions and spur broader adoption of risk-driven network management. This work does not raise any ethical issues. We preserved user privacy and anonymity throughout this study.

Phase	Start date	End date	# Days
Pre-COVID (P_0)	11/4/2019	3/15/2020	133
Shelter-in-Place (P_1)	3/16/2020	5/3/2020	49
Re-opening (P_2)	5/4/2020	2/28/2021	301

Table 1: Measurement phases in this paper.

2 Traffic Surges During COVID-19

Recent news reports and measurement studies suggest significant traffic surges globally during the COVID-19 pandemic [7, 10, 15, 24, 28]. As a major social media platform, Facebook witnessed higher user engagement under social distancing. In this section, we measure Facebook's user-facing traffic to motivate the need for a risk-driven backbone management system.

Throughout the paper, we categorize our measurement period into three time phases (P_0 to P_2) listed in Table 1. The first phase, *Pre-COVID* (P_0), is our baseline to capture the state of the network before the global shut-down due to the pandemic. The second phase, *Shelter-in-Place* (P_1), marks the period when the US and European countries started to introduce extreme COVID-19 regulations, such as border closures, flight reductions, and school closures. The third phase, *Re-opening* (P_2), represents the slow re-opening phase when strict shut-down orders were relaxed [2].

Significant traffic increase. Figure 1 plots the traffic volume from our Data Center (DC) regions to Point-of-Presence (PoP) sites in four geographical regions. The traffic volume is normalized against average traffic during the pre-COVID phase (P_0). The figure shows a significant traffic surge starting mid-March 2020 in all regions, matching the timeline of global social distancing. In particular, we measure a traffic surge of 86% in Asia, 78% in Europe, 65% in North America, and 70% in South America in the P_1 phase.

Beyond the New Year traffic spike. Traffic volume spikes are not unusual. Today's service providers consider well-known flash-crowd events, such as Cyber Monday, in their traffic modeling [45] and network operation planning [49]. However, as Figure 1 depicts, the COVID-19 traffic increase has two unique differences. First, the traffic peak during phase P_1 was substantially higher than that of New Year's Eve (31

December 2019). The peak volume was 1.62× the 2020 New Year's Eve in Asia, 1.65× in Europe, 1.68× in North America, and 1.61× in South America. Second, flash-crowd events are usually short-lived, but the traffic surges remained high for several weeks during the pandemic.

The above observations highlight the challenges posed by social distancing on large-scale network operations. Under high traffic load, operators need to answer a natural question: "is my network at risk?" This question motivates us to quantify network risk and use it as a guiding signal to drive network management.

3 Risk-Driven Backbone Management

Satisfying Service Level Objectives (SLOs) is the ultimate goal of network management. Risk analysis is an indispensable and effective means to guarantee SLO compliance under different failure scenarios. In this section, we dive into the details of RSS, our risk-driven backbone management framework. We begin with the description of Facebook's traffic classification and routing schemes (§3.1), followed by our definition of risk metrics that align with SLO requirements of different service classes (§3.2). Next, we describe our failure modeling technique (§3.3). Finally, we present the design and implementation of RSS, our risk simulation system (§3.4).

3.1 Traffic Classification and Routing

Quality of Service (QoS). Facebook classifies the backbone traffic into four service classes. In this paper, we refer to them as QoS classes 1 to 4, where class 1 is the highest priority. Different classes of service use different queue assignments and routing policies. Flows with higher priorities have greater availability guarantees and can tolerate more failures compared to those in lower priority classes. This is often realized by over-provisioning extensive backup paths for redundancy. QoS class 1 contains essential network control traffic including network signaling and routing protocol messages to manage our network gear; class 2 is for critical services including most of our user-facing traffic; class 3 is our default class for most internal applications; and class 4 is for heavy, bulk data transfers. To reduce operational costs, we constantly look for opportunities to move traffic into class 4.

Routing. Our backbone uses a centralized network controller to make routing and Traffic Engineering (TE) decisions [22]. The centralized controller implements different traffic allocation algorithms for different QoS classes. To minimize the latency experienced by flows in QoS classes 1 and 2, we use a Constrained Shortest Path First (CSPF) approach that provisions TE tunnels for these flows up to the physical capacity of the network links. Flows are assigned to paths with the smallest round trip latencies. The bandwidth for QoS class 2 is allocated after class 1, and we reserve headroom on each link for potential traffic bursts for these two classes. QoS classes

Algorithm 1 Compute risk metrics for QoS class q

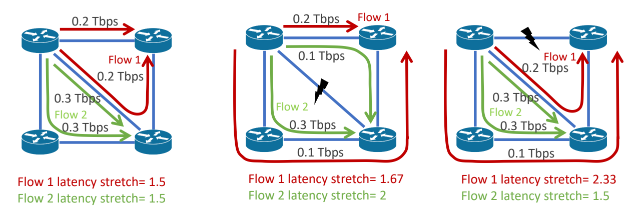
```
 1: procedure CALCULATE DEMAND LOSS, AVAILABILITY AND LATENCY STRETCH FOR QOS CLASS $q$ UNDER FAILURE SCENARIOS $S$
    ▷ Input: $S$: set of considered failure scenarios
    ▷ Input: $T$: set of Traffic Engineering tunnels on the IP topology $G$
    ▷ Input: $F^q = \{f\}$: set of flows in QoS class $q$
    ▷ Input: $d_f$: bandwidth demand of flow $f$
    ▷ Output: $V^q$: QoS class $q$'s availability
    ▷ Output: $L^q_f = \{< L^{s,q}_f, s.probability >\}$: for flow $f$, a distribution of latency stretch $L^{s,q}_f$ per failure scenario and its failure probability
    ▷ Output: $X^q$: QoS class $q$'s demand loss
 2:     Initialize flow $f$'s availability $V^q_f = 1, \forall q, f$
 3:     Initialize flow $f$'s demand loss in scenario $s$: $X^{s,q}_f = 0, \forall q, f$
        ▷ Iterate on all failure scenarios in S
 4:     for all $s \in S$ do
            ▷ TE bandwidth allocation $b^{s,q}_f$ and per-tunnel split ratio $a^{s,q}_{f,t}$
 5:         $\{b^{s,q}_f\}, \{a^{s,q}_{f,t}\}$ = TrafficEngineering($G, T, F^q, s$)
 6:         for all $f \in F^q$ do
                ▷ Flow $f$'s bandwidth-weighted latency
 7:             $l = (\sum_{t \in T_f} t.rtt \times a^{s,q}_{f,t}) / (\sum_{t \in T_f} a^{s,q}_{f,t})$
                ▷ Flow $f$'s latency stretch
 8:             $L^{s,q}_f = l / \min_{t \in T_f} t.rtt$
 9:             $L^q_f$.append(<$L^{s,q}_f$, $s.probability$>)
10:             if $b^{s,q}_f < d_f$ then
                    ▷ Flow $f$'s demand loss
11:                 $X^{s,q}_f = X^{s,q}_f + (d_f - b^{s,q}_f)$
                    ▷ Flow $f$'s availability reduction
12:                 $V^q_f = V^q_f - s.probability$
13:     $V^q = \min_{f \in F^q}(V^q_f)$
14:     $X^q = \max_{s \in S}(\sum_{f \in F^q} X^{s,q}_f)$
15:     return $V^q$, $L^q_f$, $X^q$
```

3 and 4 use a combination of K-Shortest Paths (KSP) and Multi-Commodity Flow (MCF) algorithms with the objective of minimizing the maximum link utilization in the network. We pre-assign TE tunnels for traffic flows between each router pair, then rely on a Linear Program (LP) to load-balance the traffic over all tunnels. Lower priority traffic uses the bandwidth left by higher priority traffic on each link. When failures bring certain links down, traffic is automatically re-distributed across remaining tunnels until the next TE execution where a new optimal traffic allocation is calculated.

3.2 Risk Metrics

This paper defines a set of key metrics to quantify a network's risk to potential failures. These risk metrics satisfy two requirements. First, they capture different aspects of failure events by quantifying the network's response from multiple dimensions. Second, since QoS classes have different levels of tolerance to failures, our risk metrics relate to QoS classes and reflect their SLO guarantees. As a result, we use the following metrics for each QoS class q:

(1) Demand Loss (X^q): For a failure scenario s, the demand loss is the total amount of lost traffic by all flows in q caused by s. The overall demand loss of QoS class q is the maximum, or worst-case, demand loss across all the considered failure



0.2 Tbps

Figure 2: An example with two flows (green and red arrows) from the same QoS class q under three failure scenarios. Risk metrics computed by Algorithm 1 are as follows: worst-case demand loss (X^q) = 0.3 Tbps, worst-case availability (V^q) = 99.81%, flow 1's latency stretch (L_1^q) = {<1.5, 99.81%>, <1.67, 0.18%>, <2.33, 0.11%>}, and flow 2's latency stretch (L_2^q) = {<1.5, 99.81%>, <2, 0.18%>, <1.5, 0.11%>}.

scenarios $s \in S$.

(2) Availability (V^q): The percentage of time that a flow's demand is completely satisfied (100% admitted) across all failure scenarios reflects the availability of that flow. Similar to demand loss, we compute our availability metric as the lowest availability among all flows in QoS class q.

(3) Latency Stretch (L_f^q): For a failure scenario s, the latency stretch $L_f^{s,q}$ of flow f in QoS class q is the ratio of the average tunnel latency (weighted by the tunnel bandwidth assignments) divided by the shortest TE tunnel latency without failure. We use Round-Trip Time (RTT) as a proxy for tunnel latency but other metrics such as hop-count and fiber length can also be used. The overall latency stretch L_f^q across all failure scenarios is a distribution, represented as the latency stretch $L_f^{s,q}$ of each failure scenario associated with its time probability of occurrence.

Algorithm 1 describes how these metrics are calculated by RSS in detail. We first initialize each flow's availability and demand loss to 1 and 0, respectively (lines 2-3). For all considered failure scenarios $s \in S$, we execute the Traffic Engineering (TE) formulation to find the per-flow satisfied bandwidth $b_f^{s,q}$ and the per-tunnel traffic allocations $a_{f,t}^{s,q}$ for each flow (line 5). Then, we calculate the three risk metrics using the outputs of TE. Flow f's latency stretch is calculated as the bandwidth-weighted latency l divided by the minimum latency across all tunnels (lines 7-8). Flow f's demand loss is captured by the difference between satisfied bandwidth $b_f^{s,q}$ and flow's demand d_f (line 11). If the demand is not fully satisfied, availability is reduced by the probability of the failure scenario s (line 12). Finally, we select the availability of QoS class q to be the worst availability experienced by all flows $f \in F^q$ (line 13), and demand loss to be the maximum loss across all scenarios $s \in S$ (line 14).

Figure 2 shows an example of the risk metrics computed by Algorithm 1 for two flows from the same QoS class under three failure scenarios. The healthy state is shown in Figure 2(a) and labeled as scenario 1. Figure 2(b) illustrates scenario 2 where flows 1 and 2 experience 0.1 Tbps and 0.2 Tbps of demand loss, respectively. Hence, the total loss for this QoS class adds up to 0.3 Tbps. In scenario 3, shown in Figure 2(c), only flow 1 loses 0.1 Tbps traffic, so the total loss is 0.1 Tbps. The demand loss for this QoS class is thus 0.3 Tbps — the highest loss across all scenarios. To obtain the availability for this QoS class, we first compute the availability of each flow. The demand of flow 1 is fully satisfied in only the no-failure case (scenario 1). As a result, its availability is computed as the probability (fraction of time) that the network is healthy: $1 - \frac{10\ hours}{1\ year + 10\ hours} - \frac{20\ hours}{3\ years + 20\ hours} = 99.81\%$. The demand of flow 2 is fully satisfied in scenarios 1 and 3, hence its availability is $1 - \frac{20\ hours}{3\ years + 20\ hours} = 99.92\%$. The availability of this QoS class is the lowest availability across both flows, which is 99.81%. To simplify the calculation of latency stretch in this example, we assume the latency of each link to be 1. Because the shortest tunnel latencies for both flows are 1, their bandwidth-weighted latency stretches in the healthy state (scenario 1) are both 1.5, as shown in Figure 2(a). In scenario 2 (Figure 2(b)) the latency stretch values for flows 1 and 2 are $\frac{0.2\times1+0.1\times3}{0.2+0.1} = 1.67$ and $\frac{0.1\times2+0.3\times2}{0.1+0.3} = 2$, respectively. Similarly, in scenario 3 (Figure 2(c)) the latency stretch values for flow 1 and 2 are $\frac{0.2\times2+0.1\times3}{0.2+0.1} = 2.333$ and $\frac{0.3\times1+0.3\times2}{0.3+0.3} = 1.5$, respectively. We then associate each failure scenario's probability to the corresponding latency stretch value to construct the latency stretch distributions.

3.3 Failure Modeling

High-fidelity failure modeling is important for network planning to meet SLOs. Hence, modeling failure scenarios is an essential component in calculating the risk metrics that we defined in the previous section. The goal of failure modeling is to estimate the likelihood of a failure scenario as well as the duration of the failure event. In this section, we explain Facebook's production failure model.

3.3.1 Characterizing Failure Events

We use two main variables to characterize failure events in our backbone:

(i) ***Time Between Failures*** *(TBF)* represents the duration between the recovery and the occurrence of two consecutive failures. This metric captures how reliable a network component (such as switch, linecard, or a fiber path) is. For most components in our backbone network, TBF tends to be thousands or even tens of thousands of hours.

(ii) ***Time To Repair*** *(TTR)* measures how long each failure event lasts. This metric depends on the efficiency of the network operation. Some failures (e.g., subsea fiber cuts) are more difficult to repair than others (e.g., switch failures).

Our experience indicates that fiber-related failures in our backbone are the most devastating failure scenarios in terms of capacity loss and time to repair. As a result, our primary focus to model failures is on fiber-related issues.

Each fiber i under each failure scenario j is represented with a tuple $(TBF_{i,j}, TTR_{i,j})$. We use historical data analysis to estimate the values in each tuple. However, modeling every fiber in the backbone individually adds excessive complexity and will overwhelm the system. We need an intelligent clustering method to model fibers with similar features together. Moreover, we cannot completely rely on empirical observations. For instance, newly deployed fibers do not have historical failure data. As a result, we model $TBF_{i,j}$ and $TTR_{i,j}$ based on known features such as the length of the fiber and its supplier. The next section describes how we address these challenges.

3.3.2 Capturing Common Features and Data Sources

A naive approach to model failures is to use past failure events to compute TBF and TTR from historical data. However, there are practical challenges with this approach. First, rare failure events may not have enough historical data to faithfully compute their TBF and TTR. Second, data can be noisy. In particular, repair times are often recorded manually in our ticketing system, which may not be completely accurate. Third, data sources may belong to different administrative domains. For instance, leased fibers are operated by third-party vendors and we may not have access to the complete failure data. To address these challenges, we use a combination of common features and several data sources to model the failure characteristics of each fiber as accurately as possible.

Common Features. Each fiber is different, but there are common features that we can use to characterize a fiber without having its exact TBF and TTR. Below are the failure features we use in our system.

- *Fiber length:* Longer paths are more likely to experience fiber cuts due to greater surface area.
- *Vendor:* Fibers from certain vendors are more reliable than others, depending on their physical characteristics, operation quality, and contractual obligations to us.
- *Operational ownership:* Some fibers are purchased from the builder directly, while others may be leased or bought from indirect parties. We expect that without direct access to the fibers, subcontracted fibers have longer repair times.
- *Install type:* Subsea fibers are known to have longer repair time due to the difficulty in accessing the fiber or limited supply of maintenance ships. Similarly, aerial fibers are expected to have higher failure rates compared to buried fibers because the fiber is exposed to disasters and accidents.
- *Geographical region:* Failure rates can be higher in certain areas with frequent natural disasters, e.g., hurricanes. Repair times vary based on the weather condition, and can grow because of catastrophic events.

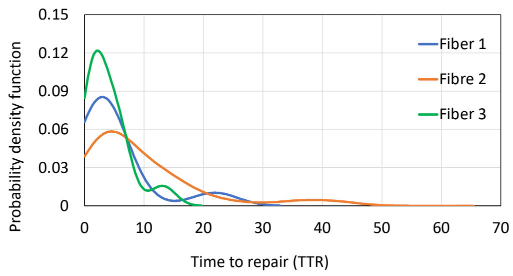

Figure 3: Distribution of time to repair for subsea fibers.

- *Urban density:* Fibers are more likely to be impacted in urban settings due to more frequent human activities, and hence accidental fiber cuts.
- *Shared Risk Link Group (SRLG):* Some fibers may fail together due to shared conduit or geographical proximity. An SRLG is considered as a single entity, hence, in our risk simulation system, we consider each SRLG as a single failure scenario.

Data sources. The impact of each feature can be analyzed using real-world data. We use three data sources for this purpose. (*i*) *Operational tickets:* Our Network Operation Center (NOC) maintains hundreds of incidents ticketed to our vendors. Each ticket contains confirmed failure information such as failed links, downtime, and failure root causes. We use this service as a historical benchmark for availability. However, the data is manually maintained, hence, the accuracy and coverage are both limited. (*ii*) *Continuous measurements:* We monitor counters from both IP-layer switches and optical-layer transponders and ROADMs. IP counters are collected every minute via the standard monitoring protocol SNMP. Optical counters are collected every three minutes using our optical-layer monitoring protocol TL1. To identify failures, we look for the Loss of Signal (LOS) on the Optical Service Channel (OSC) accompanied by the loss of IP links. (*iii*) *Fiber lifetime:* The above data sources both report discrete failure incidents, yet some fibers may not have failure events in recent years. Thus, we use the fiber lifetime dataset from our fiber inventory to compute the uptime of each fiber.

3.3.3 Failure Modeling Framework

We develop a failure modeling framework to best utilize the above data for estimating the failure model parameters. In particular, we take a two-step process.

1. Clustering. We start with a list of fibers and their failure characteristics from the data sources described in the previous section. Each record contains $< f_1, f_2, \ldots, f_k, TBF_t, TTR_t, TBF_d, TTR_d >$, where f_k is the k^{th} element in the feature set, TBF_t and TTR_t are the TBF and TTR values from the tickets, and TBF_d and TTR_d are those from the continuous measurements. We then use a Bayesian clustering algorithm to identify groups of fibers that share

	MTTR	MTBF
Subsea fibers vs. non-subsea fibers	90×	36×
Leased fibers vs. non-leased fibers	1×	0.4×
Fibers in the most different region vs. fibers in other regions	2×	5×

Table 2: MTTR and MTBF of different fiber categories.

similar failure characteristics. The output of this step is a set of clusters $(C_1, \dots, C_g)$, where each C_i contains a set of fibers.

2. Bayesian Hierarchical Model. Next, for each cluster, we use an exponential hierarchical model to fit the distribution of TBF and TTR separately. We find the mean TBF (MTBF) and mean TTR (MTTR) from both fitted curves and use them in RSS (§3.4). The accuracy of this model is evaluated in §4.1.

Operational observations. In the following, we summarize some of our empirical measurement results that have provided inspirations for our failure modeling.

Subsea TTR follows arbitrary distribution. Figure 3 shows the TTR distributions of three subsea fibers from our empirical failure data source. Each subsea fiber has a unique TTR distribution, due to its physical properties such as the length and placement under the ocean that determines the accessibility for repair endeavors. This observation deviates from a common technique to use a simple exponential distribution for TTR in two major ways. First, unlike exponential distribution, there is a lower bound for the TTR. This lower bound corresponds to the physical time constrains such as the time to secure permits to enter the water and the sailing time. Second, the distribution is multi-modal since each subsea fiber has distinct parts with different failure profiles depending on the depth under water.

Impact categories. We categorize three key factors that have significant impacts on the failure model: whether a fiber is subsea, leased, or belongs to a particular region. Table 2 shows the relative impact of different fiber categories on MTTR and MTBF. If a fiber is subsea, its MTTR is 90× longer than that of non-subsea fibers, and its MTBF is 36× longer. This is because subsea fibers are less frequently cut, but once they are cut, they will take much longer to be repaired. Leased fibers have similar MTTR as non-leased (Facebook-owned) fibers, but are 2.5× more likely to fail in terms of MTBF. For the region factor, we select the region with the largest difference from the rest ones, and we observe a 5× difference in MTBF and 2× difference in MTTR. These results show the drastic differences between fiber types and indicate the importance of clustering fibers into appropriate failure groups.

3.4 Risk Simulation System (RSS)

3.4.1 System Design

RSS performs periodic simulations (e.g., every 30 minutes) to report the risk metrics defined in Section 3.2. Figure 4

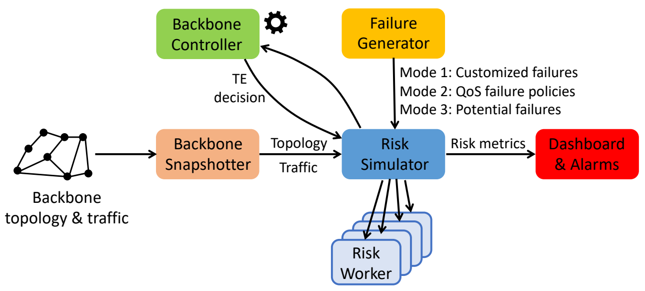

Figure 4: Risk Simulation System architecture.

depicts our risk simulation pipeline. For each simulation run, the *Backbone Snapshotter* polls the backbone routers for the latest IP topology and traffic demand. The *Failure Generator* generates hypothetical failure scenarios to be simulated. The *Risk Simulator* takes in such information to simulate routing on the residual topology under different failures. To simplify system implementation, we reuse the binary of our centralized *Backbone Controller* which computes the TE solution using a global optimization formulation. Since routing simulations for different failure scenarios are independent, we shard them onto a number of *Risk Workers* for parallelization. The risk metrics are calculated from the worker instances and displayed on a real-time risk dashboard. Risk values higher than pre-defined thresholds will raise production alarms.

Calculation of the risk metrics requires failure probabilities, which can be derived from MTBFs and MTTRs — the mean values of the failures' TBF and TTR distributions in Section 3.3. For most failures, the TBF and TTR follow exponential distributions. However, the TTR for subsea fibers is arbitrary and hard to model. As a result, we estimate their metrics from our empirical failure observation in production.

Suppose a failure scenario includes n failed fibers $\{f_1, f_2, ..., f_n\}$. For a particular fiber f_i, the probability of being available is $A(f_i) = \frac{MTBF_i}{MTBF_i + MTTR_i}$, and the probability of being under failure is $P(f_i) = 1 - A(f_i)$. Therefore, the probability of the entire failure scenario is $P(f_1, f_2, ..., f_n) = \Pi_{i=1}^{n} P(f_i)$, and the available probability is $A(f_1, f_2, ..., f_n) = 1 - \Pi_{i=1}^{n} P(f_i)$. Given the failure probability of each failure scenario, the risk metrics can be calculated using Algorithm 1.

RSS supports three modes of operation. Mode 1 is for fine-grained simulation of customized failures that are expected to happen in the near future. For example, it is part of our decommission workflow where capacity is removed, or migrated from one fiber to another, according to the backbone expansion plan. Before decommission tasks are carried out, RSS is used to generate failure scenarios that reflect the decommission plan. The risks associated with these scenarios are then taken into account to ensure there is sufficient protection capacity in the network. Mode 1 also serves for risk monitoring and mitigation under natural disasters. For instance, in response to a hurricane forecast, we simulate failure scenarios relating to the hit regions and shift traffic as necessary. Similarly, as COVID-19 goes on, we plan to simulate failure scenarios for specific geological locations based on the severity of the pandemic.

Mode 2 is fine-grained simulation of pre-defined failure scenarios for different QoS classes given their protection policies. In production, the protection policies include four categories of critical fiber failures: (1) single fiber failures, (2) SPOFs where multiple SRLGs use fibers in the same conduit or have the same geographical proximity, (3) dual subsea failures where two subsea fiber paths fail simultaneously, and (4) dual DC failures where two fiber paths from the same DC fail simultaneously. These four categories include over 6000 failure scenarios in the Facebook backbone. As described in Section 3.1, different QoS classes protect against different failure categories. QoS classes 1 and 2 carry our critical services and have full protection against all the above failure categories. QoS class 3 (default class for our internal traffic) relaxes on dual DC failures, because they account for over 50% of the failure scenarios but are less likely than single fiber failures and SPOFs and have less severe consequences compared to dual subsea failures. QoS class 4 (background bulk data transfers) is best-effort service without failure protection. We use Mode 2 in RSS to validate the QoS performance and guide network maintenance.

Mode 3 is coarse-grained simulation of a large number of potential failures in the backbone, where the exact number is determined by a cutoff threshold. The cutoff threshold can be defined in different forms, such as by failure probability, the number of concurrent failures, MTTR, or the protection cost (in terms of the protection capacity, construction cost, and maintenance work), under the intuition that we value failures that are more likely to happen, take a longer time to repair, or are affordable to protect against. We typically have a quick scan of the network health considering *millions* of failure scenarios. This simulation mode must be coarse-grained given the large number of failure scenarios. We bypass the computation-heavy global TE optimization with efficient routing approximations, which will be discussed in Section 3.4.2. This mode of operation offers a tradeoff between simulation accuracy and runtime, and the choice depends on the number of failure scenarios and how close to production the simulation needs to be (e.g., replaying production situations in Mode 1 and 2 vs. a big picture of the network in Mode 3).

3.4.2 System Optimizations

RSS is implemented using around 18,000 lines of C++ code. This system is highly optimized for fast execution time. Today, it can finish a fine-grained simulation of one failure scenario in an average of 250 seconds and a coarse-grained simulation of a failure scenario in 0.1 second. Important performance improvements attribute to the following optimizations.

Parallelization. Our risk simulation is highly parallelizable by nature. Our first implementation was based on a two-layer master-slave architecture where the failure scenarios were distributed across the slave nodes and the simulation results were aggregated to the master. The master node was overwhelmed with the aggregation load when we scaled to 50 slaves, hence we added another layer in the middle to aggregate the intermediate results generated by slaves and then transmit them to the master. Today, we use tens of aggregators and hundreds of slave nodes to optimize the execution time of RSS.

Routing simplification. Our fine-grained simulation emulates the production backbone by executing the TE algorithm when a failure happens. This process is computationally expensive, especially when we simulate a large number of failure scenarios. Thus, for coarse-grained simulations, we simplify the TE implementation with shortest-path routing of small units of sub-flows. Specifically, we split each traffic flow in the backbone demand matrix, usually hundreds of Gbps or several Tbps big, into minimal sub-flows around 1 Gbps and pack them one by one onto the shortest path until there is no remaining capacity in the network. The result is close to production TE when the sub-flows are sufficiently small.

Merge duplicate failures. Different fiber failures can result in the same failure scenarios on the IP layer, which can be effectively merged during risk simulation. For example, failures of different SRLGs may cause different fiber spans to be down, but they create the same failure scenario for the IP links over the fiber paths traversing any of these fiber spans. Because the risk is ultimately simulated on the IP-layer network, RSS translates the fiber failures into IP-layer failures and merges duplicate failure scenarios. The failure probability of a merged failure scenario equals to the sum of the probabilities of each individual failure event.

Identify dominating failures. We further reduce the simulation time by only simulating failures with severe consequences. We define dominating failures as the ones that contain subsets of other failures. For example, the failure scenario with fiber cuts $\{f_1, f_2\}$ is a dominating failure of single fiber failures f_1 and f_2 alone. Note that this simplification only applies to the calculation of demand loss, which does not rely on the probabilities of failure scenarios (the other two risk metrics, latency stretch and availability, need to factor in failure probability). This is because the failure probability of a dominating failure is much smaller than the probabilities of its subset failures. In production, we usually use this approach for the Mode 1 simulation, where the demand loss of expected failure events is a critical signal for network maintenance.

4 Evaluation

In our daily operation, we keep monitoring the health of the backbone network with the risk metrics (Section 3.2) produced by RSS (Section 3.4). Here we report the risk measurement results from November 2019 to September 2020

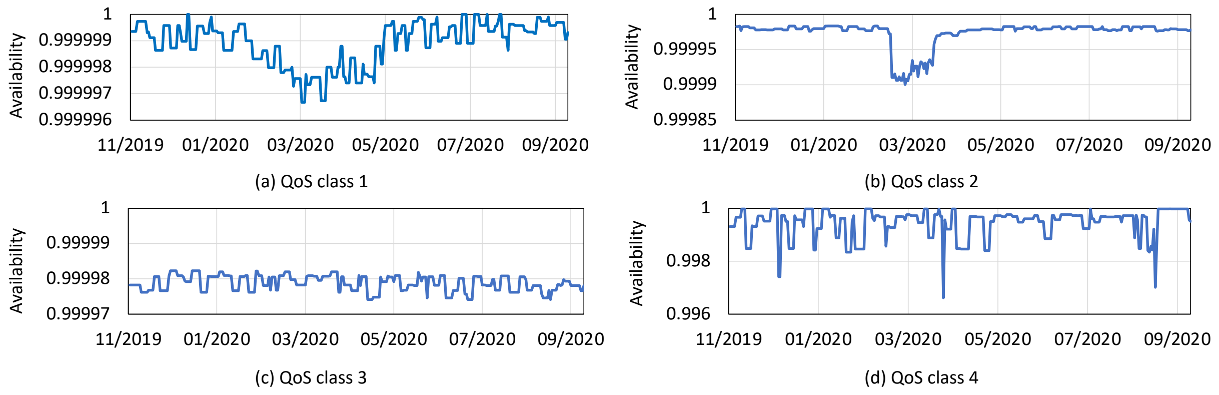

Figure 5: Availability over time for each QoS class.

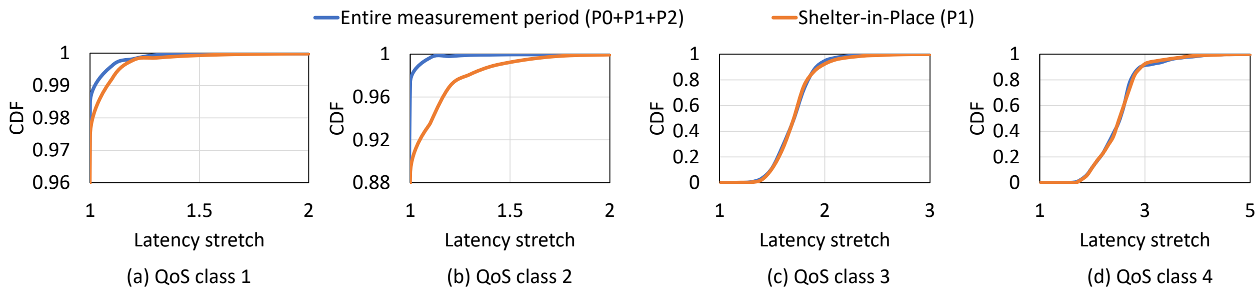

Figure 6: CDF of per-flow latency stretch for each QoS class.

and share our operational experience to survive the extreme conditions under COVID-19.

4.1 Observations with RSS

An important input into RSS is production traffic. During COVID-19, we observed an increase in network risk triggered by significant traffic surges (Figure 1). However, most risk metrics remained at a reasonable level, indicating that our backbone was robust under the COVID-19 stress test.

High availability. As shown in Figure 5, different QoS classes all achieved high availability over time, constantly reaching the SLO goals. The traffic increase during social distancing mostly related to the user traffic in QoS class 2, causing its availability to drop sharply from around 0.99998 to 0.9999. QoS class 1 also experienced a minor availability reduction, as the traffic for highly critical user services increased as well. The change was smoother compared to QoS class 2, because QoS class 1 also contains system control traffic irrelevant to user behaviors. QoS classes 3 and 4 that mostly comprise machine-to-machine computational traffic showed no obvious decrease in availability. These results suggest that availability is highly sensitive to traffic volume. On the positive side, our backbone infrastructure is over-provisioned, making it robust against the unprecedented traffic surge.

Low latency stretch. From Figure 6, we see a minimal change of latency stretch during the shelter-in-place period (P_1). Recall from Section 3.1 that QoS classes 1 and 2 use CSPF routing. As shown in the figure, over 97% of the flows in QoS classes 1 and 2 had a latency stretch of 1 throughout the entire measurement period ($P_0 + P_1 + P_2$), meaning they went through the shortest paths. The latency stretch of QoS class 2 was slightly higher than that of class 1, because the bandwidth for QoS class 2 is allocated after class-1 flows are fully accommodated. Similar to the availability results, latency stretch degraded the most in QoS class 2 during the shelter-in-place period (P_1) due to the traffic increase. Yet, the stretch still remained low regardless of the COVID-19 increase: it stops at 1.7 for most flows in QoS class 2, and at 1.4 for QoS class 1, though with a long tail not shown in the figures. QoS classes 3 and 4 use a combination of KSP and MCF routing, so they generally take longer paths. The mean latency stretch for QoS class 3 was 1.71, and 2.53 for QoS class 4. COVID-19 caused little increase of latency stretch for these two traffic classes, which is consistent with the trend of traffic growth and availability change.

Accurate failure modeling. We evaluate the accuracy of our failure model (§3.3) by comparing the TTRs and TBFs of observed fiber failures in North America against our model's predictions. As shown in Figure 7, our failure model is close to the actual observed values. To quantify the difference between prediction and observation, we perform a Kolmogorov-Smirnov (KS) test [1] on the null hypothesis that the measurements and the model-generated samples are drawn from the same distribution. We report the KS statistic and p-value in Table 3. Both p-values are large, meaning the two distributions match. Lastly, we directly compute the prediction accuracy, as the difference between each observed and predicted value,

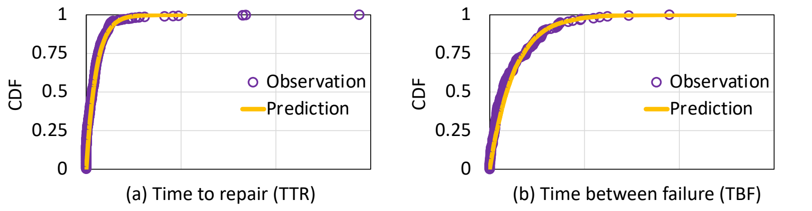

Figure 7: CDF of TTR and TBF from failure prediction vs. observation (the values on the x-axis are anonymized).

	KS stats	$p-$value	accuracy
TTR	0.05	0.25	94%
TBF	0.03	0.47	98%

Table 3: Kolmogorov-Smirnov (KS) test statistics and accuracy of TTR and TBF models.

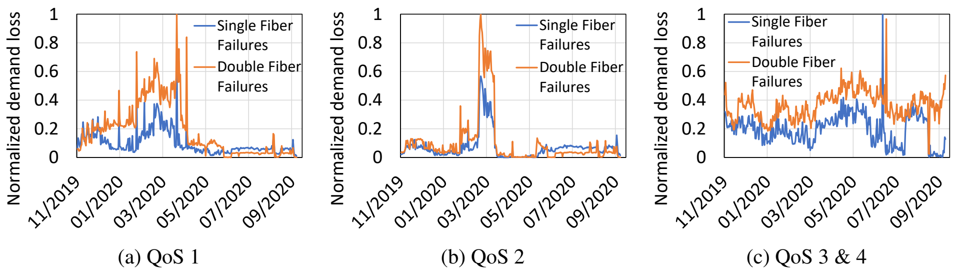

Figure 8: Normalized demand loss per QoS class.

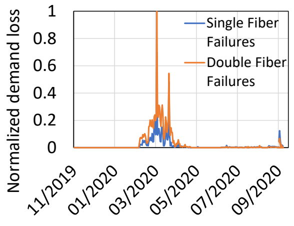

Figure 9: QoS class 2 downplayed into class 3&4.

divided by the observed value. Our model achieves 94% accuracy for TTR and 98% accuracy for TBF prediction.

4.2 Risk Mitigation

Demand loss as a guide. Demand loss is a rigid risk metric, which captures the highest traffic loss across all simulated failure scenarios. It guides our operations for mitigating potential risk. Figure 8 shows the demand loss for each QoS class over time. For confidentiality reasons, we normalize the numbers in each QoS class against the highest loss value. We group different types of failures that we track into two categories: single fiber failures and dual fiber failures. These categories capture the major failures we protect against in production. The figure shows that the demand loss increased during the P_1 phase for QoS classes 1 and 2. In particular, the mean value of risk during the shelter-in-place phase (P_1) increased by 80% compared to the pre-COVID period (P_0) in QoS class 1, and by 3.6× in QoS class 2. QoS classes 3 and 4 did not have a significant change in their demand loss values during the pandemic, and the loss increase in March 2020 was due to traffic migration between regions because of an internal policy change. Note that dual failures, though less common in practice, induce 2.14× higher loss on the fabric than single failures, on average. This worst-case analysis makes us operate the network conservatively, which was especially beneficial during the pandemic period.

QoS downplay. Another key technique to save capacity for the most critical traffic is to adjust the QoS assignment. By default, all traffic from a service is assigned the same QoS class. However, a service usually contains traffic from both user requests and system metadata, whose importance should be differentiated. This coarse-grained performance isolation causes over-protection of unimportant traffic, and the resulting capacity waste should be recycled for traffic increase. We have developed an internal system that leverages inference mechanisms to identify the true traffic priorities and correct their QoS labeling. For example, we find that on-off and periodic traffic patterns are common signals for machine-created traffic, which can be downgraded to a lower class. Figure 9 zooms into QoS classes 3 and 4 in Figure 8(c) and shows the demand loss of the downplayed traffic. The loss only appeares during the shelter-in-place phase (P_1) as the result of traffic shift to alleviate the stress from QoS class 2.

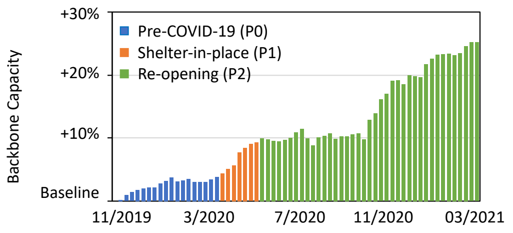

Figure 10: Backbone capacity measured per week.

Proactive capacity enhancement. We deploy optical wavelengths periodically to augment the capacity of our backbone. Figure 10 shows the weekly measurement of backbone capacity over a year, normalized by the capacity value before P_0. We observe an aggressive capacity increase starting from the P_1 phase compared to the pre-COVID times (P_0). This capacity increase is also visible in Figure 8, leading to a significant drop in demand loss in April and May 2020. We observe a continued capacity increase during the re-opening phase (P_2). Although social distancing during the COVID-19 pandemic paused most of our site work for deploying new

fibers, we had sufficient dark and under-provisioned fibers from previous planning cycles. Our "plan ahead" strategy gave us enough headroom for emergency capacity enhancement, and our fully-automated optical management system allowed us to provision wavelengths remotely.

5 Insights on RSS Improvement

Besides a stress test of our network infrastructure, COVID-19 and the resulting social distancing also created unusual situations beyond normal assumptions of network operations. These edge cases have given the networking community a unique opportunity to rethink fundamental design assumptions of networks. In this section, we share our recent progress on failure modeling and traffic forecasting to shed light on future evolution of risk simulations.

5.1 Responsive Failure Modeling

Our failure modeling (Section 3.3) uses years of failure measurement data to ensure model accuracy and stability, and it is accurate in the long run (Figure 7). However, prior studies claimed network failures are often caused by human activities and network operations [19, 20, 29, 30, 38]. Indeed, we confirm that the lack of human activities during the shelter-in-place phase (P_1) as well as the increase of network upgrade and capacity augmentation activities during the re-opening phase (P_2) changed the failure characteristics. In response to the change, we recalibrated our failure model to increase the weight of failure statistics during the P_0, P_1 and P_2 periods.

The recalibration relies on Facebook's centralized failure ticketing system, which automatically detects network failures and infers possible root causes. For this purpose, we categorize failure tickets into two groups: (*i*) optical-layer failures (e.g. fiber/amplifier/transponder issues) and (*ii*) IP-layer failures (e.g. router/interface down). For each group, we record the number of active failure tickets every hour and plot the probability density function of each phase in Figure 11. Our observations are as follows.

Optical-layer failures. Figure 11(a) compares the probability density function of hourly active optical-layer failure ticket numbers among the pre-COVID (P_0), shelter-in-place (P_1) and re-opening (P_2) phases. The dashed lines in the figure represent the moving average of each phase. We observe reduced optical-layer failures during P_1 compared to P_0. We attribute this finding to the significant reduction in human activities at our backbone facilities during global social distancing. For instance, limited construction work can lead to fewer fiber cuts, and fewer human contractors on-site may result in fewer accidental link flaps, as suggested in prior work [19]. We observe more active optical failure tickets in the re-opening phase (P_2), as our network operation team was actively augmenting the capacity of our backbone.

IP-layer failures. Figure 11(b) shows the probability density function of hourly active IP-layer ticket numbers during the P_0, P_1 and P_2 phases. In contrast to optical-layer failures, we find no significant changes in IP-layer failures between P_0 and P_1, and the two distributions largely overlap with each other. This is likely because IP-layer tickets, such as router/interface hardware failures, are mostly mechanical issues and do not correlate with human activity. However, similar to the optical-layer failures, in the re-opening (P_2) phase, the IP layer also experienced more active failure tickets due to our aggressive capacity provisioning operations. Moreover, since the pandemic continued to enforce limitations on our failure repair staff, the P_2 phase suffered from longer repair times.

Confirmation with statistical hypothesis test. The results in Figure 11 suggest that optical and IP-layer failure distributions behave differently during the P_1 phase. To confirm this observation, we apply a statistical hypothesis test on the time-series distribution of active number of tickets between the P_0 and P_1 timelines and set the null hypothesis to be: *the means of the distributions are the same*. We apply Welch's t-test on the optical and IP-layer categories separately to validate the null hypothesis. Table 4 reports the mean number of active tickets and the corresponding p−values for each category. Considering a p−value threshold of 0.01, the null hypothesis cannot be rejected for IP-layer tickets, suggesting the pandemic did not have a significant impact on the IP-layer failures during P_0 and P_1. In contrast, the null hypothesis is rejected for optical tickets suggesting that the average number of active optical tickets changed in a statistically significant manner. Note that we do not run hypothesis tests over P_2 because its mean values in both the IP and optical layers differ a lot from those of P_0 and P_1, which already indicates

Figure 12: Traffic volume and mobility patterns in six US cities during the COVID-19 pandemic.

differences in the probability distributions.

Insights. These findings call for responsive failure modeling. When special events cause failure characteristics to change, the failure prediction model should be adjusted to rely more on recent failure measurement points. However, the model stability might be at stake with short-term data collection, and the challenge lies in balancing stability and agility to have an accurate model. The COVID-19 crisis required us to respond quickly, and the fast development of the pandemic gave us little time for drastic redesigns of the failure model. The various failure generation modes in RSS make it adaptive to different failure models. For instance, our customized failures in Mode 1 are designed for failure scenarios of particular interests that may deviate from the failure model. We leveraged this feature to feed RSS with short-term failure statistics for close monitoring of the network health during COVID-19. The failure model is hard to change in Modes 2 and 3, hence, we applied a scaling factor to the failure distributions to generate more failures. These false positives helped us operate the network more cautiously during the pandemic. Moving forward, we are working on more responsive failure modeling with a sliding window that automatically assigns weights to different measurement periods.

5.2 Traffic Prediction with External Signals

The risk observations we report throughout this paper use current production traffic as input, yet RSS can also take in projected traffic to forecast future risk. At Facebook, we perform demand forecasting every quarter to predict the traffic volume in the next 6 months to one year. Our prediction used to be accurate, but the traffic grew beyond the predicted upper bound since the pandemic started. At the peak, we saw a 26% difference between actual and predicted upper-bound traffic.

In our operational experience, we have seen rich examples of how external non-networking signals can be leveraged to aid network management. For instance, it is common practice to strengthen the guard on PoP or DC regions that have received hurricane warnings, and we keep a close watch on traffic blackholing in areas with frequent armed conflicts. In this section we demonstrate that human *mobility* metrics can also be used to better predict the traffic volume.

To demonstrate this finding, we use population mobility data from the SafeGraph [5,41] database built from 20 million mobile devices. As an approximation of mobility, we sum the total number of trips that take place in a geographical region based on aggregated cellphone GPS data, and normalize it by the population of the trip origin. We consider six major US cities and plot the variations of traffic and mobility over time in Figure 12. Interesting findings imply opportunities and challenges in our proposal of mobility-aided traffic prediction.

Negative correlation between traffic and mobility. Figure 12 shows the traffic volume and mobility rate normalized to their corresponding averages during the P_0 phase. While there is a fair amount of overlap between traffic and mobility in P_0 across the cities, we observe a strong negative correlation between traffic and mobility since the start of P_1. We see the general trend that when mobility drops, traffic increases; and as mobility increases slowly, traffic falls as well. The sporadic spikes of mobility and traffic also match well, forming zigzags in opposite directions. The gap between the traffic and mobility curves closes down in the P_2 phase when the cities started to re-open and social distancing reduced.

Variations across cities. Each city shows some uniqueness despite the same trend. Chicago, Dallas, Los Angeles, and Miami have similar patterns that network traffic gradually decreased while mobility continued to increase after the pandemic peak in mid-Mach 2020. In Chicago, traffic increased by 99% and mobility rate decreased by 36% during the shelter-in-place phase (P_1) compared to the P_0 phase baseline. Dallas, Los Angeles, and Miami had around a 40-70% traffic increase and a 35% mobility drop. Roughly, the drop in mobility rate corresponds to different levels of traffic reduction across cities. For example, in Miami and Los Angeles the traffic volume almost returned back to normal in the P_2 phase, while Chicago still showed a 25% average traffic increase, and Dallas had around 10% average traffic increase. On the other hand, New York City and Seattle have contrasting patterns, with both an uptake in traffic and a downtake in mobility appearing since November 2020. For Seattle, we also observe ups and downs in traffic volume, with occasional spikes up to 74%.

Insights. An intrinsic limitation of traditional network management is the complete reliance on in-network signals. It fails to track social influences on the network infrastructure, which has been proven to be heavily underestimated during COVID-19. Our mobility case study shows the potential benefit of embracing offline signals from the outside world. On occurrences of social events, we can make mobility the main signal for traffic prediction. As Figure 12 shows, traffic peaks can be inferred from the steep drops in mobility rate. However, it is challenging to estimate the traffic volume when it recovers, as mobility rate does not show significant changes in that case. We may need other signals to understand user behaviors better. Fortunately, though, risk management cares about worst-case scenarios. Thus, an accurate prediction of the peak traffic is already a big win for risk prevention.

6 Related Work

Risk-aware network management. There have been recent proposals to apply risk to capacity planning [4, 6] and traffic engineering [8, 12, 31, 46]. The definition of risk is different across proposals, including probabilistic models of failures [6, 8], revenue shortfall [31], early signs of failures (e.g., hardware abnormality and performance degradation) [46], user-specified undesirable events and their associated probabilities [12], and the likelihood of losing customer traffic during planned network changes [4]. In this paper, we describe Facebook's definition of risk as a set of SLO-related metrics that quantify the impacts of potential failures. We are also the first to apply risk simulation to backbone management and to develop a production system.

Internet under COVID-19. There are reports on the impacts of COVID-19 on the Internet [10, 13, 17, 24, 32, 33], as well as measurement studies on the PoP traffic [7], mobile traffic [28], Internet traffic [15], and cybercrime [47] during the pandemic. We share similar observations on the traffic increase, but we present a comprehensive study on the impact of COVID-19 from the perspective of risk management.

Backbone failures. Prior work on understanding backbone failures includes statistical modeling [3, 9, 42] and real-world measurements on both the optical layer [18, 19, 38, 43] and the IP layer [11, 14, 23, 25, 26, 29, 30, 35]. Our failure analysis confirms the observation in previous papers that a good proportion of failures are human-related [19, 20, 29, 30, 38].

Traffic classification with QoS. QoS can provide differentiated performance for different categories of traffic [16, 48]. There have been rich discussions on traffic classification methods in the prior work [36, 39, 40, 44]. In recent years, with the development of SDN, traffic classification can be deployed with centralized control on a private enterprise network [34]. Facebook follows these discussions and categorizes the backbone traffic into four classes of QoS. To maximize user satisfaction while considering network risks, our traffic classification scheme can dynamically adjust traffic flows' QoS categories so as to prioritize critical traffic flows and guarantee service level objectives.

7 Conclusion

This paper introduces RSS, a risk simulation system deployed at Facebook. We present our risk analysis with RSS during the COVID-19 pandemic period and beyond. Motivated by the surge of traffic volume, we define risk metrics to quantify the impact of COVID-19 and show our strategies to mitigate the risk. We keep the network running at low risk levels during this challenging time and propose that having responsive failure modeling and using external signals such as human mobility can help understand the social impacts on the network to further improve network management. Our experience and insights are useful for managing large-scale backbones in the post-pandemic world, where we are likely to face an ever-growing demand for online services. We hope that our experience can inspire and guide practitioners towards embracing risk-driven network management and ultimately making it a key strategy for ensuring high availability of networked services.

Acknowledgments. Many people in the Network Infrastructure team at Facebook have contributed to RSS over the years. In particular, we would like to acknowledge Max Noormohammadpour, Siyang Xie, Bob Kamma, Abhinav Triguna for their early work on RSS. We also would like to thank Arash Vakili, Ariyani Copley, Brian Bierig, Debottym Mukherjee, Lu Huang, Tyler Price, Sandrine Pasqualini for their operational support during the COVID-19 time period. We would like to acknowledge Facebook for the resource it provided for us. And finally, we thank Omar Baldonado, Gaya Nagarajan, our shepherd Haonan Lu, as well as our anonymous reviewers for their comments. This work was partly supported by NSF grants CNS-2008624 and ASCENT-2023468, as well as by SystemsThatLearn@CSAIL Ignite Grant.

Staying Alive: Connection Path Reselection at the Edge

Raul Landa, Lorenzo Saino, Lennert Buytenhek and João Taveira Araújo
Fastly

Abstract

Internet path failure recovery relies on routing protocols, such as BGP. However, routing can take minutes to detect failures and reconverge; in some cases, like partial failures or severe performance degradation, it may never intervene. For large scale network outages, such as those caused by route leaks, bypassing the affected party completely may be the only effective solution.

This paper presents Connection Path Reselection (CPR), a novel system that operates on *edge networks* such as Content Delivery Networks and edge peering facilities [52, 64] and augments TCP to deliver transparent, scalable, multipath-aware end-to-end path failure recovery.

The key intuition behind it is that edge networks need not rely on BGP to learn of path impairments: they can infer the status of a path by monitoring transport-layer forward progress, and then reroute stalled flows onto healthy paths. Unlike routing protocols such as BGP, CPR operates at the timescale of round-trip times, providing connection recovery in *seconds* rather than minutes. By delegating routing responsibilities to the edge hosts themselves, CPR achieves *per-connection* re-routing protection for *all* destination prefixes without incurring additional costs reconstructing transport protocol state within the network. Unlike previous multipath-aware transport protocols, CPR is *unilaterally deployable* and has been running in production at a large edge network for over two years.

1 Introduction

Survivability is a core design tenet of the Internet, and a key factor in its enduring success. In reviewing the formative years of the DARPA Internet Protocols, Clark [19] listed survivability second in importance only to the top level goal of interconnecting existing networks:

> It was an assumption in this architecture that synchronization would never be lost unless there was no physical path over which any sort of communication could be achieved. In other words, at the top of transport, there is only one failure, and it is total partition. The architecture was to mask completely any transient failure.

The Internet today falls short of this assumption. Failures are not only common on the Internet, they are often visible [25, 28, 29], sometimes spectacularly so [39, 41, 42, 53, 54]. While large outages are rare, transient reachability fluctuations, colloquially referred to as *internet weather*, are frequent [25]. Attempting to prevent all sources of outages is an exercise in futility: failures are endemic to every component at every layer along every path on the Internet, and subsets of components interact to form complex failure conditions which cannot be anticipated. Instead, the most cost-effective way of improving reliability on the Internet is to *circumvent failures when they occur*. Traditionally, this task has fallen upon network providers, who rely on routing protocols such as the Border Gateway Protocol (BGP) and Open Shortest Path First (OSPF) to route around failures. Routing alone, however, is not enough.

Firstly, since the successful delivery of keepalive messages does not imply the successful delivery of client traffic, routing protocols can only detect a subset of failure conditions. For example, a BGP session may be hashed onto a healthy Link Aggregation Group (LAG) member, while other links in the same group falter. Misconfigurations, such as those that result in route leaks, can impact large swathes of the Internet [26, 35, 41, 53]. Such events, undetected by routing protocols, often require manual intervention to mitigate at significant cost to the stakeholders involved.

Secondly, the time required by routing to re-establish a consistent state after a failure increases with the size of the network and can take minutes [37], during which loops and blackholes can occur [28, 29]. Even detection itself can be slow. The recommended value for the *BGP hold timer* (the time after which a non-responsive BGP peer is marked as failed) is 90s [33, 48], but many implementations set the default value as high as 180s [4, 5, 11, 18] or even 240s [23]. Even with sophisticated monitoring infrastructure [17, 32, 51], transient performance degradations have often disappeared by the time corrective updates can fully propagate.

Rather than relying on routing reconfiguration, protocols such as SCTP [55] and MPTCP [24] propose pushing the responsibility for mitigating path failures to the transport layer. Unfortunately, multipath transport protocols have struggled with adoption, and are today still circumscribed to niche use cases. Although multipath-aware protocols provide compelling reliability improvements, the current Internet architecture provides limited means (and incentives) for network providers to push multipath options out towards clients. With deployments limited to subsets of traffic or client population [16, 36, 46], their promise remains largely unfulfilled.

Edge networks [51, 52, 64] provide a natural vantage point from which to improve reliability, acting as a critical intermediary between application/content providers, hosted on highly centralized cloud infrastructure, and a globally distributed set of clients. By providing caching, security and compute functions as close to clients as possible, edge networks have positioned themselves to carry most of the customer facing traffic on the Internet [51, 52, 64]. Further, because they are expected to commit to SLAs guaranteeing the successful processing of end user requests, they end up bearing the costs of network layer failures and have a tremendous economic incentive to improve reliability. Conveniently, they also have the means. Unlike access/transit providers, edge networks have end-to-end visibility of traffic, and can therefore detect and react to failures faster and at finer granularity. By design, edge networks are multihomed and have access to better path diversity than end clients.

This paper presents Connection Path Reselection (CPR), a software-based approach improving the end-to-end reliability of edge network traffic. The key intuition behind it is that edge networks do not need to rely on BGP to learn of path degradation: they can infer the status of a path by monitoring transport-layer forward progress, and then reroute stalled flows onto healthy paths. This not only improves connection recovery, but also allows traffic to be shifted on a per-flow basis, greatly reducing the likelihood of load-induced cascading failures. Unlike previous proposals, CPR is unilaterally deployable, applicable to all flows, and simple to configure. Its implementation is entirely contained in a server-side kernel patch; it does not require programmable switches or any extra infrastructure. CPR has been in production for over two years at Fastly, a multi-Tbps edge cloud provider, where it successfully mitigates ~120 degradation events every day, each ~8 minutes long (over ~16 hours per day).

Having described our motivation, the remainder of this paper is organized as follows. First, we discuss the background of this work (§2), explain first how CPR detects path impairments (§3) and reroutes traffic as a result (§4). We then share results from production measurements (§5), followed by some operational considerations (§6). Finally, we compare CPR with related work (§7) and present our conclusions (§8).

2 Background and motivation

Edge networks (as understood in *e.g.,* [52, 64]) have unique characteristics that must be considered when designing a mechanism to improve end-to-end customer traffic reliability.

Edge networks support a diverse and changing set of applications. Early edge networks such as Content Delivery Networks (CDNs) were designed to support a narrow segment of Internet traffic: large, static content that could benefit from caching. This narrow traffic profile allowed for a wide set of potential optimizations. Edge networks have since evolved to support a much wider set of use cases (security, edge compute) and applications which no longer fit a neat traffic profile: a video client may need to retrieve small manifest files before requesting video chunks, or a browser session may download cached assets while maintaining a long-polling connection over which it receives update notifications. As such, edge networks today represent a microcosm of Internet traffic, not a segment. While it may be tempting to focus our efforts on improving reliability for a subset of traffic, performance degradation on any flow can adversely impact an entire application. A further complication is that it is not always a given that end clients will retry. For example, packaging a container image can involve retrieving potentially hundreds of individual assets. Failure to acquire any single one of these assets can result in the entire build process failing, at which point a user must decide whether to retry. This implies that we must detect *any* potential source of failure, for *every* type of flow, independently of its source, length, or capabilities of the end-client. We must also take into account that most traffic towards end-users will likely flow through middleboxes.

Edge networks are constrained by physical capacity. Points of Presence (POPs) are limited by physical space, and are designed to maximize the number of requests per second (RPS) they can serve [59]. Peak RPS is primarily dictated by storage and compute capacity - not bandwidth. Unlike traditional cloud environments, we cannot increase the physical footprint of network hardware, since that would necessarily reduce the amount of hardware dedicated to serving requests. Given our motivation for improving reliability is to reduce costs, we can not do so at the expense of efficiency.

Edge networks have unpredictable traffic patterns. Edge networks are subject to sudden fluctuations in demand due to flashcrowds or DDoS attacks. While physical capacity at any given POP is fixed, operators can shift traffic between POPs by adjusting DNS and BGP anycast configurations. This traffic engineering wreaks havoc on any potential solution that acts only on a set of heavy-hitter prefixes which is periodically updated. For instance, a POP located in Los Angeles may only observe traffic from prefixes in southern California in normal conditions, but this can change abruptly if *e.g.,* a POP in San Jose undergoes maintenance, or if a DDoS attack targets POPs in Japan. Traffic patterns shift dramatically during significant congestion and routing events, which is precisely when reliability suffers the most. Our design takes these constraints into account, and presents a system which strives to:

- detect and react to failures affecting *any flow, at any point in its lifetime*;
- minimize operational and infrastructure costs;
- interact safely with concurrent traffic engineering and routing processes.

Such a system is possible because edge networks support routing architectures which expose multipath capability to end servers [57,64]. By maintaining multiple routing tables in the kernel and allowing transport sockets and userspace applications to select which one to use on a per-packet basis, edge servers can override standard BGP route selection and instead implement objective-driven routing policy by themselves.

The benefits of path diversity have been amply studied (*e.g.,* [21,60]), in particular for stub networks [27]; even when performance gains are not forthcoming, cost benefits can be achieved [6]. Previous work on path-switching revealed that it is possible to improve average path loss performance by an order of magnitude on average by dynamically switching paths [56]. Previous work on CDN multihoming demonstrated 25% performance improvement for 3 out of 4 metro areas simply by selecting the best of two transit providers, with comparable reliability improvement [7]. One specific type of simple path diversity is highly prevalent: *path load balancing*. 72% of source-destination network pairs explored in [12, 13] show evidence of load balancing; for ~12% of these, load balanced paths are asymmetric and explicit selection can significantly improve end-to-end latency. A more recent study [47] showed even more significant benefits: not only do paths from large cloud providers show latency differences between load-balanced paths exceeding 20ms to 21% of public IPv4 addresses; 8 pairs of datacenters were found to have latency differences between load-balanced paths exceeding 40ms. Path diversity is high for edge networks: in the CPR deployment presented here each POP typically connects to a few transit providers and several peers[1].

This is the starting point for Connection Path Reselection (CPR). *Given the multipath capabilities of edge servers, how can we extend TCP to circumvent failures?* Focusing on TCP is appealing not only because its congestion control and loss recovery mechanisms are sufficient on their own for a large class of end-to-end impairments, but also because *any* automated, short-timescale re-routing of large volumes of traffic can override traffic engineering and create undesirable traffic distributions. By performing path selection decisions at the *connection* (rather than the *route/prefix*) level, CPR minimizes its impact on traffic volumes.

CPR is embedded within TCP and implemented as a server-side patch to the Linux kernel, and relies on extensions to the `tcp_sock` struct to keep essential re-route-related state. Because the kernel itself abstracts the IP address version at the socket level, CPR naturally covers both IPv4 and IPv6 traffic. Since CPR is parsimonious with both its execution and instrumentation state, it remains scalable even under extreme situations such as flashcrowds or DDoS attacks. The operation of CPR can be decomposed into two independent sub-problems: how to detect genuine path failures through *impairment detection*, and how to circumvent an impaired route through *path reselection*. We will tackle each of these problems in turn.

[1] See §5.3 and appendix A.1 for further details.

3 Impairment detection

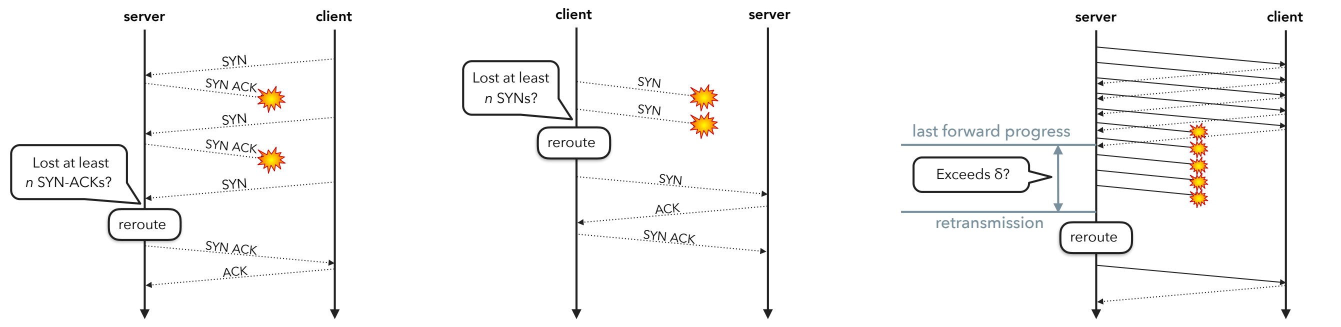
The main task of CPR's *impairment detection* algorithms is to accurately identify path failures based on transport layer performance in a timely manner. A key challenge is to distinguish between spurious packet loss, which should be recoverable with retransmission over the same path, and persistent failures, which are better addressed by selecting a different one. From a transport layer perspective, connections routed over an impaired path experience *stalls*, *i.e.,* fail to make forward progress for some amount of time in spite of retransmissions. CPR works by detecting stalls and using them as a signal to select an alternate path, with the objective of eventually resuming forward progress.

Two different impairment detection mechanisms are necessary, each addressing complementary stages in the TCP connection lifecycle. The first (§3.1) deals with path impairments before connection establishment; the second (§3.2) deals with impairments arising after connections have successfully established.

3.1 Pre-establishment impairments

A TCP connection is initiated by a client transmitting a SYN packet to commence a three-way handshake, to which the server will reply with a SYN-ACK. If the server's outbound path has failed before a connection is established, the SYN-ACK transmitted by the server will be lost. The client then retransmits the SYN after a predefined interval (1s on Linux [3]), to which the server will reply again with a SYN-ACK that will also be lost. This retry behavior continues until the path becomes available again or the client stops retrying (a Linux client retries 6 times by default). In such cases (fig. 1a) CPR will declare a stall upon exceeding the threshold of n presumed lost SYN-ACKs. Upon detecting a stall, route reselection is triggered on every subsequent SYN-ACK retransmission until the connection is successfully established or the client times out.

This detection mechanism is quite coarse because its ability to detect a failure is limited by the frequency of SYN retransmissions at the client. The precision and speed of failure detection could be improved if the server proactively retransmitted SYN-ACKs at a higher frequency without waiting for



(a) *Inbound* pre-establish (b) *Outbound* pre-establish (c) *Established*

Figure 1: Impairment detection and reroute

SYN retransmissions from the client. This would however create an amplification vector that could be exploited by SYN flood attacks and therefore would not be safe to deploy in untrusted environments.

CPR's pre-establishment impairment detection algorithm cannot be used when SYN cookies are enabled, because then the kernel will not keep any state for incoming pre-establish connections. This is a desirable feature. By default, the Linux kernel sends SYN cookies upon listen queue overflow, which is typically triggered by SYN floods. This will result in SYN-ACK stall detection being disabled during an attack, and SYN-ACKs using the preferred path.

Finally, we note that the same mechanism could be applied to connections initiated by edge servers (see fig. 1b), whereby we reroute after a given number of lost SYN packets rather than SYN-ACK packets. This case is less relevant in practice however, since most edge server traffic results from inbound connection requests.

3.2 Post-establishment impairments

For established connections (see fig. 1c) CPR verifies, before a retransmission, whether the connection has failed to make forward progress for a time threshold δ. If so, it declares a stall and selects a new egress path. CPR marks a connection as making forward progress whenever an (S)ACK is received for data that has been sent, but not yet acknowledged. This requires storing a timestamp variable in each TCP socket to keep track of forward progress. The algorithm operates as follows:

- clear the timestamp as long as there are no outbound segments in flight, and set it to the current time when the segment that is at the front of the transmit queue is transmitted *for the first time*;
- update the timestamp to the current time whenever the connection makes forward progress, *i.e.,* receives an (S)ACK that acknowledges data byte ranges previously transmitted but not yet acknowledged;
- clear the timestamp when the last outstanding byte range has been fully acknowledged;
- declare a stall when (re)transmitting a TCP segment if 1) the timestamp is set, and 2) the time elapsed since the timestamp exceeds a threshold δ.

Because this algorithm declares stalls *on retransmission*, connections that become idle whilst using paths that subsequently fail cannot declare a stall until their first retransmission. This behavior minimizes spurious path reselection.

Algorithm parameters. As with n, setting an appropriate value of δ needs to strike an appropriate tradeoff between reactivity and accuracy. The key challenge is to ensure that the threshold works consistently well across connections, regardless of their RTT. Setting δ to a fixed, global value would lead to either spurious stalls for high RTT connections, or sluggish response for low RTT connections. This can be addressed by defining δ in terms of path properties already estimated by TCP. We could, for instance, define δ as a multiple μ_{rto} of the connection retransmission timeout (RTO) T_{rto}, so that $\delta = \mu_{\text{rto}} T_{\text{rto}}$. As usual, $T_{\text{rto}} = \texttt{srtt} + 4 \times \texttt{rttvar}$, where `srtt` is the smoothed round-trip time and `rttvar` is the round-trip time variance [50]. Unfortunately, this solution on its own could be problematic for connections with very low `srtt` and `rttvar`, because, given a low value of δ, temporary router queue build-ups and subsequent increased latency may be misidentified as stalls and trigger spurious reroutes. We guard against this issue by defining δ_{min}, a lower bound for δ, and setting $\delta = \max(\delta_{\text{min}}, \mu_{\text{rto}} T_{\text{rto}})$.

Using a small value for μ_{rto} (*e.g.,* $\mu_{\text{rto}} = 1$) may spuriously trigger reroutes during the slow start phase of the connection. For paths with moderate background packet loss, RTO expiration is more likely to happen when there are few TCP segments in flight, *e.g.,* during slow start: once the connection has filled its *bandwidth-delay product*, a constant stream of incoming ACKs makes the triggering of RTOs less likely.

Rate limiting reroutes. Re-routing onto a new path does not necessarily result in recovery: the new egress path could share a failure with the original one, or the impairment responsible for the stalling could be on the inbound path. When this occurs, CPR will simply continue to probe paths until forward progress is made. If the reroute threshold δ of the connection is low, the connection may end up being rerouted multiple times in rapid succession. This could result in CPR not being able to gather enough data about the state of a new path to make an accurate decision about its suitability before trying yet another path. We addressed this by implementing a *rate limiting* over periods of length `wait`, so that connections will not be re-routed more than once in every period.

Triggering stall detection logic. Since CPR performs stall detection on retransmission with a timeout expressed as a multiple of the RTO, it is natural to ask whether stall detection logic could be co-located with the RTO triggering logic of the TCP state machine. The answer is negative, because not all retransmissions relevant to connection forward progress are triggered by RTO expiration. Consider the case where the outbound path used by a connection has failed and both the local and the remote ends have outstanding (unacknowledged) data. It is possible for retransmissions by the local end to keep being triggered by the reception of retransmissions from the remote end, before a local RTO can elapse. For this reason, stall detection logic *reuses* the RTO value, but is evaluated *independently* of RTO logic at relevant points in the TCP state machine (*e.g.,* when sending retransmissions).

4 Path reselection

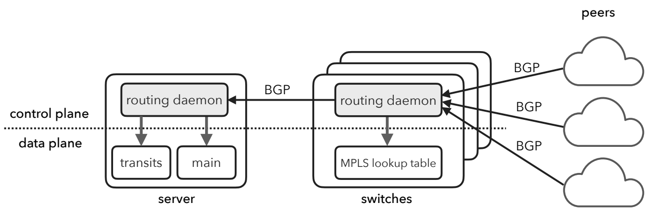


Figure 2: Routing architecture

CPR leverages a routing architecture similar to Espresso [64] and Silverton [14, 57] which push visibility of all available routes down to edge hosts. In this architecture (depicted in fig. 2) each host is connected to a number of switches, which are in turn connected to a number of upstream providers. These include both transit providers and settlement-free peers, connected directly through Private Network Interconnects (PNI) or Internet Exchange Points (IXP).

Each switch performs two tasks. First, an MPLS label is configured for each upstream provider, and a corresponding nexthop entry is inserted into the local routing table. Second, BGP route updates received from upstream providers are tagged with the associated MPLS label, and forwarded to routing daemons on the host. The routing daemon on end hosts populates two routing tables:

- The **main** table contains all policy-preferred routes among those learned from all peers, and is used for routing traffic under *normal* circumstances *i.e.,* when path reselection has not been requested. It contains routes preferred under performance, capacity and cost constraints.
- The **transits** table is populated with all *default routes* (*i.e.,* 0.0.0.0/0 or ::/0) learned from upstream providers. Since settlement-free peers do not provide universal reachability (*i.e.,* export a full routing table), only default routes provided by transit providers are included.

Given the routing architecture in fig. 2, and having access to the *main* and *transits* table, the next objective of CPR is to provide a mechanism to allow the stall detection algorithms in §3 to select a new path for a stalled connection. We achieve this by associating a reroute counter r with each connection, and incrementing it every time a stall is declared for that connection. This counter is stored in the 4 most significant bits of the firewall mark (*fwmark*) of a connection, a 32 bit value that can be used to tag packets traversing the Linux network stack and make routing decisions about them. To make rerouting based on r possible, we made two relevant changes. First, we changed the Equal Cost Multipath (ECMP) hashing function used by the Linux kernel. The standard Linux implementation of ECMP selects a nexthop by hashing the connection *5-tuple* (*i.e.,* source and destination IP addresses, source and destination ports and protocol number). *CPR includes the value of the reroute counter r into the hash computation*. Second, we configure an *ip rule* to ensure that, for any connection for which $r > 0$, a next hop is looked up from the *transits* table rather than from the *main* table. Hence, *we use r as a flag that triggers CPR-specific routing for connections that have suffered stalls*. The combined effect of these two changes is that simply incrementing the reroute counter will force a new route lookup.

Figure 3: Path reselection upon stall detection

As an illustration, consider a hypothetical connection that has not yet experienced a stall, as shown in fig. 3. At this point in its lifetime, $r = 0$, route lookups are performed using the *main* table, and the BGP-defined egress path is used. When the stall detection algorithm (§3.2) declares a stall, it increments r. From that point on, since $r > 0$, route lookups are performed using the *transits* table, and the next hop for IP packets forming this connection is pseudorandomly selected among all the nexthops of the default route present in the transits table according to ECMP(5-tuple, r). Since each increment of r forces a new route lookup, as r increases the stalled connection will follow a unique, pseudorandom sequence of egress paths which will depend on both its 5-tuple and the ECMP hash used. The aggregate effect of this process is that rerouted connections are homogeneously "load balanced" among all available egress paths.

We now show that CPR should be able to resolve recoverable stalls with relatively few retries. If n_p is the number of egress paths available, of which n_s lead to *stalled* connections, each path reselection is a Bernoulli trial with a success probability $p = \frac{n_p - n_s}{n_p}$. The number of re-routes k required until recovery will be geometrically distributed [2] so that $P(X \leq k) = 1 - (1-p)^k$. Hence, the expected maximum number of re-routes that will be required to find a good path with a given probability β is $k^* = \frac{\log(1-\beta)}{\log(1-p)}$. Even a conservative[2] $p = 50\%$ and $\beta = 95\%$ results in only $k^* \approx 4$ re-routes.

We note that, although fig. 2 states that the *main* table should contain a full routing table, CPR does not *require* this to be the case. As noted above, path reselection only relies on the *transits* table. Further, although our implementation uses MPLS to steer specific flows towards a given provider, this can also be done using GRE tunneling [64] or DSCP marking [52]. Routes can be pushed down to the host using BGP add-path [62] or proprietary mechanisms. Our architecture is just one of many that could support CPR deployment; the basic primitives of CPR are applicable to many scenarios.

5 Evaluation

This section evaluates the performance of CPR in a large edge cloud production deployment with daily traffic peaks on the order of tens of Tbps. All results were collected through passive measurements of production traffic.

5.1 Parameter tuning

Tuning CPR involves resolving a tradeoff: whereas unnecessarily rerouting connections could place them on paths with potentially lower performance and higher cost, failing to react to a recoverable path impairment increases its potential to harm client connections. This section discusses how we tuned the CPR parameters (§3) to resolve this tradeoff between accuracy and reactivity.

Tuning pre-establishment impairment detection. The only parameter involved in detecting impairments prior to connection establishment is n, the number of presumed lost SYN-ACKs after which a reroute is executed (§3.1). Hence, at this stage tuning involves determining the value of n after which timely connection establishment becomes unlikely without CPR intervention.

We proceeded by instrumenting servers in three distinct geographical regions (North America, Europe and Asia) with CPR disabled. We then measured how many SYN retransmissions occurred for all connections that were eventually

[2]See §5.3 and appendix A.1 for further details.

n	APAC	EU	NA
0	.63	.64	.70

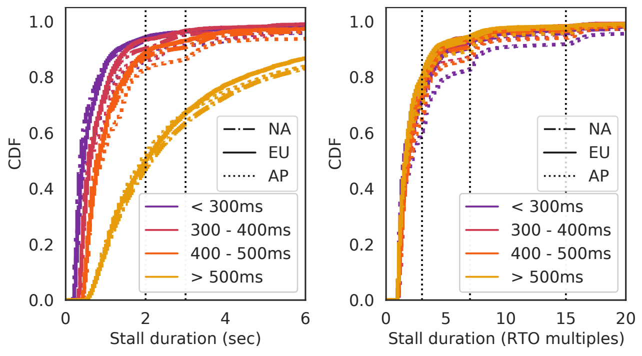
RTO	1.79	.57	2.18
2s	.34	.36	.10
3s	.23	.24	.06

Table 2: Proportion of connections experiencing at least one stall during their lifetime, as a function of the stall duration (%)

established[3]. As shown in table 1, only ~0.63% to ~0.7% of connections experience impairments before establishing, depending on the region. This means that more than ~99.3% of connections establish without any retransmissions. Further retransmissions help connection establishment, but with noticeable diminishing returns. For example, after two consecutive retransmissions without a reroute, the probability of a connection being successfully established was between ~0.05% to ~0.12%. Based on these findings, we set $n = 2$ in our production configuration.

Tuning post-establishment impairment detection. We addressed the tuning of δ_{min} and μ_{rto} (§3.2) in two steps. First, we followed a similar measurement methodology as that used to tune n, this time focusing on connections experiencing at least one RTO expiration during their lifetime. Our results, reported in table 2, provide evidence of significant regional variability. Whereas ~0.1% of connections in North America experience stalls lasting for 2 seconds or more, this increases to ~0.35% for connections in Europe or Asia-Pacific[4]. However, these results also show that the probability that a connection recovers after experiencing a stall for 2 or 3 seconds was very low irrespective of geographical region.



(a) (b)

Figure 4: Duration of TCP stalls by region and RTO

[3]This was done during a period free of obvious biases such as outages, high-load client events, DDoS attacks, etc.

[4]These values constitute a lower bound; during the active phase of an impairment event the proportion of affected connections can rise by an order of magnitude or more (see §5.2).

The next step was to investigate the time required for a connection to resume forward progress after an RTO (fig. 4). We begin by noting the two vertical lines in fig. 4a: these correspond to the two candidates found in the previous study. For connections with RTO $\leq$ 500ms, most of the probability mass in the dataset lies to the left of the first line, providing evidence that for these connections the length of a stall is largely independent of RTO and $\delta_{\text{min}} = 2\text{s}$ is sufficient to ensure adequate impairment detection.

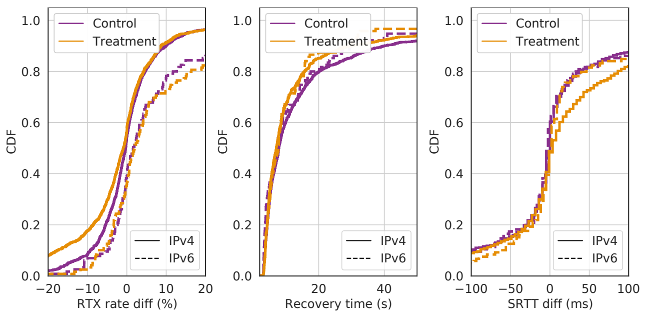
To understand how best to handle connections with RTO > 500ms, we first note the probability mass "bumps" in fig. 4b. These intervals of 3, 7 and 15 RTOs stem from TCP retransmission behavior under exponential backoff. Since the majority of the probability mass lies to the left of the first line, a large proportion of connections will recover on their own before $\mu_{\text{rto}} = 3$, irrespective of their RTO. This addresses the high RTO connections that were not already covered by $\delta_{\text{min}} = 2\text{s}$, and provides a rationale to set $\mu_{\text{rto}} = 3$.

Finally, we set `wait` (§3.2) by observing day-to-day operation of the system in production. We select `wait` $= 1\text{s}$ sec on the basis of keeping the volume of steady-state rerouted traffic to a sufficiently low level.

5.2 Evaluating benefit and non-harm

Methodology. To ascertain the impact that CPR has on ongoing connections we follow an *experimental* approach, in which we (pseudo)randomly label some connections as part of a *treatment* group, and the remainder as part of a *control* group for which path reselection logic is disabled. While the state and output of the impairment detection algorithms are maintained for both groups, network-layer path changes are triggered only for treatment connections. This setup allows us to explore the degree to which the benefits of CPR during path outages outweigh its potential costs when no impairments are present. We begin by exploring whether rerouting a stalled connection could make its performance significantly worse than doing nothing. To the extent that the answer to this question is negative, CPR will be innocuous when triggering due to stalls not associated with path impairments, and hence, non-recoverable by rerouting. We then move on to analyze the benefits that CPR provides during path impairment episodes.

Evaluating non-harm in the steady state. For both treatment and control we quantify the *reroute effect* on connection properties such as RTT or retransmission rate. Since connection properties need time to settle to their new values after a reroute in order to be meaningful, we focus on long-lived connections. We define the *onset* of a stall as the TCP sending event immediately prior to an RTO, and the *full resolution* as the first sending event after forward progress is restored and 30[5] segments have been sent. We define the reroute effect on a connection property as the difference between its value at



(a) (b) (c)

Figure 5: Steady-state reroute effect experiment results

onset and at *full resolution*.

The CDF of the reroute effect on the TCP retransmission rate[6] is presented in fig. 5a. Whereas it seems to be negligible for IPv6, for IPv4 the treatment connections have a greater proportion of their probability mass on the negative effect sizes, implying that rerouted IPv4 connections tend to have lower retransmission rates after the reroute than before it. This points towards CPR having *some* small benefit during the measurement period. Otherwise, the curves are very close to one another, providing evidence that CPR is not introducing significant retransmissions during steady state.

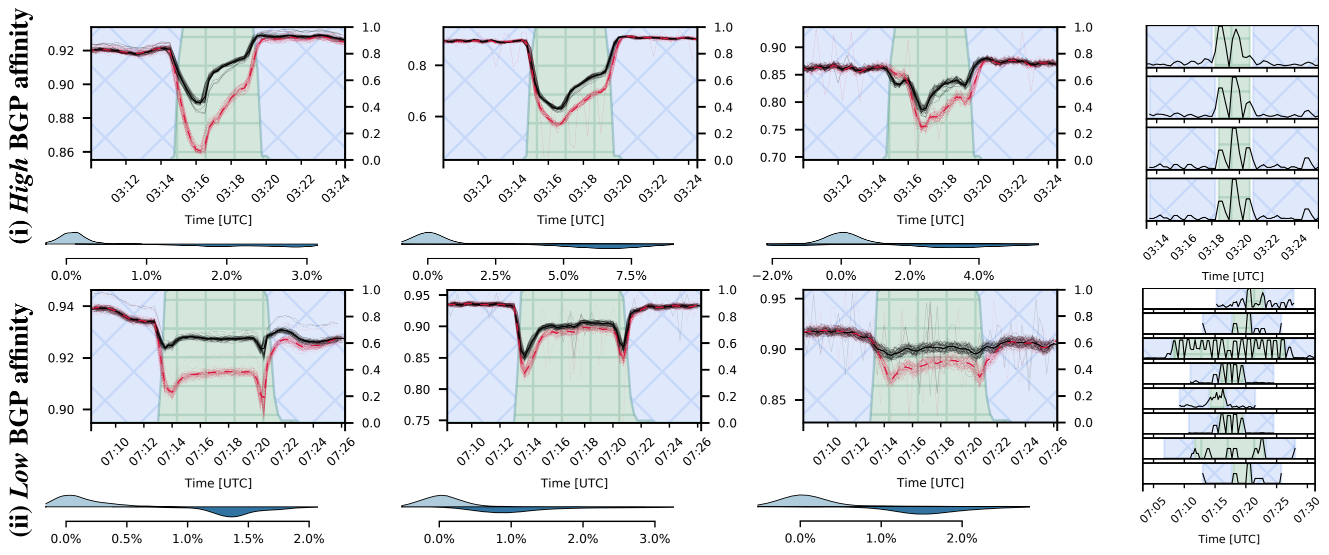
We can also use the results of the previously described reroute effects experiment to understand the effect of CPR on stall recovery speed. From fig. 5b we can see that treatment connections tend to have shorter resolution times compared to control connections, both for IPv4 and IPv6. The effect during steady state is small, as expected: ~80% of control connections recover within 20s of a reroute, compared to ~85% of treatment connections.

Finally, fig. 5c shows the effect of reroutes on `srtt` (§3.2). Again, a seemingly negligible effect for IPv6 is accompanied by a clear effect for IPv4, this time demonstrating higher `srtt` values after the reroute (usually by less than ~30 ms, but sometimes more than ~100 ms). This performance penalty is expected since our BGP traffic engineering policy optimizes for latency, and is more finely tuned in IPv4 than in IPv6 due to operational maturity. Since CPR explicitly reroutes away from paths selected by this policy, we are more likely to experience an increase in RTT than not. In this light, our configuration of CPR is an expression of the extent we are willing to subvert local routing policy in an attempt to recover from failure. Since this is a matter of policy, we observe there is no single correct configuration, but a range of potentially acceptable outcomes.

Evaluating benefit during stall events. During path impairments, the most common outcome for control connections is *failure* (rather than *e.g.,* increased RTT or retransmission

[5]This number was arbitrarily selected to provide enough samples for TCP connection properties to stabilize.

[6]Every connection in this dataset experienced a stall during the measurement period. Hence, retransmission rates are expected to be higher than the blended averages typically reported.



(a) $\pi_\bullet$(HEALTHY) (b) $p^o_\bullet$(HEALTHY|SYNRCVD) (c) $p^i_\bullet$(CLOSE|HEALTHY) (d) BGP events

Figure 6: CPR operation during two stall events (i and ii). The timeseries plots in figs. 6a to 6c show the *control* • (dashed) and *treatment* • (solid) group values (**left y-axis**). Each one of the *thin* lines corresponds to a single host; *thick* lines track the average for all hosts in a POP. In the same plot we also show the proportion of hosts in a POP for which the timestamp has been classified as part of an *active event* ⊞ or its *context* ⊠ (**right y-axis**). Beneath each timeseries plot we show a violin plot for the PDF of $\Delta\pi$ (fig. 6a) or $\Delta p^\bullet$ (figs. 6b and 6c), the difference between treatment and control values, for both *context* • (top) and *event* • (bottom) periods. Each subplot in fig. 6d shows BGP update/withdrawal rates for peering sessions which triggered anomaly detection in proximity to the active event span. Since only relative changes are relevant, y-axis tickmarks have been removed.

rates). Hence, to accurately assess the benefits of CPR we must look beyond the reroute effect measures presented above. Broadly, we resort to anomaly detection on the performance differences between treatment and control groups in order to identify *stall events*. The benefit of CPR for a given stall event can then be measured by comparing treatment and control performance differences during the event, with the corresponding performance differences during the immediately adjacent timespans. We refer to the union of timespans immediately preceding and following a stall event as its *context*.

In order to identify stall events, we instrumented the kernel to export additional metrics. First, we store per-connection information on the operation of the recovery mechanism as part of the socket metadata; this includes the reroute counter r, last forward progress timestamp, etc. Second, we maintain aggregate counters in the kernel which track state transitions as each connection traverses both TCP and CPR state machines. Each edge server aggregates separate counters for treatment and control group connections, allowing us to estimate the efficacy of CPR on each host according to multiple performance measures[7], including:

- $\pi_\bullet$(HEALTHY), the proportion of TCP connections in the HEALTHY state;
- $p^o_\bullet$(HEALTHY|SYNRCVD), the proportion of TCP connections that transition out from the SYNRCVD state towards the HEALTHY state, per unit time. This gives an indication of the instantaneous probability of connections connecting successfully; and
- $p^i_\bullet$(CLOSE|HEALTHY), the proportion of TCP connections that transition into the CLOSE state from the HEALTHY state, per unit time. This gives an indication of the instantaneous probability of connections closing while healthy (rather than stalled).

We present two CPR stall events in fig. 6, embedded in their *context* so that their impact is clearly visible. Each event is presented along its *BGP affinity score*, a synthetic measure of the degree to which observed routing plane events are correlated with transport layer anomalies (appendix C). Our examples were selected to juxtapose the case where there is a *high* BGP affinity score (i), and therefore an association between CPR and BGP behavior, and a *low* BGP affinity score (ii). In both cases we can observe that immediately after the start of the stall event (at the left context/event boundary) CPR treatment connections start experiencing better performance, as inferred from a higher $\pi_\bullet$(HEALTHY) (fig. 6a). Treatment connections also have better chances of establishing (fig. 6b), evidencing connection setup distress for control connections, and exhibit a greater chance of closing while HEALTHY, rather than when STALLED (fig. 6c). When taken together, these facts point towards a small but significant proportion of affected connections, both *established* and *pre-establish*, clearly benefiting from CPR, irrespective of the BGP affinity of the event. When a clear association with BGP is present, such as with fig. 6d (i),

[7]A more detailed overview of stall event detection is included in appendices B and C.

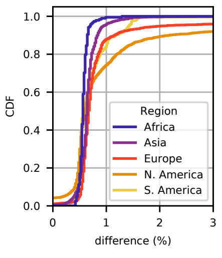
the benefits provided by CPR are materialized significantly before the associated BGP event is resolved. Conversely, fig. 6d (ii) demonstrates that CPR can recover just as effectively in cases for which BGP provides no remediation.

Each violin plot beneath a CPR time series event subplot in figs. 6a to 6c shows the benefit that CPR provided to connections assigned to the treatment group during the event. For state occupancies we rely on $\Delta\pi = \pi_t - \pi_c$, the difference between treatment and control values (similarly, for state transitions $\Delta p^{\bullet} = p_t^{\bullet} - p_c^{\bullet}$). For instance, in fig. 6a we can see that although the distribution of $\Delta\pi(\texttt{HEALTHY})$ was centered at zero outside the event period, it moved to the right during the active phase of the event, irrespective of BGP affinity. For (i) we see that CPR allowed an additional ~3% of connections (over the entire POP and to all destinations) to remain in the HEALTHY state compared with the control group; for (ii) this is reduced to ~1.4%. On the other hand, from $\Delta p^{o}(\texttt{HEALTHY}|\texttt{SYNRCVD})$ (fig. 6b) we see that during (i) CPR allowed an additional ~7% of connections in the POP moving out from a SYNRCVD state to enter the HEALTHY state; during (ii) this is reduced to ~1%.

Evaluating benefit globally. Having explained the typical characteristics of stall events using individual examples, we now focus on 1) measuring CPR effectiveness at a global scale, and b) identifying the circumstances under which CPR is most effective. To this end we perform statistical aggregation on data collected from ~80 POPs over ~12 months. As before, we focus on *recovered events*, defined as stall events which show evidence of improvement in performance measures (*e.g.,* those presented in fig. 6). We do this for two reasons. First, whereas improved treatment group performance unequivocally points towards TCP stalls that can be resolved by path reselection, anomalies where CPR provides no benefit are uninformative: there are many possible causes of TCP stalls unrelated to resolvable path impairments (*e.g.,* wireless access roaming or dis-association) for which re-routing cannot be expected to help. The second reason is implementation-related. Since performance data such as presented in fig. 6d is only kept aggregated at host level (rather than at prefix or connection granularity) it is difficult to directly associate a CPR event with a set of destination prefixes/ASes, and hence, to a BGP-based ground truth. For recovered events this is not an issue: CPR itself provides direct confirmatory evidence of path impairment mitigation[8].

We will denote the daily per-POP average CPR state occupancy during the active phase of stall events (rather that their context) as $\mathbb{E}[\Delta\pi]$. This measure can be used to directly understand which geographies benefit the most from the deployment of CPR, as shown in figs. 7a and 7b. First, in fig. 7a we can see that most of the probability mass for $\mathbb{E}[\Delta\pi(\texttt{HEALTHY})]$ lies on the *positive* semi-axis regardless of geography, imply-

[8]Note however that, since our CPR deployment could *in principle* fail to recover from some stall events, our reported prevalence findings suffer from survivorship bias [63] and must be interpreted as lower bounds.



(a) $\mathbb{E}[\Delta\pi(\texttt{HEALTHY})]$

ing that $\pi_t \geq \pi_c$ and hence that the proportion of HEALTHY connections was higher for the treatment than the control group (median $\in [0.57\%, 0.68\%]$). Conversely, fig. 7b shows that most of the probability mass for $\mathbb{E}[\Delta\pi(\texttt{SYNRCVD})]$ lies on the *negative* semi-axis (median $\in [-0.46\%, -0.19\%]$), so that $\pi_t \leq \pi_c$. This means that CPR allows connections to both 1) connect faster and 2) spend less time stalled. We note that whereas $\pi_t(\texttt{HEALTHY})$ benefits are greatest in Europe (median = 0.68%) and Asia (median = 0.65%), $\pi_t(\texttt{SYNRCVD})$ benefit is particularly strong in South America (median = −0.46%) and Africa (median = −0.38%). However, as shown in fig. 7c, these benefits are accompanied by a cost: every day more than ~10% of connections on up to ~30% of PoPs experience stall events. Although the immense majority of these stalls are associated with abandoned connections and hence carry negligible traffic, we note that non-recoverable stalls induce a sustained level of background reroutes.

In contrast to figs. 7a to 7c, figs. 7d and 7e show weaker region dependence. Although fig. 7d provides some evidence that recovered stall events occur roughly proportionally to both 1) the aggregate traffic volume and 2) the interconnection density of a region, the difference between regions is small. Similarly, fig. 7e shows that most recovered events last under 20 minutes, irrespective of region (median $\in [7.1, 9.4]$). However, we note that this distribution can be heavy tailed: we have observed uncommon, longer events that span multiple hours. These can have "macroscopic" effects, triggering operational responses and re-routing over 20% of PoP traffic.

We finally turn our attention to the severity of recovered events. We define a heuristic *severity index* based on the normalized performance difference between treatment and control connections during the event and its associated context. The higher the number of standard deviations between treatment and control variables during the event itself, compared to before and after it, the higher the severity for the event (see appendix C). Perhaps unsurprisingly, fig. 7f shows that CPR routinely recovers from higher severity events in densely connected regions. However, the distinction between the North and South America curves in figs. 7d and 7f is instructive. Whereas in fig. 7d the former is always beneath the latter, in fig. 7f the opposite occurs. This shows that CPR helps recover from more events in regions with nontrivial BGP routing where complex business agreements and undersea cable topology can make BGP-only recovery more challenging.

As a complement to the per-POP statistics presented in fig. 7, we report that globally CPR mitigates on average ~120 impairment events every day with a median duration of ~8 minutes. Informally, this amounts to over ~16 hours per day. While this improvement may appear quantitatively modest, in practice these performance degradations bear a high cost in the absence of mitigation. Many of them exhibit no proximal cause, making them notoriously hard to debug. Even when an underlying cause is understood, many performance problems are short-lived and will be resolved by the time engineering or customer support resources have been mobilized to address them. In opportunistically mitigating either type of deterioration, CPR has an outsized impact in improving the reliability of services provided by edge networks, at virtually no cost.

5.3 Path coverage

Given that CPR deflects traffic among upstream providers when mitigating path impairments, it is informative to estimate the degree to which reroutes are likely to result in disjoint data plane paths. To this end, we analyze all routes learned from every provider in a given POP. Since all transits offer full routing tables, every destination prefix will have a set of available routes. In addition to these routes, we may have additional peering routes learnt from PNIs or IXPs. One of these paths (learnt from either peering or transits) will be *selected* as an outcome of BGP policy; the remaining routes (learnt over transits) represent valid *alternate* paths.

We proceed by defining each AS in the selected path to be *node-protected* if there is an alternate path for the same destination that does not include it. Then, we define *AS-node diversity* as the proportion of node-protected ASes in the selected path. Similarly, we can define an AS pair in the selected path to be *link-protected* if there is an alternate path that does not include the same AS pair in the same order, which leads to the entirely analogous definition of *Inter-AS-path diversity* as the proportion of link-protected AS pairs in the selected path. Since CPR will eventually explore every available path to every destination, these two measures can be used as proxies for the probability of recovery given a failure event involving any given destination prefix[9].

[9]Two practical qualifications are in order. First, since a packet can traverse different router-level paths within the same AS between given ingress and egress pairs, and multiple peering points between two adjacent ASes in an AS path, both quantities are lower bound estimates of actual dataplane path diversity. Second, under these definitions a number of high-volume destination prefixes advertised by directly connected peers will be counted as presenting zero diversity whilst in reality presenting negligible impairment risk as their path reliability is very high. These have been removed from the analysis in §5.3, but are reported in their entirety in appendix A.1.

An analysis of ~900k globally distributed routes revealed traffic-volume-weighted AS-node diversities of 90.8% and 86% for IPv4 and IPv6 respectively; these rise to 93.7% and 90.5% when considering Inter-AS-path diversity. The significant path diversity available to CPR evidenced by these numbers is a consequence of a strict requirement for edge networks: POPs must be interconnected to multiple transits in order to survive outages of individual providers or local exchange points. Since most client traffic is preferentially exchanged over peering, the addition of a transit provider has a limited impact in improving latency. Instead, multihoming is primarily a form of insurance. In this light, CPR is of great interest to edge network operators in that it extracts greater value from what is otherwise a necessary cost.

6 Operational considerations

CPR has been in use for over two years. This section revisits some of our original assumptions in the light of our accrued experience, as well as highlight some of the tweaks that were required along the way.

Per-route overrides. While it is beneficial to enable CPR by default on edge hosts, and the parameters derived in §5.1 are adequate for a wide range of conditions, there are cases where it is desirable to override configuration on a per-route basis. For example, rerouting intra-POP traffic onto transits is ineffective as a mitigation strategy, and costly due to the large volume of traffic exchanged between hosts within a POP.

Linux already allows per-route configuration of *features*, such as ECN or SACK. We expanded this method to allow the configuration of CPR on a per-route basis, and extended our edge host routing daemon to be able to inject routes into the *main* routing table accordingly. Over time, this has allowed us to selectively disable or experiment with CPR on a per-route basis as an integral part of our BGP policies. This evolution was gradual: what started exclusively as a server-side, transport layer extension has been progressively incorporated operationally as an extension of our routing infrastructure.

Middleboxes. Rerouting ongoing connections could in theory adversely interact with stateful middleboxes, which would be presented with packet streams for which the TCP three-way handshake happened in a different path (and hence was not observed). The expected outcome of this potential problem, increased TCP RST rates or silently dropped packets for treatment connections compared with control (see §5.2), has not been observed in practice after multiple years of sustained, worldwide, multi-Tbps usage. This is not unexpected, since

CPR does not modify the TCP header in any way. From the perspective of intermediate devices, CPR reroutes are indistinguishable from other reroutes events, such as those triggered by BGP or ECMP rehashes.

Prefix aggregation. It is natural to consider extending CPR by aggregating per-connection information and using it to influence routing. If many connections in a given prefix stall, only to recover successfully after a reroute, we could avoid future stalls by overriding the route for that prefix. Evaluating this approach is outside the scope of this paper, but the implementation is far from straightforward once we consider its risks. Firstly, as evidenced by §§5.1 and 5.2, not all transport-layer impairments will be correctable by path reselection. This means that there is always the danger of overriding routing and traffic engineering policy in an attempt to resolve a suspected problem that cannot be fixed that way. This risk is severely amplified by performing routing interventions on entire prefixes. A related threat is that, in addition to natural variability, stall signals are also susceptible to adversarial manipulation. Using stall recovery information to route entire prefixes would amplify the impact of such an attack, potentially burdening the edge network with higher transit costs or end-users with higher latency. Finally, there is no *a priori* reason to assume that the same routing intervention will have the same effect on every subprefix covered by an Internet-advertised prefix. Whereas this tradeoff is irreconcilable at the prefix level, it is trivially accommodated at the connection level.

Avoiding peering offload. As noted in §4, whereas routes in the *main* table are learned from *both* settlement-free peers and transits, routes in the *transits* table are *only* learned from transits. Therefore, CPR path reselection can re-route connections away from PNIs and IXPs and onto transits, which would typically result in greater costs and potentially less direct paths to destinations. During our design phase we accepted this limitation because the alternative is for connections to remain stalled; an opportunity to recover then makes the cost benefit positive. Although the nature of colocation facilities makes it relatively rare for a single POP to be connected to multiple IXPs, it would be beneficial to be able to failover from PNIs to IXPs. In our current architecture, this capability can only be provided at the cost greater routing complexity (defining the set of failover routes on a per-destination basis).

Path reselection. While one could envision more complex path selection algorithms than those presented in §3, in our experience the additional complexity does not translate to significant benefits. The simplicity of CPR is a core feature, providing quick recovery and effective load balancing without burdening operators with configuration overhead.

Userspace support. CPR need not be limited to the kernel, it can be leveraged or selectively disabled by any userspace application. To support this, we reserved bits in *fwmark*, which can be set via a `setsockopt` system call, to communicate application intent to the Linux kernel networking stack.

We reserve one bit in *fwmark* to signal that the connection for the given socket must not be rerouted. This allows CPR to be disabled on a per-connection basis for measurement and debugging purposes. For example, it may be necessary for a connection to be sent over an application-defined path to test path performance or to debug networking issues.

In order to support UDP based transport protocols, we allow userspace applications to directly manipulate the value of r. Surfacing control over the reroute counter through the *fwmark* effectively pushes route reselection out of the kernel.

QUIC. One of the primary drivers for userspace support of CPR has been the ongoing deployment of QUIC [38]. QUIC supports connection migration [31], and over time we expect this to be the primary mechanism for path failover. As of today, however, QUIC connection migration may be disabled by either peer, and can only be used after connection establishment. Furthermore, migration must be initiated by the receiver, who must send a probe packet from a new local address. CPR on the other hand covers connection establishment, and can be triggered unilaterally on the sender side, where stalls are more quickly detected. Since there is nothing intrinsic to CPR that makes it fundamentally incompatible with connection migration, we view both methods as complementary and are actively experimenting with CPR within QUIC. While validating the use of CPR within QUIC is the subject of future work, the implementation itself is straightforward and bears testament to the overall elegance and simplicity of CPR.

7 Related work

Although multiple solutions in the literature address the detection and mitigation of path impairments, none provides feature parity with CPR. To the best of our knowledge, the design of CPR is unique in its simplicity, which makes it extremely easy to deploy. It is the only solution providing path failover at a connection granularity, which does not require switches with programmable dataplanes or support from the client endpoint, and which makes it possible to identify and mitigate performance degradation even if a connection is not currently established.

Our work is most closely related in motivation and approach to INFLEX [58] and Blink [28]. Both use transport-layer triggers to reroute traffic and, unlike CPR, rely on programmable data plane switches. While INFLEX reroutes stalled flows on a per-connection basis, it does so by installing ephemeral route entries onto a switch. It can therefore not support failover for all connections at the scale edge networks operate. Blink on the other hand relies on the ability to monitor sequence numbers of ongoing TCP flows. This poses not only scale concerns, which Blink addresses by limiting itself to only monitoring high volume prefixes, but also cannot work on encrypted transport protocols such as QUIC. Finally, by detecting failures and re-routing on a route/prefix granularity, Blink suffers from the same pitfalls of traditional

Table 3: Comparison of path failover mechanisms

Feature	BGP [48]	MPTCP [24]	SWIFT [29]	INFLEX [58]	Blink [28]	CPR
Pre-establish connection support	✓	✗	✗	✓	partial	✓
Partial failures support	✗	✓	✗	✓	partial	✓
Granular failover	✗	✓	✗	✓	✗	✓
Support all connections and prefixes	✓	✓	✓	✗	✗	✓
No client support required	✓	✗	✓	✓	✓	✓
No switch support required	✓	✓	✗	✗	✗	✓
$O(\texttt{seconds})$ convergence	✗	✓	✗	✓	✓	✓
Production validation	✓	✓	✗	✗	✗	✓

routing protocols. Smaller failures can go undetected, and reroute decisions can result in substantial changes in traffic allocation, exacerbating the risk of cascading failures due to downstream congestion. CPR on the other hand can be enabled for all flows, and can detect outages and impairments on a per-connection basis. Re-routing is also performed on a per-flow basis, and as a result traffic can be offloaded and distributed in a more granular fashion. CPR can also afford more sophisticated failure detection implementations, for example based on RTT variation, that passive monitoring in switch dataplanes cannot support.

SWIFT [29] infers the extent of failures through the analysis of BGP updates. While it reduces the time to route convergence, its reliance on BGP route updates makes it oblivious to a wide array of failure scenarios. By the authors' own admission, it is also unable to improve the time taken to receive BGP updates, which itself is on the order of multiple seconds [28]. CPR bypasses routing messages altogether, and can more accurately detect more types of failure in less time by simply piggy-backing on existing transport mechanisms.

Although a number of egress routing control systems aim to mitigate some of the same issues as CPR (*e.g.,* Espresso [64] or Edge Fabric [52]), CPR again differentiates itself by operating on individual connections rather than prefixes. This makes it complementary to such systems: it is possible to use them to apply intelligent egress traffic engineering, whilst still relying on transport extensions like CPR to mitigate transient, sub-prefix path impairments. In fact, since CPR depends on specific routing primitives for its operation (*e.g.,* those provided by Silverton [14, 57]), CPR *requires* a subset of the functionality provided by these systems.

FlowBender [34], similarly to CPR, uses transport-layer metrics to trigger path reselection decisions, but for the purpose of intra-datacenter load balancing. However, in contrast to CPR, it 1) requires Explicit Congestion Notification (ECN) which is not safe to use with anycast traffic [49, 59]; and 2) requires control of the ECMP hashing configuration of routers along the path to implement its reroute mechanism. These two issues make it unsuitable for providing resilience against Internet path failures. Similarly, although SD-WAN solutions (*e.g.,* [22, 65]) can achieve for overlay networks results similar to CPR, they are neither unilaterally deployable nor a good fit to the business model of an edge cloud network.

Multipath TCP (MPTCP) [24] makes it possible to establish single connections over multiple paths and load balance traffic automatically to the best performing path. Inheriting from previous multipath-aware transport such as shim6 [44] and SCTP [55], MPTCP has slowly gained traction in niches such connection handoff [10]. In the same way the usage of CPR is not at odds with QUIC, we do not view CPR as inherently incompatible with MPTCP. CPR works well precisely where MPTCP often falls short, for example by improving reliability for short lived flows which dominate web traffic, protecting connection establishment, or exploiting path diversity without requiring clients to explicitly identify distinct paths (*e.g.,* with distinct addresses). In contrast with CPR, MPTCP provides no value when interacting with legacy TCP clients, since it is not unilaterally deployable. By tying itself to a legacy wire format, MPTCP is also less forward looking than QUIC. Given the significant economic investment required to deploy and support a new transport protocol, it is unsurprising that edge networks have collectively focused on the latter. Over time we expect QUIC to fully assimilate the explicit multipath capabilities of MPTCP, while still falling back to implicit multipath mechanisms such as CPR.

8 Conclusion

This paper presented Connection Path Reselection (CPR), a novel system that improves the reliability of *edge networks* [52, 64] by inferring the status of a path by monitoring transport-layer forward progress, and rerouting stalled flows onto healthy paths.

CPR is unabashedly simple, and follows in a long tradition of incremental improvements to the Internet which push the boundaries of best effort delivery. While it cannot protect flows against all failures, the cases in which it is effective come virtually for free. Our implementation is trivial to configure, effortless to operate, requires no additional hardware and exploits path diversity already available to edge networks. By operating at the transport layer, CPR provides faster recovery than is attainable by routing alone, as well as detecting a wider array of potential failures on a per-connection basis without incurring additional state.

Importantly, this paper is not a proposal - CPR has been deployed in production at a large scale edge network for over two years. We evaluate our design within this context, and document our assumptions for the benefit of a wider community. To the extent of our knowledge, CPR both complements existing routing and traffic engineering mechanisms, and can coexist with multipath enhancements to transport protocols in the future. As a bridge between the two, CPR is a step towards the collective goal of ensuring that only a complete partition is capable of stalling an Internet transport connection.

Acknowledgements

We would like to thank our shepherd Italo Cunha and the anonymous reviewers for their feedback. We are also very grateful to the engineers at Fastly who have contributed to the deployment, monitoring and operation of CPR over the years.

Appendix

A Path diversity

This section provides additional results on path diversity both at the AS path level (extending the analysis presented in §5.3) and at the dataplane level in the specific case of paths between pairs of POPs.

A.1 AS path diversity

This section extends the analysis of AS path diversity presented in §5.3 by reporting path diversity results disaggregated by remote AS type and IP version.

We classify destination ASes according to the CAIDA AS classification dataset [1]. This dataset provides an *AS type* for each candidate destination AS: *Transit/Access* for business providing Internet connectivity; *Content* for ASes which provide content hosting and distribution; and *Enterprise* for other entities that are mostly users, rather than providers of Internet access, transit or content. ASNs for which a classification is unavailable were tagged as *Unknown*.

Our findings are presented in fig. 8. Path diversity seems to induce a stable ordering in which *Content* destination ASes

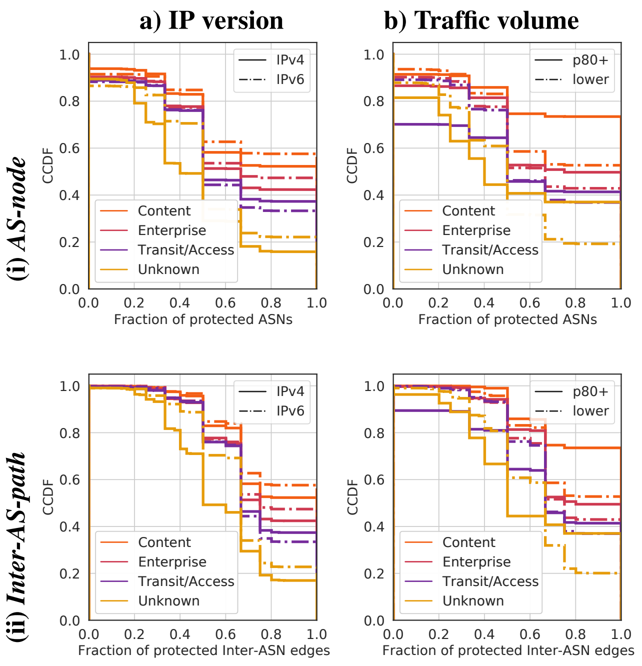

Figure 8: Relationship between both AS-node / Inter-AS path diversity and *AS type*, disaggregated by a) *IP version* of the advertised prefix and b) *Traffic volume* served.

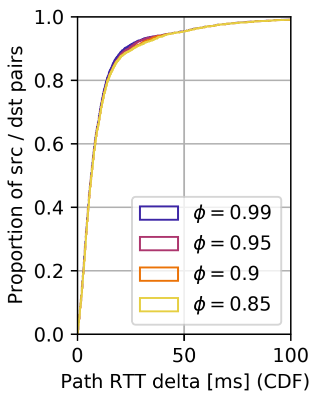
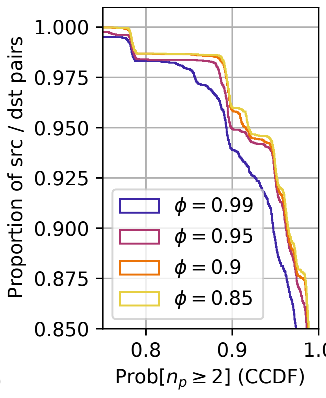
have the highest diversity, followed by *Enterprise*, *Transit/Access* and *Unknown*. While Inter-AS path diversity is understandably higher than AS-node diversity, the ordering appears for both measures. This suggests that, in general, *Content* ASes value path diversity the most; this is unsurprising given the benefits multihoming provides in content delivery [7, 40]. Although similar arguments can be made for multihoming of *Access* [8, 21] and *Enterprise* [9] networks, in practice they exhibit lower path diversity, potentially because they operate at a different cost tradeoff point. Whereas every intermediate AS is node-protected for ~50% of *Content* ASes, this only happens for ~40% of the *Enterprise* and *Transit/Access* prefixes. Overall, there is slightly improved path diversity for IPv6 compared to IPv4, except for *Transit/Access* networks (see fig. 8 i-a and ii-a).

We also consider *size* in our analysis, motivated by the intuition that large, well funded entities may plausibly enjoy better path diversity than smaller ones. We approach this issue by using traffic volume as a proxy for size, disaggregating those prefixes lying in the top 20th percentile (80th percentile overall) by traffic volume served from our edge cloud network. The result of this is presented in fig. 8-b. Although the conjecture that larger entities may enjoy better path diversity is confirmed for every *AS type*, it is emphatic for *Content* destination ASes: around ~75% of high-volume content provider prefixes are fully node- and link-protected (fig. 8 i-b and ii-b respectively). While ~30% of *Transit/Access* destination prefixes seem to not be node-protected at all, as reported in fig. 8 these correspond to directly connected peers for which path reliability is very high. On the other hand, ~40% of *Transit/Access* destination prefixes are both AS-node and Inter-AS-path protected.

A.2 Dataplane path diversity between POPs



(a) RTT delta between the shortest and longest paths between POP pairs



(b) Proportion of time that two or more paths are available between POP pairs

Figure 9: Inter-POP end-to-end path measurements

Although the BGP-based results presented above are sufficient to justify our path selection approach, as stated in §5.3 they constitute lower bounds. For some use cases it may be advantageous to directly measure dataplane multipath diversity. In this section we present data indicative of the results of such an analysis. We make use of a measurement mesh between our ~80 globally distributed POPs, which continually perform independent RTT measurements over each one of their transit providers. By exploring loss episodes in this mesh we can estimate the probability that, if a BGP-preferred path is unavailable between two POPs, CPR can find another one by random choice.

During a given 30 second measurement window, we compute the *availability* α of a POP-to-POP path as the ratio between the number of *ping* probes for which a response was received and the total number of probes sent. We then compare this to a threshold ϕ, and define a path as *unavailable* if $\alpha < \phi$. We present two measurements using this setup. First, in fig. 9a we show the CDF of the RTT difference between the shortest and longest *available* paths between two given POPs. We can see that in ~80% of cases this RTT delta is of at most ~12.5ms; for ~95% of cases this upper bound rises to 50ms. Note that, in general, *the behavior of this RTT difference is not impacted by our choice of* ϕ. This suggests that, for a large proportion of paths between POPs, alternative paths with similar RTT are available simply by choosing an alternative egress - even for relatively high availability requirements. In some cases, though, these paths *can* induce significant additional delay, and hence this effect cannot be dismissed out of hand.

We also compute the proportion of measurement windows, over a 7 day period, in which at least two POP-to-POP paths were available between any two POPs. This is presented in fig. 9b, which shows that for $\phi = 0.9$, ~96% of POP pairs have two or more *available* paths between them for at least ~90% of the time. Since data collection noise from using *ping* invariably leads to packet losses that do not correspond to path impairments, these numbers constitute a lower bound for the actual data plane path availability. Nevertheless, even this rough approximation shows that the random retry strategy presented in §4 with alternative paths being simply defined by using alternative egress transits is good enough for CPR.

B CPR state probability reconstruction

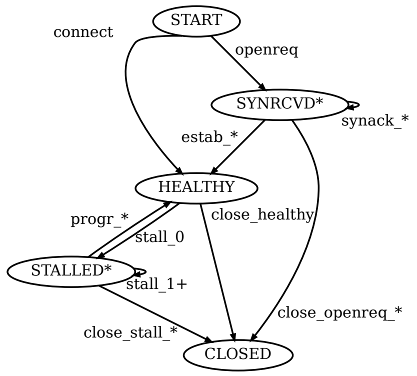


Figure 10: The CPR Finite State Machine

This section provides additional details regarding the computation of stall-event-related CPR performance measurements like those described in §5.2.

CPR state machine. A summarized representation of the CPR state machine is presented in fig. 10. Although CPR tracks the number of individual reroutes while in the `SYNRCVD*` and `STALLED*` states, these internal subdivisions and their associated transitions have been omitted (this is denoted in fig. 10 with * or +). Stall detection logic is evaluated at relevant TCP events (*e.g.,* retransmissions). Transitions between states represent either TCP events (*e.g.,* `openreq`, `estab*`), CPR events (*e.g.,* `stall*`, `progr*`) or both (*e.g.,* `synack*`, `close*`). `SYNRCVD*` and `STALLED*` correspond to points in which path reselection logic can be triggered.

For incoming connections, the `SYNRCVD` meta-state is entered when a SYN is received (`openreq`); this will elicit a SYN-ACK response from the local TCP stack. If this SYN-ACK is acknowledged, the TCP connection enters the `ESTABLISHED` state, and CPR the `HEALTHY` state. Outgoing connections enter the `HEALTHY` state directly upon termination of the three-way handshake. When connections terminate naturally (`close_healthy`), they leave both the TCP and the CPR state machines. The `SYNRCVD` meta-state subsumes one `synack*` transition for every ACK/SYN-ACK retransmission, and the `STALLED` meta-state one `stall*` transition for every time a stall is declared (see §3.2). The `progr*` transitions capture the possibility of the connection making forward progress again after a number of stalls. The `close*` transition, which corresponds to connection termination, can happen before connection establishment completes (`close_openreq*`), after suffering one or more stalls (`close_stall*`), or as part of an orderly teardown while healthy (`close_healthy`).

Probability reconstruction. Each TCP connection will increment treatment or control counters *for every transition in* fig. 10. To turn these monotonically increasing counters into meaningful probability estimates they are processed in 15 second windows that we denote *export intervals*.

We begin with $\pi_\bullet(A)$, the instantaneous occupancy of a state A, where the subscript will be used to refer to the *treatment* or *control* groups. We note that the value of $\pi_\bullet(A)$ at a given time can be obtained by keeping track of the total number of connections that have entered A and subtracting the total number of connections that have left it; this can be directly computed from the exported counters.

We continue by defining $p_\bullet^\bullet$, the probability estimates for transitions in fig. 10. As before, the subscript will denote either the *treatment* or *control* groups; however, the superscript will be used to denote either *outflow* or *inflow* probabilities. Borrowing from the usual conditional probability notation, we denote an outflow probability $p_\bullet^o(B|A)$ as the probability that, when a connection transitions *out* from state A, it will move on to state B; likewise, we denote an inflow probability $p_\bullet^i(B|A)$ as the probability that a connection transitioning *in* to state B originated from state A. An estimate of $p_\bullet^o(B|A)$ at the end of an export interval can be obtained by computing the ratio of the rate at which connections transitioned from A to B and the *total* rate at which connections transition out from A during that export interval; a similar (but opposite) procedure can be used to compute $p_\bullet^i(B|A)$ (rates can be trivially computed by discrete differentiation). Using $p_\bullet^\bullet$ we can compute specialized measures that can be helpful when estimating the strength of the association between re-routing and stall-related connection properties, such as *e.g.,* the *risk* ratios

$$\rho(A) = \frac{\pi_t(A)}{\pi_c(A)}$$

and

$$\gamma^\bullet(B|A) = \frac{p_t^\bullet(B|A)}{p_c^\bullet(B|A)}.$$

C Stall event extraction

This section provides additional details regarding the extraction of CPR stall events, like those described in §5.2.

To extract *stall events* from raw performance counters we begin by estimating their *span*, defined as the set of timestamps over which they are considered to be *active* (having a correlated effect over the stall-related performance measures $\pi_\bullet/p_\bullet^\bullet/\rho/\gamma^\bullet$ of multiple hosts in the same POP). This is achieved by first identifying candidate per-host events, which can then be clustered at the POP level.

The identification of candidate per-host events begins with standard multidimensional anomaly detection (see *e.g.,* [45,61] and references therein) aimed to identify performance degradation event *candidates*; this yields a series of points in time when treatment/control performance differences over multiple time series may be suggestive of an event. In our case, we use standard peak-finding techniques (see *e.g.,* [45, 61] and references therein) to find "potentially interesting" timestamps for each stall-related performance measure time series, and use the intersection of all these subsets of active timestamps as our set of candidates. These are further refined by applying clustering and de-noising based on the inter-event durations between successive per-host event candidates. This can be achieved by identifying continuous sequences of candidate timestamps. If the separation between any two of these sequences is smaller than a given clustering threshold, they are aggregated as part of the same event candidate; conversely, if after this process their total time span is smaller than a given threshold, the whole candidate set is discarded. This will yield a number of per-host event *spans*, each subsuming multiple candidates.

To model the state of the world both before the event started and after it ended we assign to each *span* a *context*: two time periods, one preceding it and one following it. This can be used as an experimental framework of sorts: if the candidate event finding logic described above correctly identified a set of event candidates, we would expect to find a definite statistical difference between values of at least some $\pi_\bullet/p_\bullet^\bullet/\rho/\gamma^\bullet$ for timestamps within the candidate *span* and those within the *context*. For every performance time series $\rho/\gamma^\bullet$, we compute the average *Mahalanobis distance* [43] between its *context* distribution and its actual values within the candidate span. The resulting set of distances can then be used to reject the candidate if it does not provide enough evidence that the recovered span encompasses a genuine impairment. These distances will also be used to define an event *severity*, following the assumption that a larger context/span difference indicates a more impactful event.

The next stage of the computation is to bring together sets of events at the POP level that happen at approximately the same time and which may hence share an underlying cause. To achieve this, we create a graph where the vertices are the per-host events, and links denote that the spans of the two event nodes *overlap*. This will generate dense cliques when many host-level events overlap, which would happen if multiple edge hosts in a POP experienced correlated stalls as a result of the same event. Although any graph clustering algorithm could be used (*e.g.,* modularity optimization [15, 20]), trivial detection using connected components [30] has proven to be good enough. Once per-POP events have been identified, event properties from their constituent per-host events (*e.g.*, duration, severity) are aggregated into comparable per-POP event properties.

The logic described can be reused to identify spikes in BGP updates or withdrawals for all the peers and transit providers in a given POP, yielding a number of *BGP events*. These can then be used to enrich the events found from $\pi_\bullet / p^\bullet_\bullet / \rho / \gamma^\bullet$ by using a *bookending* co-occurrence heuristic: if a BGP event happens immediately before the CPR event *starts*, it bolsters the conjecture that the CPR event was *caused* by the BGP event; if it happens immediately before the CPR event *ends*, it bolsters the conjecture that it *mitigated* it. By imposing time thresholds on the maximum time difference between the CPR and the BGP event spans and measuring the deviation between the center-of-mass of the BGP event and the start and end timestamps of the CPR event it becomes possible not only to assign suspected peers or transit providers to a given per-POP event, but also to provide a measure of the association strength between a BGP event and a CPR event. We use this to define a *BGP affinity* score to each per-POP event. Finally, the resulting per-POP events are discarded if they violate any one of a number of data quality policies, such as any of the hosts involved being put into maintenance during the per-POP event span; the total number of connections in an edge node being too low, which could induce numerical instability when calculating probabilities; the total number of nodes which observed the per-POP event being too low, which could point towards a false positive; etc.

Debugging Transient Faults in Data Center Networks using Synchronized Network-wide Packet Histories

Abstract

Data center network faults are hard to debug due to their scale and complexity. With the prevalence of hard-to-reproduce transient faults, root-cause analysis of network faults is extremely difficult due to unavailability of historical data, and inability to correlate the distributed data across the network. Often, it is not possible to find the root cause using only switch-local information. To find the root cause of such transient faults, we need: 1) *Visibility*: fine-grained, packet-level and network-wide observability, 2) *Retrospection*: ability to get historical information before the fault occurs, and 3) *Correlation*: ability to correlate the information across the network.

In this work, we present the design and implementation of *S*yNDB, a tool with the aforementioned capabilities to enable root cause analysis of network faults. We implement and evaluate *S*yNDB with realistic topologies using large scale simulation and programmable switches. Our evaluations show that *S*yNDB can capture and correlate packet records over sufficiently large time windows (∼4 ms), thus facilitating the root cause analysis of various network faults.

1 Introduction

Large cloud providers need to quickly resolve network faults to meet their high SLA (service level agreement) requirements [35, 66]. However, a data center is a distributed system that is prone to bugs caused by non-deterministic timing of distributed events [43]. Therefore, debugging network failures occurring in modern data centers is extremely challenging due to the scale and complexity of interactions in a dynamic environment. Network faults in modern data center networks are often transient and non-reproducible. A recent study [66] reports that some network faults could not be reproduced even with techniques such as EverFlow [67] or Pingmesh [30]. Further, for a given network fault, the root cause can come in many forms. For example, a packet drop due to a table miss can happen either due to a parity error [66] or due to temporal inconsistency during a network update [36, 54]. Due to the complex nature of network faults, the key bottleneck in quickly resolving them lies in finding the root cause. For example, in AliBaba's production network, 90% of the total time required to resolve a network fault is spent in finding the root cause [66]. Another study from Facebook's network [47] notes that 29% of network failures go without establishing the root cause.

[*]Work done at National University of Singapore
[†]Equal Contribution

In this paper, we focus on the problem of finding the root cause of transient and hard-to-reproduce network faults with many possible root causes. To better understand the difficulty in finding the root cause, let's consider an example scenario of a microburst. When a microburst occurs at a switch port, there is a uniform distribution of packets from different sending hosts responsible for the microburst (more details in §7.2.1). This indicates a fan-in traffic pattern with no single offending flow. Now, there are two possible root causes for such a fan-in to occur. First, the sending hosts themselves are sending the data in a synchronized fashion. In this case, the issue needs to be resolved at the sending hosts by using techniques such as application-level jitter [53]. The other possible cause could be that the sending hosts are already introducing application-level jitter, but still result in a microburst due to non-deterministic interaction with other network traffic (see §7.2.1 for details).

One way to differentiate the root causes is to look at the packets involved in the microburst before it happens. If the packet arrival times at the first-hop switches connected directly to the sending hosts are synchronized, then the root cause is synchronized traffic. Otherwise, the microburst is due to non-deterministic interactions of flows in the network and even more details are required to identify the root cause. Therefore, in order to find the root causes of complex network faults, we believe that a network monitoring system needs to have the following capabilities:

- ***Visibility:*** Observability in space, the ability to observe network-wide metrics at a packet-level resolution (e.g. packet arrivals and departures at all ports for all switches). Aggregate states such as flow level statistics will not be able to provide sufficient visibility to the underlying sequence of events.
- ***Retrospection:*** Observability in time, the ability to be "always on" and look back on past network-wide states *before* the fault has occurred. When the problem is detected, the events leading to the problem would have already occurred and information related to these past events is lost unless additional effort is made to preserve the history. Such a capability is especially necessary to deal with faults that are transient, hard to reproduce and caused by non-deterministic interactions.
- ***Correlation:*** The ability to correlate network-wide events at small timescales. This is required if faults occur due to the interaction of traffic flows across multiple switches. Without this capability, it would not be possible to correlate events from different parts of the network.

Going back to the aforementioned microburst scenario, *retrospection* allows us to look at network metrics before the microburst at the different first-hop switches with *visibility* at the granularity of packet arrivals. *Correlation* allows us to compare these arrival times across the different first-hop switches. If the root cause is not synchronous source traffic, we can again make use of these three capabilities to see what other non-deterministic interactions transpired in the network that led to the fan-in microburst. We elaborate more on this latter root cause in §7.2.1.

Several of the existing approaches [7, 32, 34, 37, 62, 63, 66] provide visibility to a good extent. But they either do not provide retrospection and correlation capabilities or provide them only partially (see Table 1). Since network faults occur unpredictably, providing retrospection typically requires the system to be "always on" in terms of collecting telemetry information. In this sense, NetSight [32], an "always on" version of postcard mode INT [7] comes closest to providing all the three properties with its packet-level visibility and retrospection capabilities. However, it does not provide a strong correlation property since it assumes that the postcards are received in order and out-of-order postcards can be corrected using topology information. Therefore, it can only correlate packets within a single flow at best. A strawman approach to achieving the three properties would be to augment a NetSight like approach with a precise data-plane time synchronization mechanism such as DPTP [38] so that it can now provide strong correlation with synchronized timestamps across the switches. However, such a solution does not scale to today's large data center networks because of the "always on" approach of NetSight in recording telemetry data. While efficient recording of telemetry data is achieved by trigger-based approaches such as INT-MX [7], PathDump [59], BurstRadar [37] and NetSeer [66], they compromise on retrospection since the packet history is not recorded, especially for switches and flows not involved in the trigger.

In this paper, we present, *S*yNDB, a packet-level, synchronized network-wide monitoring and debugging framework that provides all the 3 desired capabilities of *visibility*, *retrospection* and *correlation*. For *visibility*, *S*yNDB leverages programmable data-plane switches to capture packet-level telemetry information at nanosecond time resolution. A common issue with dataplane-based telemetry systems is that the metrics to be captured need to be specified at compile time [51]. To address this issue, *S*yNDB provides an interface to the network operator to specify and change the metrics at runtime *without* having to re-program the switch data-plane. For achieving retrospection, the key trade-off is that "always on" approaches are too expensive, while cheaper trigger-based approaches do not provide strong network-wide retrospection. We find a middle ground with *S*yNDB. Our key idea is to leverage the switch data-plane as a fast temporal storage to perform continuous recording of packet-level telemetry information (*packet records*) over a moving time window (*recording window*). When no network fault is detected, the recording window moves ahead and the older data beyond the record time-length is discarded. When a network fault is detected on any switch, the switch broadcasts a priority message to other switches in the network. On receiving this message, these switches send the packet records from the recent recording window to a monitoring server (collector) for permanent storage. At the monitoring server, the synchronized, network-wide packet-level data enables root cause analysis. In this way, *S*yNDB provides retrospection efficiently by exporting network-wide historical telemetry information only when a fault occurs. To correlate the telemetry information from different switches, *S*yNDB uses DPTP [38] to synchronize the switch data-planes. DPTP is a recently proposed time synchronization protocol for the network data-plane. *S*yNDB is thus able to provide visibility, retrospection and correlation capabilities all under the same framework.
In summary, we make the following contributions:

1. We present the design of *S*yNDB, the first network monitoring and debugging framework that provides all the three capabilities of visibility, retrospection and correlation for finding the root cause of transient and hard-to-reproduce network faults (§3).
2. For flexible visibility, we develop an abstract interface and a run-time support for the operator to configure and dynamically change the operating parameters of *S*yNDB such as fault detection conditions and the recorded metrics, without needing to re-program the data-plane (§5).
3. In order to achieve efficient retrospection capability, we design packet-level telemetry caching mechanism in the data-plane (§3.2). In doing so, we address the challenges of limited data-plane storage by developing compression techniques to minimize memory requirement while still retaining packet-level statistics (§3.2.1). We also develop techniques to further reduce the telemetry information exported for each fault trigger (§3.2.1).
4. We demonstrate the effectiveness of *S*yNDB by showing how it can be used to identify the root cause for transient and hard-to-reproduce network faults (§7). In particular, we demonstrate how *S*yNDB can identify different root causes for the same network fault using two different scenarios involving a microburst.

We have implemented *S*yNDB on Intel Tofino [8] switches using P4. The packet records at the collector are stored in a relational DBMS facilitating debugging of network faults using SQL queries (§4 and §6).

While *S*yNDB is designed to deal with transient and hard-to-reproduce network faults, it can be used as a tool to debug common network faults as well (Appendix B). In addition, *S*yNDB can be considered complimentary to existing frameworks such as INT [7] and NetSeer [66] by providing the capability to perform network-wide event correlation and retrospection.

Table 1: Comparison of *S*yNDB with existing solutions

Solution	Visibility	Retrospection	Correlation
Per-packet Postcards [32]	Packet-based	Yes, Always On	Partial
INT [7]	Packet-based	No, network trigger	Partial
SwitchPointer [60]	Packet-based (Flow-level locality)	Yes, host trigger	Partial
Sketch Frameworks [46, 62]	Flow-based	Past Aggregated Counts, N/A	No
BurstRadar [37]	Packet-based	No, fixed network trigger	No
Speedlight [63]	Switch Metrics	No, Scheduled	Causal Consistency(μs)
NetSeer [66]	Flow-based	No, fixed network triggers	No
*S*yNDB	Packet-based	Recent History, Programmable network triggers	$<100ns$ (DPTP [38])

2 Related Work

Network monitoring literature is wide and extensive, but none of the existing works provide all the three capabilities of visibility, retrospection and correlation required to find the root causes of transient and non-reproducible network faults. Here we mention some of the most relevant works.

Network Based. Query-based streaming telemetry systems like Marple [51], Sonata [31], etc as well as sketch-based frameworks [34, 46, 62] can provide network-wide visibility and retrospection but only with aggregated metrics and without any network-wide correlation capability. *S*yNDB is complementary to these streaming telemetry systems in that it additionally correlates information collected across the network and supports complex fault triggers based on input from the streaming telemetry system. Systems such as BurstRadar [37], Mozart [45], and INT-MX [7] that perform trigger-based data collection cannot provide retrospection. Mozart [45] involves coordination between network devices to start collection of telemetry data while coordination in *S*yNDB is to export already collected network-wide telemetry data. Through switch-local timestamps, INT-MX can only provide partial correlation and no network-wide correlation. Both PathDump [59] and SwitchPointer [60] leverage end-host storage to collect packet-level telemetry information providing retrospection. However, the fault triggers for both of them are only host-based and SwitchPointer provides only partial correlation with its millisecond-level epochs. Speedlight [63] uses synchronized network snapshots to provide microsecond-level casual consistency which is insufficient for correlation required in the example scenario in §1. Further, since it requires advance scheduling of snapshots every few milliseconds, it cannot provide retrospection. NetSeer [66] captures the flows that were affected by certain events like packet drops, path changes, and congestion, and mainly helps in fault localization - where the fault occurred and affected which flow (5-tuple). It only provides flow-level visibility and no retrospection or correlation. NetSight [32] which is equivalent of an "always on" version of postcard mode INT [7] (INT-XD) provides network-wide packet-level visibility and retrospection. However, it does not provide strong correlation capability as it generally assumes in order arrival of postcards. Even if strong correlation can be achieved with mechanisms such as DPTP [38], NetSight's "always on" recording is very expensive and does not scale to multi-petabit data center networks [58]. As we show in §7.3, NetSight can require 5TB or more storage per switch for every hour. The main bottleneck is the limited network bandwidth available for exporting the recorded data from the switches and the slow write speeds of data storage devices where the data would eventually end up. Other than scalability, this approach is also wasteful since network faults do not occur all the time [48] and, more than 60% of data center bugs occur due to the untimely delivery of a single message [43].

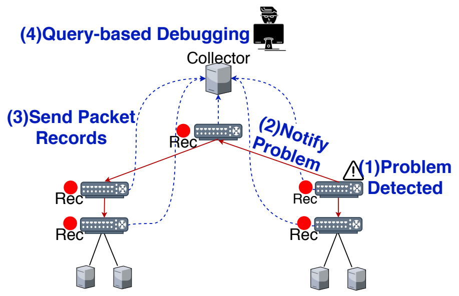

Figure 1: *S*yNDB Overview : Switches continuously maintain packet records, but send them to collector for debugging only upon detecting a problem

End-Host Based. Trumpet [50] performs end-host based monitoring of packets based on specific triggers to perform coordinated monitoring of network events. DETER [44] performs TCP replay for diagnosis of fine-grained TCP events. It constructs switch queues using simulation of the recorded TCP Packets in the end-hosts. Although it can help in debugging obscure TCP performance issues, it cannot diagnose problems inside the network at small time scales. Confluo [40] provides an end-host stack to diagnose network-wide events. However, it cannot provide packet level event correlation inside the network. SIMON [26] applies network tomography technique to reconstruct the switch queuing behaviour based on NIC packet timestamps. *S*yNDB is complementary to these techniques as it provides visibility, retrospection and correlation capabilities inside the network.

Table 1 summarizes recent related works based on their capabilities of visibility, retrospection and correlation.

3 Design

*S*yNDB provides fine-grained (packet-level, nanosecond resolution) and network-wide telemetry information, in a synchronized manner to ensure *visibility*, *correlation* and *retrospection*. *Visibility* and *correlation* are ensured by collecting packet-level telemetry and leveraging data-plane time synchronization. For Retrospection, the key idea is to leverage the switch data-plane as a fast temporal storage for recording packet telemetry information over a moving time window. One of the advantages of recording telemetry information in the switch data-plane is that *S*yNDB can record information about *all* packets within a time window at line rate.

When no network fault is detected, the recording window moves ahead and older telemetry data beyond the window size is discarded. Hence, the recording window always maintains the recent history. When a trigger condition (e.g. packet loss or high latency) is observed at any switch (Step 1), high priority trigger packets are broadcast to all switches (Step 2), as shown in Figure 1. Upon reception of trigger packets, a switch collects all the packet records from the recording window and forwards them to the collector to be stored in a database (Step 3). Once data collection is completed, the operator can debug the fault using packet records collected both before and after the fault (Step 4). Debugging can be performed by operators using SQL queries. Details of the various components of *S*yNDB are explained in the following sections, namely *Visibility* (§3.1), *Retrospection* (§3.2) and *Correlation* (§3.3).

3.1 Visibility

Packet Records. To generate packet-level telemetry data, we record information for each packet that enters a switch. We call this information a *p*-record. Each *p*-record contains 3 basic fields: $[pID, pTime_{in}, pTime_{out}]$. pID is the packet ID which is comprised of a combination of the hash value of the packet headers (5-tuple flow key) and TCP/UDP checksum. The hash value helps in associating packets from the same flow, whereas the checksum helps in uniquely tracking each packet within the flow. Although hash collisions are possible, we can resolve them using topology and timing information. $pTime_{in}$ captures the time when the packet enters the switch. $pTime_{out}$ is the time when the packet leaves the switch. Additional fields are appended by the network operator to a *p*-record to capture statistics, such as queue depth, link utilization, forwarding table version, port counters, etc. An operator can specify such additional fields via *S*yNDB configuration (§5). To identify a *p*-record with a particular flow, the flow hash to 5-tuple flow key mapping could be temporarily stored in NICs (or hosts) and retrieved on demand.

3.2 Retrospection

After a *p*-record is generated in the data-plane for each packet, we store them in a ring buffer array in the switch data-plane. This ring buffer array maintains only the recent *p*-records and we call this the *history* buffer.

Trigger Initiation. While *S*yNDB collects *p*-records for each packet in the data-plane, it requires a trigger to initiate data collection. These triggers can be events such as congestion at a link, packet drops or packet reordering. The trigger conditions are monitored in the data-plane. Once a trigger is hit, the *p*-records can be transmitted to the collector.

To initiate network-wide *p*-record collection, we create a trigger packet to be broadcast (with priority) to other switches through the data-plane. In *SyNDB*, when a trigger condition is hit, a new trigger packet is created. The trigger packet is an Ethernet frame with a trigger header consisting of: 1) Trigger ID, 2) Trigger Type: unique type to classify trigger, and 3) Trigger Time: time when the trigger was hit.

The switches receiving the trigger packets further broadcast it to their neighboring switches and so on. Due to redundancies in trigger packet broadcast (multiple paths in data center topology), unless the network is partitioned, trigger packets reach the entire network. On receiving a trigger packet in the data-plane, the switch stops storing *p*-records in the *history* buffer and instead uses a fixed buffer (we call it *future* buffer) for subsequent storage of *p*-records. If a switch had previously received a trigger packet with the same ID, then it is dropped. The *history* buffer and *future* buffer contains *p*-records of packets before and after the trigger condition respectively.

Conceptually, the size of the *history* buffer that is needed to be stored for debugging purpose depends on the round-trip-time (RTT). In a data center context, recent measurements show that VM-to-VM RTTs vary between 5μs to 100μs [24]. For a packet rate of 1 Bpps, 1 million *p*-record entries could maintain at least 1 millisecond duration of history if the switch pipeline is fully utilized. This translates to packets corresponding to at least 10's of RTTs available for debugging. In practice, the packet rate is usually much lower than 1 Bpps and this translates to a much longer time window. We present our evaluation on the time window in §7.1 and discuss the sizing of *future* buffer to enable continuous recording in §7.3.

***p*-record Collection**. Upon receiving a trigger packet with a new trigger ID in the data-plane, collection of *p*-records is performed. The control-plane initiates the data-plane packet generator which generates collection packets to read the *p*-records from the history buffer. A collection packet can read only one *p*-record each time it traverses through the switch [16], before being forwarded to the collector via a mirror-port. Consequently, we recirculate the collection packet multiple times in the data-pane to coalesce multiple *p*-records into a single packet. This reduces the large serialization overhead, if each packet contained exactly one *p*-record.

Once the number of *p*-records in a packet has reached a threshold (configured by switch control-plane), the collection packet is forwarded to the collector. A collection cycle ends when all the *p*-records stored in the data-plane have been transmitted or sufficient time has elapsed since the trigger. The collection cycle repeats upon a new trigger hit. It is important to note that regular traffic forwarding is not disrupted during the trigger and collection process. For cases when an additional trigger is hit during collection process of the previous trigger, a new trigger packet is generated and collection period is extended (discussion in §7.3). Techniques such as bulk DMA read could also be employed to collect p-records. However, such techniques require additional packetization in the control-plane to forward the whole set of p-records to a controller. The pseudo-code for recording, trigger and collection is shown in Appendix A.

Aggregating Triggers. *S*yNDB supports operator to specify collection to be performed when a set of trigger conditions occur within the historical time window. To support this, upon receiving a trigger packet, *S*yNDB maps the trigger type to a bit-index in a temporal trigger bit-array. It also sends the trigger packet to the control-plane where a timer for each trigger type is maintained, and the bit corresponding to the trigger type is cleared upon expiration. Hence, the temporal trigger bit-array represents the lists of triggers that occurred in the network for the past historical time window. Based on this trigger bit-array value, collection could be configured to be performed. The triggers are customizable by the network programmer, and is presented later (§5).

3.2.1 Reducing Collection Overhead

As *S*yNDB collects data only on event triggers, the amount of data collected is expected to be much smaller compared to continuous monitoring. To further reduce the data collected for each trigger, *S*yNDB implements two mechanisms, a compression scheme on the p-record and a scope reduction on the network level.

p-Record Compression: *S*yNDB performs the following p-record compression while ensuring packet ordering:
1. Compress pID : Consecutive packets from the same flow do not need their pID stored. Instead, a counter corresponding to the last pID is incremented.
2. Compress $pTime_{in}$: Similarly, incoming packets within a time window (e.g. 64 ns) do not need the $pTime_{in}$ stored individually. Instead, a counter for the number of packets received in the past time window is incremented. The packets within the time window are assumed to have uniform inter-arrival times. The same approach is applied to $pTime_{out}$. In the best case, a single (pID, $pTime_{in}$, $pTime_{out}$) tuple plus the corresponding (n-bit) packet counters are sufficient to represent (2^n) packets in the same time window.

Reduction on the Network Level: On detecting a fault, *S*yNDB performs collection of p-records from all switches in the network. This may burden the collector with unnecessary data if the network is huge and the root cause is localized. We mitigate this by a simple technique. Each switch maintains a list of links from which it received the packets for the historical time window. Upon fault trigger, instead of broadcasting trigger packets, they are selectively multicast to only the links from where the packets were received in the recent recording window. The intuition behind this is that we are interested in where the current set of packets came from. This solution provides the ability to trace every packet which appeared in the trigger switch to its source, while reducing the number of switches involved in the collection.

3.3 Correlation

Time-synchronization. *S*yNDB uses global timing information to correlate packet records from multiple switches to help construct an accurate network-wide ordering of events. Hence, the data-plane clocks (used for $pTime_{in}$ and $pTime_{out}$) across switches are synchronized to a fine granularity to avoid timing inconsistencies. To rightly correlate established events in distributed systems using "happened before" relation, causal consistency [41] is essential. In *SyNDB*, since a trigger event is the captured reference point, causal consistency is the right model to correlate events happened before the trigger event. We derive the necessary condition to ensure causal consistency below.

Let's consider two directly connected switches X and Y, with internal clocks C_X and C_Y respectively. We denote the synchronization error $|C_X - C_Y|$ between the internal clocks by T_{err}. Packet A is transmitted from switch X to switch Y. Packet A leaves switch X at $TimeOut_X$, and enters switch Y at $TimeIn_Y$, after a propagation delay D. $TimeOut_X$ corresponds to the time packet A enters the egress pipeline in switch X after queuing. This is the latest available time in the data-plane for a packet [16]. Similarly, $TimeIn_Y$ corresponds to the time packet A enters the ingress pipeline at switch Y. Consequently, propagation delay now becomes the sum of egress pipeline delay, packet deparsing delay, MAC processing delay, and wire delay.

$$D = EgressDelay + DeparserDelay + MACDelay + WireDelay \tag{1}$$

To ensure *causal consistency* between packet records, we should see packet A leave switch X before reaching switch Y. In short, $TimeOut_X$ should be less than $TimeIn_Y$. This will be true if the synchronization error between the internal clocks is less than the propagation delay.

$$T_{err} < D \tag{2}$$

If the condition stated in this equation can be met, we can ensure consistency between any set of packets transmitted between two adjacent switches.

Previous works on network time synchronization have shown that the T_{err} between neighbouring switches is in the order of tens of ns [38, 42]. Additionally, real world data shows that D between two adjacent switches ranges between 360 ns to 1900 ns under varying traffic conditions [38]. Thus it is possible to achieve causal consistency between adjacent switches, using current time synchronization techniques. The same principle can also be extended between switches separated by several hops in the network. In such cases, we observe that the increase in propagation delay is higher than the increase in T_{err}, thus ensuring consistency between switches across multiple hops.

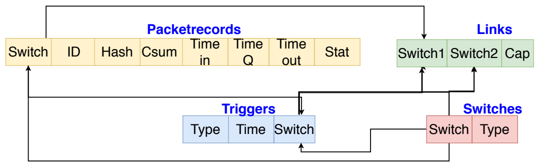

Figure 2: *S*yNDB Debugger Database Schema

4 *S*yNDB Debugger

The collector composes of multiple servers which store and analyze the *p*-records. The *p*-records are stored in a relational database (RDBMS) which allows the *p*-records to be queried using SQL. The collector also stores information regarding the trigger events, network topology, and position of switches within the topology. Before storing *p*-records in database, *S*yNDB performs hash collision removal using topology and timing information. The hash collision removal is performed using a simple heuristic based on the ground-truth of the queuing time of a *p*-record and the identity of the switch. Duplicate hashes found are then re-assigned with other *p*-record ids. The *p*-records are organized using tables in a relational database as shown in Figure 2.

1. Packetrecords: This table stores basic and custom fields within each *p*-record. Each *p*-record stores: 1) Switch ID, 2) Packet ID, 3) Packet Hash, 4) TCP/UDP Checksum 5) Time In, 6) Time Queued, 7) Time Out and, 8) Operator-specified statistics. Note that Packet ID is just a combination of packet hash and the checksum. They are stored separately to facilitate flow-level queries as well as packet-level queries.

2. Triggers: This table stores information regarding each trigger event. Each trigger event stores: 1) Trigger Type, 2) Trigger Time, and 3) Trigger Origin Switch. This enables *S*yNDB to classify network faults based on the trigger type.

3. Links: This table stores the topology of the data center, as specified by the network operator. We do not infer the topology from the packetrecords table because it is possible for some links to have zero utilization. Each link stores the endpoints and the link capacity.

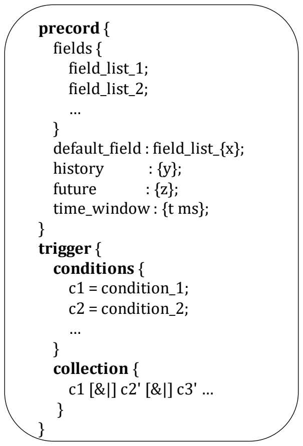
4. Switches: This table stores the position of a switch in the topology, e.g. ToR, Aggregation, Core, etc.

To determine the root cause of a network fault, we use SQL queries on the above tables. For example, in the case of an incast, culprit packets and their routes can be obtained by combining information from packetrecords, triggers, and links tables. The output of these queries can also be used to replay or build dashboards using tools [6, 12, 17], which are beyond the scope of this work.

We list some example queries below (scenarios in §7.2):

1) List the events in the trigger switch using:
```
Select * FROM packetrecords JOIN triggers
         ON packetrecords.switch = triggers.switch;
```

2) List the packets in the trigger switch and the routes taken:
```
Select * FROM (packetrecords as P) WHERE id
         IN (select id from packetrecords JOIN triggers
         ON p.switch = triggers.switch
         AND p.time_in<triggers.time) ORDERBY time_in ASC;
```



```
precord {
  fields {
    field_list_1;
    field_list_2;
    ...
  }
  default_field : field_list_{x};
  history       : {y};
  future        : {z};
  time_window : {t ms};
}
trigger {
  conditions {
    c1 = condition_1;
    c2 = condition_2;
    ...
  }
  collection {
    c1 [&|] c2' [&|] c3' ...
  }
}
```

Figure 3: *S*yNDB Configuration Syntax

5 *S*yNDB Configuration

*S*yNDB provides an interface for defining *p*-records and triggers for programmable switches. The programmer configures the following parameters in *S*yNDB: 1) the network statistics (fields) to be collected in *p*-records, 2) the number of *p*-record entries to be collected, and 3) the trigger (fault) conditions to initiate a collection of *p*-records. The fields specified in the configuration could be: 1) switch-provided metadata (queue depth, ingress port, egress port), 2) packet header data (flow-id), and 3) data that is computed and stored in user metadata by the programmer (link_utilization, counters, EWMA). The *S*yNDB configuration is compiled, then translated to P4 and finally embedded with the original switch P4 program. Figure 3 shows the interfaces to define *p*-records and trigger conditions.

A *p*-record defines a list of field_lists. Each field_list contains one or more (metadata) fields [13] from the Packet Header Vector (PHV) [16] supported by the switch architecture and defined in the user's P4 program. A "default_field" list is specified by the programmer which is the active field_list to be included in each *p*-record. The current *active* field_list can be changed during runtime. The "history" refers to the total size of the *history* buffer, while "future" refers to the size of the *future* buffer. The "time_window" is the target historical window (in milliseconds), and this is used to maintain the trigger and broadcast window. The user declares a list of trigger conditions, which are predicates operating on header/metadata fields. For example, meta.link_utilization > 90. Finally, based on the triggers declared, the collection can be configured to be performed using individual triggers or a combination (AND(&), OR(|) of multiple triggers defined). For example, let c be the local trigger condition and c' be a trigger condition happening elsewhere in the network. A representation like $c1\&c2'$ would trigger a coordinated collection by a switch A only if condition $c1$ occurs at A, and $c2$ has occurred in another switch in the network. Defining triggers conditions and collection could be based on several

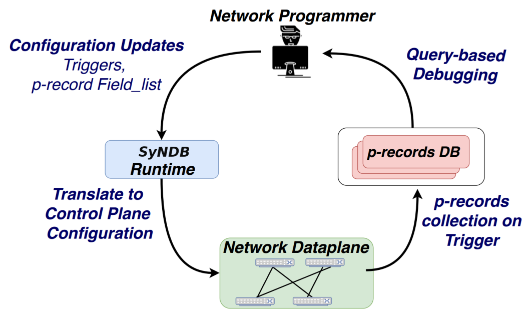


Figure 4: *S*yNDB from Programmer's perspective

network metrics in the network like packet drop, high packet queuing, loops, etc. Additionally, it could be based on well documented symptoms and alarms observed by network operators [28, 43, 47].

***SyNDB*-Runtime**. In practice, there is a need to make changes to the *p*-record structure and trigger configurations while *S*yNDB is running without the need to recompile and load a new P4 program. *SyNDB*-Runtime facilitates changing the configuration in the following ways: 1) Adding a new field_list or editing the active field_list, and 2) Adding/removing trigger conditions. Note that these changes are restricted to the available PHV contents in the data-plane as there is no modification to the parser of the underlying P4 program.

When the *S*yNDB configuration is compiled, the compiler enumerates all the PHV contents (packet headers, switch and user-defined metadata) of the P4 program. It then creates template tables with actions for each PHV container to be stored in the *p*-record. This facilitates the runtime to dynamically add/remove the fields to be recorded in each *p*-record. The fields could be TCP sequence number, TCP flags which are part of packet headers, or ingress_port, queue_depth, etc. which are part of the switch meta-data. The field to be added cannot be a metric (e.g. EWMA) that is not defined or a packet header that is not parsed by the already compiled P4 program. Since PHV contents are limited, enumerating and storing them in actions do not significantly increase data-plane resource consumption. The maximum bytes in a *p*-record and the number of *p*-record entries (*recording window*) is fixed at compile-time based on the available hardware resources (stateful ALUs and SRAM). To facilitate addition/removal of trigger conditions at runtime, *S*yNDB configuration compiler uses similar enumeration technique and generates range-based match-action tables. Since collection is performed based on the trigger bit-array value, this value is added/modified based on the collection condition changes. Additionally, *SyNDB*-Runtime updates the collector each time the *S*yNDB configuration is changed, to ensure that *p*-records are stored correctly.

Figure 4 summarizes the *S*yNDB workflow. A network programmer configures the statistics to be recorded and the fault triggers. The configuration can be continuously tweaked to suit the statistics that the programmer wants to keep an eye on using *S*yNDB-Runtime.

6 Implementation

***S*yNDB Dataplane.** We have implemented *S*yNDB on Intel Tofino [8] switches using P4 ($\sim$1900 LoC). We use DPTP[1] for time synchronization between switches. We use DPTP since it is implemented on PSA [16] and provides a global timestamp in the data-plane. We store the baseline contents of *p*-record in both ingress and egress pipeline. Ingress pipeline maintains the write_index of the *history* ring buffer array upon a packet arrival and stores the *pID* and $pTime_{in}$. Egress pipeline stores $pTime_{out}$ and custom field_list to be captured. *pID* is a combination of 16-bit flow hash, and 16-bit TCP/UDP checksum. $pTime_{in}$ is a 32-bit global timestamp (at nanosecond granularity) of the packet when it enters ingress pipeline of the switch. On the other hand, $pTime_{out}$ is a 24-bit field which captures time when the packet enters egress pipeline. A 24-bit value allows to calculate upto 16 ms of queuing. The basic uncompressed *p*-record is 11-bytes in size. To implement compression, we maintain separate 8-bit counter array associated with *pID*, $pTime_{in}$ and $pTime_{out}$. Trigger conditions are implemented using TCAM tables which create a trigger packet upon match. A trigger packet is created by cloning the current packet and inserting a new header type for trigger packet after stripping the payload and other headers. By using a TCAM match for the trigger table, different aggregate conditions of individual triggers can be supported using wildcards. We implement *S*yNDB control-plane, which performs : 1) Time-keeping of temporal trigger bit-array, 2) Updating multicast port-group, 3) Set up packet generators for *p*-record collection.

***S*yNDB Runtime.** We have implemented the compiler for *S*yNDB configuration using Rust ($\sim$4000 LoC). It takes as input the configuration and the switch P4 program, and generates a P4 code that implements *p*-record storage, trigger conditions and collection logic. *p*-record storage and trigger conditions are executed using stateful ALUs. Additionally, the runtime environment (implemented in Python) accepts commands to modify configuration such as: 1) changing the active field_list, 2) adding new field_list, and 3) adding/removing trigger conditions. These configurations translate to control-plane configuration updates of the composed switch P4 program. The runtime supports addition of new fields to *p*-records, by varying the recording parameters of the set of pre-enumerated PHV contents from the control-plane. A similar approach is also used for modifying trigger conditions. The maximum set of trigger conditions and contents in *p*-records are specified during the generation of the P4 program.

Finally, we implement the collector using `n2disk` utility (with *PF_RING* [15]) to store collection packets as PCAP files in the local disk. Additionally, we implement a Python program to parse the PCAP files, decompress and store individual *p*-records in a MySQL database. The collector also

Figure 5: Evaluation Topology Testbed

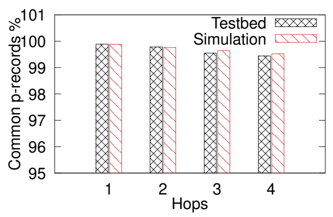

Figure 6: Comparison of testbed and simulator for common *p*-records

takes as input the *S*yNDB configuration for initializing the database. Each time the active field_list is modified through the *S*yNDB runtime, the update is passed on to the collector.

7 Evaluation

We evaluate *S*yNDB using a hardware testbed as well as large-scale simulations. Our hardware testbed consists of 4 physical servers, and 2 Intel Tofino Wedge100BF-32X switches [18]. The servers and the switches are virtualized to create a fat-tree topology [19] (see Figure 5(a)). Switches S1-S5 are virtualized on the first physical switch ("Tofino A") using 10G loopback links while switches S6-S10 are virtualized on the other physical switch ("Tofino B"). Each virtual switch is configured to have 10K and 5K *p*-records in the history and future buffer respectively. Each *p*-record entry is 16 bytes in size. Figure 7 shows the *S*yNDB configuration that we use in the testbed-based evaluation. Additionally, we synchronize each virtual switch's data-plane to S10 using DPTP (see Figure 5(b)).

For large-scale simulations, we have built a packet-level simulator[2] in C++ (~6K LoC) that implements low-level packet transmission and forwarding behaviors for hosts, links and switches. To validate our simulator, we compare its results with those from the testbed for the following experiment. For the topology in Figure 5(a), we send 10 Mpps CBR traffic along the path S1-S4-S10-S9-S7 with each switch storing 10K *p*-record entries. Switch S7 generates a trigger after receiving 10,000 packets which is then broadcast to other switches to initiate *p*-record collection. Based on the *p*-records available at the collector, in Figure 6, we plot the percentage of common *p*-records seen by other switches compared to those seen by S7. We observe that the testbed and simulation results match each other closely – due to hop delays experienced by the trigger packet, the percentage of common *p*-records reduces slightly with increasing number of hops from S7.

Figure 7: *S*yNDB Configuration for Evaluation

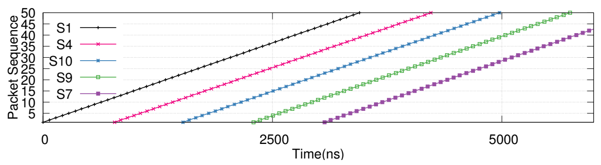

Figure 8: Sequence of packet arrival for 10Mpps CBR traffic

The evaluation is divided into three parts. In §7.1, we evaluate *S*yNDB for consistency in *p*-records and large scale operation. In §7.2, we present different network debugging scenarios with one in full details. Finally, we evaluate the overhead of *S*yNDB in §7.3.

7.1 Design Validation

In this section, we evaluate the *S*yNDB for its ability to provide consistent *p*-records at packet-level granularity and to provide retrospection and correlation at scale.

7.1.1 Consistency of *p*-records

To ensure that the *p*-records captured by *S*yNDB are consistent, the time synchronization error should be less than the propagation delay between adjacent switches (equation (2)). In our hardware testbed (Figure 5a), we measure DPTP synchronization error as well as the propagation delay between adjacent switches. We observe that the worst case synchronization error is less than 50 ns while the propagation delay varies between 400-450 ns. Thus, synchronization error is much lower than the propagation delay between two switches and hence captured *p*-records should be consistent with the ground truth. To validate this further, we send a CBR traffic of 10 Mpps (limited due to 10G host links) along the path S1-S4-S10-S9-S7, with each packet annotated with a sequence number along. The switches record the sequence number of each packet in the corresponding *p*-record. After receiving 5000 packets, switch S1 generates a trigger packet (trigger *d* in Figure 7) which when received, each switch sends the *p*-records to the collector. In Figure 8, we plot the packet sequence number against time for a sequence of 50 packets. We observe that every packet is recorded in the next switch

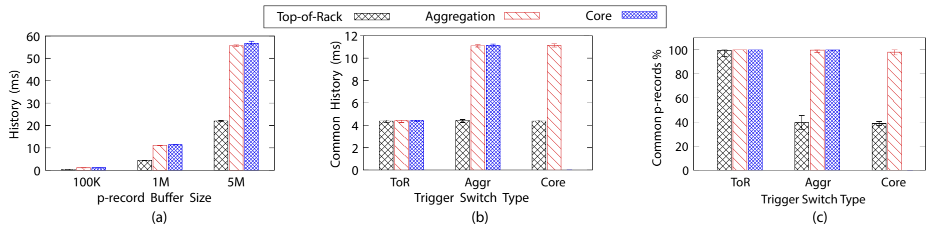

Figure 9: Simulation results for history captured at the trigger switch, correlation history and percentage of common p-records for different trigger switch types

only *after* it has left the previous switch. Furthermore, the timestamps increase linearly. This behavior confirms that the *p*-records captured by *S*yNDB across all the switches in the network are consistent and at expected intervals.

7.1.2 Retrospection and Correlation at Scale.

We perform large scale simulations to evaluate how much retrospection and correlation *S*yNDB provides in realistic traffic scenarios.

Simulation Setup. All simulation runs were done on a k=24 fat-tree topology (720 switches, 3456 hosts) with 100G links. The network has a total bisection bandwidth of 172.8 Tbps. For generating packets from the hosts, we use distributions of packet size and inter-packet gap as measured by Benson et al. [20] from a data center hosting web applications. We configure the traffic pattern such that 75% of total traffic is intra-rack as observed in cloud datacenters [20]. On top of these basic traffic characteristics, we add additional incast traffic such that 30% of the host links experience 100% utilization for 10% of total simulation time. The inter-packet gap distribution from Benson et al. is originally for 1 Gbps switch links. We scale it to adjust the load on 100 Gbps host links such that the average utilization (over 100 ms interval) is about 34%, with the busiest 5% of links experiencing about 42% utilization. These utilization characteristics are similar to those reported by Facebook [55]. All switches are configured with a *p*-record history buffer of 1M entries. We also configure a hop delay of 1 μs per switch such that the maximum RTT across the network (inter-pod) is $\sim$11.5 μs [21]. Each simulation run simulates 100 ms of network run time and delivers about 5.2B packets. Within each run, we generate 50 triggers on randomly chosen switches across the three switch types – top-of-rack (ToR), aggregation (Aggr) and Core. The following results are based on the aggregate data from 10 independent simulation runs.

We use two metrics to compare *p*-record buffers between the triggering switch and the upstream switches from which it receives packets: (i) Common *p*-records (Figure 9(c)): the percentage of common *p*-records between the trigger switch and the upstream switches. (ii) Common History (Figure 9(b)): the time difference between the latest and oldest common *p*-record. While the first metric quantifies the correlation using the similarity of *p*-records between the switches, the latter reflects the ability of *S*yNDB to perform retrospection.

For triggers originating at the ToR switch, the maximum common history that can be captured at other upstream switches is limited by the history at the ToR switch ($\sim$4 ms). Note that $\sim$4 ms history is worth $\sim$350 RTTs since maximum RTT in our setup is $\sim$11.5 μs. For triggers originating at the Aggr/Core switches, history of $\sim$11 ms is recorded. This is expected since the ToR switches experience higher packet rates (due to 75% intra-rack traffic) and hence provide smaller history relative to Aggr and ToR switches.

As for percentage of common *p*-record, we can capture $\sim$100% of common *p*-records in the upstream switches in many cases. The exceptions are for cases where the trigger switch is the Aggr/Core. The percentage of common *p*-records with other ToR switches is $\sim$40% since the *p*-records in upstream ToR switches are quickly overwritten by newer intra-rack packets. Note that in a fat-tree topology a packet passes through exactly one Core switch. Hence, if the trigger switch is a Core switch, there is no upstream Core switch.

Figure 9(a) shows the time window history that can be recorded for different *p*-record buffer sizes.

Takeaway: The simulation results show that the amount of history that can be captured depends on the incoming packet rate and the buffer size. For the traffic load and distribution used in the evaluation, *S*yNDB is able to consistently capture common *p*-record across different upstream switches. The time history available for retrospection varies from 4ms to 11ms using a buffer size of 1M *p*-record.

7.2 Network Debugging Scenario

In this section, we show how *S*yNDB can be used to debug one of the most common transient network faults, namely microburst [37, 47]. The evaluation uses the same configuration setup as defined in Figure 7 on the hardware testbed in Figure 5. Each *p*-record is configured to contain the custom "field_list: SyNDB_scenario". It contains three metrics : 1) Ingress Port 2) Link Utilization and 3) Drop Counter.

Ingress port of a packet is provided by the switch meta-data. Link utilization is calculated over a window of 10 μs in the data-plane using a low-pass-filter. Drop counter is the number of packets which missed the forwarding table. Additionally, we configure *S*yNDB to perform collection of *p*-records based on three triggers : (1) High Queuing Delay (trigger *a*), (2) Table Lookup Miss (trigger *b*) and (3) Network Configuration Update (trigger *c*). Data collection is initiated when a switch receives trigger *a* or a switch receives both triggers *b* and *c*. In each of the following case studies, we generate data and control traffic to emulate the corresponding network faults. The host data traffic is generated using MoonGen [23].

7.2.1 Microbursts

Microburst is a common problem in data centers where congestion is caused by a short burst of packets lasting for at most a few hundred microseconds [56, 65]. Traffic bursts occur due to various reasons like application traffic patterns (e.g. DFS, MapReduce), TCP behavior and also NIC-offloads (segmentation, receive) [39]. The complex interactions and traffic patterns make microbursts debugging extremely complicated. It is necessary to find the root cause to determine how the issue should be resolved.

In this experiment, we demonstrate how two microburst events that are detected by the same trigger can be attributed to different root causes using *S*yNDB. In one scenario, the microburst is due to incast of synchronized application traffic. In the other scenario, the microburst is caused by the interaction of uncorrelated flows with different source-destinations.

Synchronized Application Traffic. We consider the commonly known fan-in traffic pattern of data center networks exhibited by applications such as MapReduce and Distributed File System (DFS). This is an incast traffic pattern where many sources transmit to a small number of destinations within a short time window. These short bursts of traffic increase the queuing delay at microsecond time-scales. The challenge in identifying the root cause of such microburst is that many sources contribute to the total traffic and the burst occurs only for a very short time.

We setup the experiment with hosts H1 to H6 sending data to H8 as shown in Figure 10. Each host sends a burst of 10 1500-byte packets at an average rate of 1 Gbps to H8 via ToR switch S7. All links have capacity of 10 Gbps. In the experiment, the sources started in an asynchronized fashion, but over time transmissions from different hosts can synchronize their transmissions causing sudden spikes in queuing delays on switch S7, triggering the trigger *a*. Such synchronization of periodic messages over time has been known to occur in routing message updates [25].

With *S*yNDB, to determine if the issue of microburst is caused by synchronized fan-in traffic, a query of the queuing delay at S7 together with the packet arrival information at the ToR switches before the microburst detection can be performed at the collector as shown below:

```
SELECT switch, ingress_port, time_in  FROM packetrecords
    WHERE id IN (SELECT id FROM packetrecords AS A
    JOIN triggers as T  ON (A.time_in < T.time
    AND A.switch = T.switch)) AND switch
    IN (SELECT switch FROM switches WHERE type = "tor");
SELECT time_queue FROM packetrecords where switch=7;
```

Listing 1: Query to list the packet arrival times at ToR switch ports and queuing delay at S7

The answer to the query is shown in Figure 10. The top

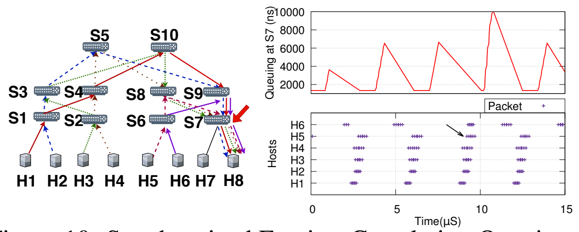

Figure 10: Synchronized Fan-in : Correlating Queuing at S7 and Packets arrival sequence at ToR Switches

right plot in the figure illustrates the queue buildup over time. When we correlate the packet arrivals from different hosts before the bursts occurred, we see that the packets that make up the bursts are transmitted by hosts H1 to H6 synchronously and reach S7 at about the same time. The root cause of this microburst from H1 to H6 can thus be determined as host-based synchronized traffic.

Non-Synchronized Application Traffic. Synchronized incast is just one possible cause for microburst. As discussed by Shan et al. [57], there are many other scenarios for microbursts. In this experiment, we generate microburst events through the interaction of traffic from multiple hosts that are not synchronized at host. However the individual flows, due to different queuing behaviour across hops (due to cross-traffic), arrive synchronously at the bottleneck link. In this scenario, hosts H1 to H6 send bursts of 10 packets at an average rate of 1Gbps to H8. A randomized delay of upto 5μs is added before sending a burst to minimize traffic synchronization. In addition, another flow sends a burst of 10 packets every 1ms of packets from H9 to H6 (through S1-S4-S5-S8-S6) at an average rate of 2Gbps. Note that this flow (H9 - H6) runs asynchronously and does not travel through the bottleneck switch (S7) where the microburst occurred. Nevertheless, we observe microbursts on the link from S7 to H8.

A query of the queuing delay at S7 together with the packet arrival information is shown in Figure 11. The shaded portion in the bottom right plot shows the duration in which the flow from H9 to H6 can occur. The information provided by *S*yNDB shows that the microburst is likely due to a combination of factors, namely (1) the synchronization of the bursts among the pair of flows from H1 & H2, H3 & H4 and H5 & H6; (2) the burst from H9 to H6 arriving just before the bursts from H1 & H2 in S1 and the bursts from H3 & H4 in S5. This causes a queue buildup resulting in packets from H1 to H6 arriving at S7 at about the same time. The root-cause is thus due to interaction of network queuing effect caused by cross traffic.

Additional Use Cases: Table 2 presents a list of additional use-case scenarios for *S*yNDB. We have experimentally evaluated (on the hardware testbed) the use-cases for debugging network faults related to network configuration updates and transient load imbalance whereby the use of multiple triggers is demonstrated. The details are provided in Appendix B.

Takeaway: The scenarios we presented show that in or-

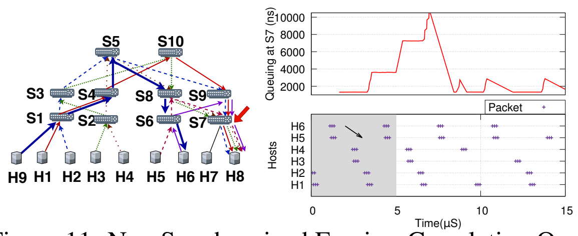

Figure 11: Non Synchronized Fan-in : Correlating Queuing at S7 and Packets arrival sequence at ToR Switches

Table 2: Use-cases of *SyNDB*

Fault and Description
Routing Bugs. Bugs in the routing protocols, for example, synchronization between LDP IGP protocols [10] could be due to timing issues such as race conditions [49]. Since *S*yNDB provides causal consistency, it helps in correlating different protocol packets and to narrow down the root-cause.
App Timing Bugs. *S*yNDB can be used to debug timing bugs in distributed systems (Hadoop [1], ZooKeeper [2]) where more than 60% of the bugs are due to a single packet [43]. In these timing bugs, a dead-lock is caused by a missed or delayed message. *S*yNDB can help to identify and track message lost or delayed by raising trigger conditions when it observes reordering or drops of certain packets.
Traffic Pattern Analysis. *S*yNDB collection could be triggered at regular intervals to study and profile traffic patterns [64] and to optimize cloud applications. In this case, *p*-records could contain the flow-id (5 tuple) to understand the interactions on a flow-level granularity.
Routing Loops Routing Loops can be detected by observing duplicate *p*-record ids at the switches.
Network Configuration Updates. Refer Appendix B
Transient Load imbalance. Refer Appendix B

der to identify the root cause of complex network faults, it is often necessary to have the *visibility* into packet statistics, the ability to look at past events (*retrospection*) and the timing information to correlate observations across switches (*correlation*). While NetSight [32] and INT-MX [7] can detect routing loops and bugs, NetSight has higher collection overhead due to its "always on" nature (§7.3). Also, while NetSight cannot perform *correlation* across the network, INT-MX cannot perform *retrospection* to identify whether the root-cause of such issues is due to configuration, race condition, etc. While Marple [51], BurstRadar [37] can detect microbursts, they do not provide *correlation* and packet-level *visibility* to inspect the root-cause of microbursts due to timing related issues like synchronized traffic. While it is possible to analyze traffic patterns in a coarse manner using systems like Speedlight [63] with tpprof [64], *S*yNDB can be used to understand microsecond-level changes in traffic.

7.2.2 Partial Deployability

*S*yNDB-enabled switches can be deployed incrementally with each new switch providing additional visibility into the network. To maximize effectiveness, deployment can start from ToR switches where most congestion events occur [65]. For DPTP synchronization, links can be added between adjacent ToR switches, which is not a complex undertaking [61]. With just *SyNDB*-enabled ToR switches, issues like microbursts(§7.2.1), application timing bugs can be debugged fully with just the ToR switches' *p*-records, while issues like routing loops, bugs, load imbalance and configuration updates can be partially debugged if the ToR switch is involved in the fault. In such cases, to infer the core network's states, network tomography techniques [26] can be employed.

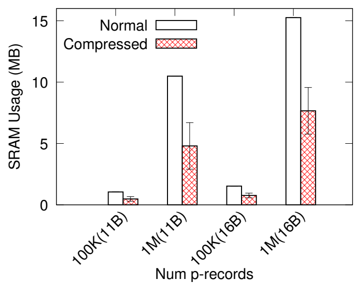

Figure 12: SRAM consumption for different packet rates and *p*-record size

7.3 *S*yNDB Overhead

SRAM Overhead. We estimate the total amount of SRAM consumption used by the *history* buffer based on a compressed *p*-record size of: 11 bytes (baseline compressed *p*-record), 16 bytes (evaluation configuration in Figure 7 + baseline compressed *p*-record) in Figure 12. We plot the SRAM consumption for different profiles in Figure 7. For example, "100K(11B)" represents 100K precords with 11-byte baseline *p*-record.*S*yNDB consumes an average of ∼5 MB while consuming ∼10 MB of SRAM to record 1 Million uncompressed baseline *p*-records respectively. For 16-byte *p*-records, we observe the SRAM overhead to be about ∼7 MB on average.

Compression saves 50% of SRAM memory on average, and can save upto 80% depending on the traffic pattern. The SRAM consumption can be easily accommodated by latest switching ASICs [3, 4, 11] which contain SRAM greater than 100 MB. Recent studies [65] have observed high utilization only across a few switch ports during congestion events. Thus the pipeline utilization is usually much lower than its capacity. To support lower packet rates like <500 Mpps, *S*yNDB uses about 2 MB of SRAM. The programmer can trade-off between the total capture duration and the memory budget.

Collection Overhead. We measure the overhead incurred at the switch to collect the *p*-records. To perform collection, the switch control-plane sets up packet generator in the data-plane packets to inject collection packets at 100 Mpps. The collection packets typically coalesce *p*-records (64 *p*-records per packet) by recirculation. Collection of 10000 compressed *p*-records requires 104 collection packets on average. We observe that it takes a total time of 245μs to evict the *p*-records. Also, it takes only 45μs to collect these packets in the data-plane using packet generator and recirculation, with the majority of the time being signalling from the control-plane to start the packet generator. We believe this timing overhead would be reduced drastically in upcoming architectures [9] which support triggering packet generation from data-plane events.

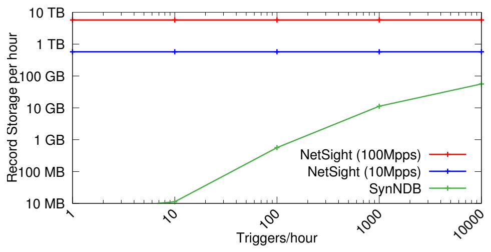

Figure 13: Storage overhead comparison with NetSight

The overall pipeline overhead incurred is about 100 Mpps and bandwidth consumption is limited to re-circulation port and the collection forwarding port (e.g. mirror port), thus not affecting regular data-plane traffic. In order to collect 1M compressed *p*-records (1ms history at 1 Bpps), it takes only about 323μs on an average. Out of this, it takes 123μs to recirculate 7800 packets to collect the compressed *p*-records, and 200μs to trigger the packet generation. *S*yNDB can resume recording (in *history* buffer) after half the *p*-records are collected in about 260μs. This means *S*yNDB can ideally support upto $\approx$ 6000 triggers/sec. Note that, *S*yNDB has a *future* buffer to store *p*-records once trigger condition is met. To support continuous recording of all future events, the minimum duration the *future* buffer needs to capture is 260μs.

With a 1ms *history* buffer, the ability to support 1000 triggers per second without any break in recording is sufficient to enable continuous monitoring. Hence, *S*yNDB can capture microbursts occurring every few milliseconds [65] as well as network incidents separated by hours [47].

We observe that the latency to receive, decompress and store the *p*-records in the collector takes few hundreds of milliseconds per switch on a single collector server. Complex queries with several join operations take several seconds or more. Query optimizations are beyond the scope of this work.

Comparison with Other Debugging Tools. Next, we compare the total storage overhead of *S*yNDB to that of NetSight [32]. NetSight creates a post-card by stripping the packet payload, and attaching switch ID and ingress port to the post-card. We compare the storage overhead incurred at the collector from a single switch for *S*yNDB compared to NetSight for a period of 1 hour. *S*yNDB performs collection only upon fault triggers while NetSight performs collection throughout the network operation. In Figure 13, we plot the overall storage incurred for an hour of network operation with increasing number of triggers/hr. We assume both NetSight and *S*yNDB store 16-byte post-cards/*p*-records per packet. Irrespective of the frequency of faults, NetSight collects about 500 GB and 5 TB of data per hour from a single switch at 10 Mpps and 100 Mpps packet rates, respectively. *S*yNDB on the other hand collects only 56 GB per hour for 10000 triggers/hr and 1 Bpps data-plane traffic. This means, when *S*yNDB monitors packets at the maximum rate (e.g. 1.6 Tbps), the total fraction of data exported for debugging is 0.01%.

Switch Resource Overhead. We evaluate the total hardware resource consumption of *SyNDB* (with configuration shown in Figure 7) compared to the baseline switch.p4 [14]. switch.p4[3] is a baseline P4 program that implements various common networking features applicable to a typical data center switch. As we implement *S*yNDB along with DPTP, we show the total resources consumed by all the components (switch.p4, DPTP and *SyNDB*) in Table 3. The majority of resources required for *S*yNDB arise from the need to store *p*-records in the data-plane. We observe that *S*yNDB consumes 33% of the stateful ALUs and 15% of the SRAM to store *p*-records and trigger conditions in the evaluation configuration. Thus, *S*yNDB can be implemented on top of switch.p4 in programmable switch ASICs available today.

Table 3: Hardware resource consumption of *S*yNDB compared to the baseline switch.p4

Resource	switch.p4	DPTP [5]	*S*yNDB	Combined
SRAM	29.58%	2.29%	15.31%	47.18%
Stateful ALU	14.58%	8.83%	33.33%	56.74%
VLIW Actions	36.72%	4.43%	6.25%	47.4%
TCAM	32.29%	0%	1.04%	33.33%
Hash Bits	34.74%	3.99%	14.14%	52.87%
Ternary Xbar	43.18%	0%	0.63%	43.81%
Exact Xbar	29.36%	2.34%	12.5%	44.2%

8 Conclusion and Discussion

In this paper, we design and implement *SyNDB*, which to the best of our knowledge, the first system providing packet-level *visibility*, *retrospection* and *correlation* to tackle transient faults. *S*yNDB leverages data-plane time synchronization and data-plane storage (SRAM) to temporally store packet records which can be exported to aid in debugging upon network faults. It provides the unique ability of looking back at the trace of events before the occurrence of a network fault. Additionally, since it performs collection only upon occurrence of programmable event triggers, it exports only a small fraction of the data-plane traffic for targeted debugging. We study case-studies which uncover *S*yNDB's capabilities in finding the root cause of transient faults.

We believe that *S*yNDB's capability goes beyond debugging. A network device's configuration can be used along with network traces to create a "replay" of the network fault. This in turn, can be used to form regression test suites. Finally, it will also be interesting to develop tools that provide dashboards, query suggestions and an assistant (Similar to Dogga et al. [22]) to network operators using AI techniques to facilitate faster debugging.

B More Network Debugging scenarios

B.0.1 Network Configuration Updates

Networks operate in a dynamic environment where operators frequently modify forwarding rules and link weights to perform tasks from fault management, traffic engineering, to planned maintenance [52]. However, dynamic network configurations are complex and error prone especially if they

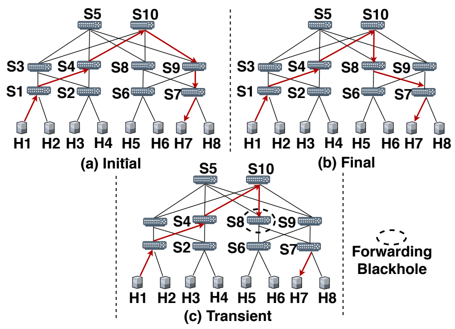

Figure 14: Network Update Scenario causing a Forwarding Blackhole at S8

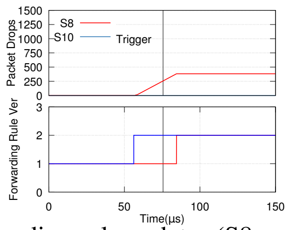

Figure 15: Forwarding rule updates (S8 and S10) leading to drops at S8

involve several devices. For example, updating the route for a flow(s) can lead to unexpected packet drops if the updates are not applied consistently or efficiently [36, 54]. In this case study, we use *S*yNDB to identify whether a transient error is due to a network update or localized hardware fault.

For the experiment, we add forward_rule_version to the *field_list SyNDB_scenario*. We assume that each forwarding rule indicates a version number and route based on destination MAC address as shown below.

```
table_add forward
    send_to_port ethernet_dstAddr <dstMac> =>
    output_port <num> entry_ver <num>
```

A transient forwarding blackhole occurs when an out-of-order execution of a network update gives rise to non-deterministic network behavior leading to temporary packet loss [29]. We emulate the transient blackhole using a setup shown in Figure 14. Figures 14(a) and (b) depict the initial and final state of the network after the updated route. The routing of a flow from H1 to H7 is updated by rerouting traffic from S10 to S8. However, transitioning from configuration (a) to (b) requires updates to both S10 and S8.

In this network update, a new rule to route the flow needs to be added to S8 first and then S10 needs to update the policy to route the flows from S9 to S8. If the update at S8 occurs later than the reroute at S10, a temporary forwarding blackhole will form, resulting in packet drops.

However, the packet drop at S8 due to table lookup miss could also be flagged as a parity error [66], when the context of the table miss is unknown. To check if a delayed network update is a possible cause, with *S*yNDB, we can query (Listing 2) the forwarding rule versions observed by each packets at S10 and S8 along with the number of drops observed in

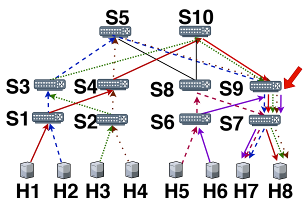

Figure 16: Congestion at S9 due to Link Load Balancing problem

Figure 15. From Figure 15, by correlating the rule version number and packet drops in time, it is clear that the packet dropped can be attributed to a transient inconsistency in rules between switches S8 and S10.

```
SELECT forwarding_rule_ver , drop_counter
    FROM packetrecords WHERE switch=8 OR switch=10;
```

Listing 2: Query for correlating network update with drops

Note that in this experiment, data collection is triggered based on an aggregating trigger defined over multiple switches. Switch S8 broadcasts the trigger *b* to other switches on detection of forwarding table miss and S10 broadcasts the trigger *c* on policy update. Trigger *b* or *c* by itself does not trigger data collection. When a switch receives both triggers (within a time window), then data collection is triggered. Such multi-switch trigger reduces both false-positives and collection overhead.

B.0.2 Transient Load Balancing Issues

Modern data center topologies such as fat-tree provide redundant paths between a source-destination pair. ECMP [27, 33, 58] is a common load balancing policy for handling multi-path routes. However, it has a lot of inefficiencies in distributing the load evenly [27, 33]. As a result, it has been observed that a subset of core-links regularly experience congestion while there is spare capacity on other links [20].

In this scenario, we setup ECMP based load balancing. Each switch calculates the hash of the 5-tuple and redirects the flow via one out of the two links. We experiment with a variety of combinations of 5-tuple flows, and use a set of combinations which can lead to load imbalance in the network. In one such combination, S9-S7 is congested, even though spare capacity is available at S8-S7. We create multiple flows in the network originating from H1 to H6 with the destination as H7 and H8 (Figure 16). The traffic (containing faulty combination) is sent at short bursts, with an overall throughput of 1 Gbps per flow. The load imbalance happens when both the core switches (S5 and S10) direct too many flows to S9,

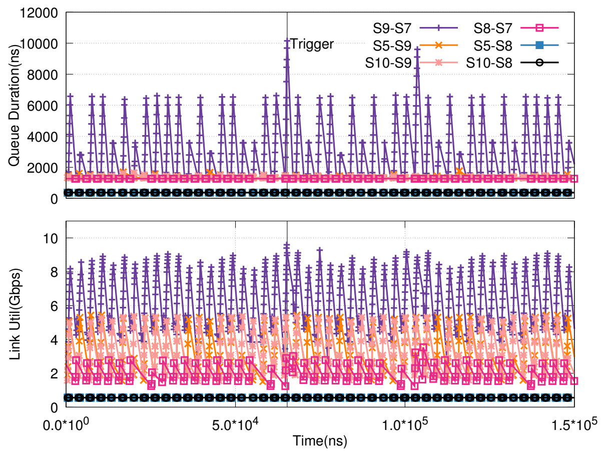

Figure 17: Link Utilization and Queuing delays observed at the core links points to load imbalance

resulting in congestion on the S9-S7 link.

With only the congestion indication, it is be difficult to determine the root cause. To determine if load imbalance is the root cause, one would have to observe the queuing duration and link utilization of various links at the same time. These network metrics are not available with both NetSight and INT. SpeedLight [63] can measure only coarse-grained link utilization (several μs). With *S*yNDB, we can plot the utilization of the links measured at the same time at packet-level granularity using the query shown in Listing 2.

```
SELECT switch1 , switch2 , link_utilization*8, time_queue
    FROM (SELECT switch1 , switch2 FROM links
    WHERE (switch1 IN (select switch FROM switches
    WHERE type !="tor") AND switch2 IN (SELECT switch
    FROM switches WHERE type !="tor"))) AS L
    JOIN (SELECT * FROM packetrecords) AS A
    JOIN (SELECT * FROM packetrecords) AS B
    ON (A.hash = B.hash AND A.switch = L.switch1
    AND B.switch = L.switch2);
SELECT forwarding_rule_ver
    FROM packetrecords WHERE switch=10;
```

Listing 3: Query for link utilization and queue depths

The result is shown in Figure 17. We can observe that there is high link utilization at S9-S7 while link S8-S7 sees no significant utilization. Furthermore, the congestion trigger at the link S9-S7 is preceded by higher than normal link utilization in links S5-S9 and S10-S9. Thus, the load distribution from the core switches (S5 and S10) to S8 and S9 is heavily skewed, with most flows being routed via S9 during some time intervals. Based on this observation, one can infer that the root cause for the congestion at the link S9-S7 is the load imbalance cause by the load balancing scheme.

Alohamora: Reviving HTTP/2 Push and Preload by Adapting Policies On the Fly

Nikhil Kansal[*], Murali Ramanujam[*], Ravi Netravali
UCLA

Abstract

Despite their promise, HTTP/2's server push and preload features have seen minimal adoption. The reason is that the efficacy of a push/preload policy depends on subtle relationships between page content, browser state, device resources, and network conditions—static policies that generalize across environments remain elusive. We present Alohamora, a system that uses Reinforcement Learning to learn (and apply) the appropriate push/preload policy for a given page load based on inputs characterizing the page structure and execution environment. To ensure practical training despite the large number of pages served by a site and the massive space of potential policies to consider for a given page, Alohamora introduces several key innovations: a page clustering strategy that favorably balances push/preload insight extraction with the number of pages required for training, and a faithful page load simulator that can evaluate a policy in several milliseconds (compared to 10s of seconds with a real browser). Experiments across a wide range of pages and mobile environments (emulation and real-world) reveal that Alohamora accelerates page loads by 19-61%, provides 3.6-4× more benefits than recent push/preload systems, and properly adapts to *never* degrade performance.

1 Introduction

Mobile web browsing has rapidly risen in popularity [15, 17, 51]. Given the importance of mobile web speeds for both user satisfaction [6, 7, 19] and content provider revenue [18], a vast array of optimizations have been developed [8, 30, 39, 40, 43, 54, 57, 61]. Yet page loads remain too slow for users in practice, taking over 10 seconds to load even with state-of-the-art mobile devices and LTE cellular networks [4, 54].

Recent studies have identified that a key culprit to slow mobile page loads is the blocking network delays that arise from the dependencies between a page's objects [39, 54]. For example, a browser may learn that it needs an image only after fetching and executing a JavaScript file, which is discovered only after downloading and parsing the page's top-level HTML. Such dependency chains essentially serialize object fetches, leading to high load times, particularly in mobile settings where access link latencies tend to be high [23, 66].

The latest HTTP/2 standard [5] anticipated the negative impact of network delays on web performance, and in response, includes several relevant features. Most notable are HTTP/2 *push* and *preload*. With push, servers can proactively send objects to clients in anticipation of future requests; requests for already-pushed objects can be satisfied locally at the client, avoiding blocking network fetches. In contrast, with preload, servers can notify clients of objects that they will soon require (potentially from other domains) by listing those URLs in HTTP headers. Clients issue requests for those objects immediately after parsing HTTP headers, and without evaluating response bodies, thereby parallelizing network and computation tasks [54].

Unfortunately, despite their promise, developing performant push/preload policies has proven to be challenging, leading to low adoption rates. For example, we find that only 5% of the Alexa top 500 pages [3] include a domain that uses push or preload; this drops to 0.9% for the Alexa top 10,000 pages. A major reason is that the performance of a given push/preload policy depends on the subtle, low-level interactions between page content, browser (cache) state and execution dependencies, client device and network resources, and QoE goals [53, 60, 69, 70]. Consequently, even for a given page, we find that using a policy outside of the execution environment for which it was designed can either forego significant (18-31%) performance benefits or degrade performance by up to 20% compared to a default page load (§2).

These results preclude the use of the static policies and guidelines promoted by prior push/preload systems [53, 54, 70], and instead highlight the need for *dynamic, adaptive* policies that explicitly target the environments in which they are deployed. For example, the aggressive push/preload policies that effectively utilize resources in high-bandwidth settings must be shrunk or dispersed across a page load as link rates drop to avoid potential network contention that slows the downloads of blocking resources. Similarly, as device CPU speeds decrease, policies should grow in size to take advantage of the (increased) blocking compute delays that leave the network idle.

We present **Alohamora**, a system that learns and applies the appropriate push/preload policies for different pages and execution environments (Figure 1). Alohamora represents its policy generation logic as an expressive neural network that is trained offline using Reinforcement Learning (RL); we list the benefits of using RL in §3. During a client page load, Alohamora's model takes as input a set of features that summarize the client's execution environment (network, CPU, cache contents), and structural information about the page at hand, and outputs a push/preload policy intended to optimize QoE for the current load. Importantly, Alohamora *does not require new browser features*, and involves minimal server changes: servers provide structural information about their pages (which content management systems commonly track [14, 30, 67]), and Alohamora's policy generation runs transparently on a co-located frontend server.

[*] These authors contributed equally to this work.

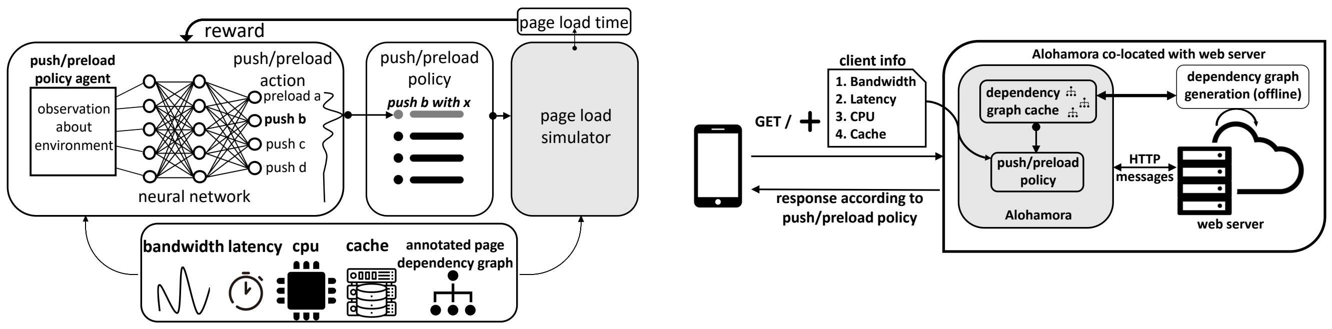

Figure 1: **Alohamora trains (left) its push/preload policy generation model using Reinforcement Learning, exploring a large search space of environments and policies, and learning from the resulting (simulated) performance. During client page loads (right), for each origin, Alohamora collects the required inference inputs from client browsers (using existing features) and servers which track changes to their page dependency graphs; the generated policies are applied transparently for the remainder of the page load.**

Realizing Alohamora's data-driven approach to HTTP/2 push/preload policy generation requires overcoming two key practical challenges with respect to training efficiency:

- **Generalizing across pages (§4)**: websites commonly serve thousands of pages, and it is impractical to incorporate each into the training process. However, failing to incorporate different pages during training may hide push/preload insights, and result in poorly generalizable models. To overcome this, Alohamora leverages our observation that even though sites serve thousands of URLs, their pages typically cover a far smaller number of page structures. The key idea is that these *shared structural properties typically dictate the efficacy of different push/preload strategies*. Thus, Alohamora needs not train on multiple pages with the same structural properties, as those would contribute similar push/preload insights. More specifically, push/preload benefits are dictated by resource utilization during the load process, which in turn can be characterized by 1) browser and inter-object dependencies, and 2) the overheads imposed by tasks involving the network and CPU. By extracting this structural information from a site's pages and clustering pages accordingly, we find that Alohamora is able to strike a desirable balance between the number of pages required for training and model generalizability.
- **Simulating page loads (§5)**: Alohamora's training involves testing different push/preload policies in diverse environments. However, the large number of potential environments and push/preload policies per page (exponential in terms of object count), coupled with the high mobile load times described above, make this approach far too slow. For example, even for a single environment, exploring the thousands of potential policies for `nytimes.com` would require 30 days on a powerful desktop machine. To handle this, Alohamora introduces a novel page load simulator which faithfully (errors of 0.4-2.2%) predicts the performance of a policy 3-4 orders of magnitude faster than running a real browser; for context, this cuts training time to 20 minutes for `nytimes.com`. To the best of our knowledge, Alohamora's simulator is the first to faithfully predict page load performance *across metrics and environmental conditions*, without requiring costly profiles [68] or emulation [60] for each environment. The key insight is in *judiciously extracting invariants about the page load process and superimposing variable resource constraints* by simulating browser-environment interactions; invariants (e.g., page/browser dependencies) are collected via a single profiling run with a real browser, while variable properties about the target environment and push/preload policy are taken as input. The simulator is general enough to support other optimizations that modulate network/compute delays [2, 40, 43, 57] or scheduling policies [8, 39].

We evaluated Alohamora using more than 500 web pages, and a wide range of mobile networks, client devices, and cache conditions. Our experiments, both emulation and real-world, reveal that Alohamora reduces page load time and Speed Index by 19-61% and 15-48%, respectively, compared to a default page load (i.e., no push/preload) and standard push/preload-all policy. In addition, Alohamora marginally (0.9-1.7×) outperforms WatchTower [43], a recent proxy-based accelerator, and delivers 3.6-4× more benefits than Vroom [54], a state-of-the-art push/preload system. Importantly, whereas Vroom slows down 24-34% of page loads, Alohamora properly adapts to *never degrade performance*. Source code and experimental data for Alohamora are available at https://github.com/nkansal96/alohamora.

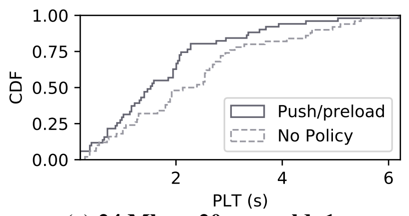
2 Background and Motivation

We begin with an overview of HTTP/2 (§2.1), and then present measurements that illustrate the potential benefits and challenges with HTTP/2 push and preload (§2.2).

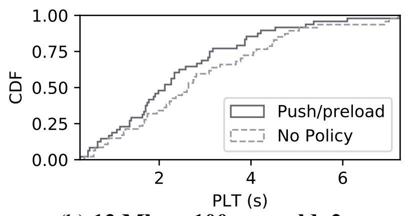
2.1 HTTP/2 Overview

HTTP/2 [5] alters the traditional HTTP/1.1 page load process primarily by adding the following new features:

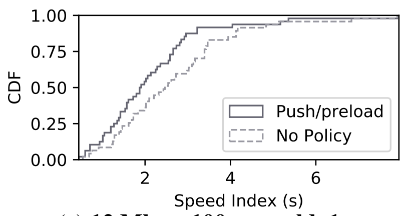
- **Request multiplexing:** With HTTP/1.1, browsers can open and reuse multiple concurrent TCP connections per origin. In contrast, HTTP/2 permits only a single con-



(a) **24 Mbps, 20 ms, cold, 1×**



(b) **12 Mbps, 100 ms, cold, 2×**



(c) **12 Mbps, 100 ms, cold, 1×**

Figure 2: **Push/preload benefits when policies are explicitly tuned to the deployment environment's available resources. Environments are listed as {bandwidth, latency, cache setting, CPU slowdown}. Results are shown for either Page Load Time (PLT) or Speed Index.**

nection per origin, and allows browsers to multiplex requests onto that connection as parallel *streams*. Unlike HTTP/1.1 pipelining, HTTP/2's multiplexing permits out-of-request-order delivery to avoid head of line blocking. HTTP/2 also mandates the use of TLS (and thus, HTTPS).

- **Server push:** Unlike HTTP/1.1 servers which only serve objects in response to explicit client requests, HTTP/2 servers can *push* objects that they own in anticipation of future requests. Servers have flexibility in defining a *push policy*, which specifies the mapping between objects that are explicitly requested and the set of files pushed along with them. Pushed objects are usable for the duration of the current page load, regardless of the associated HTTP caching headers. Note that pushed objects that are already in the browser's cache imply wasted network bandwidth.
- **Preload:** HTTP/2 also carried over HTTP/1.1's preload feature, which enables servers to list URLs to fetch directly in HTTP Link headers. Upon parsing such Link headers (i.e., before parsing the response body), browsers will immediately issue requests for the listed URLs; responses are not evaluated until the objects are referenced by the page. Thus, like push, preload enables servers to help browsers pre-warm their caches rather than relying on object execution to discover downstream objects. However, preload differs from push in that: 1) requests are client-driven and still involve network delays *to* origin servers, 2) the risk of re-downloading cached objects is eliminated since preload requests pass through the browser cache, and 3) servers can specify to preload third-party objects, not just objects that they own.
- **Stream prioritization:** HTTP/2 offers a mechanism with which both clients and servers can explicitly specify how parallel request streams on a single TCP connection share network and server-side processing resources. In particular, endpoints can annotate each request with a single integer that denotes its target share of the resources.

In this paper, we focus on the HTTP/2 push and preload features because they are configured by servers, i.e., Alohamora's target deployment location. In contrast, stream priorities are usually specified by browsers [11, 64], and yield limited benefits [31]. We note that push/preload policies exhibit a notion of prioritization that we do consider: "push A+B with C" and "push B+A with C" are different policies.

2.2 Limitations of Static Push/Preload Policies

Push/preload policies have been widely studied, yielding mixed performance results [16, 53, 54, 60, 70]. The key reason is that the performance of a policy depends on numerous page and environmental properties. To better understand the relationships between these properties and push/preload policies, we performed a study involving 50 random pages from the Alexa top 500 US sites [3]. Our results use the same methodology and environmental parameters (network, device CPU, cache, QoE metrics) described in §6.1.

For each environment and page combination, we selected the best policy using a brute force search. Since the number of potential policies for a page scales exponentially with the number of objects (which regularly exceeds 100), a complete brute force search across environments is impractical. Instead, to ensure practicality and sufficient coverage, we weighted object types based on their potential for blocking the client-side page load (i.e., JS $=$ CSS $>$ image $>$ font) [39, 59]. To generate a policy, we randomly selected the number N of objects to push/preload, and then sampled the object types N times according to their relative priorities (picking randomly within each type). Finally, we randomly selected the fraction of objects to mark as push vs. preload, and for each object, we randomly selected an earlier object in the load to push/preload from. Using this approach, for each page, we generated 200 policies and picked the one that delivered the largest improvements.

Takeaway 1: Push/preload has potential. For each environment and page pair, we compared the best push/preload policy (selected explicitly for that pair) to a default page load (i.e., no push/preload). Figure 2 shows representative results for several settings. As shown, when selected explicitly based on the environment, push/preload policies are able to provide significant speedups. For instance, in the {24 Mbps, 20 ms RTT, cold cache, 1x CPU slowdown} setting, median (95th percentile) page load time benefits are 18% (44%).

Takeaway 2: Push/preload policies do not generalize well. Despite the potential benefits, our results also highlight that push/preload policies quickly degrade in performance when run outside of the precise environments for which they were tuned. To evaluate this, we performed multiple experiments in which we started with a fixed environment, and selectively modulated each environmental factor while keeping the oth-

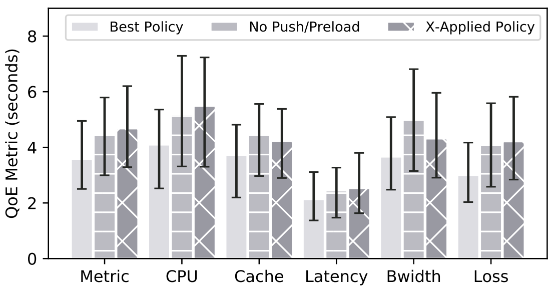


Figure 3: **Push/preload performance degrades as the environment changes. The base configuration was {12 Mbps, 100 ms, cold cache, 1x CPU, PLT}; each cluster modulates only one factor. "Best Policy" was tuned to each setting, and "X-Applied" applies the base configuration's best policy to each setting. Bars show medians, with error bars spanning 25-75th percentiles.**

ers fixed. In each resulting environment, we compared the performance of 1) the best policy for the fixed environment, 2) the best policy for the resulting environment, and 3) no push/preload. Figure 3 depicts our results for one fixed environment; we omit results for others due to space constraints, but note that the trends persist. These results illustrate two significant drawbacks to using push/preload policies across environments. First, they leave significant (18.4-30.7%) performance gains on the table compared to policies designed explicitly for the deployment setting. Second, and worse, they can degrade performance compared to a default page load. For instance, performance degrades by 6% (20%) at the median (95th percentile) when device CPU speeds change. These slowdowns are even more pronounced when multiple environmental factors are modified in parallel.

Summary: Collectively, our results suggest that, to realize the significant performance potential of push/preload, policies must be designed to explicitly consider page properties and characteristics of the target deployment environment.

3 Design Overview

Figure 1 shows the high-level design of Alohamora's offline training and online (i.e., during client page loads) inference phases. In this section, we will describe the workflow for each task in the context of a single web page. We present extensions to ensure practical training via cross-page generalization (§4) and page simulation (§5) in subsequent sections.

3.1 Offline Training

Why RL? Alohamora represents its push/preload policy generator as a neural network that is trained using Reinforcement Learning (RL) [32]. RL offers several advantages in this setting compared to more standard, supervised learning approaches. Most notably, the search space of push/preload policies is massive (exponential in terms of the number of objects in a page, which regularly exceeds 100), and it is impractical to generate a labeled training dataset that incorporates all of the fruitful push/preload policies for a page. RL overcomes this by using an efficient exploration strategy, whereby experience of prior tested policies is used to dynamically guide the traversal through the large search space.

Training with Reinforcement Learning involves learning from a large number of experiments and generally operates as follows. A *learning agent* interacts with an *environment*, and at each step, the agent *observes some state* in the environment, performs an *action*, and receives a *reward* from the environment. The overall goal of the learning agent is to maximize the cumulative (discounted) reward that it receives from the environment. In our case, the environment is a mobile page load setting, i.e., a combination of a device, network, and browser cache. The training process is structured as a series of *episodes*, each of which considers a single page and environment, and evaluates a running push/preload policy (starting with an empty one) that is incrementally modified to include an additional action. An action is a push/preload decision for a single object. We describe each component in more detail below.

Action/Action space: The action space lists the set of possible push/preload decisions for all objects in a page. Each action is represented as a six-tuple ($type$, $domain$, $push\_object$, $push\_ancestor$, $preload\_object$, $preload\_ancestor$). $type$ lists the action to perform (push, preload, nothing); $domain$ represents the domain whose objects to consider if the action is "push" ("preload" can consider objects from any domain); $push\_object/preload\_object$ and $push\_ancestor/preload\_ancestor$ list the object to push/preload and the object to do so with, respectively. Note that objects are identified by ID numbers here, not precise URLs, because URLs can vary on short time scales [8]; IDs are converted into URLs during inference (§3.2).

Episode: At the start of an episode, Alohamora first selects a random operating environment by picking values for the average network bandwidth, latency, and loss rate, as well as the mobile device CPU speed, and browser cache settings (time since the last load of the page, which in turn dictates cache contents [41]). Because the space of each value is continuous and thus infinitely large, we discretize each into bins that are sized according to prior work [43] and our own empirical analysis of the impact that changes to each factor have on push/preload performance. In particular, we group network bandwidth/latency/loss rate to the nearest 5Mbps/10ms/0.5%, and CPU speed to the nearest 1× slowdown relative to a baseline. This lets us consider far fewer environments without sacrificing model generalizability.

In addition to the environment specification, the agent is given access to an *annotated dependency graph* for the page (Figure 5). Traditional web dependency graphs [8, 39, 43, 59] are directed acyclic graphs with a node per page object, and edges that represent initiator relationships (i.e., a parent's computation triggered the fetch of a child). We add annotations (§5.1 details how annotations are made) which list, for each object, information about its 1) size, 2) computation delays, 3) content type (e.g., HTML), 4) ordering (timing) relative to both all other page objects and only those objects belonging to the same domain, 5) cache status, and 6) candidacy for push/preload. Candidacy reflects the fact that only recurring objects in a page should be considered for push/preload, in order to reduce the potential for wasting bandwidth; we determine candidacy in the same way as prior work [54], by loading the page several times and extracting a stable list of URLs. Collectively, the operating environment and annotated dependency graph represent the *observable state* that the agent can glean from the environment.

Throughout an episode, the agent selects actions according to a probability distribution over the potential space of 6-tuples (i.e., the action space described above). The probability distribution function starts as uniform, but is dynamically updated based on the agent's experiences. More formally, the agent uses a policy gradient method [33] in which it estimates the gradient of the expected total reward for each possible new action—the agent selects the action predicted to deliver the highest reward. For each new action that is added to the running push/preload policy, the updated policy is evaluated in the environment to obtain a reward that is fed back to the agent along with the *observable state*.

Each episode ends when the agent either chooses an action of *type* "nothing," repeats an action to push/preload an object that is already represented in the running policy, or selects an invalid (i.e., disallowed) action, e.g., pushing across domains or preloading an ancestor object. Regardless of which reason ends an episode, upon completion, Alohamora automatically assigns a reward of 0 to signal to the agent that the terminal policy is not one to consider. The policies learned for each episode are ultimately aggregated to generate Alohamora's overall push/preload policy generation model. We note that training can be configured to adhere to a preset bandwidth cap for pushed objects, i.e., we can end an episode if a policy that pushes an undesirably high number of bytes arises.

Reward function: Structuring the reward function requires careful thought because each action in an episode is not entirely independent. Thus, rather than simply using the page load metric of choice, we structured our reward function to take into account the relative improvement or degradation (on the metric of choice) per action, giving a boost in reward as the agent discovers a set of actions that leads to a new global (i.e., within an episode) minimum. More formally, we define the reward for the i^{th} action in an episode as:

$$R_i(P_i, P_{i-1}, P_{\text{best}}) = \begin{cases} \frac{k_1}{P_i} & P_i < P_{\text{best}} \\ \frac{k_2 P_{i-1}}{P_i} & P_i < P_{i-1} \\ \frac{-k_2 P_i}{P_{i-1}} & P_i > P_{i-1} \end{cases}$$

where P_i, P_{i-1}, and P_{best} are the raw values for the target QoE metric for the current, previous, and best-so-far policies in the episode, respectively. k_1 and k_2 are constants, where $k_1 >> k_2$. The idea is to give a positive (negative) reward proportional to an improvement (regression) in QoE. We note that the reward function is compatible with any QoE metric that denotes improved performance with lower values. We consider different reward structures in §6.5.

Implementation: Alohamora trains its models with Ray [36], using the RLLib [26] and Tune [27] libraries. Each model is a recurrent neural network that consists of 2 densely-connected layers with 256 units and the `tanh` activation function, followed by an LSTM with cell size 256. As shown in §6.5, LSTMs are helpful given the sequential nature of each episode: they prevent the agent from infinitely deferring its reward and always choosing longer policies over shorter ones. Training stops after 150 iterations, or if the standard deviation in the past 50 rewards is less than 5% of the last one (whichever comes first).

Our implementation uses the latest A3C [33] algorithm, but is compatible with others [34, 65]. As reported in prior work, A3C may incur high convergence times when network conditions or reward signals exhibit high variance during training [29]. Alohamora's training process sidesteps this in two ways. First, in addition to reducing training times, Alohamora's page load simulator eliminates noise in the observed reward signal. Second, Alohamora trains on deterministic emulated networks (including time-varying links) using Mahimahi [44], so network characteristics are unchanged within each training episode.

3.2 Online Inference

At runtime, Alohamora introduces a frontend server (or reverse proxy) that is colocated with the existing server for a domain (Figure 1); colocating ensures that end-to-end HTTPS security is preserved. All client requests first hit the Alohamora server, whose goals are to 1) collect the information required to query its policy generation model, 2) query the model, and 3) apply the suggested policy to the current load. Each origin in a page independently runs Alohamora to generate its own policy; training explores a sufficient number of policies to enable an origin to *hedge* against the set of policies that other origins may employ. We present results for partial deployment scenarios in §6.

Data collection for inference: The information required to query the policy generation model matches the *observable state* from training, i.e., network bandwidth, latency, loss rate, CPU speed, cache status, and annotated dependency graph. Alohamora collects the required network, device, and cache information through its interactions with clients, and the annotated dependency graphs directly from origin servers. Importantly, all data collection involving clients leverages existing interfaces that modern browsers already expose. In other words, *Alohamora does not require any new browser features, and instead only needs certain pre-existing features to be enabled.*

To extract network latencies, Alohamora's server analyzes the SYN/SYN-ACK time during the client's initial connection setup. Further, summaries of the client's cache are collected using either the latest cache manifest standards [46], or a server-based cookie which logs the time since the user's last load of the page [12]. We note that caching information is collected on a per-domain basis in order to preserve existing web privacy guarantees, i.e., a domain only learns about the cached objects that it owns. CPU speeds are set based on the HTTP User-Agent header that denotes the client device [37]. Lastly, average network bandwidth and loss information are collected using browser user experience reports [9].

Alohamora also requires an up-to-date dependency graph to determine the precise URLs to push/preload according to the generated policy. Alohamora relies on origin web servers to collect and share updated dependency graphs offline [30], as those servers are the first to be aware of page changes. In particular, content management systems [14, 67] support hooks that fire any time a page-altering change is pushed, e.g., for A/B testing. Alohamora adds a transparent hook to collect up-to-date dependency graphs, which requires only a lightweight (headless) load of the largely local page [40, 43].

Applying push/preload policies: Upon receiving a client request for a page, Alohamora's server queries its model to generate a push/preload policy that directly targets the current load. The resulting policy is a listing of object IDs to push/preload, and the corresponding ancestors. Alohamora then uses the latest dependency graph to translate IDs to precise URLs (according to positions in the dependency graph). Finally, to enforce the policy, the Alohamora server issues local HTTP(S) requests (mimicking client HTTP headers) to the colocated origin server, which responds with the up-to-date objects. Alohamora then applies the policy to the returned object headers throughout the rest of the page load.

4 Generalizing Across Pages

In practice, sites commonly serve thousands of different pages. Unfortunately, incorporating each page into the training process would be far too slow and resource intensive. Consequently, Alohamora faces a tricky tradeoff: train on only a few of a site's pages and achieve efficient training at the risk of omitting pages that warrant unique push/preload strategies, or train on many of a site's pages to develop generalizable policies at the expense of high training overheads.

Alohamora addresses this tradeoff by leveraging the observation that, even though sites serve thousands of different pages, those pages typically cover a *small number of page structures*, e.g., because they are automatically generated using a fixed set of templates, and thus share styles, JavaScript libraries, etc. [30, 48]. For example, news sites intuitively comprise a main home page, category home pages, and several classes of article pages. The key idea here (validated below) is that these shared structural properties typically dictate the efficacy of different push/preload strategies, and thus, we need not train on multiple pages that are structurally similar.

The primary challenge with leveraging this insight is in determining precisely which pages in a site are necessary to consider during training. Answering this implicitly requires an understanding of what pages have sufficient structural similarity from the perspective of the push/preload policies that they warrant. In other words, how should we represent and compare pages to determine structural similarity? Our goal is for representations to be coarse enough to avoid deeming all pages as structurally different (which would eliminate savings in training efficiency), but also detailed enough to capture structural differences that affect policies.

4.1 Clustering by Page Structure

We observe that the efficacy of a push/preload policy depends on the utilization of network and client device resources throughout the page load process. Building off of this, the primary determinants of resource utilization are 1) browser- and page-imposed dependencies [38, 39, 59], e.g., JavaScript execution blocking HTML parsing, and 2) the duration and overhead of different page load tasks involving the network or CPU. To capture all of these factors and identify page structures that warrant similar policies, Alohamora uses the annotated dependency graphs described in §3. Recall that the structure of these dependency graphs captures inter-object dependencies and constraints on request scheduling, while the per-object annotations characterize network and CPU overheads of fetch and execution tasks.

Given these dependency graphs (or trees) for each page that we hope to accelerate for a site, Alohamora defines the distance between two page's trees T_i and T_j as the tree edit distance between them; we use the state-of-the-art APTED algorithm [50]. The cost of inserting/deleting a node is set to 1, and the cost of each change to any part of a node's label (content type, size, execution time, etc.) is set to 0.25, i.e, label alterations are equally weighted such that changes to all labels are equivalent to a node insertion/deletion. To avoid incorporating label edits that minimally impact push/preload strategies, Alohamora deems objects that have sizes or execution times within $\delta\%$ of each other as equivalent; we use $\delta = 25\%$ but find the precise value to have little impact as node insertions/deletions dominate difference values.

After computing the distances between each pair of trees, we construct a *distance matrix D* where $D_{i,j} = \text{distance}(T_i, T_j)$. With this, Alohamora can run any clustering algorithm that operates on non-Euclidean distance functions—we use agglomerative clustering [63]—to group pages that are structurally similar from a push/preload perspective. During clustering, we minimize the average distance between the pages in a cluster while permitting islands (a cluster of size 1); we sweep a range for the target number of clusters, and choose the lowest one which, if increased, does not result in a new island. From there, Alohamora only considers a single (random) page per cluster for training.

Handling page changes: Recall that origin servers track changes to their page dependency graphs and share those graphs with Alohamora's runtime server (§3). A natural question is how to determine when a change to a page's dependency graph is substantial enough to deem Alohamora's model suboptimal (for that page) and prompt a retrain? To answer this, upon receiving a graph from an origin server, Alohamora re-clusters by computing the pair-wise distances between the new graph and graphs for all pages used in training. If the new clustering results remain stable such that the new graph falls into an existing cluster, then Alohamora needs not retrain. On the other hand, if the new page forms an island, then Alohamora will automatically trigger a re-train. During re-training, Alohamora will still use its model to service pages whose graphs have not substantially changed.

Prior work has shown that page dependency graphs remain structurally similar over long time scales (e.g., weeks), with only the precise URLs changing over short periods [8, 39, 43]. Thus, we expect retraining with Alohamora to be infrequent in practice. For example, we verified that the clustering results from Figure 4 are unchanged across 2 weeks.

4.2 Evaluations

We performed case studies on 100 randomly selected sites in the Alexa top 500 US list [3]. For each site, we ran a monkey crawler [1] that generated a list of 300 URLs by performing random interactions (e.g., clicks) starting from the site's landing page. From this set of URLs, we selected 30 pages that covered the logical clusters that we perceived for the page, e.g., articles vs. home page vs. user profile pages. For each of the 30 pages, we generated the corresponding annotated dependency graph, computed the pair-wise tree edit distances to all other pages, and performed the clustering described above. The generated clusters largely matched our high-level clustering intuition, e.g., for `The Atlantic`'s website, there exists a cluster for the home page (1), articles (21), category pages (5), and user profile pages (3).

We evaluated our clustering strategy for each site as follows. We first ran a brute force search (§2.2) to find the best push/preload policy for each of the site's considered pages. We then applied each page's best policy to all of the other pages for the site, including those in the same cluster, and those in other clusters. In each case, we measured the fraction of potential push/preload benefits that a page x's best policy achieved for another page y (as compared to the improvements delivered by y's best policy). In the event that a referenced object was missing for a page, we removed the corresponding action from the policy; this was rare as policies are based on fetch order IDs, not precise URLs.

Figure 4 lists our results for one environment; we note that the trends held for the other environments in §6.1. As shown, we find that push/preload policies are able to generalize well within a cluster, but not across clusters for a given page. In particular, at the median, policies that are generated and applied to the pages within a cluster achieve 89.6% of the potential push/preload benefits; this number drops to 36.3% for

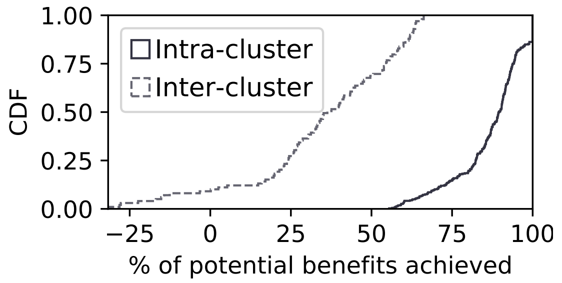

Figure 4: **Policies generalize well within (but not across) Alohamora's clusters. Results are for the {24 Mbps, 20 ms, 2× CPU slowdown, PLT} setting, and consider 100 sites, with 30 pages each. For each site, we applied each page's best policy to all other pages, and measured the % of potential benefits achieved.**

policies that are applied across clusters. §A.2 shows results for two representative pages, and also presents end-to-end results for Alohamora's policies given this clustering strategy.

5 Page Load Simulator

Even for a single page, training is impractical due to the large number of policies and environments, and the slowness of mobile page loads. To accelerate training (§3), Alohamora uses a novel page load simulator that, given an annotated dependency graph for a page, a target execution environment, and a push/preload policy as input, outputs an estimated QoE (e.g., PLT, SI) value. Unlike prior simulators (§A.1), Alohamora's is able to faithfully predict load performance (with any policy) across metrics and environments, without requiring costly profiles [68] or emulation [60] per environment—this is critical for Alohamora's training as loading pages in each environment would forego most simulation speedups. We will start by describing our simulator's operation in the context of cold cache loads, no push/preload, and PLT, and then relax those assumptions in §5.4 and §A.1. We note that Alohamora's simulator focuses on HTTP/2 page loads.

5.1 Collecting Simulator Inputs

The first step in the simulation process is to profile a load of the target page to extract information characterizing properties dictated by page composition [39] or browser dependencies [38, 59]. These properties do not describe the operating environment (which we will simulate), but instead dictate how page load tasks should share the simulated resources.

To extract such information, Alohamora records the target page with a record-and-replay tool [44], and replays the page over an unshaped local network with desktop-level CPU resources. During replay, Alohamora extracts an annotated dependency graph (Figure 5) that matches the ones used in §3 and §4.1. In particular, the graph structure captures the inter-object ordering and dependency constraints, and we add additional annotations that characterize each object's size, execution time, content type, etc. To aid simulation, we further break down an object's network and compute delays into:

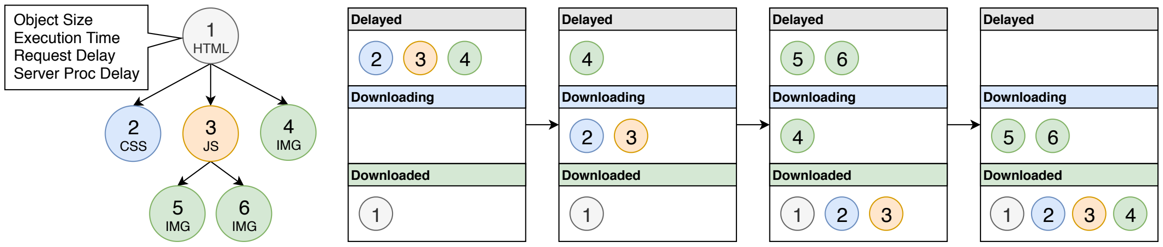

Figure 5: **Operation of Alohamora's page load simulator. The simulator operates in steps, as objects flow through these three queues, incurring blocking (e.g., connection setup, inter-object dependencies), network, and compute delays, respectively. Once an object is executed, its children are added to the top (as *delayed*) to simulate the browser discovering those dependencies.**

- **execution time:** time spent parsing, executing, or rendering the object with the well-provisioned CPU; this does not include the time to execute any referenced objects.
- **request delay:** the amount of time between when the object's parent has finished downloading, and when the object's request is issued; this embeds the parsing/execution delays of the parent, as well as any synchronous processing delays for objects referenced earlier in the parent's execution, e.g., a blocking external `<script>`.
- **server-processing delay:** server-side delay in generating and serving the response; we extract this information directly from web record-and-replay frameworks [30, 44].

In addition to this dependency graph, Alohamora's simulator also takes as input an environmental specification, listing the average network bandwidth, latency, and loss rate (Mbps, ms, %), device CPU speed (slowdown compared to profiling CPU speed), and browser cache contents.

5.2 Simulating the Execution Environment

In order to enforce the specified network and CPU values on all page load tasks, Alohamora's simulator uses a new **Request Queue** abstraction. Here, we describe how the Request Queue operates on objects passed into it; we will then describe how objects get added to the Request Queue.

At any time, the Request Queue keeps track of three types of objects using three subqueues: *delayed*, *downloading*, and *downloaded*. *Delayed* objects are those that have been discovered by the browser, but whose downloads are currently blocked, e.g., due to connection setup delays or the object's *request delay*; *downloading* objects are currently being fetched over the network; *downloaded* objects have been fetched and are currently being evaluated (or awaiting evaluation). At a high level, the Request Queue operates in steps, whereby objects flow through these queues, and once executed, children are added to the top (as *delayed*) to simulate the browser discovering those dependencies. In order to determine how long an object stays in each queue, the Request Queue models the interaction between the browser and environment, with respect to network and CPU usage.

Enforcing latency/loss overheads: In order to compute the number of round trips required to download an object, the Request Queue considers two factors. First, if the object is the first to be downloaded from a given domain, the Request Queue adds 2 RTTs to account for the TLS handshake that HTTP/2 mandates. Second, the Request Queue estimates the number of round trips required for the TCP-level data transfer by (approximately) keeping track of TCP window state for each connection (assuming cubic) and assuming that concurrent objects fairly share the window. More specifically, it assumes an initial congestion window of 10 [22], additively increases the window as bytes are downloaded, and halves the window on each idle RTO (200 ms) or probabilistic packet loss. Note that these round trip counts are computed when an object is added to the Request Queue, and are thus approximate since currently downloading objects may complete prior to the new object moving to *downloading*.

Enforcing bandwidth overheads: Across all concurrently *downloading* objects, the Request Queue must enforce an appropriate split of the specified network bandwidth. The simulator treats the bandwidth specification (either average bandwidth or a packet delivery trace [44]) as characterizing the access link, which is commonly the bottleneck in wireless networks [66] and is shared by all origins' connections. By default, the Request Queue assumes that outstanding requests fairly share the available bandwidth, thereby disregarding discrepancies in cross-connection window state.

Enforcing CPU overheads: The Request Queue modulates the *execution delay* and *request delay* for each object by multiplying by the magnitude of the CPU slowdown factor. The simulator ignores CPU core counts, and instead focuses on clock speeds, which have been shown to be the main factor affecting browser performance [10]. To support parallel iframe execution, the Request Queue subtracts out execution times from concurrently *delayed* objects across frames.

Request Queue operation: The Request Queue proceeds in discrete "steps". In each, the Request Queue inspects the lists of *downloaded*, *downloading*, and *delayed* objects, and finds the object(s) that are scheduled to either finish execution first, finish downloading first (fewest bytes remaining), or transition to *downloading* soonest, respectively. Each step is clocked by the duration t until those object events complete. After computing t, the Request Queue will subtract t from the *execution delays* of all *downloaded* objects, subtract the number of bytes that can be downloaded in t from all currently *downloading* objects, and subtract *t* from the blocking delays for all currently *delayed* objects. It will then move all *delayed* objects whose blocking delays have expired to the *downloading* queue, and mark all objects that complete *downloading* as *downloaded*. We discuss how *downloaded* objects affect subsequent resource discovery next.

5.3 Simulating Page Loads

Starting from the root node in the dependency graph (i.e., the top-level HTML), each time an object is marked as *downloaded* by the Request Queue, the simulator immediately adds all of that object's direct children as *delayed* to the Request Queue, simulating the browser's discovery of those objects. In other words, each child of the completed object is scheduled in a one-step look-ahead process, resulting in a dependency graph traversal that is breadth-first across each object's children, but not necessarily across siblings with different parents (Figure 5). Note that, after its children are added to the Request Queue, the parent object remains in the *downloaded* queue until its *execution delay* expires; in parallel, each child incurs its own *request delay* which characterizes the offset in the parent's execution until it is discovered.

This simple approach closely mimics the browser graph traversal strategy [39, 59], but with one issue: execution dependencies between an object's children. For instance, consider a simple scenario in which the top-level HTML includes two adjacent HTML `<script>` tags that reference files $S1$ and $S2$, both of which have children. Because browsers are unaware of the potential state dependencies between these two JavaScript files, upon discovering the first `<script>` tag, HTML parsing would halt and trigger a synchronous (i.e., blocking) fetch and execution of $S1$ [39]. This has several implications on dependency graph traversal, which Alohamora's simulator must account for:

- during a real load, the children of a parent may not be scheduled in a single burst. The simulator accounts for this by including an object's *request delay* (which accounts for inter-children blocking delays) in the duration that the Request Queue marks it as *delayed* (§5.2).
- even with the enforced *request delay*, it is possible for the Request Queue to mark $S2$ as *downloaded* before $S1$, e.g., if $S2$ is far smaller and the simulated network is bandwidth-constrained. This could result in cascading discrepancies in graph traversal since $S1$'s children should be handled before $S2$'s. To handle this, the simulator also exposes the Request Queue to IDs listing the object fetch orders logged in the profiled load. These IDs inherently follow the order in which browsers require, or are blocked on, specific objects. With this information, the Request Queue treats *downloaded* objects as a priority queue, signaling object completion to the graph traversal component only once the next required object (i.e., the lowest incomplete ID) is complete. Asynchronously-fetched objects are returned after their closest synchronous neighbors.

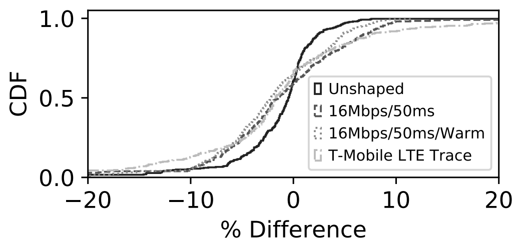

Figure 6: **Faithfulness of the Alohamora simulator's predicted PLT compared to measurements from a real browser.**

We note that, despite these strategies, the simulator's dependency graph traversal still faces potential inaccuracy in the fact that objects involving a blocking dependency, such as $S1$ and $S2$ in the above example, may download concurrently and share network resources. However, the simulator bounds the cascading effects of these inaccuracies on the page load process by ensuring that the ordering of downstream object discovery faithfully mimics that of a real browser.

Measuring PLT: As *downloaded* objects complete execution in the Request Queue, they are marked with a completion time relative to the start of the page load. PLT is the maximum object completion time [42]. In §A.1, we discuss how other metrics such as Speed Index are measured.

5.4 Simulating Push/Preload Policies

To support push/preload, when an object is being added to the Request Queue, the simulator also schedules the corresponding objects to push and preload along with that object (as per the input policy). The objects added for push/preload largely share the blocking delays of the ancestor since push/preload objects cannot begin downloading until the ancestor does. In particular, the Request Queue imposes the ancestor's *request delay*, but alters the remaining delays in two ways: 1) their server-side processing delays are preserved (and not adopted from the ancestor), and 2) preload objects incur an additional network RTT to account for the download of the ancestor's response HTTP headers (0.5 RTT) and transmission of the preloaded object's request (0.5 RTT).

Once scheduled, the key challenge is in determining how pushed/preloaded objects affect the delays from the profiled load; this delta could be positive or negative due to, e.g., bandwidth contention. To understand this, once the simulator hits a pushed/preloaded object, it determines how the object's download progress compares (or will compare) to the case when the object was not pushed/preloaded. This is done by simulating the load without that object being pushed/preloaded, and comparing the resulting delays. Note that, if the pushed/preloaded object is blocking, delays for downstream siblings are edited to reflect the observed deltas.

5.5 Evaluations

We evaluated our simulator by comparing to a real browser on two metrics: fidelity in predicted performance and overall runtime. We follow the same setup as described in §6.1.

	Median	95th Percentile
Alohamora's simulator	4.7	22
Unshaped	1347	3815
24Mbps/20ms/2x CPU	5936	16683
12Mbps/60ms/4x CPU	9631	27765

Table 1: **Per-page runtimes (ms) of Alohamora's simulator (top row) and a real browser in different execution environments.**

Fidelity: Figure 6 shows that Alohamora's simulator reports highly faithful load times compared to a real browser. For example, in an environment with no network or CPU shaping and a cold browser cache, the simulator's reported load times were within 0.4% and 4.3% of the real browser, at the median and 95th percentile, respectively. Median discrepancies marginally increase to 1.4%, 1.7%, and 2.2% as fixed-rate (16 Mbps, 50 ms link) and time-varying (T-Mobile LTE) network shaping, and caching are incrementally added; we note that the errors for all other tested environments are within 4% of these numbers. Further, the low error rates persist when evaluating push/preload policies (§A.1).

Runtime: As shown in Table 1, Alohamora's simulator evaluates page loads 3-4 orders of magnitude faster than real browsers, with the discrepancies growing as the target environment becomes more resource-constrained. §A.1 describes how simulation times vary with policy length. For context, these runtime savings enable Alohamora to *reduce the training time for a page from 10s of days to just 10s of minutes*.

6 Evaluation

6.1 Methodology

To create a reproducible test environment and cover a wide range of environments, our evaluation mainly involves emulation using the Mahimahi record-and-replay tool [44]; we present real-world experiments in §6.4. Our main corpus comprised the Alexa top 500 US landing pages [3], but we also used non-landing and less popular pages in §A.2. We recorded versions of each page at multiple times to mimic different warm cache scenarios: back to back loads, and loads separated by 4, 12, and 24 hours. Mobile-optimized (including AMP [21]) pages were used when available. Experiments used Google Chrome for Android (v72).

Our emulation evaluation considered a broad range of network bandwidths (6-48 Mbps, as well as Verizon and AT&T LTE traces [44]), latencies (0-100 ms), loss rates (0.5-5%), and client device conditions (CPU slowdowns of 1-4×, relative to a desktop with an Intel Xeon Gold 5220 CPU @ 2.20GHz). Network emulation was performed using Mahimahi [44], and CPU constraints were enforced using Chrome's Devtools Protocol [13]. Unless otherwise noted, Alohamora generated a single policy generation model per page that covered the aforementioned conditions; results for Alohamora's cross-page models based on clustering (§4) are shown in §6.6. Further, in accordance with §3, dependency graphs for inference were made just prior to the experiments.

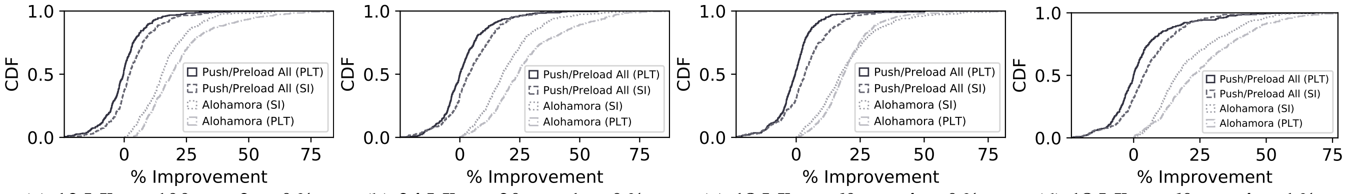
We compared Alohamora to default page loads (i.e., no push/preload) and two standard push/preload strategies: 1) the *push/preload all* strategy where, on the first incoming request, each origin pushes all static resources that it owns, and preloads all referenced static third-party resources, and 2) the *push/preload all JavaScript* strategy which operates in the same manner but only considers JavaScript objects that (unlike images) may trigger subsequent object fetches. With both strategies, push/preload order matches the order in which objects are referenced by a page. Our analysis, described in §A.2, revealed that *push/preload all* consistently delivers larger speedups than *push/preload all JavaScript*. Thus, for brevity, we only present results comparing Alohamora with *push/preload all*.

Our evaluation considers two performance metrics: page load time (PLT) measured as the time between the `navigationStart` and `onload` events, and Speed Index (SI) (measured with pwmetrics [24]) which captures the time needed to fully render the initial viewport. Due to space constraints, we present results for select settings, but note that presented trends persist in all tested scenarios. For all results, domains make push/preload decisions *independently* with Alohamora, and objects can only be pushed within a given domain, e.g., `google.com` cannot push an image belonging to `g.static` (which Google owns).

6.2 Page Load Speedups

Cold cache: Figure 7 illustrates Alohamora's ability to accelerate cold cache page loads across four representative settings. For example, in a {24 Mbps, 20 ms, 1× CPU slowdown, 0% loss} environment, median (95th percentile) PLT improvements with Alohamora were 24% (61%); the push/preload all strategy achieved only -0.2% (22%) improvements. Alohamora's benefits persist as network and CPU conditions change, although the generated policies vary: benefits are 19% (45%) when conditions degrade to {18 Mbps, 60 ms, 4× CPU slowdown, 0% loss}, 22% (57%) when 1% loss is introduced, and 14% (60%) over a time-varying Verizon LTE trace (not shown). Figure 7 also shows that Alohamora provides substantial SI benefits, ranging from 15-19% and 36-48% at the median and 95th percentile. Importantly, across all settings, Alohamora's push/preload policies *never degraded performance* compared to a default page load. This is in stark contrast to the static push/preload all policy, which slowed down 40% of pages by up to 22%.

Warm cache: Figure 8 shows that, across a wide range of warm cache browsing scenarios, Alohamora accelerates page loads compared to both a default page load and a static push/preload all strategy. For instance, for back-to-back (i.e., perfectly warm-cache) page loads, median PLT improvements are 0.9 s and 0.4 s for Alohamora and the push/preload all strategy, respectively. These relative improvements persist (12-18%) as the time between page loads increases.



(a) **12 Mbps, 100 ms, 2×, 0%** (b) **24 Mbps, 20 ms, 1×, 0%** (c) **18 Mbps, 60 ms, 4×, 0%** (d) **18 Mbps, 60 ms, 4×, 1%**

Figure 7: **Load time (PLT and SI) improvements over a default page load for a static push/preload all strategy, and Alohamora. Environments are listed as {bandwidth, latency, CPU slowdown, loss rate}. Results used cold browser caches.**

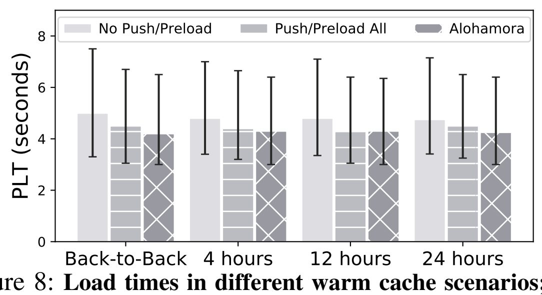


Figure 8: **Load times in different warm cache scenarios; "No push/preload" is a default page load. Bars represent medians, with errors bars spanning 25-75th percentiles. Results are for the {12 Mbps, 100 ms, 2×, 0%} setting.**

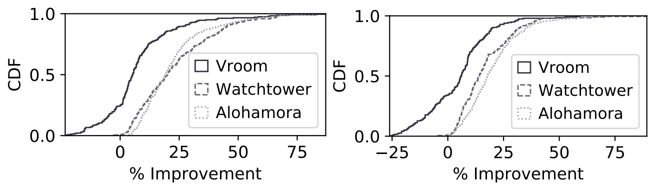

(a) 12Mbps, 100ms, 2×, 0%, PLT (b) 24 Mbps, 20 ms, 1×, 0%, SI

Figure 9: **Comparison with Vroom [54] and WatchTower [43].**

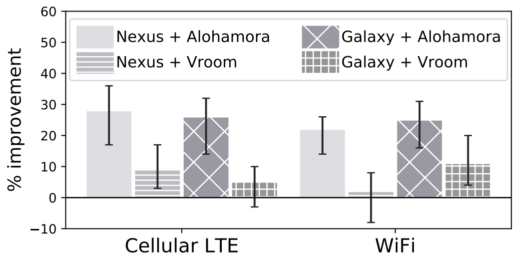

Figure 10: **PLT improvements over a default page load with Alohamora and Vroom, in the wild. Results used cold caches.**

6.3 Comparison to State-of-the-Art

We compared Alohamora with two recent mobile web accelerators, Vroom [54] and WatchTower [43]. Vroom improves upon the push/preload all policy by using a client-side scheduler to integrate priorities into the ordering of pushed/preloaded objects. In contrast, WatchTower selectively uses proxies (per origin) that fetch objects on behalf of clients using fast wired networks. Client-origin-proxy latencies were set as if proxies were run on Amazon EC2 in California, and WatchTower ran in HTTPS-sharding mode.

As shown in Figure 9, Alohamora outperforms Vroom on both PLT and SI. For example, in a {12 Mbps, 100 ms, 2× CPU slowdown, 0%, PLT} environment, benefits with Alohamora are 3.6× and 1.4× higher than Vroom's at the median and 95th percentile, respectively. The main reason for this discrepancy is that, even though Vroom adds dynamism to push/preload in the form of priority-based scheduling, Vroom remains too constrained to adapt to diverse execution environments. In particular, the set of objects to push/preload are static and match the push/preload all approach. This is partly evidenced by the fact that Vroom still harms a large fraction of page loads, e.g., 34% in the {24 Mbps, 20 ms, 1× CPU slowdown, SI} setting. In contrast, Alohamora can vary all aspects of the push/preload policy (objects, orderings, etc.) to best cater to the target setting, and *never harm performance*. Figure 9 also shows that Alohamora marginally outperforms WatchTower (0.9-1.7× more median benefits) *without* requiring per-origin proxy servers.

6.4 Real-World Experiments

We also evaluated Alohamora in the wild, using the same 500-page corpus from §6.1, live Verizon LTE and residential WiFi networks, and 2 mobile phones: a Nexus 6 (Android Nougat; 2.7 GHz quad core processor; 3 GB RAM) and a Galaxy Note 8 (Android Oreo, 2.4 GHz octa core; 6 GB RAM). To apply Alohamora's policies without relying on origin web server modifications, our setup uses an NGINX reverse proxy server [45]. The proxy was run on a c4.large Amazon EC2 instance in California, which had a median latency of 11 ms to the origin web servers in our corpus.[1]

Immediately prior to the experiment, the proxy downloaded the dependency graph for each page, and all of the static objects in the graph that are candidates for pushing. The proxy also housed Alohamora's learned model for each page. At runtime, all requests from the mobile device were forwarded to the proxy via DNS rules; even with a single proxy, browsers still opened a separate connection per origin server since connection setup decisions are based on domain name (not IP address). Upon receiving the first request per origin in a page, the proxy generated and applied a policy (for that origin), pushing cached resources and rewriting HTTP headers to reflect preload decisions. The proxy could also apply Vroom's policies or forward requests to origin servers.

As shown in Figure 10, median PLT improvements were 2.3-11× higher with Alohamora than Vroom; SI results followed the same trend, but were elided for space. Figure 10

[1]These proxy-to-origin latencies present a pessimistic setting, since Alohamora is designed to run directly on origin web servers.

	Reward	LSTM	BW	CPU	Latency	Loss
C1	66 (97)	61 (93)	49 (93)	48 (90)	57 (94)	59 (91)
C2	69 (97)	65 (95)	58 (95)	54 (94)	59 (92)	62 (92)

Table 2: **Impact of removing features/properties in Alohamora's model. Results are reported as median (95th percentile) percentage of potential PLT improvements (compared to Alohamora's full model). "Reward" considers the intuitive $-PLT$ reward function. C1 and C2 are the $\{$12 Mbps, 100 ms, 2$\times$, 0%$\}$ and $\{$24 Mbps, 20 ms, 1$\times$, 1%$\}$ settings, respectively.**

also illustrates Alohamora's ability to properly adapt to conditions in the wild: whereas Vroom harms performance for up to 43% of pages, Alohamora *always* sped up loads.

6.5 Understanding Alohamora's Benefits

Ablation study: To understand the relative impact of each of Alohamora's features and model properties, we performed an ablation study (Table 2). Our results reveal that bandwidth, latency, CPU, and loss information all play significant roles in Alohamora's ability to generate performant push/preload policies, with the removal of CPU inputs resulting in the largest median degradations (46-52%). Our results also highlight the importance of Alohamora's reward function and incorporation of LSTM. For instance, (intuitively) setting the reward to $-PLT$ leads to performance degradations of around 30% because it becomes easy for the agent to artificially inflate the observed reward by selecting policies with fewer actions, i.e., the earlier policies in an episode will be favored as the cumulative reward will be lower. Removing LSTM, on the other hand, led to degradations of $\sim$35%, largely due to the lack of a discount factor that guides the agent to avoid unnecessarily favoring longer policies (§3).

Alohamora's policies: To understand the learned insights behind Alohamora's benefits, we analyzed its generated push/preload policies. Admittedly, we observe that policy composition and the mix between push/preload varied dramatically across pages and resource settings; indeed, subtle interactions between these properties were a primary motivator for Alohamora's machine learning-based approach. However, we note the following common principles:

- In lower bandwidth settings, Alohamora either 1) reduced the policy length or cut data-intensive objects, or more commonly, 2) spread the same set of pushed/preloaded objects out across a larger set of parents in order to stagger downloads and reduce bandwidth contention.
- With slower CPUs, Alohamora's policies are careful to only push objects whose bytes could be downloaded until the next blocking JavaScript file is required; the goal is to prevent downstream CPU tasks from blocking on the network. In these cases, Alohamora's policies preloaded additional resources with the goal of having their downloads start (after the 0.5 RTT to contact the server) only after the next blocking resource was downloaded. In essence, the idea is to perfectly interleave downloads of non-blocking resources with the execution of blocking resources.
- For image-heavy sites (e.g., `pinterest.com`), Alohamora commonly excluded JavaScript/CSS files from its policies, and instead pushed/preloaded images that are rendered towards the top of the viewport, particularly in high-bandwidth settings or when SI is the target metric. The reason is that these pages have flat (not deep) dependency graphs, so blocking JavaScript files do not trigger cascaded serial network fetches; instead, image downloads have a larger blocking impact on load times.

We leave a more detailed analysis of Alohamora's generated policies, and an exploration into whether those policies could be converted into fixed general heuristics, to future work.

Unnecessary data usage: A well-documented risk with HTTP/2 push is in having servers push objects that are not needed by or already cached at the client browser [43, 54]. Alohamora avoids this issue in two ways: browser cache contents are explicitly considered during policy generation, and only resources that consistently appear in a page are considered for push/preload (§3.1). Consequently, we observe that Alohamora's policies do not waste any bandwidth, i.e., all pushed/preloaded objects are used in the targeted page load.

Training times: Training an Alohamora model for the median page in our corpus required 76 iterations and took a total of 19.4 minutes to reach convergence using an Amazon EC2 `c5.18xlarge` instance. This translates to a monetary cost of $0.62. We note that training costs are incurred offline and infrequently: Alohamora must retrain only when a new or modified page falls outside of the previous cross-page clusters, which we observe occurs on the order of weeks (§4.1).

Inference times: Alohamora's policy generation adds negligible delays to overall load times: median (95th percentile) inference times are 11 ms (40 ms), respectively.

6.6 Additional Results

We briefly summarize our remaining experiments here due to space constraints, and defer details to the §A.2.

Incremental deployment: We ran experiments to understand how benefits vary with different adoption rates. We found that benefits (unsurprisingly) increase as more domains adopt Alohamora, but simply having the top-level origin can achieve 56% of the potential median benefits.

Cross-page clustering: We performed an end-to-end evaluation of Alohamora's clustering strategy (§4) by training a model for each of the 100 sites in Figure 4, using only a single page per cluster. These models achieve 85-90% of the improvements achieved when training on pages individually.

Other pages, input errors, and energy savings: Alohamora's benefits persist (and in fact, increase) for interior pages and less popular sites, are robust to errors in network or device measurements, and yield per-page mobile device energy reductions of 16-23%.

7 Related Work

We discuss the most closely related work here, and present additional related work in §A.3.

Server push systems: Numerous studies have explored the performance of HTTP/2 (formerly SPDY), both with and without server push and preload [16, 20, 53, 54, 60, 70]. Like us, these works have found mixed performance benefits due to the subtle relationships between HTTP/2 and network characteristics, page composition, and TCP semantics. However, these prior efforts have all investigated and promoted static policies and configuration guidelines. In contrast, Alohamora leverages a data-driven approach to dynamically tune push/preload policies by explicitly factoring in both page composition and the target execution environment.

Mobile-optimized pages: Certain systems, most notably Prophecy [40], automatically rewrite web pages and return post-processed versions of objects to clients that reduce client compute and network costs. Unlike Prophecy, Alohamora does not alter page content, which has proven to be error-prone in practice [2]. Further, Alohamora can accelerate Prophecy pages which require at least one HTML file per frame, and unmodified image and style files—these are the static files which Alohamora targets for push/preload.

Proxy-based accelerators: Compression proxies [2, 47, 55, 58] compress objects in-flight between clients and servers, while remote dependency resolution proxies [43, 44, 56, 57] perform certain object fetches and computations on behalf of clients. Though performant, such acceleration proxies violate the end-to-end security guarantees of HTTPS. WatchTower [43] addresses this dilemma, but at a significant deployment cost, as each origin in a page must operate its own proxy. Alohamora avoids such security concerns by relying only on end-to-end HTTP/2 optimizations.

Dependency-aware scheduling: Klotski [8] analyzes pages offline to identify high-priority objects, and uses knowledge of network bandwidth and page structure to stream them to clients before they are needed. Klotski's dynamic prioritization hinges on global knowledge of object fetches, which proxies provide at the cost of security; in contrast, Alohamora origins operate independently and hedge against the decisions that other origins may make. Polaris [39] uses a client-side scheduler that reorders requests to minimize serial round trips without violating dependencies. However, unlike Alohamora, Polaris relies on clients to discover page resources, and thus cannot eliminate certain serial fetches.

8 Conclusion

Configuring HTTP/2 push/preload policies has proven challenging, as benefits depend on complex interactions between dynamic page, network, device, and browser properties. This paper presents Alohamora, a mobile web optimization system that dynamically generates HTTP/2 push/preload policies using Reinforcement Learning. To ensure practicality, Alohamora introduces novel techniques that drastically reduce the number of pages to consider for training, and the cost of training any one page—these benefits come without a drop in model generalizability. Across a broad range of settings, we find that Alohamora outperforms default loads and recent push systems by 19-61% and 3.6-4×, respectively.

Acknowledgements. We thank Harsha Madhyastha, Vaspol Ruamviboonsuk, and Anirudh Sivaraman for their valuable feedback on earlier drafts of this paper. We also thank our shepherd, Aruna Balasubramanian, and the anonymous NSDI reviewers for their constructive comments. This work was supported in part by NSF grant CNS-1943621.

Table 3: **Median (95th percentile) simulator runtimes in milliseconds with varying push/preload policy length.**

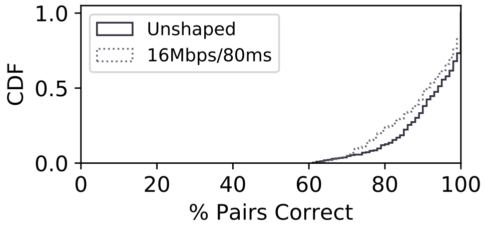

Figure 11: **Alohamora's simulator is able to correctly compare push policy pairs (in terms of relative performance).**

A Appendix

A.1 Additional Simulator Details

Additional performance metrics: We extended Alohamora's simulator to return the Speed Index and above-the-fold time [42], which is the time-instant version of Speed Index (§6.1). For this, during profiling, the simulator determines the positional information for each page component. Note that this information is dictated by page content, and can be parsed in relation to the target viewport size, i.e., we can collect positional coordinates for each page component during the profiling load, and then determine the visible content for any given viewport size [42]. With this information, the simulator identifies the set of page objects that affect the visual aspects of the target browser viewport, and characterizes performance as the time when the last node in the collected set completes its load. The simulator is also amenable to other performance metrics. For instance, to evaluate Ready Index [42], the profiling step must measure the fraction of the viewport that is visually or functionally affected by each object's execution; performance would be progressively tracked as the weighted average between time and each object's fraction.

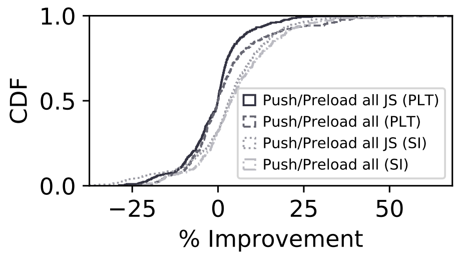
Warm cache page loads: In order to handle warm-cache browsing scenarios, the simulator takes an additional input: the list of resources that it should consider as cached, which can be computed by analyzing HTTP headers according to a desired warm cache timing, i.e., the time between the cold and warm cache page load [41]. The simulator then operates as normal, but sets the network RTTs required to fetch a cached resource, and the bytes that must be downloaded, to 0; *request delays* for downstream children of blocking resource are also updated.

Simulator speed vs. push/preload policy length: Table 3 shows that the simulator's runtime does steadily increase as the length of the push/preload policy under test grows. The reason is that Alohamora's approach to handling push/preload policies requires re-simulations of the page a number of times that is quadratic with the policy length. We note, however, that the resulting runtimes are still several orders of magnitude lower than default browsers, and Alohamora rarely requires investigation of policies longer than 20 objects (§6).

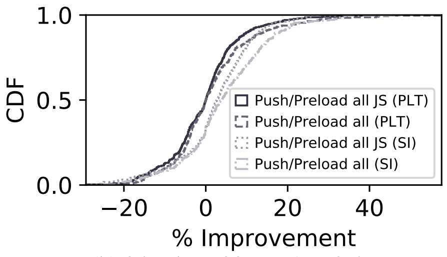
Push/preload fidelity results: §5 presented results showing the low error rates that Alohamora's simulator achieves for page loads that do not use push/preload policies. With respect to push/preload policies, the key property required for Alohamora's training is to be able to determine which of two policies results in superior performance. To evaluate the simulator's faithfulness for this, we generated 20 random push/preload policies for each page in our corpus. For each page, we counted the fraction of policy pairs for which the simulator correctly predicted the relative performance (correctness was defined by a real browser). As shown in Figure 11, the simulator correctly reported the relative comparisons across pairs 90% of the time.

Comparison to prior simulators. Several recent works have proposed web page load simulators and emulators. Here we briefly describe these prior approaches, explain their limitations for Alohamora's training scenario, and contrast them with the operation of Alohamora's simulator.

- EPLOAD [60] controls the variability in the page load process (for reproducible measurements) by profiling a page load and recording fine-grained delays between browser compute tasks (including dependencies captured by WProf [59]). EPLOAD then replays the page load process by replaying those blocking delays (via injected sleeps), but making fetches over a live (controlled) network. Thus, EPLOAD *emulates* the page load process, running live network tasks and forcing compute delays to match those from the profiled load. In contrast, Alohamora *simulates* the entire page load process, by respecting the invariant dependencies enforced by a browser and page content, as well as by modeling the interactions between the browser and underlying environment. This difference is critical to Alohamora's simulation goals: simulation enables Alohamora to evaluate push/preload policies in a few milliseconds (rather than 10s of seconds); EPLOAD's emulation approach does not shrink load times, and instead focuses on fine-grained reproducibility. Consequently, EPLOAD would not be able to accelerate training with Alohamora. Beyond this fundamental difference, Alohamora's simulator also is able to evaluate HTTP/2 push/preload policies, simulate a variety of environmental factors (CPU speeds, etc.), and evaluate performance on multiple performance metrics (e.g., Speed Index)—EPLOAD lacks these features.
- RT-H2 [68] uses profiles of HTTP/1.1 page loads to estimate the predicted performance changes for the scenario when those profiled loads were converted to using HTTP/2. The system's page load conversion model considers how HTTP/2 features (e.g., request multiplexing) affect the ordering of different page load tasks, as well as



(a) 18 Mbps, 60 ms, 4×, 1%



(b) 24 Mbps, 20 ms, 1×, 0%

Figure 12: **Performance comparisons between two existing (standard) push/preload strategies: push/preload all and push/preload all JavaScript (JS). Results are relative to default page loads (i.e., no push/preload).**

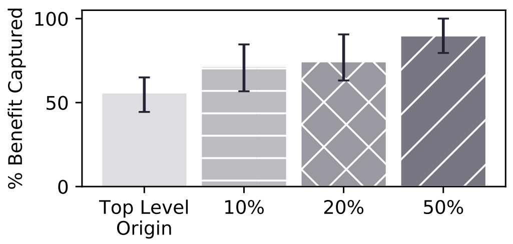


Figure 13: **Percentage of potential benefits achieved when X% of origins in each page run Alohamora. Results are for the {12 Mbps, 100 ms, 2×} setting. Bars show medians, with error bars spanning 25-75 percentiles.**

the cascading effects that those changes have on underlying network resources (e.g., TCP semantics). While similar to Alohamora's simulator with respect to approximate TCP modeling, the core limitation of RT-H2 (with respect to Alohamora's training) is that RT-H2 can only predict the performance of HTTP/2 page loads within the exact same settings as seen in the HTTP/1.1 profiles. In other words, RT-H2 cannot use its profiles to predict HTTP/2 performance outside of the profiling environments. This is problematic for Alohamora's setting, as this implies that a profile would have to be collected for every environment considering during training—this would forfeit most of the simulation benefits. Beyond this, unlike Alohamora, RT-H2 does not consider different performance metrics, compute resources, preload, or variable push policies.

A.2 Other Results

Comparison of existing push/preload strategies: In determining a competitive performance baseline to compare Alohamora with, we considered two standard push/preload (static) heuristics: *push/preload all* and *push/preload all JavaScript*. As noted in §6.1, these strategies solely differ in the set of objects that they consider for push/preload. Using the same experimental setup from Figure 7, we compared these two strategies in terms of speedups that they provide over a default page load. Figure 12 presents representative results. As shown, *push/preload all* provides roughly the same (0-1% more) speedups as *push/preload all JavaScript* at the median, and 5-17% larger speedups at the 95th percentile.

Incremental deployment: Since origins make independent push/preload decisions with Alohamora, we ran experiments to understand how Alohamora's benefits vary with different adoption rates. For each page in our corpus, we ordered the domains in the page according to the fraction of objects that they contribute. We then ran experiments where only the top X% of origins used Alohamora; origins not running Alohamora did not push/preload any objects. We also specifically considered the case where only the top-level origin deployed Alohamora. As expected, Figure 13 reveals that benefits increase as more domains adopt Alohamora. However, simply having the top-level origin can achieve 56% of the potential (i.e., with 100% adoption) median benefits.

Cross-page clustering: To this point, the presented results considered Alohamora models that were trained for a single page (across environments). In order to evaluate Alohamora's ability to train generalizable models across a site's pages, we consider the 100 sites presented in §4 (Figure 4). For each site, we trained a single Alohamora model using only a single (randomly selected) page from each cluster, and evaluated across all of the site's pages. Alohamora's cross-page models are able to achieve within 85-90% of the improvements achieved when training individually on each tested page; this slight degradation comes with the significant benefit of improved training efficiency.

Robustness to input errors: To generate push/preload policies, Alohamora's models ingest a variety of observations that collectively characterize the execution environment. While cache contents require zero approximation to collect, network and CPU measurements can be noisy and hard to report accurately. We evaluated Alohamora's ability to deliver speedups in the face of noisy inputs characterizing network and CPU speeds by considering the following errors: average bandwidth, latency, and loss errors of {1, 2, 3} Mbps, {10, 20, 30} ms, and {0.5, 1, 2}%, and CPU slowdown errors of {1, 2, 4}×. We find that Alohamora's generated policies are largely robust to such errors. For instance, median PLT improvements dropped by only 3.4%, 4.6%, and 3.9% in the {24 Mbps, 20 ms, 2× CPU slowdown} environment with errors of 2 Mbps, 20 ms, and 1%, respectively. Similarly, a CPU slowdown error of 1× resulted in only a 2.6% reduction in PLT improvements.

Additional pages: In addition to the 500-page corpus that we used for our primary experiments (§6.1), we also eval-

	Cluster 1	Cluster 2	Cluster 3
Cluster 1	88% (91%)	50% (55%)	52% (59%)
Cluster 2	57% (52%)	94% (89%)	59% (55%)
Cluster 3	61% (56%)	49% (57%)	100% (93%)

Table 4: **Evaluating Alohamora's cross-page generalization approach. Results are for the {24 Mbps, 20 ms, 2× CPU slowdown} setting, and 30 pages per site. Here we show results for two representative pages that yielded 3 clusters each: NPR (clusters with 19, 8, and 3 pages) and CNN (1, 17, and 12 pages). For each cluster, we picked a random page and found its best policy (via brute force search). We then applied that same policy to the other pages in the same cluster, and to pages in different clusters. Results list the % of possible push/preload benefits for the median page in each cluster, and are presented as CNN (NPR). Takeaway: policies generalize well within clusters (blue regions), but not across clusters (white regions).**

uated Alohamora on two additional sets of sites: 1) 100 interior pages that were collected using a monkey crawler [1] that clicked links on each landing page in our primary corpus, and 2) 100 less-popular landing pages that were randomly selected from the Alexa top 10,000 list (excluding the top 500). Using the same experimental setup described in §6.1, we find that the previously reported trends persist, and in fact, Alohamora's benefits increase. For example, in the {24 Mbps, 20 ms, 1× CPU slowdown, 0%} setting, median PLT improvements with Alohamora were 26% and 27% for the interior and less-popular corpora, respectively; for comparison, the push/preload all strategy achieved benefits of only 3% and 5%. These results are consistent with the observations in prior work [40] that interior and less popular pages are typically more complex, and involve longer serial dependency chains that can be optimized.

Energy usage: To evaluate the impact that Alohamora has on mobile device energy usage, we reused our real world experimental setup (§6.4) and connected the Nexus 6 smartphone to a Monsoon power monitor [35]. Overall, we observed that Alohamora reduces median per-page energy consumption by 23% and 16% compared to a default page load, on the LTE and WiFi networks, respectively. The savings are higher in the LTE setting primarily due to the fact that LTE radios consume more energy than WiFi hardware when active [57]—the higher network latencies on LTE networks lead to more significant load time reductions, which in turn produce larger energy savings.

Clustering: Table 4 presents evaluation results for Alohamora's clustering strategy using two representative sites; these results are a subset of those in Figure 4.

A.3 Additional Related Work

Mobile-optimized pages: Certain sites cater to mobile settings by serving pages that involve less client-side computation, fewer bytes, and fewer network fetches. For example, Google AMP [21, 25] is a recent mobile web standard that requires developers to rewrite pages using restricted forms of HTML, JavaScript, and CSS. Unlike AMP, Alohamora accelerates legacy pages without developer effort. Further, Alohamora's adaptive push/preload policies can improve the performance of AMP pages because all page resources still must traverse a client's slow mobile access link.

Prefetching: Prefetching systems predict user browsing behavior and optimistically download objects prior to user page loads [28, 49, 62]. Unfortunately, such systems have witnessed minimal adoption due to challenges in predicting what pages a user will load and when; inaccurate page and timing predictions can waste device resources or result in stale page content [52]. In contrast, Alohamora generates push/preload policies only after a user navigates to a page, and considers the environmental conditions and page properties collected in situ.

Oblique: Accelerating Page Loads Using Symbolic Execution

Ravi Netravali
UCLA

Abstract

Mobile devices are often stuck behind high-latency links. Unfortunately for mobile browsers, latency (not bandwidth) is often the key influence on page load time. Proxy-based web accelerators hide last-mile latency by analyzing a page's content, and informing clients about useful objects to prefetch. However, most accelerators require content providers to divulge cleartext HTTPS data to third-party analysis servers. Acceleration systems can be installed on first-party web servers, avoiding the violation of end-to-end TLS security; however, due to the administrative overhead (and additional VM costs) associated with running an accelerator, many first-party content providers would prefer to outsource the acceleration work—if outsourcing could be secure.

In this paper, we introduce Oblique, a third-party web accelerator which enables secure outsourcing of page analysis. Oblique symbolically executes the client-side of a page load, generating a prefetch list of symbolic URLs. Each symbolic URL describes a URL that a client browser should fetch, given user-specific values for cookies, the `User-Agent` string, and other sensitive variables. Those sensitive values are never revealed to Oblique's analysis server. Instead, during a real page load, the user's browser concretizes URLs by reading sensitive local state; the browser can then prefetch the associated objects. Experiments involving real sites demonstrate that Oblique preserves TLS integrity while providing faster page loads than state-of-the-art accelerators. For popular sites, Oblique is also financially cheaper in terms of VM costs.

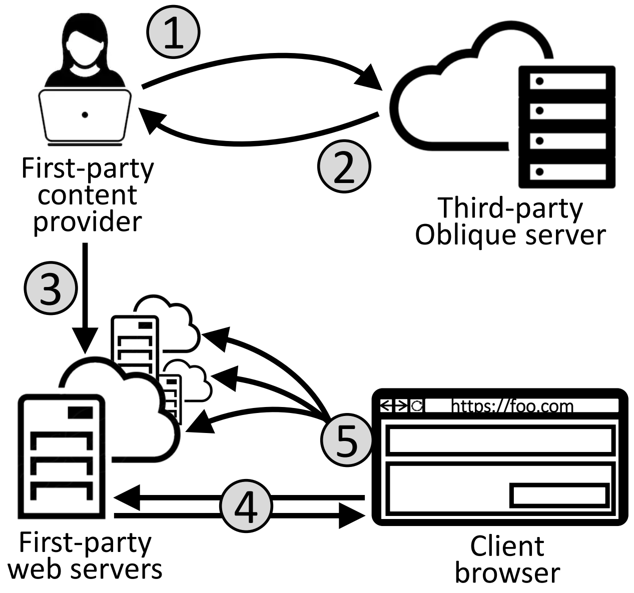

Figure 1: Overview of Oblique's design. A developer uploads page content to Oblique's analysis server (①). Oblique returns the path constraint tree for the page (②). The developer uploads the page content to web servers (③), injecting Oblique's JavaScript library into the page's HTML. Later, when a user loads the page (④), the prefetching library uses the path constraint tree to prefetch objects (⑤).

1 Introduction

Two trends are reshaping modern web services: the increasing prevalence of mobile traffic, and the continued shift from HTTP to HTTPS. 53% of all page requests now originate from smartphones [5]. 90% of those requests use HTTPS [16].

Many mobile users (particularly in emerging markets) are still stuck behind slow 3G and 4G links; even high-bandwidth 5G links often suffer from 4G latencies [11]. Unfortunately, page load times are usually determined by latency, not bandwidth [21, 24]. A variety of mobile page accelerators try to mask last-mile latency by (1) analyzing the objects (e.g., HTML and JavaScript files) that are contained by a page, and then (2) reducing the perceived fetch latencies for those objects (e.g., using server-side pushing [1,24,29,34,35] or client-side prefetching [21,29]). Unfortunately, the shift from HTTP to HTTPS has created tensions between security, performance, and the financial cost of hosting a web site. Accelerators like Silk [1] that perform remote dependency resolution [3,24,35] route client traffic through third-party proxies; these proxies are owned by browser vendors or mobile providers, and are operated for the benefit of customers. The proxies require access to cleartext HTTPS content to determine which objects to prefetch (§2). Thus, content providers that use HTTPS are faced with a dilemma: allow third-party proxies to man-in-the-middle TLS connections, or forgo the performance benefits provided by outsourced web accelerators. The former choice breaks end-to-end TLS security, and the latter option hurts page load times.

A content provider could decide to run a first-party web accelerator like Vroom [29] locally; this approach would avoid revealing cleartext HTTPS data to an untrusted middlebox. However, the content provider would incur a new financial penalty. Running a web accelerator requires extra CPU cycles and memory space beyond what is required to run a traditional web server. The content provider would have to pay for those extra VM resources.

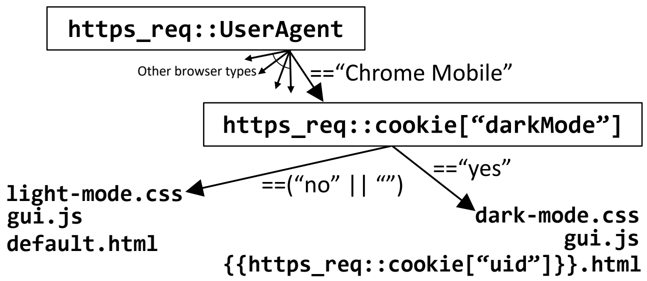

Figure 2: A simplified example of a path constraint tree. At page load time, Oblique's client-side JavaScript library traverses the tree, using load-time concrete values to trace a path to a leaf. The leaf enumerates which URLs Oblique should prefetch. Those URLs may need to be concretized with load-time values (e.g., a cookie value in this example).

In this paper, we introduce Oblique, a new system for accelerating page loads. Oblique's goal is to improve the load time reductions provided by state-of-the-art accelerators, while enabling *cheaper, more secure outsourcing* of the analyses which identify the objects that a client should prefetch. Figure 1 depicts Oblique's architecture. When a content provider creates a new page, the provider feeds the new content to a third-party Oblique server. The server performs a *symbolic page load*, exploring the possible behaviors of a web browser and a web server during the page load process. The output of the symbolic page load is a *path constraint tree*, as shown in Figure 2. Each leaf is a set of URLs that a client should prefetch, and each path from root to leaf represents symbolic constraints on the actual client-side and server-side state that is observed at the time of a real page load. During an actual page load, Oblique inspects concrete state like a client's cookie, traces a path through the constraint tree, and prefetches the relevant objects using a client-side JavaScript library.

Security: Oblique's offline analysis server does not see concrete instances of uniquely-identifying client data. For example, the server does not observe concrete values for any user's cookies or `User-Agent` string. Instead, the analysis server only sees page content that could have been fetched by any actor on the internet who can issue HTTPS requests. Later, during an actual page load, the analysis server is totally uninvolved, and receives no information about sensitive concrete values. In contrast, remote dependency resolution (RDR) forces clients to divulge cleartext HTTPS traffic, exposing cookies and other private values.

Financial cost: Oblique's offline symbolic analysis occurs when a new page version is created. The analysis cost (as measured by VM rental fees) is amortized across all client loads of the page. For popular pages, this amortized expense will be less than the aggregate per-page-load costs incurred by third-party RDR or first-party accelerators like Vroom. RDR must launch a proxy-side web browser for every client-initiated page load, whereas a Vroom-enabled web server must analyze HTML on-the-fly (§5.2).

Performance: In addition to Oblique's security and cost benefits, Oblique also loads pages up to 16% faster than RDR and Vroom (§5.2). The reason is that Oblique's symbolic analysis enables more accurate prefetching: fewer unnecessary objects are prefetched, and more objects that are truly needed are prefetched. For example, Oblique can accurately model URLs that embed random numbers; these numbers are represented symbolically in a path constraint tree, and are late-bound to concrete values at page load time (when a client generates concrete random numbers). In contrast, Vroom and RDR early-bind random numbers at analysis time, resulting in wasted prefetches, or potentially prefetchable objects being ignored (§3.3).

Summary: This paper provides three contributions:

- We describe how to symbolically evaluate client-side page load activity (§3.2), using concolic execution to model the JavaScript engine and the rendering engine. Core technical challenges involve tracking symbols that flow across the DOM interface, and preventing Oblique's third-party server from gaining insights about sensitive client-side values derived from nondeterministic functions like `Math.random()`.
- We also describe how to symbolically evaluate the *server-side* half of a page load. By analyzing both sides of a load, Oblique can generate even better prefetching hints (§3.4). The core challenges involve the complexities of HTML templating engines, and the careful orchestration needed to ensure that server-side symbols propagate to the symbolic analysis of client-side behavior. To analyze both client-side and server-side behavior, Oblique requires access to backend code and data; that state is sensitive, so Oblique should execute on first-party machines in this mode.
- We build and evaluate an Oblique prototype, and compare it to prior state-of-the-art load accelerators. When Oblique executes in third-party analysis mode, it only analyzes client-side symbols; in this mode, first-party developers can securely outsource prefetch analysis to Oblique, enjoying better security than RDR, and faster page loads than both RDR and Vroom. For popular pages, Oblique also provides lower economic costs due to better amortization of analysis overheads. If page owners are willing to run Oblique on first-party infrastructure, Oblique's client+server analysis can unlock even greater reductions in load time.

Oblique requires no changes to end-user browsers, and reduces overall page load times by up to 31%. To the best of our knowledge, Oblique is the first web accelerator that securely enables outsourced prefetch analysis for HTTPS content.

2 Background

A web page's *dependency graph* [21] captures the load-order relationships between a page's constituent objects. For example, a page's top-level HTML might contain references to a JavaScript file and an image. To load the page, a browser must fetch and evaluate both objects. Evaluating the JavaScript file might generate additional fetches, e.g., because the executed JavaScript code uses the `Fetch` API to issue new HTTP requests. Evaluating the image file causes the associated pixels to be displayed; the reception of the image data may also trigger JavaScript `onload` event handlers. Those handlers can generate more fetches. The overall page load completes when a critical subset of a page's objects have been fetched and evaluated. Different load metrics use different criteria to identify the critical subset (§5).

Web accelerators leverage knowledge of a page's dependency graph to reduce a page's load time. One popular approach is remote dependency resolution (RDR) [1,3,23,24,26,35]. An RDR system deploys a proxy server that has low-latency paths to the internet core. An end-user's browser sends each page load request to the proxy. Upon receiving such a request, the proxy launches a headless browser (i.e., a browser that lacks a GUI). The proxy-side browser loads the requested page and streams the fetched objects to the user's browser. By doing so, the proxy can partially mask the user's high last-mile latency: the page's dependency graph is resolved via the proxy's fast network links, and the bytes in each discovered object are pushed to the client as soon as the proxy receives those bytes.

RDR can reduce page load times by up to 40% [24]. Unfortunately, RDR proxies are computationally expensive to run, because web browsers (even headless ones) are complex, resource-intensive applications. A proxy can use backwards program slicing [37] to try to only execute the JavaScript code that influences calls to functions like `Fetch()`. However, slices are often inexact, and the degraded prefetching underperforms traditional RDR for 34% of pages [34].

An RDR proxy must act as a man-in-the-middle for TLS connections. Doing so allows the headless browser to parse cleartext web content and fetch the same objects that a user's browser will eventually want to fetch. However, breaking TLS's end-to-end security is obviously problematic; it allows RDR proxies to see user cookies and other sensitive HTTPS content.[1] This security violation also plagues non-RDR accelerators that perform third-party analysis of dependency graphs [6,22,40]. Cryptographic schemes that allow middlebox computation over encrypted TLS data [32] are insufficiently expressive to analyze dependency graphs; prefetch analysis requires a Turing-complete language to parse HTML and evaluate JavaScript.

Vroom [29] is a first-party web accelerator: dependency analysis runs on infrastructure belonging to the content provider. For each page, Vroom performs both offline and online analysis. The offline phase runs periodically (e.g., once an hour), using a headless browser to collect the set of URLs loaded by a page. Across multiple offline page loads, Vroom identifies a "stable set" of URLs that were fetched during each load. When a client initiates a real page load, a Vroom-modified web server parses HTML on-the-fly while streaming it to the client, extracting the embedded URLs. These embedded URLs, plus the ones found during offline analysis, comprise the set of URLs to prefetch. The web server induces the client to speculatively load these URLs via a combination of HTTP/2 push [2] and `<link>` prefetch hints [42].

Vroom's analyses run on first-party machines, so HTTPS secrets are not leaked to third parties. However, Vroom's online analysis cannot be outsourced securely: a benevolent mobile provider who wants to run Vroom on behalf of its users will have to break the HTTPS confidentiality of real user page loads. Vroom's offline phase also requires hand-tuning to deal with the heterogeneity of client browsers. For example, many sites define mobile and desktop versions of each page. A server determines which version to return by examining the `User-Agent` header in a client's HTTP request. Vroom's offline phase must be manually configured to explore the state space of all client-specific parameters like `User-Agent` and the client's screen size. Oblique's symbolic analysis allows Oblique to automatically explore this state space.

3 Design

At a high level, Oblique's offline analysis generates a *prefetch tree* for a page. The tree informs a client which HTTPS objects to prefetch in which situations. The input to the tree traversal is client-specific, potentially-sensitive information like cookie values; the output is a set of URLs. Oblique generates the tree by symbolically evaluating the client-side of a page load (§3.2). The URLs (found at the leaf nodes) are symbolic expressions that a client makes concrete by plugging in client-specific information that is never revealed to Oblique. If a page uses Node [25] (a popular server-side JavaScript framework) to generate HTML, Oblique can also symbolically evaluate server-side code (§3.4). Receiving visibility into both client and server execution allows Oblique to generate prefetch trees with more true positives and fewer false negatives: in other words, clients will fetch more useful objects and fewer unnecessary ones.

3.1 Overview of Concolic Execution

Oblique uses a particular variant of symbolic evaluation called concolic execution [14,31]. In concolic execution, a program is given a concrete set of initial inputs. The program is then executed under the observation of the concolic framework. The concolic framework assigns a "shadow" symbolic expression to each input value and to each internal program variable. An input's initial symbolic expression is only con-

[1]WatchTower [24] allows each HTTPS origin to run its own RDR proxy. This approach solves the security problem by exacerbating the computational overhead problem, since now *every* HTTPS origin must run a proxy.

strained by the limitations of the input's type. For example, a `uint32` input x might receive an initial concrete value of 2, but an initial symbolic constraint of $(0 \leq x \leq 2^{32}-1)$. During the program's execution, the assignment $y = x/2$ would result in y receiving the concrete value of 1, and the symbolic constraint $y == x/2$. When the program's execution hits a branch statement (e.g., `if(x >= 42){...}else{...}`), execution proceeds along the appropriate path, but the symbolic expressions for the branch-test variables are updated. In the running example, the `else` clause is executed because x (equal to 2) is less than 42; x's symbolic constraint is updated to become $(0 \leq x < 42)$. As the program continues execution, variables receive updated concrete values and updated shadow constraints. Eventually, the program halts or a timeout fires. The concolic framework then explores a different execution path by backtracking along the branch history and selecting a branch direction to invert. In the running example, the concolic framework might choose to explore the taken side of the branch `if(x >= 42){...}else{...}`. To do so, the framework inverts the relevant part of x's symbolic expression, generating the constraint $(42 \leq x \leq 2^{32}-1)$. The framework consults an SMT solver [7, 12] to generate a concrete value for x that satisfies the new constraints. Concolic execution then proceeds down the new branch until the program terminates or a timeout fires. This backtrack-and-explore pattern repeats until all execution paths have been discovered or (more likely) the overall time budget for concolic execution expires. For each discovered path, the framework records the *path constraints*, i.e., the symbolic constraints on all of the input variables which must be true for the path to be taken. Note that path constraints are different than the symbolic constraints on a particular variable. In our running example, the constraint on y is $y == x/2$. The path constraints for that execution path are the aggregate set of constraints placed on x and the rest of the program inputs.

3.2 Analyzing Client-side Behavior

In the context of a concolic page load, the program inputs are client-specific environmental variables. These environmental variables determine the content returned by web servers, and the execution paths taken by a page's JavaScript. For example, when a server receives the HTTP request for an HTML file, the server may examine the `User-Agent` header to determine whether to return the mobile-optimized HTML or the desktop-optimized HTML. The value for the local browser's `User-Agent` header is accessible to JavaScript via the `navigator.userAgent` variable; JavaScript code might inspect that variable to execute different code paths for different browsers. Thus, a client's user agent string is an input to the concolic page load. Table 1 enumerates the client-side inputs that Oblique considers.

Figure 3 depicts the life-cycle for a concolic page load. A distributor assigns concrete values to the inputs; the cookie value is set to an empty string, and other inputs are set to

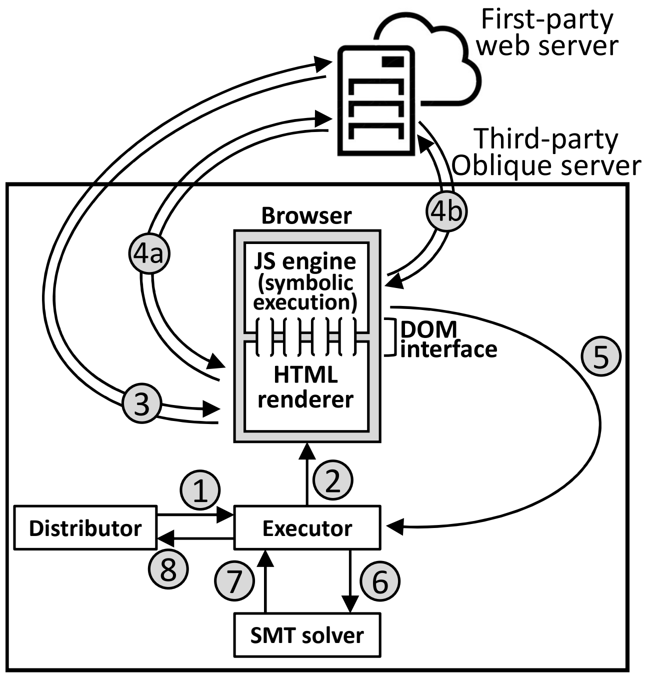

Figure 3: Overview of Oblique's approach for symbolically evaluating a client-side browser. See the mainline paper text for a description of each step.

default values for mobile Chrome. The distributor hands these values to the executor (①). The executor launches a modified web browser (②) that fetches the page's top-level HTML (③). The HTTP request for the top-level HTML uses the environmental values selected by the distributor. Note that the returned HTML will be a concrete string, not a symbolic one.

As the browser parses the HTML, the browser fetches and evaluates non-JavaScript files like CSS and images (4a). When a JavaScript file is fetched (4b), Oblique evaluates it using a modified version of the ExpoSE concolic engine [17]. As the JavaScript code executes, Oblique records the path constraints, and updates JavaScript variables with concrete values and symbolic constraints. When JavaScript code dynamically fetches an HTTP object (e.g., via `fetch(url)`), Oblique uses the *concrete* value of `url` to issue a real fetch. However, Oblique also records the symbolic constraints on `url`. These constraints, which represent a *symbolic URL*, are added to the prefetch list for the current execution path. As a contrived example, a symbolic URL might have the value "`x.com/?{{encodeURI(navigator.userAgent)}}`"; this URL would allow a web server to return different HTML to mobile clients and desktop clients.

In the prior example, the `{{}}` notation indicates a symbolic expression. The example also demonstrates how Oblique is enlightened about certain native functions like `encodeURI()`. Native functions are JavaScript-invocable methods whose implementations are provided by C++ code inside the browser.

Input name	HTTP header	JavaScript variable	Description
User agent	User-Agent	`navigator.userAgent`	The local browser type, e.g., "Mozilla/5.0 (Windows; U; Win98; en-US; rv:0.9.2) Gecko/20010725 Netscape6/6.1"
Platform	Included in User-Agent	`navigator.platform`	The local OS, e.g., "Win64"
Screen characteristics	N/A	`window.screen.*`	Information about the local display, e.g., the dimensions and pixel depth
Host	Host	`location.host`	Specifies the host and port number used by request
Referrer	Referer	`document.referrer`	The URL of the page whose link was followed to generate a request for the current page
Origin	Origin	`location.origin`	Like Referrer, but only includes the origin, omitting path information
Last modified	Last-Modified (response)	`document.lastModified`	Set by the server to indicate the last modification date for the returned resource
Cookie	Cookie (request), Set-Cookie (response)	`document.cookie`	A string containing "key=value" pairs

Table 1: Symbolic inputs to a client-side page load.

Oblique intentionally avoids the concolic execution of native code, since JavaScript-level semantics are the only ones of importance. However, to ensure that native methods correctly propagate JavaScript-level symbolic constraints, Oblique must associate a symbol policy with each native method. A policy describes how the symbolic inputs to a native method should be translated to symbolic outputs for the method. Oblique assigns policies to the most popular native methods that were seen in our test corpus (§5.1). Those methods include the ones defined by the `Math`, `String`, and `RegExp` objects. If a page invokes a native method that lacks a symbol policy, Oblique uses the concrete return value as the symbolic constraint; in other words, the native function acts as a black box that never returns symbolic data.

An HTML renderer maintains an internal data structure called the DOM tree. The DOM tree mirrors the structure of a page's HTML, with each HTML tag having a corresponding DOM node. JavaScript code uses the DOM interface to query or modify the DOM tree, e.g., to implement animations and register event handlers for GUI activity. During a symbolic page load, Oblique associates the DOM tree with a concrete HTML string and a symbolic one; the latter allows JavaScript-level symbols to flow into and out of the DOM tree via DOM methods. For example, given a reference `r` to a `<div>` tag's DOM node, JavaScript code could display the browser type using the assignment `r.innerHTML = navigator.userAgent`. A read of `r`'s parent in the DOM tree (e.g., `r.parentNode.innerHTML`) would return a string whose symbolic value contains `{{UserAgent}}`.

As the page load unfolds, Oblique logs the symbolic URLs that are passed to network APIs like `fetch()`. Oblique also interposes on the DOM interface, and logs the symbolic URLs which cross that interface. For example, suppose that JavaScript code uses the `Node.appendChild(imgNode)` method to add a new `<img>` tag to the page. Oblique would log the symbolic URL associated with the `imgNode.src` attribute; logging the URL reflects the fact that executing `Node.appendChild(imgNode)` causes the browser to fetch an image from a remote server.

Oblique's HTML renderer also logs the static, non-symbolic URLs in a page. These URLs are directly specified in a page's static HTML (e.g., `<link rel="stylesheet" href="styles.css">`) or dynamically injected by JavaScript via the DOM interface. The prefetch list for an execution path contains the static, non-symbolic URLs and the dynamic, possibly-symbolic URLs that are fetched by the path.

Oblique declares the page load to be done when the JavaScript `onload` event fires. The browser fires this event when the browser has finished the HTML parse, fetched all objects discovered by the parse, and evaluated all of those objects. As shown in Figure 3, the JavaScript engine informs the executor about the path constraints for the page load (⑤). The executor asks the SMT solver to invert a branch direction at some point along the path (⑥). Inverting the branch direction changes the symbolic constraints on the input values (§3.1). The SMT solver generates concrete input values that satisfy the new constraints (⑦). The executor returns those concrete input values to the distributor (⑧). These values represent a new test case that would cause the page to explore a different execution path.

The distributor launches many executors in parallel, running each one on a separate core. As the executors complete and return new test cases, the distributor launches new executors to explore new test cases. The distributor stops creating new executors once a predetermined time budget expires, or there are no more paths to explore. Higher budgets allow Oblique to discover more execution paths, but are more expensive in terms of VM costs. We evaluate these tradeoffs in Section 5.2.

When an executor completes its concolic page load, it logs two things: the list of symbolic URLs fetched by the page load, and the symbolic constraints on client-specific inputs like cookies. Once all executors have finished, the distributor analyses the aggregate set of executor logs to generate a tree of path constraints. Figure 2 provides an example of such a tree. Each leaf contains a set of symbolic URLs; each root-to-leaf path represents the client-specific input values which indicate that a page load will fetch the URLs at the leaf. The distributor translates the constraint tree into a JSON data structure. Finally, the distributor generates a JavaScript library that traverses the tree; at each node, the library applies regular expressions and comparison operators to the JavaScript representation of client-specific inputs (see Table 1). For example, the JavaScript code `/CriOS(54|55)/.test(navigator.userAgent)` determines whether the local browser is Chrome version 54 or 55 that runs atop iOS. Upon arriving at a leaf, the library concretizes the symbolic URLs in the leaf, and then prefetches those URLs using `XMLHttpRequest`.

Oblique sends the prefetching library (which embeds the JSON constraint tree) to the first-party web developer. The developer adds the library as an inline `<script>` tag at the beginning of the associated page's HTML. Later, when a real client browser loads the page, the library issues asynchronous prefetches, populating the local browser cache. As the browser's HTML parse examines the rest of the page and discovers references to external objects, the browser can pull those objects from its cache, avoiding wide-area fetch latencies.

3.3 Nondeterministic JavaScript Functions

JavaScript defines two categories of nondeterministic functions. Timestamp functions like `Date()` and `Performance.now()` read the system clock. Random number generators like `Math.random()` and `crypto.getRandomValues()` create pseudorandom or cryptographically-random byte sequences.

JavaScript code may consult nondeterministic functions during the construction of a dynamic URL. For example, a page might contain code like `if(Math.random() > 0.7){url="a.jpg"}else{url="b.jpg"}`. In that example, the URL embeds no symbols, but its value is controlled by the output of a nondeterministic function. Code like `url=Date() + ".jpg"` would create a URL that directly embeds the output of a nondeterministic function.

Both kinds of dynamic URLs will induce prefetch misses for RDR. The reason is that RDR uses a headless browser to generate a page's dependency graph (§2). The headless browser and the client-side browser will likely generate different nondeterministic values; thus, the two browsers will likely generate different dynamic URLs. To prevent such divergence, RDR could log the nondeterminism observed by the headless browser, and then force clients to use the logged sequence. This approach is the same one used by deterministic replay debuggers to faithfully recreate previously-observed program executions [8, 20]. However, in the context of accelerating page loads, this approach can break functionality. Clients will receive old wall-clock readings, and calculate elapsed time periods that do not accurately reflect the client's true perception of time. As a result, clients may fetch stale content or improperly calculate frame rates for animations. From the security perspective, exposing a client's `crypto.getRandomValues()` sequence to a third party is undesirable, because the client might use the sequence to derive keys or nonces.

Vroom will also suffer prefetch misses for dynamic URLs that are influenced by nondeterministic functions. Vroom's offline analysis identifies a stable set of URLs that are fetched by several different loads of a page (§2). Vroom's stable set analysis will drop URLs that only differ by a timestamp or a random number. The analysis will also drop URLs that do not directly embed nondeterminism, but are fetched via branching paths whose directions are chosen by nondeterminism.

Oblique handles these dynamic URLs without forcing clients to divulge their nondeterminism to third parties. During an offline symbolic execution, Oblique creates a unique, hidden variable for each invocation of a nondeterministic function. Oblique treats this variable as a client-specific input, akin to `document.cookie` or `User-Agent`. This approach enables Oblique to track how the outputs of nondeterministic functions influence branch decisions and the construction of dynamic URLs. For example, suppose that during symbolic execution, a page's JavaScript code invokes `Math.random()` twice, and then calls `Performance.now()`. Oblique generates the hidden variables $\mathtt{rand}_0$, $\mathtt{rand}_1$, and $\mathtt{pnow}_0$. As the symbolic page load continues, the load may generate dynamic URLs like `https://foo.com/?{{rand`$_0$`}}.js`. Oblique places these URLs in the prefetch list as normal. The symbolic execution may also branch on the values of $\mathtt{rand}_1$ and $\mathtt{pnow}_0$, just like the symbolic execution might branch on `User-Agent`. Later, during a real client-side page load, Oblique's prefetch library concretizes hidden variables before traversing the path constraint tree. In the previous example, the prefetch library would make two calls to `Math.random()`, and one call to `Performance.now()`. With the hidden variables now concretized, and with client-specific values like `User-Agent` in hand, the prefetch library can now traverse the path constraint tree and concretize all of the URLs that reside at the appropriate leaf.

The library prefetches the concretized URLs. Finally, the library dynamically patches [20] nondeterministic functions like `Math.random()` and `Performance.now()`, forcing those methods to return the values in the log of concretized hidden variables. The prefetching library is the first JavaScript code that executes in a page. Thus, as the rest of the page's JavaScript code executes, that code will craft dynamic URLs using the same nondeterministic values that Oblique used to construct prefetched URLs.

This approach may still result in unnatural calculations of elapsed time. For example, a page's normal JavaScript code may call `Performance.now()`, execute a lengthy computation, call `Performance.now()` again, and then use the elapsed time to construct a dynamic URL. If Oblique's prefetching library concretizes the two hidden variables using back-to-back calls to `Performance.now()`, the elapsed time used to influence prefetching will be much smaller than the elaspsed time used by the page's normal JavaScript. At worst, this will cause a wasted prefetch; Oblique only prefetches HTTP GET requests which (unlike POST requests) cannot induce side effects on the server. In future work, we hope to devise mechanisms to allow concolic execution to estimate wall clock time. This ability would enable Oblique to concretize hidden timestamp variables with higher fidelity.

JavaScript is an event-driven language. Thus, the execution order of event handlers (e.g., timers and GUI events) is another source of nondeterminism. Oblique does not attempt to control these sources of randomness, because the event loop only goes live after a page's HTML parse completes. This means that event-loop nondeterminism cannot affect URLs fetched during the HTML parse (e.g., via the `.src` attribute of HTML tags, or `XMLHttpRequests` issued by JavaScript). Event-loop nondeterminism *can* affect URLs fetched after the HTML parse completes.

3.4 Analyzing Server-side Behavior

When a web server receives a request for a page's top-level HTML, the server might dynamically construct the returned HTML. For example, the server might inspect the `User-Agent` string in the HTTP request, and return mobile content or desktop content as appropriate. As another example, the server might use the request's cookie to populate the HTML with user-specific URLs, e.g., corresponding to images of a user's previous purchases on an e-commerce site. Oblique's analysis from the previous sections will not detect this potential diversity of embedded URLs. The reason is that the prior analysis assumes that a page has only one version of its top-level HTML, and thus only one set of embedded JavaScript files; if this assumption is true, then the only goal of symbolic analysis is to explore branch paths in the fixed JavaScript code, identifying the dynamically-fetched URLs.

3.4.1 The Workflow

To generate more accurate prefetch lists for dynamically-generated pages, Oblique can optionally perform symbolic execution of both client-side JavaScript (that runs in a browser) and server-side JavaScript (that runs in the Node framework [25]). The end-to-end workflow looks like this:

- **Phase 1:** Oblique first performs a concolic execution of the server-side request handling code. For each test, the inputs are the HTTP request state, as well as nondeterministic function values (e.g., from Node's `crypto.randomBytes()` method). For each concolic path that is explored, Oblique logs the concrete HTML string that is generated, building a *server-side* path constraint tree. Each leaf contains a concrete HTML string, with each root-to-leaf path representing the constraints on server-side inputs that enable the concrete HTML string to be generated.
- **Phase 2:** Each concrete HTML string is fed to the client-side symbolic execution pipeline from Section 3.2. The output of that pipeline is a *client-side* path constraint tree. Each leaf contains symbolic URLs to prefetch, and each root-to-leaf path represents the symbolic constraints on client state that trigger the fetching of the leaf's URLs.
- **Phase 3:** Once Oblique has finished all of the symbolic executions (both client-side and server-side), Oblique creates a "super-constraint tree" which combines the knowledge gleaned from the individual constraint trees. The super tree maps Phase 1 path constraints on server-side inputs to the appropriate client-side path constraint tree from Phase 2; in other words, each leaf in the super tree is a client-side path constraint tree.

When a real client loads the page, the web server uses the values in the HTTP request to traverse the super tree; if the super tree branches on the return values of server-side nondeterministic function, the web server concretizes those values using the approach from Section 3.3. When the server reaches a leaf in the super tree, the server injects the leaf's prefetching library into the dynamically-constructed HTML. The subsequent construction process for the HTML is guided by the values in the HTTP request, and possibly by nondeterministic functions; those functions return the already-concretized values which guided the traversal of the super tree. When the client receives the HTML, Oblique's prefetching library executes as described in Section 3.2.

3.4.2 Templating Engines

In Phase 1, Oblique symbolically executes the server-side request handler. A developer has two options for specifying an entry point into request-handling code. First, a developer can register an `http.Server.request` event handler with Oblique. When a client request arrives, Node creates a new `http.IncomingMessage` object and invokes the handler. Oblique uses the object's HTTP headers as test inputs for concolic execution of the handler.

```
------ Server-side JavaScript ------
app.get('/', function(req, res) {
  //...examine req and derive the template parameters,
  //and then...
  res.render('template.ejs',
             {userAgent: req.headers['user-agent'],
              userID: 'alice',
              userName: 'Alice',
              nonce: random_value});
});
----------- template.ejs -----------
<html>
  <head></head>
  <body>
    <p1> Welcome to foo.com, <%= userName %>! </p1>
    <% if (userAgent.includes('Android')) { %>
      <img src='site-logo-mobile.jpg'>
    <% }  else { %>
      <img src='site-logo-desktop.jpg'>
    <% } %>
    <img id='session-<%= nonce %>'
         src='<%= userID %>.jpg'>
  </body>
</html>
```

Figure 4: An example of dynamic HTML generation using EJS templates. EJS directives are shown in bold.

The disadvantage of the prior approach is that, during the construction of dynamic HTML, a server may consult *IO-based* sources of nondeterminism. For example, the server may issue a database query, or send an RPC to an external server. Oblique does not log and replay such IO responses. Thus, the concretized Phase 1 HTML that Phase 2 consumes may be different than the dynamic HTML that is generated at the time of an actual page fetch. Such a mismatch would hurt Oblique's prefetching accuracy.

Oblique can avoid this problem if server-side code uses a template engine to generate dynamic HTML. For example, consider EJS [9], a popular template framework. EJS defines a `render(html, dict)` method. The first argument is a template string (e.g., "`<html>Hello {{name}} at {{tstamp}}`"). The second argument is a dictionary which maps template arguments to program variables (e.g., `{name: httpReq.cookie.uid, tstamp: Date.now()}`). EJS examines the template and automatically generates a JavaScript program; this program, which is executed by `render()`, performs the necessary computations to parse `dict` and emit the customized HTML. Figure 4 provides a more complex example of an EJS template.

If a developer uses EJS, then she can tell Oblique to concolically analyze the EJS-created templating JavaScript. The output of Phase 1 is now different: it consists of server-side path constraint trees that are associated with just the templating JavaScript, not the overall handler call chain. Each leaf still contains a concrete HTML string that is passed to the concolic client-side analysis in Phase 2. However, a leaf also contains the *symbolic* HTML string that was output by the Phase 1 analysis. The symbols in this string come from the `dict` argument to `render()`. In the example from Figure 4, the symbolic HTML references the `dict` arguments `userName`, `nonce`, and `userID`. Note that the `dict` argument `userAgent` does not appear in symbolic HTML; that argument is branched upon in the path conditions, but is not directly embedded in the HTML itself.

With template integration, Phase 3 is altered as well. When the web server receives a request, the server executes the request handler up to the invocation of `render()`. At that point, the server has queried any sources of nondeterminism (IO-based or otherwise); the server now possesses concrete values for all the inputs to `render()`. The server can then traverse the super tree, find the appropriate symbolic HTML, concretize it, extract the static URLs inside the concrete HTML, and then inject the appropriate prefetching library. Note that extracting static URLs from the concretized HTML is faster than a naïve top-to-bottom HTML parse, since Oblique has a priori knowledge of the offsets where the URLs will be.

3.5 Security Analysis

Oblique's security properties depend on whether symbolic analysis examines only client behavior, or both client and server behavior. Consider the scenario in which Oblique only analyzes client-side activity. In this case, Oblique only requires access to first-party content that is already publicly accessible via first-party web servers. From the perspective of a first-party web server, Oblique's third-party analysis engine looks like a normal end-user browser that issues normal HTTPS fetches. During a concolic page load, Oblique does track symbolic constraints on sensitive user values like cookies and `User-Agent` strings. However, these constraints represent a universe of possible values for sensitive variables; the constraints are insufficiently precise to allow Oblique to determine *the specific sensitive values that belong to a particular user*. For instance, we did empirically find JavaScript code which tested cookies for substrings that were user-agnostic; a common pattern was to inspect a cookie for a string representing the current date. However, JavaScript code did not contain the logical equivalent of a giant regular expression which scanned the local cookie, testing whether the cookie contained any value from an explicit list of valid user ids. Such JavaScript code does not exist because it would allow anyone to download the enclosing JavaScript file and learn all of the valid user ids for a site! Thus, Oblique's symbolic constraints on cookies are insufficient to induce concrete cookie values belonging to specific users. Similarly, if Oblique analyzes a page and determines that a possible load path will target Android users that possess a certain set of screen dimensions, this information does not allow Oblique to infer the screen dimensions and platform value for a particular user.

To analyze server-side behavior, Oblique requires access to server-side code; that code is inaccessible to public web clients. During the concolic execution of that code, Oblique might also query sensitive databases, or contact sensitive network hosts that are inaccessible to public internet hosts. Thus, if a developer wants Oblique to analyze both client-side and server-side behavior, Oblique should be run on first-party machines. Compared to Vroom (which is also a first-party accelerator), Oblique will provide faster page loads (§5.2).

3.6 Limitations

Oblique is not guaranteed to optimize every object fetch made by every page. For example, during concolic execution, a page's JavaScript may invoke unmodeled native functions, i.e., browser-provided C++ functions for which Oblique lacks a symbolic execution policy (§3.2). If concolic execution reaches one of those functions, Oblique must always treat the return value as fully concrete. Doing so will hurt path coverage if the program later branches on the value, since concrete values cannot be "inverted" to force a new branch direction to be explored.

Even if a page avoids unmodeled native functions, path coverage may suffer when symbolic path constraints are difficult to invert. If the constraint solver times out while trying to generate concrete inputs for a new path to explore, the path will not be explored. If this happens, Oblique can miss opportunities to discover prefetchable URLs. We evaluate Oblique's sensitivity to time-out parameters in Section 5.2.

During concolic execution, Oblique may trigger interactions with external entities. For example, a concolically-executed browser may issue `XMLHttpRequests` to remote servers. Oblique should only be used with pages for which such interactions are idempotent (either literally or for practical purposes). This limitation is shared by all prefetching systems which issue queries to live services to perform content analysis.

4 Implementation

To implement Oblique's symbolic analysis, we modified ExpoSE [17]. ExpoSE performs concolic execution of pure JavaScript code, but does not handle environmental interactions like network IO. We modified ExpoSE to interface with two different environmental interfaces: the Node runtime and the Electron [10] HTML renderer. Oblique uses the Node runtime when analyzing server-side code, and uses the Electron runtime when simulating client-side loads. As explained in Section 3.2, we enlightened ExpoSE to model a DOM tree symbolically, so that JavaScript-level symbolic values can flow into and out of the DOM interface. Our changes to ExpoSE were non-trivial, totalling roughly 4,300 lines of code.

Oblique's client-side prefetching library is small, containing approximately 300 lines of Javascript code. When Oblique runs in third-party mode (§3.2), web servers require no modifications (other than having to include Oblique's prefetching library at the top of each page's HTML). When Oblique runs in first-party mode (§3.4), web servers must be enlightened to traverse the super-constraint tree, concretize nondeterministic values, and interact with Oblique's templating infrastructure. To implement an Oblique-compatible web server, we created a front-end HTTP layer that sat in front of a commodity web server. The front-end layer used the nghttp2 HTTP library and the myhtml HTML parser to implement the activities described above.

5 Evaluation

In this section, we compare Oblique's performance to that of Vroom and RDR, two state-of-the-art accelerators for mobile page loads. Our evaluation primarily focuses on the variant of Oblique that only analyzes client-side behavior, since we can evaluate this variant on a large number of commercial sites. Using a corpus of 200 real pages, we find that Oblique reduces page loads by up to 31%, outperforming Vroom and RDR by up to 17% while also reducing VM costs for popular sites (§5.2). Oblique provides these advantages while also enabling secure outsourcing of prefetch analysis (§5.2). In Section 5.3, we use a site that we control to provide a case study of the benefits of analyzing both client-side behavior and server-side behavior. We demonstrate that, if first parties are willing to run Oblique, they can unlock even greater reductions in load time than what client-only analysis provides.

5.1 Methodology

Our experiments used a Galaxy S10e phone that ran Chromium v78. The browser ran atop Linux on Dex [30], a runtime that enables Samsung phones to execute traditional Linux executables; Linux on Dex made it easier for us to write testing scripts and other experimental infrastructure. We automated the initiation of page loads and the collection of load time metrics using the Browsertime [33] library. Internally, Browsertime manipulated Chrome via Selenium's WebDriver APIs [36, 43].

To test Oblique, Vroom, and RDR with real websites, we built a Mahimahi-style tool [23] to record the objects in live web pages. Afterwards, when our test phone sent an HTTP request to an Oblique web server, a Vroom web server, or an RDR proxy, the web server or proxy responded with recorded content if the request hit in the replay cache; otherwise, the web server or proxy issued a live fetch to the appropriate content server. We ran Oblique and Vroom web servers, and RDR proxies, on a Digital Ocean VM with 8 2.3 GHz cores, 16 GB of RAM, and a 2 Gbps NIC. The RDR proxy used headless Chrome [28] to load pages. Vroom's offline analysis also used headless Chrome. The online Vroom web server was a derivative of nghttp2 [38] that used MyHTML [4] and Katana [27] to parse HTML and CSS.

Our phone had an LTE connection with a round-trip time of 47 ms to our Digital Ocean VM. Our test corpus contained 200 pages from the Majestic Million [19]. We selected the 200 most popular pages for which the RTT between our phone and a page's web server was less than the the RTT between our phone and our Digital Ocean VM. This setup resulted in conservative estimates of the benefits provided by Oblique, Vroom, and RDR, relative to the baseline scenario in which our phone contacted normal web servers directly. For each combination of <page, load time metric, acceleration technique>, we loaded each page 5 times and recorded the average. By default, Oblique and Vroom pages were loaded one hour after the completion of offline analysis, but we perform sensitivity analysis on this parameter in Section 5.2.

5.2 Client-only Analysis

PLT: We first explored Oblique's performance when only the client side of a page load is analyzed. Figure 5 shows results for the page load time (PLT) metric. PLT, as measured by the time to the browser's `onload` event, captures how long a page needs to fetch and evaluate all objects referenced by a page's static HTML. Note that PLT only waits for some dynamically-generated fetches to complete. In particular, PLT waits for fetches triggered by the insertion of new DOM nodes (e.g., `document.body.appendChild(newImg)`), but not for fetches triggered directly by network APIs like `fetch(url)`. Thus, PLT underestimates the extent to which Oblique, Vroom, and RDR reduce overall fetch latencies for a page.

Figure 5a shows that, for a 47 ms RTT and a cold browser cache, Oblique provided the average page with a 24.1% reduction in PLT, relative to a baseline (i.e., non-accelerated) page load. Oblique reduced PLTs by 17.3% more than RDR, and 5.4% more than Vroom. To explore Oblique's benefits with higher RTTs; we connected the smartphone to a desktop machine via WiFi, and used netem [18] to inject additional latency along the smartphone/desktop link. As expected, Oblique's benefits improved as phone-server RTTs grew, because of the increasing value of hiding last-mile latency. For example, Figure 5c shows PLT results for an emulated RTT of 150 ms. Oblique improved the average baseline PLT by 31.4%, outperforming RDR by 16.3% and Vroom by 6.2%.

A page load's *prefetch hit rate* is the fraction of requested objects that hit in the browser cache due to a successful prefetch. As shown in Figure 6a, Oblique enjoyed better prefetch hit rates than both Vroom and RDR. Indeed, Oblique's primary advantage over Vroom was the ability to successfully prefetch dynamic URLs that embedded nondeterministic symbols (§3.3); this advantage is reflected in Figure 6b.

We define a page load's *wasted prefetch rate* as the fraction of prefetched objects that were never requested during the page load. Figure 6c demonstrates that RDR has a much higher percentage of wasted prefetches. The reason is that, for each client-initiated page load, RDR loads the page twice: once on the proxy, and once on the real client machine. Both client-side and server-side nondeterminism may cause the URLs fetched by the proxy's page load to be different than the URLs fetched by the client's browser. Oblique avoids this problem by handling nondeterministic URLs symbolically. In contrast, Vroom's stable-set algorithm simply filters out many nondeterministic URLs. Thus, Vroom has fewer wasted prefetches than RDR, because Vroom does not prefetch nondeterministic URLs that RDR erroneously pulls; however, as shown in Figure 6b, Vroom has a worse hit rate than Oblique due to worse handling of nondeterministic dynamic URLs.

In comparison to RDR, both Oblique and Vroom benefited from informing clients early about the URLs to prefetch. For example, Oblique discovered all of these URLs offline, and prefetched them via the first JavaScript code that executed on a page. Vroom included `<link>` preload tags at the beginning of a page's HTML, and server-pushed other objects to prefetch. In contrast, RDR streamed objects to a client as the proxy discovered those objects; the deeper a page's dependency graph was (§2), the larger the comparative advantage provided by Oblique offline discovery approach. Vroom discovered some prefetch URLs offline, and others during the online, server-side HTML parse. However, Vroom aggressively notified clients about the offline-discovered URLs using server push and `<link>` preload tags.

Warm caches: Figure 7a depicts PLTs for all four systems when browser caches were warm. As expected, all systems enjoyed lower PLTs. Oblique and Vroom had similar performance, but still outperformed RDR.

Speed Index: We also evaluated the ability of Oblique, Vroom, and RDR to improve a page's Speed Index [41]. Speed Index is a visual metric that represents how quickly a page's above-the-fold content is rendered. A page's Speed Index is $\int_0^{end} 1 - \frac{p(t)}{100}\,dt$, where *end* is the time of the last pixel change, and $p(t)$ is the percentage of pixels that have already received their final value; lower Speed Indices are better. The formula rewards page loads whose overall rendering time is fast (meaning that *end* values are small). Given two pages with the same *end* value, the formula rewards the page which renders more pixels earlier. Note that Speed Index ignores whether JavaScript files or below-the-fold content has arrived; thus, like PLT, Speed Index underestimates the extent to which accelerators have successfully prepositioned objects.

Figures 7b and 7c show Speed Index results for RTTs of 47 ms and 150 ms. The basic trend is the same one observed for PLT: Oblique has better performance than Vroom, and Vroom has better performance than RDR. However, all of the acceleration systems improve PLT more than Speed Index. For example, with cold caches and a 150 ms RTT, Oblique reduces PLT by 31.4%, but Speed Index by only 20.4%. The reason is that Speed Index only considers visual content, and only cares about the loading of JavaScript files to the extent that the evaluated code modifies a page's above-the-fold graphics. However, deep chains in a page's dependency graph are often caused by JavaScript files whose evaluation triggers the loading of additional JavaScript files [21]. All three accelerators let clients resolve those dependency chains more quickly, but this has less impact on Speed Index than PLT.

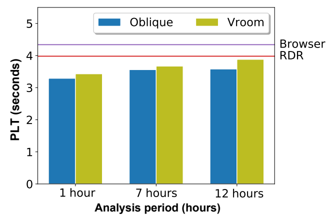
(c) Speed Index (150 ms RTT)

Figure 7: Warm-cache PLTs and Speed Indices (both cold and warm caches). Note that subfigures (b) and (c) have different y-axis scales.

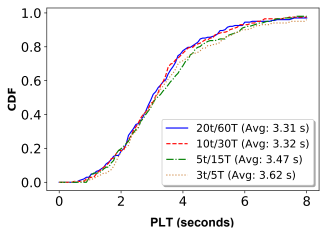
Stale analytic results: In Figures 5 and 7, the offline analyses for Oblique and Vroom occurred one hour before a page load. Figure 8a depicts average PLTs when Oblique and Vroom used analytic data from farther in the pass. Unsurprisingly, Oblique and Vroom performed better with more recent analytic data. However, for up to 12 hours of staleness, Oblique maintained its advantage over Vroom; both Oblique and Vroom also maintained their advantages over RDR and a non-accelerated browser.

Additional analysis time: Given an infinite amount of time, Oblique's offline analysis would be guaranteed to find a complete tree of path constraints; in other words, every possible concretization of client-side symbols would be covered by some root-to-leaf tree path. In practice, Oblique's symbolic analysis is constrained by two parameters: t represents the maximum execution time for a particular execution path,[2] and T represents the overall amount of time that Oblique will analyze the page. By default, Oblique uses $t = 10$ minutes and $T = 30$ minutes. If fully exploring a particular path requires more time than t, Oblique will only discover a subset of the URLs associated with the path. If discovering all paths in a page takes longer than T, Oblique will not generate a prefetch list for the undiscovered paths.

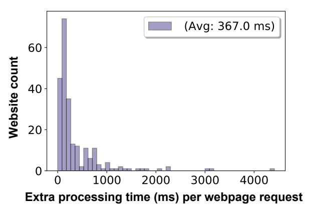
[2] A timeout occurs when the SMT solver cannot negate a branch condition in the current path (§3.1).



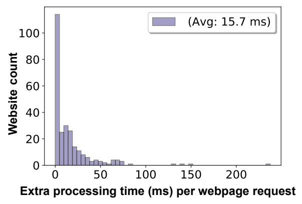
(a) PLT as a function of the staleness of the offline analytic data. These results use a 47 ms RTT and cold caches.



(b) PLT as a function of the time budget given to Oblique's offline symbolic analysis. These results use a 47 ms RTT and cold caches.



(c) RDR: Per-page-load computational time required by a proxy.



(d) Vroom: Additional per-page-load computational time required.

Figure 8: The impact of stale Oblique/Vroom analyses, and the additional computational overheads of RDR and Vroom.

Figure 8b depicts Oblique's PLT benefits for different values of t and T. In those experiments, the PLT for a page was defined as the average PLT across all discovered paths; to test the PLT for a particular discovered path, our test browser used concretized client-side symbols that triggered the path. Figure 8b shows that Oblique is basically insensitive to t values above 10 minutes and T values above 30 minutes. The reason is that, for the average page in our test corpus, only 7 minutes were needed to completely explore a path; furthermore, the median page only contained 7 execution paths.

Economic costs: For a given version of a page, Oblique performs an offline analysis once, constructs a path constraint tree, and then incurs no online costs during a real client load. In contrast, RDR must launch an RDR proxy for each client load, and Vroom must perform online HTML parsing. Figures 8c and 8d depict those per-page-load CPU costs.

A VM owner pays for a virtual CPU by the second or by the hour. Once a virtual CPU is fully loaded, any additional computation to perform will force the VM owner to rent more virtual CPU seconds. For a fully-loaded virtual CPU, Vroom requires a VM owner to pay for an additional 15.7 ms of additional compute time per page load. Thus, Oblique's offline analysis becomes cheaper than Vroom's smaller (but repeated) online costs after $T/15.7$ page loads, where T is Oblique's offline analysis time in units of milliseconds. For example, with a T of 30 minutes, Oblique becomes financially cheaper after 114,650 page loads; with a T of an hour, Oblique becomes cheaper after 229,299 loads. Since RDR imposes much heavier computational overheads than Vroom, Oblique becomes cheaper much faster—after 4,904 loads or 9,809 loads for a T of 30 minutes or a T of an hour. Importantly, these estimates assume that, when a page changes, Oblique's prior analysis is totally invalidated. We are currently investigating how Oblique can use incremental symbolic execution [13, 15] to amortize our analysis costs even more aggressively.

5.3 Oblique in First-party Mode

When Oblique runs on first-party infrastructure, Oblique can symbolically evaluate client-side and server-side behavior. However, to do this, Oblique must be able to examine backend code. We had no access to server-side code for the commercial sites in our test corpus; thus, we had to evaluate first-party Oblique on a collection of modified open-source sites that we ran ourselves. Due to space restrictions, we focus on a single case study of an open-source EJS site. In the text below, Oblique-C refers to a setup in which Oblique can only analyze client-side activity. Oblique-SC refers to a setup in which Oblique can evaluate both server and client behavior.

Gallery Viewer [39] is a site whose core functionality is displaying a rotating set of images. Each image is associated with metadata like an author, a category (e.g., "nature scenes"), and a description of the image; metadata is stored in on-disk JSON files. Users can also chat with each other in real time, and submit comments on particular images. From the perspective of Oblique, the site is interesting because of how it uses cookies and random number generators. The site assigns a unique cookie to each user. When a user requests the page's top-level HTML, the server uses the cookie to query a server-side table of user preferences. The table indicates the types of images that a user likes to view. Given those preferences, the server leverages a random number generator to select random images from the user's preferred image categories. The server inserts the associated image URLs into the dynamically-generated HTML that is returned to the user's browser.

For this particular site, no client-side symbols are relevant to prefetching. However, two kinds of server-side symbols are relevant: the cookie value in the HTTP request for the top-level HTML, and the random numbers that are used to select image URLs.

- Oblique-SC correctly prefetches all of the image URLs. During Phase 1 of analysis (§3.4), Oblique-SC symbolically evaluates the templating JavaScript, creating a symbolic HTML string. In Phase 3, i.e., during a real page load, Oblique-SC runs the server-side event handler up to the call to `render()`. At that point, Oblique-SC concretizes the symbolic HTML using the live cookie data and logged values from the random number generator. Oblique-SC then extracts the image URLs from the concretized HTML, and creates a prefetch library that downloads those URLs.

- Oblique-C lacks visibility into server-side behavior. Thus, an Oblique-C client incorrectly prefetches the URLs in the concretized HTML that was seen during offline analysis.
- Vroom correctly prefetches the image URLs; the Vroom web server identifies the URLs during the on-the-fly HTML parse.
- RDR incorrectly prefetches the image URLs. The HTML returned to the proxy's headless browser will contain different URLs than the ones in the HTML returned to the user's browser; the URLs in the first HTML file are prefetched by the client.

For a cold browser cache and a 47 ms RTT, Oblique-SC and Vroom had similar performance, with PLTs of 2.01 seconds and 2.06 seconds, respectively. Oblique-C did only slightly better than RDR (2.29 seconds versus 2.37 seconds). The non-accelerated page load required 2.76 seconds.

Oblique-SC has larger computational costs than Oblique-C; during offline analysis, more symbolic execution is required, and during an actual page load, web servers must participate in Phase 3 activity. The extent to which Oblique-SC is preferable to Oblique-C depends on whether first parties want to pay these costs, and the extent to which a site uses server-side symbols to generate HTML. However, the results from Section 5.2 demonstrate that Oblique-C alone can provide impressive reductions in page load time.

6 Conclusion

Oblique is a new system for accelerating mobile page loads. Oblique uses symbolic execution to analyze the various ways that a page load could proceed. For each potential outcome, Oblique creates a list of symbolic URLs that the corresponding page load would fetch. These URLs are concretized at the time of an actual page load, and then prefetched using Oblique's client-side JavaScript library. Oblique works on unmodified browsers, and provides faster page loads than current state-of-the-art approaches. When run in third-party mode, Oblique enables secure outsourcing of prefetch analysis while also enabling reductions in VM costs.

SENSEI: Aligning Video Streaming Quality with Dynamic User Sensitivity

Abstract

This paper aims to improve video streaming by leveraging a simple observation—users are more sensitive to low quality in certain parts of a video than in others. For instance, rebuffering during key moments of a sports video (*e.g.,* before a goal is scored) is more annoying than rebuffering during normal gameplay. Such *content-dependent* dynamic quality sensitivity, however, is rarely captured by current approaches, which predict QoE (quality-of-experience) using one-size-fits-all heuristics that are too simplistic to understand the nuances of diverse video content.

The problem is that none of these approaches know the true dynamic quality sensitivity of a video they have never seen before. Therefore, instead of proposing yet another heuristic, we take a different approach: we run a *separate crowdsourcing experiment for each video* to derive the quality sensitivity of users at different parts of the video. Of course, the cost of doing this at scale can be prohibitive, but we show that careful experiment design combined with a suite of pruning techniques can make the cost negligible for content providers. For example with a budget of just \$31.4/minute video, we can predict QoE 37.1% more accurately than recent QoE models.

Our ability to accurately profile time-varying user sensitivity inspires a new approach to video streaming—*dynamically aligning higher (lower) quality with higher (lower) sensitivity periods*. We present a new video streaming system called SENSEI that profiles and incorporates dynamic quality sensitivity into existing quality adaptation algorithms. We apply SENSEI to two state-of-the-art adaptation algorithms, one rule-based and one based on deep reinforcement learning. SENSEI can take seemingly unusual actions, *e.g.,* lowering quality even when bandwidth is sufficient to prepare for higher quality sensitivity in the near future. Compared to state-of-the-art approaches, SENSEI improves QoE by 15.1% or achieves the same QoE with 26.8% less bandwidth on average.

1 Introduction

An inflection point in Internet video traffic is afoot, driven by more ultra-high resolution videos, more large-screen devices, and ever-lower user patience for low quality [2, 10]. At the same time, the video streaming industry, after several decades of evolution, is seeing diminishing improvements: recent adaptive bitrate (ABR) algorithms (*e.g.,* [45, 56, 83]) achieve near-optimal balance between bitrate and rebuffering events, and recent video codecs (*e.g.,* [54, 72]) improve encoding efficiency but require an order of magnitude more computing power than their predecessors. The confluence of these trends means that the Internet may soon be overwhelmed by online video traffic,[1] and new ways are needed to attain fundamentally better tradeoffs between *bandwidth usage* and user-perceived *QoE* (quality of experience).

We argue that a key limiting factor is the conventional wisdom that users care about quality in the same way throughout a video, so video quality should be optimized using the same standard *everywhere* in a video. This means that lower quality—due to rebuffering, low visual quality, or quality switches—should be avoided identically from the beginning to the end. We argue that this assumption is not accurate. In sports videos (*e.g.,* the one in Figure 1), a rebuffering event that coincides with scoring tends to inflict a more negative impact on user experience than rebuffering during normal gameplay. But there are also sports videos where scoring is not the most quality-sensitive part. Thus, user quality sensitivity *varies with the video content dynamically over time*.

Unfortunately, both the literature on ABR algorithms and the literature on QoE modeling adopt the conventional wisdom. Most ABR algorithms completely ignore the content of each video chunk: they focus on balancing high bitrates and low rebuffering times, and thus consider only the size and download speed of the chunks. Traditional ways of modeling QoE are also agnostic to the substance of videos, although recent QoE models—*e.g.,* PSNR [38], SSIM [80], VMAF [11], and deep-learning models [33, 48]—try to find frames that users are more sensitive to by studying the structure of pixels and motions to gauge their saliency. These heuristics seek to generalize across *all videos* and thus resort to generic measures (like pixel-level differences), but it is unclear if any heuristic can capture the diverse and dynamic influence a video's content can have on users' sensitivity to quality.

For example, models like LSTM-QoE [33] assume that users are more sensitive to rebuffering events in more "dy-

[1] This is vividly illustrated by the recent actions taken by YouTube and Netflix (and many others) to lower video quality in order to save ISPs from collapsing as more people stay at home and binge watch online videos [12].

namic" scenes. In sports videos, however, non-essential content like ads and quick scans of the players can be highly dynamic, but users may care less about quality during those moments. In the video in Figure 1, LSTM-QoE considers normal gameplay to be the most dynamic part, but the most quality-sensitive part of the video according to our user study is the goal. A key insight is that the impact of the substance of a video on users' sensitivity to quality cannot be fully explained by pixel-level patterns or cross-frame motions. Some recent work tries to predict user's dynamic sensitivity, but they either need access to users' viewing history [35] or use off-the-shelf computer-vision saliency models [34] whose predictions have little correlation with quality sensitivity on videos they have never seen before (§2.3 elaborates on this).

The dynamic nature of quality sensitivity suggests a new avenue for improvement. One can achieve *higher QoE with the same bandwidth* by carefully lowering the current quality in order to save bandwidth and allow higher quality when users become more sensitive. Similarly, one can attain *similar QoE with less bandwidth* by judiciously lowering the quality when quality sensitivity is indeed low. In short, we seek to *align higher (lower) quality of video chunks with higher (lower) quality sensitivity of users*.

We present SENSEI, a video streaming system that incorporates dynamic quality sensitivity into its QoE model and video quality adaptation. SENSEI addresses two key challenges.

Challenge 1: How do we profile the unique dynamic quality sensitivity of each video in an accurate and scalable manner?

Crowdsourcing the true quality sensitivity per video: Instead of proposing another heuristic, SENSEI takes a different approach. We run a *separate crowdsourcing experiment for each video* to derive the quality sensitivity of users at different parts of the video. Specifically, we elicit quality ratings directly from real users (obtaining a "ground truth" of their QoE) for multiple renderings of the same video, where each rendering includes a quality degradation in some part of the video. SENSEI automates and scales this process out using a public crowdsourcing platform (Amazon MTurk), which provides a large pool of raters, while using pruning techniques to reduce the number of rendered videos that need to be rated. We then use these ratings to estimate a *weight* for each video chunk that encodes its quality sensitivity, independent of the quality of other chunks. While crowdsourcing has previously been used to model QoE, SENSEI is to our knowledge the first to scale it to *per-video* QoE modeling.

Challenge 2: How do we incorporate dynamic quality sensitivity into a video streaming system to enable new decisions? Today's video players are designed to be "greedy": they pick a bitrate that maximizes the quality of the next chunk while avoiding rebuffering events. But in order to utilize dynamic quality sensitivity, a player must "schedule" bitrate choices over *multiple* future chunks, each having a potentially different quality sensitivity. This means that some well-established behaviors of video players, *e.g.,* only rebuffer when the buffer is empty, may need to be revisited.

Refactoring ABR logic to align with dynamic quality sensitivity: SENSEI works within the popular DASH framework. It integrates the aforementioned per-chunk weights into existing ABR algorithms to leverage the dynamic quality sensitivity of upcoming video chunks when making quality adaptation decisions. The per-chunk weights enable new adaptation actions that "borrow bandwidth" from low-sensitivity chunks and give them to high-sensitivity chunks. For example, SENSEI may lower the bitrate even when bandwidth is sufficient, or initiate a rebuffering event with a non-empty buffer, to afford higher bitrates when quality sensitivity becomes higher. We apply SENSEI to two state-of-the-art ABR algorithms: Fugu [83], a more traditional rule-based algorithm, and Pensieve [56], a deep reinforcement learning-based algorithm.

Using its scalable crowdsourcing approach, SENSEI can predict QoE more accurately than state-of-the-art QoE models. For example, with a budget of just \$31.4/minute video, SENSEI achieves 55% less QoE prediction error than existing models. Compared to state-of-the-art ABR algorithms, SENSEI improves QoE on average by 15.1% or achieves the same QoE with 26.8% less bandwidth across various video genres.

Contributions and roadmap: Our key contributions are:

- A measurement study revealing substantial temporal variability in users' quality sensitivity and its potential for improving video streaming QoE and bandwidth usage (§2).
- The design and implementation of SENSEI, including: 1) a scalable crowdsourcing solution to profiling the true dynamic quality sensitivity of each video (§4,§5),[2] and 2) a new ABR algorithm that incorporates dynamic user sensitivity into existing algorithms and frameworks (§6).

2 Motivation

We begin by showing that existing approaches to modeling video streaming QoE fail to accurately capture the true user-perceived QoE (2.1). We then present user studies that reveal a missing piece in today's QoE modeling: users' quality sensitivity varies dynamically throughout a video (§2.2), and this dynamic quality sensitivity is hard to capture using prior heuristics or vision models (§2.3). However, by incorporating dynamic quality sensitivity into existing ABR algorithms, we can significantly improve QoE and save bandwidth (§2.4).

2.1 Prior QoE modeling and their limitations

QoE models are crucial to modern video streaming systems. A QoE model takes a streamed video as input and returns a predicted QoE as output. When streaming a video, the video player optimizes QoE by adapting the bitrate of each video chunk to the available bandwidth. QoE is often measured by the mean opinion score (MOS) assigned by a group of users to the quality of a video.[3]

[2]Our study was IRB-approved (IRB18-1851).

[3]Our methodology extends to other QoE metrics as well.

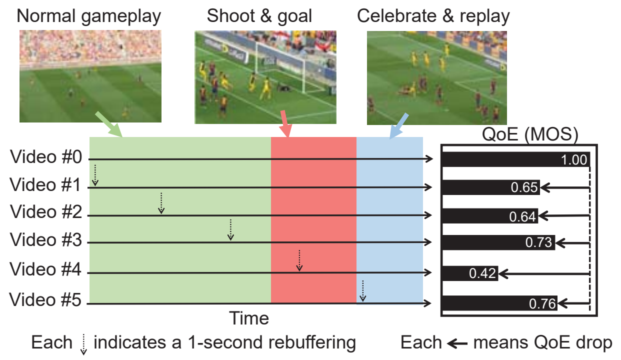

Figure 1: *Example of dynamic quality sensitivity. Users are asked to rate the quality (on a scale of 1 to 5) of different renderings of a source video (`Soccer1`), where a 1-second rebuffering event occurs at a different place in each rendering. We observe substantial differences in the QoE impact (measured by mean opinion score, or MOS) across the renderings.*

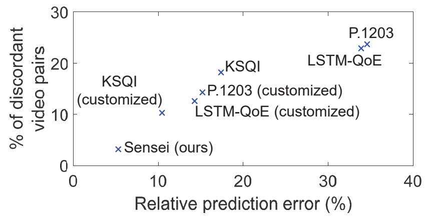

Figure 2: *Existing QoE models exhibit substantial QoE prediction errors (x-axis), which cause them to frequently mispredict the relative QoE ranking between two ABR algorithms on the same video, i.e., a discordant pair (y-axis).*

Quality metrics: Today's QoE models consider two aspects.

- *Pixel-based visual quality* tries to capture the impact of visual distortion on QoE. These metrics, such as PSNR and VMAF, are based on pixel/motion-based patterns [11, 38, 48, 63, 68, 79, 80] and recently on visual attention [27, 44, 86].
- *Streaming quality incidents* during the streaming process can negatively impact user experience, such as rebuffering, low bitrate, and bitrate switches. Their impact is modeled by metrics, such as rebuffering ratio, average bitrate, and frequency of bitrate switches during a video (*e.g.,* [18, 28]).

Some work also considers contextual factors (*e.g.,* viewer's emotion, acoustic conditions, etc.), but these are orthogonal to our focus on the video's content.

QoE models: Recent QoE models combine both pixel-based visual quality metrics and quality-incident metrics for more accurate QoE prediction. We consider three such QoE models: KSQI [29], P.1203 [66], and LSTM-QoE [33], which were proposed within the past two years and have open-source implementations. KSQI combines VMAF, rebuffering ratio, and quality switches in a linear regression model. P.1203 combines QP (quantization parameter) and quality incident metrics in a random-forest model. Most recently, LSTM-QoE takes STRRED [68] and individual quality incidents as input to a long short-term memory (LSTM) neural network designed to capture the "memory effect" of human perception of past quality incidents. (We discuss related work in §8.)

User study methodology: We evaluate these QoE models (KSQI, P.1203, LSTM-QoE) on 16 source videos randomly selected from four public datasets [21, 30, 36, 78], covering a wide range of content genres (sports, scenic, movies, etc.). These videos are streamed using one of three ABR algorithms: Fugu [83], Pensieve [56], and BBA [45], over 7 throughput traces randomly selected from real-world cellular networks [5, 65], with bandwidths ranging from 200Kbps to 6Mbps. §7.1 and Appendix A provide more details on the videos and network traces. This creates 336 (16×7×3) rendered videos. To obtain the ground truth QoE of each rendered video, we elicit QoE ratings from crowdsourced workers on Amazon MTurk [1]. We obtain at least 30 ratings from different MTurkers and use the MOS over these ratings as the true QoE of the rendered video. §4 and §5 describe our crowdsourcing methodology in detail.

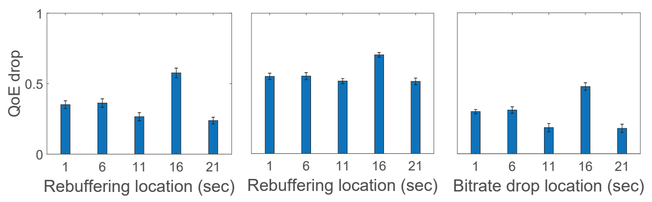
QoE prediction accuracy: Given the ground-truth QoE, we evaluate the three QoE models both with their pre-trained parameters and after customizing (retraining) them on 315 of the rendered videos selected at random. All models are tested on the remaining 21 videos; we scale their output range and the true QoE to $[0,1]$. The x-axis of Figure 2 shows the mean relative prediction error of each QoE model on the test set; relative prediction error is defined as $|Q_{predict} - Q_{true}|/Q_{true}$, where $Q_{predict}$ and Q_{true} are the predicted and true QoE of the video. We see that these errors are nontrivial; even the most accurate QoE model has over 10.4% error on average.

We also examine whether these models can correctly *rank* the QoE achieved by two different ABR algorithms. For each pair of source video and throughput trace, we first rank every two of the three ABR algorithms using their true QoE and then again using the predicted QoE. If the rank is different, this pair is called a discordant pair. The y-axis of Figure 2 shows the fraction of discordant pairs among all possible pairs (a common measure used in rank correlation): over 10.2% of pairs are discordant even for the most accurate QoE model. This suggests that using QoE predictions to compare different algorithms (*e.g.,* [45, 56, 83]) may not be reliable.

2.2 Temporal variability of quality sensitivity

Figure 2 shows that, unlike prior methods, our QoE model (§4) can predict QoE and rank ABRs significantly more accurately when applied on the same train/test set. We argue that this gap stems from a common assumption shared by all previous QoE models, which is that all factors affecting QoE can be captured by a handful of objective metrics. This premise ignores the impact of high-level video content (rather than low-level pixels and frames) on users' sensitivity to quality at different parts of the video. We now demonstrate how this quality sensitivity varies as video content changes.

Quantifying dynamic quality sensitivity: Users' sensitiv-



(a) 1-sec rebuffering (b) 4-sec rebuffering (c) Bitrate drop

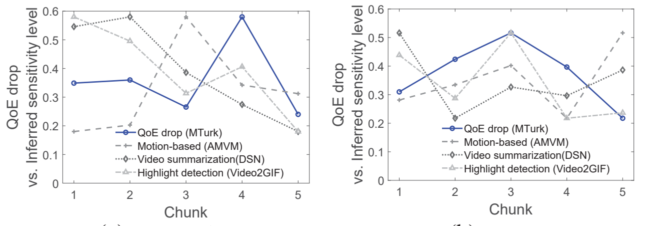
Figure 3: *Impact of different quality incidents at different points in the video in Figure 1. The pattern of variability remains the same across the different quality incidents. Error bars show standard deviation of the means.*

ity to quality at a certain part of a video is reflected by the *QoE drop* when a low-quality incident occurs at that part of the video, *i.e.,* $\Delta = Q_{before} - Q_{after}$, where Q_{before} is the MOS of the video without the low-quality incident and Q_{after} is the MOS of the video with the low-quality incident. To measure the true quality sensitivity at different parts of a source video, we create a *rendered video series* as follows. Rendered videos in a video series have the same source content and highest quality (highest bitrate without rebuffering), except that a low-quality incident (a rebuffering event or a bitrate drop) is deliberately added at different positions, *e.g.,* at the 4th second, 8th second, and so forth. Then, as before, we use Amazon MTurk to crowdsource the true QoE of each rendered video, following our crowdsourcing methodology (§4,§5).

Figure 1 shows an example video series created using a 25-second soccer video as the source video and a one-second rebuffering event as the low-quality incident. We observe significant differences between the QoE drops caused by the rebuffering event at different parts of the video. The highest QoE drop (caused by rebuffering at the 15th second) is 2.1× higher than the lowest QoE drop (rebuffering at the 10th second). This shows that a low-quality incident can have a significantly higher/lower impact on user experience if it occurs a few seconds earlier or later.

Quality sensitivity is inherent to video content: Our user study also suggests that the type of low-quality incident does not affect the ranking of QoE drops within a video series, even though it affects the absolute QoE drops. In other words, quality sensitivity seems to be *inherent* to different parts (contents) of the video. Figure 3 shows the dynamic user sensitivity of three low-quality incidents on the same source video: 1-second rebuffering, 4-second rebuffering, and a bitrate drop from 3Mbps to 0.3Mbps for 4 seconds. Although the absolute values of the QoE drops depend on the particular quality incident, the relative rankings are identical. The strong rank correlation (measured by Spearman's rank coefficient) is persistent across all videos in our dataset: 0.95 rank coefficient between the 1-second and 4-second rebuffering events and 0.94 between the 1-second rebuffering and bitrate drop.

Sources of dynamic quality sensitivity: We speculate that the dynamic quality sensitivity stems from users paying different degrees of attention to different parts of a video. In our



(a) `Soccer1` (b) `FPS`

Figure 4: *QoE rating drop when adding a 1-sec rebuffering at different points in the video, compared to chunk sensitivity levels inferred by saliency models.*

dataset, we identify at least three types of moments when users tend to be more (or less) attentive to video quality than usual. The first are key moments in the storyline of a video when tensions have built up; *e.g.,* in `BigBuckBunny` (animation) when the bullies fall into a trap set by the bunny, or in `Soccer1` when a goal is scored. The second are moments when users must pay attention to get important information; *e.g.,* showing the scoreboard in sports videos (`Soccer2`), or acquiring supplies after killing an enemy (`FPS2`). The third are transitional moments with scenic backgrounds, when users tend to be less attentive to quality; *e.g.,* the universe background in `Space`.

2.3 Modeling quality sensitivity

Can it be captured by QoE models? Traditional QoE models predict the same QoE for all rendered videos in a video series. Even models that do predict different QoE assume that the impact of video content can be captured by pixels and motions; *e.g.,* VMAF [11] (the visual quality metric used by KSQI) gives lower QoE estimates if a bitrate drop occurs when the frame pixels are more "complex". Unfortunately, the impact of content on user sensitivity discussed above cannot be fully captured by pixel-level patterns. In Figure 1, the true highest QoE drop occurs when the low-quality incident occurs during the goal, but both VMAF and LSTM-QoE predict that it occurs during normal gameplay.

Can it be captured by vision saliency? User sensitivity is conceptually similar to temporal saliency in computer vision. Can saliency/highlight detection models capture user sensitivity to quality? We examine three representative approaches.

- *Traditional motion-based models*, such as AMVM (average motion-vector magnitude) [13, 52], use the motion vector magnitudes of pixels in a chunk to indicate user sensitivity—*i.e.,* users are more sensitive to more dynamic scenes.
- *Interestingness score per frame (highlight detection)*, such as Video2GIF [39] and [34], train a regression model (using C3D [75] neural network as the spatio-temporal feature extractor) on videos with human-annotated per-frame interestingness scores.[4] The model then produces a per-frame interestingness score which might indicate user sensitivity.

[4]We notice that some content providers passively monitor the number of viewers at different parts of a video (*e.g.,* [6]), which is an alternative way of identifying highlights or high-interestingness chunks.

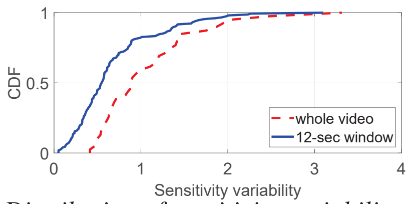


Figure 5: *Distribution of sensitivity variability when a low-quality incident (1-second rebuffering, 4-second rebuffering, or a bitrate drop for 4 seconds) is added at different points in the same video. The trend is similar even if the low-quality incident and QoE gap are localized to a 12-second window.*

- *Video summarization models*, such as dppLSTM [87] and DSN [90], infer how important each frame is to the whole story of a video, by extracting vision features [74] and using an LSTM to model temporal dependencies. The more important a frame is, the higher user sensitivity might be.

Figure 4 shows the average saliency scores (normalized to $[0,1]$) returned by these models at each chunk of two example videos. We see a weak correlation between the QoE drops caused by a 1-sec rebuffering event at different chunks and the true user sensitivity. Overall, such correlation is low for all videos in our dataset: less than 0.23 (Pearson's correlation) and 0.18 (Spearman's rank correlation). To see an example, in the soccer video (Figure 1), the part right before the goal is the most quality sensitive. However, the highlight detection and motion-based models highlight the highly dynamic scenes that pan across the audience, and the video summarization model picks diverse moments of a video, such as shot/rewind clips, whereas users pay more attention to when a goal might be scored. Appendix D gives more discussions. As a result, ABR logic based on saliency scores performs poorly (§7).

2.4 Potential gains

Dynamic quality sensitivity is prevalent: We repeat the same experiment from Figure 1 on all 16 source videos in our dataset and three low-quality incidents: 1-second rebuffering, 4-second rebuffering, and a bitrate drop from 3Mbps to 0.3Mbps for 4 seconds. This creates 48 video series in total. Figure 5 plots the *sensitivity variability* defined by $(\Delta_{max}-\Delta_{min})/\Delta_{min}$ for each video series, where Δ_{max} and Δ_{min} are the maximum and minimum QoE drop of the videos in a series. We see that 21 of the 48 video series have a sensitivity variability of over 0.99, while some have less than 0.20 variability. A similar trend holds even if we localize the low-quality incident and sensitivity gap measurement to 12-second windows. The fact that quality sensitivity varies substantially even among very nearby chunks suggests a new opportunity: we can lower the quality when sensitivity is low in order to save bandwidth for nearby chunks whose sensitivity is high.

Potential sensitivity-aware improvement: The above suggests that we can improve ABR algorithms to optimize QoE and save bandwidth by *aligning quality adaptation with dynamic user sensitivity*. We demonstrate the potential gains

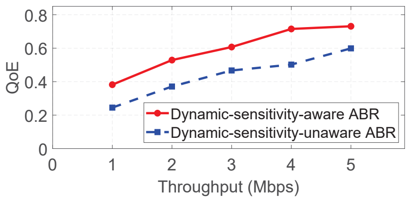

Figure 6: *Being aware of dynamic quality sensitivity can significantly improve QoE and save bandwidth.*

using an idealistic but clean experiment. We create two simple ABR algorithms whose only difference is the QoE model they optimize: one algorithm optimizes KSQI, the most accurate QoE model from Figure 2 that is *unaware* of dynamic quality sensitivity, and the other optimizes our eventual QoE model from §4, which *is* aware of dynamic quality sensitivity. Both algorithms take as input an entire throughput trace and the same 4-second video chunks encoded using the same bitrate levels. They then determine a bitrate-to-chunk assignment that maximizes their respective QoE model. Note that these ABR algorithms are idealistic because they have access to the entire throughput trace in advance, and hence know the future throughput variability. However, this allows us to eliminate the confounding factor of throughput prediction. We pick one of the throughput traces (results are similar with the other traces) and rescale it to $\{20,40,\ldots,100\}\%$ to emulate different average network throughputs.

For each source video, we create the rendered video as if it were streamed by each ABR algorithm (with bitrate switches, rebufferings, etc.). We use Amazon MTurk as before to assess the true QoE of the rendered video. Figure 6 shows the average QoE of the two ABR algorithms across 16 source videos and different average bandwidths. We see that being aware of dynamic quality sensitivity could improve QoE by 22-52% while using the same bandwidth, or save 39-49% bandwidth while achieving the same QoE.

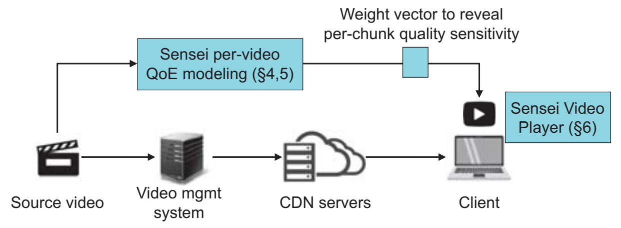
3 Overview of SENSEI

We have shown that knowing the true quality sensitivity of a video can lead to significant performance improvements when streaming the video. To unleash this potential, we present SENSEI, a video streaming system that unearths and leverages dynamic quality sensitivity. Here, we overview SENSEI (§3.1) and then introduce our crowdsourcing-based approach to per-video QoE modeling and its limitations (§3.2).

3.1 SENSEI's approach

As shown in Figure 7, SENSEI has two main components.

Per-video QoE modeling: Before streaming a video, SENSEI profiles the quality sensitivity of its chunks. As we saw in §2.2, prior QoE models fail to capture content-induced user sensitivity to quality. Instead, we advocate for directly asking human viewers to rate the quality of rendered videos with quality incidents inserted at various chunks. This reveals the true user sensitivity to quality incidents. Since quality sensitivity is unique to each video, this user study must be scaled



Weight vector to reveal per-chunk quality sensitivity
Sensei per-video QoE modeling (§4,5)
Sensei Video Player (§6)

Video mgmt system
CDN servers
Client
Figure 7: *Overview of* SENSEI.

to many videos. SENSEI uses crowdsourcing to automate and scale the per-video QoE modeling, by addressing two challenges: (1) how many (and which) rendered videos must be rated to build a sensitivity-aware QoE model (§4); and (2) how to get reliable ratings from crowdsourced workers (§5).

Sensitivity-aware ABR: Video players today are designed to maximize bitrate without rebuffering on *every* chunk. This is ill-suited to our goal of aligning quality adaptation with dynamic quality sensitivity: quality should be optimized in proportion to the quality sensitivity of the content. To achieve this, SENSEI refactors the control logic of video players to enable new adaptation actions that "borrow" resources from low-sensitivity chunks and give them to high-sensitivity chunks. We discuss the details in §6.

Instead of building a separate QoE model for each video, SENSEI reuses existing QoE models but reweights each chunk by its quality sensitivity. This is inspired by our observation that relative quality sensitivity is inherent to the content, rather than the specific quality incident (§2.2). Thus we assign a weight to each chunk to encode its inherent quality sensitivity. The abstraction of *per-chunk weights* has two benefits. First, it allows us to reuse existing QoE models by simply reweighting the quality of different chunks. Second, by using the sensitivity weights as input, the same SENSEI ABR algorithm can be used to optimize QoE for any new video.

3.2 Crowdsourcing quality sensitivity per video

SENSEI directly elicits quality ratings from human viewers to reveal their quality sensitivity to various quality incidents. However, these user ratings must be elicited *per video* and the sheer scale of this feedback can be prohibitive! To put it into perspective, QoE models are usually built from user ratings on just a handful of source videos [21,31], but getting enough user ratings requires a lab environment (or survey platform) to recruit participants and have them watch over two orders of magnitude more video content than the source videos. [5] This does not scale if we repeat the process per video.

To address this, we use crowdsourcing platforms like Amazon MTurk [1] to automate the user studies and scale them out to more videos. Crowdsourcing reduces the overhead of participant recruitment, survey dissemination, and result collection (down to about 78 minutes), and provides a large pool of participants. This allows for repeated experiments to

[5]For instance, in the WaterlooSQOE-III dataset [31], each video is streamed over 13 throughput traces with 6 ABR algorithms, and each rendered video is then rated by 30 users.

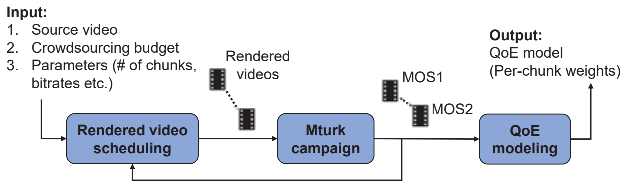

Figure 8: *Workflow of profiling dynamic quality sensitivity using a crowdsourcing platform. The arrow back to the scheduler means that crowdsourced ratings may be used to suggest more rendered videos to iteratively refine the QoE modeling.*

help control for human-related statistical noise. Although the crowdsourcing cost grows with video length, SENSEI offers several techniques to reduce the cost (see §4). Thus, the content providers can decide whether and how to initiate profiling given their budgets. Note that our reliance on crowdsourcing makes some scenarios, *e.g.,* live video streaming, currently inapplicable (see §9).

4 Profiling Quality Sensitivity at Scale

In this section, we show how to build an accurate and cost-efficient QoE model using crowdsourcing. We overview our workflow (§4.1) and then discuss low-cost methods for chunk-level reweighting (§4.2) and crowdsourcing scheduling (§4.3).

4.1 QoE modeling workflow

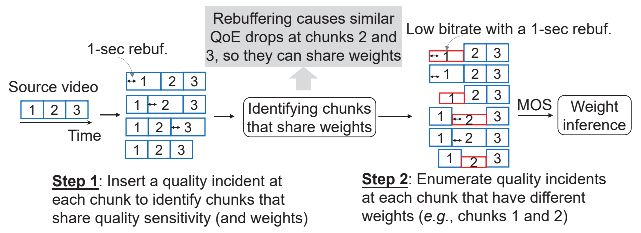
Figure 8 shows SENSEI's workflow for QoE modeling. SENSEI takes a source video and a monetary budget as input and returns a QoE model that incorporates dynamic quality sensitivity (customized for this video) as output.

- *Rendered video scheduling (§4.3):* We first generate a set of *rendered videos* from the source video. Each rendered video is created by injecting a carefully selected low-quality incident at a certain point in the video.
- *MTurk campaign (§5):* The rendered videos are published on the MTurk platform and we specify how many *participants* (MTurkers) to recruit for this *campaign*. When an MTurker signs up, they start a *survey* that asks them to watch K rendered videos and, after each video, rate its QoE.
- *QoE modeling (§4.2):* Finally, we use the MOS of each rendered video as its QoE and use regression to derive the per-chunk weights, which are then incorporated into an existing QoE model to derive the QoE model for this video.

4.2 Cutting cost via chunk-level reweighting

While crowdsourcing scales QoE profiling elastically, profiling each video can still be prohibitively expensive. Since a QoE model must capture the impact of both quality incidents and the quality sensitivity of each chunk, a strawman solution would build a QoE model with $O(N \cdot P)$ parameters, where N is the number of chunks and P is the number of parameters in a traditional QoE model. This could require a prohibitive number of ratings to build (*e.g.,* KSQI has tens of parameters).

Encoding quality sensitivity with per-chunk weights: We



1-sec rebuf.
Rebuffering causes similar QoE drops at chunks 2 and 3, so they can share weights

Identifying chunks that share weights
MOS
Weight inference
Step 1: Insert a quality incident at each chunk to identify chunks that share quality sensitivity (and weights)
Step 2: Enumerate quality incidents at each chunk that have different weights (e.g., chunks 1 and 2)

Figure 9: *A running example of the crowdsoucring scheduler for a source video with 3 chunks, 2 bitrate levels (high and low), 2 rebuffering event levels (0 and 1 second).*

leverage the insight that quality sensitivity at a chunk is inherent to its video content (§2.2). Thus, SENSEI assigns a single weight to each chunk irrespective of the quality incident, reducing the number of model parameters to $O(N)$. Then, SENSEI *reuses an existing QoE model but reweights the chunks by their quality sensitivity.* If the QoE model is *additive*, *e.g.,* the overall QoE is the sum of the QoE estimates of individual chunks q_i, or $Q = \sum_{i=1}^{N} q_i$, then SENSEI can directly reweight the chunks by their quality sensitivity. Though some QoE models are non-additive (*e.g.,* LSTM-QoE), many mainstream QoE models including KSQI and others [56, 85] are. For KSQI, the q_i take into account the impact of visual quality, rebuffering, and quality switches. SENSEI reweights the QoE model as follows:

$$Q = \sum_{i=1}^{N} w_i q_i, \qquad (1)$$

where w_i is the weight of the i^{th} chunk, reflecting how much more sensitive users are to quality incidents in this chunk than in other chunks.

Weight inference: Given any V rendered videos, if Q_j is the QoE (MOS) of the j^{th} rendered video and $q_{i,j}$ is the estimated QoE of the i^{th} chunk of the j^{th} rendered video, then we can write V equations, $Q_j = \sum_{i=1}^{N} w_i q_{i,j}$ for $j = 1,\ldots,V$. We can then infer the w_i using a linear regression.

In the remainder of the paper, we assume that KSQI reweighted by Equation 1 is the QoE model of SENSEI.

4.3 Crowdsourcing scheduler

We now turn our attention to compiling a small set of rendered videos that, after being rated, will produce enough data to reliably estimate the per-chunk weights.

Two-step scheduling: Given a source video, SENSEI's scheduler uses a two-step process to decide which rendered videos to publish and how many participants to elicit ratings from.

- First, SENSEI creates a set of N rendered videos, each with a single 1-second rebuffering event at a different chunk (recall N is the number of chunks). It then publishes these videos and asks M_1 participants to rate each video. The total rendered video duration is $O(N \cdot M_1)$. Once the videos are rated, we infer the per-chunk weights as described above.
- Second, we pick $N' \ll N$ chunks whose inferred weights are α-high or low (*e.g.,* 6 % higher or lower than the average weight). We then repeat the first step with two differences: (1) low-quality incidents are added only to these chunks, and (2) the quality incidents include B bitrates (below the highest bitrate) and F rebuffering events (1,2,... seconds). We publish the rendered videos and ask M_2 participants to rate them, for a total video duration of $O(N' \cdot B \cdot F \cdot M_2)$.

The purpose of the first step is to use a small number of participants (M_1) to get a noisy but indicative estimate of which chunks have quality sensitivity that is very high or low, so we can *focus* the second iteration on these chunks using a larger number of participants (M_2). In general, for an ABR algorithm to improve QoE-bandwidth tradeoffs, it is more important to identify which chunks have very high/low quality sensitivity than to precisely estimate the quality sensitivity of every chunk. §5 discusses the number of participants; we evaluate the effect of α, B and F in §7.4. These parameters are empirically selected and held constant throughout our tests.

Figure 9 shows an example two-step schedule for a source video. In the first step, we generate a series of rendered video with the same rebuffering event injected at different chunks. By examining the ratings of these videos from the MTurkers, we determine that chunks 2 and 3 have similar sensitivity to the rebuffering event, allowing them to share the same chunk-level weight. Thus, in the second step, we only need to enumerate the quality incidents for chunks 1 and 2. In practice, for a 20-second video, we generate 5 rendered videos in the first step for the $N = 4$ chunks, of which $N' = 2$ chunks may have high/low sensitivity, and generate 15 rendered videos in the second step for these chunks.

Quality incidents used in profiling: For the set of B bitrates, we use the bitrate levels of YouTube videos and pick three of them to cover high, medium and low visual quality; we found this to be a practical compromise. The set of rebuffering events F are chosen to match those we plan to proactively add to the video (see §6). Testing on a larger set of quality incidents would yield more data points, but our microbenchmarking results in §7.4 show that this only marginally improves model accuracy, while significantly increasing the cost.

5 Reliable QoE Crowdsourcing

SENSEI's QoE model crucially depends on the *reliability* of MTurkers' quality ratings. This section describes our user survey procedure and techniques for increasing reliability. While SENSEI mostly follows known practices [41, 43, 57], we provide some key details that arose from our experience (described below and in Appendix B).

Single-survey procedure: As shown in Figure 21, each survey starts with the instructions and rejection criteria under which the ratings will be rejected. The MTurker then watches an example video that includes a quality incident, so they know what their ratings should be based on. Then the MTurker is asked to watch a sequence of rendered videos (determined by the scheduler) and, after each video, rate its quality on a scale of 1-5. Finally, the MTurker does an exit survey.

Quality control per survey: Several measures are taken to prevent and filter out spurious user ratings. First, we show the test videos in a *randomized order* to each MTurker. This eliminates biases due to viewing order and which videos were previously watched. Second, we add *reliability checks*: we show a video without any quality incident at a random position among the test videos, and if an MTurker does not give the highest score to this video, we discard all of their ratings. We also ask the MTurker what quality incident(s) they just saw in the last video, and if they report more quality incidents than were included, that rating is discarded. This may occur if the MTurker's network connection is poor and new quality incidents are introduced. Third, we implement an engagement test to verify if the MTurker watched the video in its entirety, by monitoring the time spent on the video playback page and discarding the rating if the time is shorter than the video length. We also implement other filters, such as limiting the number or length of videos per MTurker to prevent fatigue.

Use of Master MTurkers: We follow a common practice (*e.g.,* [53]) and restrict our tests to *Master MTurkers*, a class of reliable MTurkers who have participated in over 1000 surveys and whose feedback was accepted for over 99% of their prior surveys. We find that our rejection rate from Master MTurkers is over 4× lower than normal MTurkers. One lesson we learned is that Master MTurkers are more willing to participate if the publisher (us) historically has a low rejection rate because they wish to maintain their rejection rate below 1%.

Sanity check of our dataset: To check if MTurker ratings are similar to prior lab studies [41, 77], we select three 12-second videos from a public dataset [31] whose quality ratings are collected in a lab environment, and obtain MTurker ratings for these videos. We find that the MTurker responses are similar to the in-lab study: after normalizing the ratings to the same range, the MTurkers' MOS differs by less than 3% from the in-lab study's MOS on the same video.

How many MTurkers are needed? We did a head-to-head comparison with WaterlooSQOE-III [31] and found that we need 17% more MTurkers to reduce the variance of QoE ratings down to the levels of the in-lab study. §7.4 shows how the number of MTurkers affects SENSEI's performance.

Despite the above, we acknowledge that our MTurk survey methodology could be susceptible to human factors.

6 SENSEI's ABR Logic

The key difference between SENSEI's ABR logic and traditional ABR logic is that SENSEI aligns quality adaptation with the temporal variability of quality sensitivity. We first show how SENSEI modifies a traditional ABR framework (§6.1), and then show how existing ABR algorithms can be minimally modified to benefit from SENSEI (§6.2).

6.1 Enabling new adaptation actions

SENSEI takes a pragmatic approach by working within the framework of existing players. It proposes specific changes to their input and output, as highlighted in Figure 10.

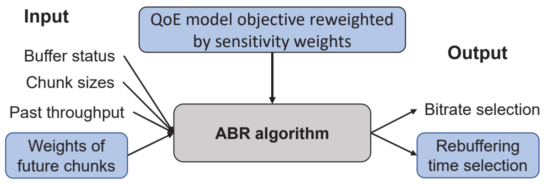

Figure 10: *ABR framework of* SENSEI. *The differences with traditional ABR framework are highlighted.*

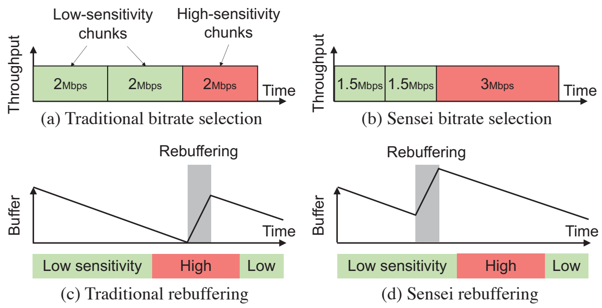

Figure 11: *Illustrative examples of* SENSEI *vs traditional ABR logic: how* SENSEI *improves quality (a vs. b) or avoids bad quality (c vs. d) for high-sensitivity chunks.*

Input: Besides the current buffer length, next chunk sizes, and history of throughput measurements, SENSEI's ABR algorithm takes as input the sensitivity weights of the next h chunks, where h is the *lookahead horizon*. A larger h allows us to look farther into the future for opportunities to trade current quality for future quality, or vice versa. In practice, we are also constrained by the reliability of our bandwidth prediction for future chunks. We microbenchmark the selection of h in §7.5.

Output: SENSEI's ABR algorithm selects the bitrate for future chunks as well as when the next rebuffering event should occur.[6] In contrast, traditional players only initiate rebuffering events when the buffer is empty.

QoE model objective: If the ABR algorithm explicitly optimizes an additive QoE model, SENSEI can modify its objective as described in §4.2. While SENSEI can be applied to most ABR algorithms (*e.g.,* [56, 83, 85]), some (*e.g.,* BBA) do not have an explicit objective that SENSEI can build on.

In theory, these changes are sufficient to enable at least the following optimizations, which traditional ABR algorithms are unlikely to explicitly do. (1) Lowering the current bitrate so that it can raise the bitrate for the next few chunks, if they have higher quality sensitivity (Figures 11(a) and (b)). (2) Raising the current bitrate slightly over the sustainable level if quality sensitivity is expected to decrease in the next few chunks. (3) Initiating a short rebuffering event now in order to ensure smoother playback for the next few chunks, if they have higher quality sensitivity (Figures 11(c) and (d)).

[6] SENSEI currently makes adaptation decisions only for the next chunk, but in principle it could plan adaptations for multiple chunks in the future.

6.2 Refactoring current ABR algorithms

We apply SENSEI to two ABR algorithms: Pensieve [56], based on deep reinforcement learning, and Fugu [83], a more traditional algorithm based on bandwidth prediction.

Applying SENSEI to Pensieve: SENSEI leverages the flexibility of deep neural networks (DNNs) and augments Pensieve's input, output and QoE objective—its states, actions, and reward, in the terminology of reinforcement learning—as described in §6.1. It then retrains the DNN model in the same way as Pensieve; we call this variation SENSEI-Pensieve. SENSEI-Pensive makes two minor changes to reduce the action space (which now includes rebuffering). First, we restrict possible rebuffering times to three levels ($\{0,1,2\}$ seconds) that can only happen at chunk boundaries. Second, instead of choosing among combinations of bitrates and rebuffering, SENSEI-Pensieve either selects a bitrate or initiates a rebuffering event at the next chunk. If it chooses the latter, SENSEI-Pensieve will increment the buffer state by the chosen rebuffering time and rerun the ABR algorithm immediately.

Applying SENSEI to Fugu: Let us first explain how Fugu works. At a high level, before downloading the i^{th} chunk, Fugu considers the throughput prediction for the next h chunks. For any throughput variation γ (with predicted probability $p(\gamma)$) and bitrate selection $B = (b_i, \ldots, b_{i+h-1})$, where b_j is the bitrate of the j^{th} chunk, it simulates when each of the next h chunks will be downloaded and estimates the rebuffering time $t_j(B,\gamma)$ of the j^{th} chunk (which could be zero). It then picks the bitrate vector $(b_i, \ldots, b_{i+h-1})$ that maximizes the expected total quality over the next h chunks and possible throughput variations: $\sum_\gamma p(\gamma) \sum_{j=i}^{i+h-1} q(b_j, t_j(B,\gamma))$. Here, $q(b,t)$ estimates the quality of a chunk with bitrate b and rebuffering time t using a simplified model of KSQI.

The SENSEI variation of Fugu, which we call SENSEI-Fugu, uses Fugu's throughput prediction and the sensitivity weights w_j of the next h chunks. SENSEI-Fugu picks the bitrate vector $B = (b_i, \ldots, b_{i+h-1})$ and the rebuffering time vector $T = (t_i, \ldots, t_{i+h-1})$, where t_j is the rebuffering time of the j^{th} chunk, that maximizes the expected total quality over the next h chunks and possible throughput variations:

$$\sum_\gamma p(\gamma) \sum_{j=i}^{i+h-1} w_j q(b_j, t_j) \tag{2}$$

Here, the chosen rebuffering times must be feasible, *i.e.,* the buffer length can never be negative.

In short, SENSEI-Pensieve and SENSEI-Fugu add an extra action (rebuffering time per chunk), and their objective function reweights the contribution of each chunk's quality using the sensitivity weights provided by our QoE model.

6.3 Player implementation and integration

We implement SENSEI on DASH.js [3], an open-source player that several commercial players are based on. We add a new field in the DASH manifest file (under `Representation`) to represent per-chunk sensitivity weights and change the parser `ManifestLoader` to parse these weights. Unlike other ABR players, SENSEI may initiate rebuffering when the buffer is not empty. We use Media Source Extensions [7] (an API that allows browsers to change player states) to delay a downloaded chunk in the browser buffer from being loaded into the player buffer. We also describe the implementation of our crowdsourcing pipeline for MTurk surveys in Appendix C.

7 Evaluation

Our evaluation of SENSEI shows several key findings:

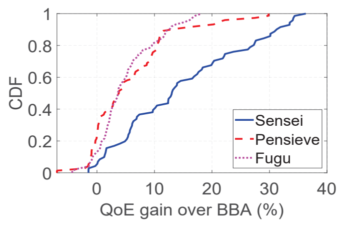
- Compared to recent proposals, SENSEI can improve QoE by 7.7-52.5% without using more bandwidth or can save 12.1-50.3% bandwidth while achieving the same QoE.
- The performance gains of SENSEI come at a cost of \$31.4/minute video, which is marginal compared to the investments made by content providers.
- SENSEI can improve QoE prediction accuracy by 11.8-37.1% over state-of-the-art QoE models.
- SENSEI's ABR algorithm consistently outperforms baseline ABR algorithms even when bandwidth fluctuates.

7.1 Experimental setup

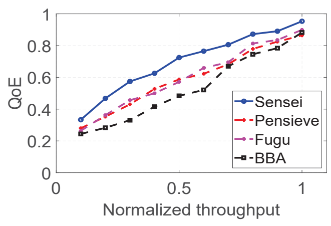
Test videos and throughput traces: Our test videos are selected from four datasets: LIVE-MOBILE [36], LIVE-NFLX-II [21], and WaterlooSQOE-III [31] are professional-grade datasets often used to train/compare QoE models in the literature. We complement these sources with videos from a user-generated dataset, YouTube-UGC [78]. The videos are randomly selected from four video genres: sports, gaming, nature, and animation. Appendix §A provides more details about the videos. To create an adaptive video streaming setup, we chop videos into 4-second chunks and encode each chunk at 5 bitrate levels: $\{300, 750, 1200, 1850, 2850\}$Kbps. We randomly select 10 throughput traces from two public datasets, FCC [24] and 3G/HSDPA [65], restricting our selection to those whose average throughput is between 0.2Mbps and 6Mbps, forcing the ABR algorithms to adapt their bitrates.

Baselines: We compare SENSEI's ABR algorithm with three baselines: Buffer-based adaptation (BBA) [45], Fugu [83], and Pensieve [56]. We keep their default settings (*e.g.,* same DNN architecture and training network traces for Pensieve, etc.). For fairness, we use KSQI as the QoE model for Pensieve, Fugu, and the SENSEI variants. This modification should improve the quality of Pensieve and Fugu, because the QoE models used in their original implementations are special cases of KSQI. We use SENSEI-Pensieve (*i.e.,* the application of SENSEI to Pensieve) as SENSEI, but confirm that the improvements of SENSEI-Fugu are similar (Figure 18a).

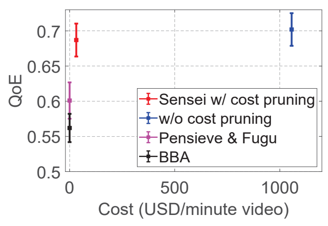
Performance metrics: We use three performance metrics. For a given source and video and throughput trace, we report the **QoE gain** of one ABR algorithm (Q_1) over another (Q_2), *i.e.,* $(Q_1 - Q_2)/Q_2$, where Q_1 and Q_2 are *rated by MTurkers*.



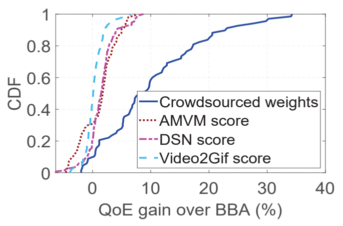
(a) QoE gains over BBA



(b) QoE vs. bandwidth usage



(c) MTurk cost vs. QoE



(d) SENSEI with crowdsourced weight vs. saliency-based weights

Figure 12: *End-to-end performance of* SENSEI *over traditional and saliency-based ABR baselines, across all videos.*

We calculate SENSEI's **bandwidth saving** by scaling down the throughput traces and determining how much bandwidth each ABR algorithm needs to achieve the same QoE. We normalize all QoE values to the range $[0,1]$. We measure the **crowdsourcing cost** paid to MTurk to get enough ratings to profile a 1-minute video. Only SENSEI incurs this cost.

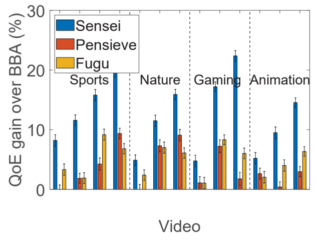
7.2 End-to-end improvement

QoE gains: Figure 12a shows the distributions of QoE gains of SENSEI, Pensieve, and Fugu over BBA, across all combinations of the 16 source videos and 10 network traces. Compared to BBA, SENSEI has at least 14.4% QoE gain for half of the trace-video combinations, whereas Pensieve's and Fugu's median QoE gains are about 5.7%. The tail improvement of SENSEI is greater: SENSEI's QoE gain at the 80th percentile is 4.8%, whereas Pensieve's and Fugu's are 0.2% and 0.7% respectively. The fact that SENSEI's gains over Pensieve (its base ABR logic) are similar to Pensieve's gains over BBA suggests the significant potential in making an existing ABR algorithm aware of dynamic quality sensitivity.

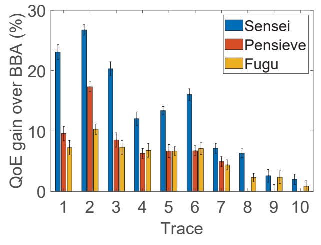
Bandwidth savings: Figure 12b shows the average QoE of different ABR algorithms across the source videos, under one throughput trace scaled down by different ratios (x-axis). We confirm the results are consistent across different throughput traces. We see that when setting a target QoE of 0.8, the bandwidth savings of SENSEI is about 27% higher compared to Pensieve and Fugu, and 32% higher compared to BBA.

QoE vs. crowdsourcing cost: Figure 12c shows the crowdsourcing cost and resulting QoE of SENSEI relative to Pensieve, both with and without the cost-pruning optimization (which is evaluated separately in Figure 16). Compared to enumerating all combinations of the quality incidents, we see that costs can be reduced by more than 32× with only a 3.1% degradation in QoE, and SENSEI is still 14.7% better on average than its base ABR logic (Pensieve with KSQI). This cost is equivalent to ∼\$31.4 per 1-minute video, which is a negligible cost for large content providers that may spend on the order of \$10 billion annually [4] for licensing popular TV shows (or making such shows).

Improvements by video and trace: Figure 13a shows the QoE gains for each video across the network traces. We see significant variability in the QoE gains across videos and even within the same genre. Figure 13b shows the QoE gains



(a) QoE gain grouped by genre



(b) QoE gain grouped by trace

Figure 13: *QoE gains over BBA for genre and for each throughput trace (ordered by increasing average throughput)*

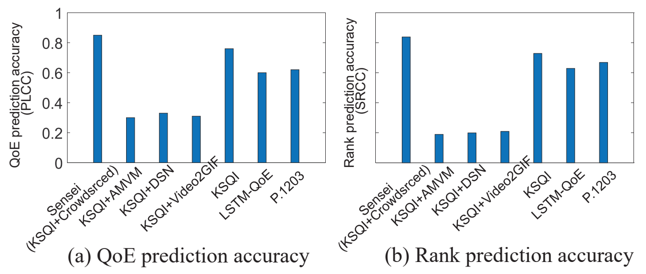
for each network trace across all videos. Overall, SENSEI yields more improvement when the average throughput is lower (towards the left). This shows that SENSEI can better maintain high QoE even when the network is under stress.

SENSEI vs. saliency-reweighted ABR: Finally, Figure 12d shows the QoE gains of SENSEI when the per-chunk weights are based on crowdsourcing results (our approach) and when the weights are based on the saliency scores produced by various saliency models (see §2.3). We normalize each model's saliency scores to sum to the sum of chunk weights of SENSEI. We see that SENSEI's gain significantly reduces if the weights are based on these saliency models, because as explained in §2.3, they fail to capture users' quality sensitivity.

7.3 QoE prediction accuracy

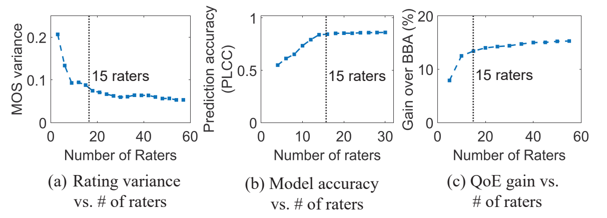
We now microbenchmark SENSEI's QoE model introduced in §4 using all 640 rendered videos generated by running SENSEI and the baseline ABR algorithms on all combinations of source videos and network traces. We obtain the "ground truth" QoE of each rendered video using our MTurk survey procedure (§4,§5). We calculate Pearson's linear correlation coefficient (PLCC) and Spearman's rank correlation coefficient (PRCC) between the predicted QoE and actual user-rated QoE. Figure 14 compares SENSEI with three baselines QoE models (KSQI, LSTM-QoE, P.1203). The PLCC (and PRCC) of SENSEI's QoE prediction is over 0.85 (and 0.84), whereas the baselines are below 0.76 (and 0.73). We evaluated several variants of KSQI (the best baseline QoE model) re-weighted by per-chunk saliency scores from the saliency models in §2.3, but their accuracies are even lower.

7.4 Cost savings on crowdsourcing



(a) QoE prediction accuracy (b) Rank prediction accuracy

Figure 14: *QoE prediction accuracy of* SENSEI*,* SENSEI*'s variants, and baseline QoE models.*



(a) Rating variance vs. # of raters (b) Model accuracy vs. # of raters (c) QoE gain vs. # of raters

Figure 15: *The effect of the number of raters*

We microbenchmark the effects of different crowdsourcing parameters on SENSEI's QoE model.

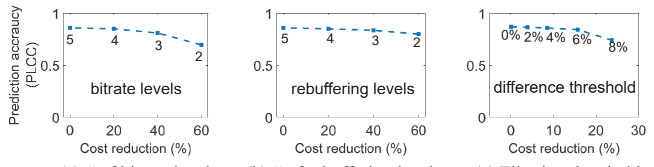
Impact of number of raters per video: Figure 15(a) shows that while the quality ratings have substantial variance with less than 5 raters, their mean value (MOS) stabilizes with more than 15 raters. As a result, having 15 raters per video (as used in SENSEI) produces a similar QoE prediction accuracy (b) and QoE gains (c) as having 30 raters.

Impact of crowdsourcing schedule granularity: Figure 16 shows the effect of reducing MTurk cost by considering (a) fewer bitrate levels (B), (b) fewer rebuffering events (F), or (c) higher threshold α used to pick which chunks to investigate in the second step. These terms are defined in §4.3. By reducing B to 3, F to 2, or raising α to 6%, we greatly reduce the cost while incurring less than 3% drop in accuracy.

7.5 SENSEI's ABR logic

Finally, we microbenchmark SENSEI's ABR logic (§6). To scale this experiment out, we use real videos and throughput traces but use the QoE predicted by SENSEI (instead of real user ratings) to evaluate QoE. We have confirmed that this yields the same QoE estimates on average as real user ratings under the same setting.

Impact of bandwidth variance: Figure 17 shows the performance of SENSEI under increasing throughput variance. We pick one throughput trace and increase its throughput variance by adding unbiased Gaussian noise. The graph begins at the variance of the original throughput trace; as variance increases, SENSEI's QoE degrades gracefully, but it still maintains a significant gain over its base ABR logic (Pensieve or Fugu). This is because SENSEI only needs to predict how likely low throughput will occur on high quality-sensitivity chunks, not all future chunks, so if the average throughput until the next such chunk is predictable, it will work well. We



(a) # of bitrate level (b) # of rebuffering level (c) Filtering threshold

Figure 16: *QoE model accuracy changes with cost.*

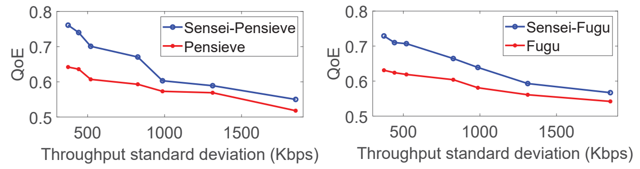


Figure 17: *QoE under increasing bandwidth variance.*

confirm the results are similar on other throughput traces.

Performance breakdown: Figure 18a shows that SENSEI achieves comparable improvement when either Pensieve or Fugu is the base ABR logic. This suggests that SENSEI's gains do not depend on the choice of the base ABR logic. Figure 18b shows that both aspects of SENSEI's control logic contributes to its improvements: (1) making ABR logic aware of dynamic quality sensitivity (1st vs. 2nd bar), and (2) injecting rebuffering judiciously (2nd vs. 3rd bar). Thus, even if a content provider cannot control rebuffering, it can still benefit significantly from SENSEI's dynamic quality sensitivity.

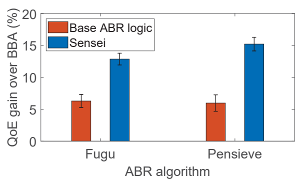
Impact of video contents: While the videos in our dataset have varying fractions (from 20% to 60%) of high-sensitivity chunks, Figure 18c tests Sensei's performance under an even wider range of high-sensitivity chunk fractions (from 0% to 100%). We create source videos with the specific fractions of high and low quality-sensitivity chunks and randomize the positions of the chunks. SENSEI has marginal improvement when the video is dominated by either high or low quality-sensitivity chunks. However, SENSEI significantly improves QoE when high quality-sensitivity chunks are 20-40% of a video (most of our videos fall in this range).

Lookahead horizon: Figure 18d tests the impact of lookahead horizon—the number of future chunks h whose quality-sensitivity weights are revealed to the ABR algorithm. A longer horizon increases SENSEI's ability to schedule quality events between low and high quality-sensitivity chunks. Empirically in our dataset, the QoE gains diminish after the lookahead horizon is greater than 4 chunks.

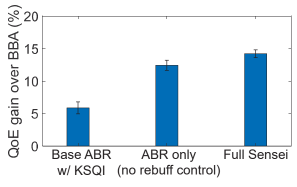
Systems overhead: We confirm empirically that compared to a video player without SENSEI, the runtime overhead of SENSEI is less than 1% in both CPU cycles and RAM usage.

8 Related Work

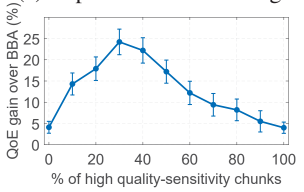
ABR algorithms: Mainstream ABR algorithms maximize bitrate under dynamic available bandwidth. Traditional ones are buffer-based (*e.g.,* [46, 50]) or rate-based algorithms (*e.g.,* [45, 69, 70]). Recent ABR algorithms explicitly optimize a given QoE objective via control theory [85], ML-based



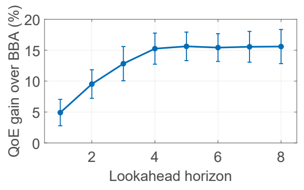
(a) Impact of base ABR logic



(b) Improvement breakdown



(c) Chunk sensitivity



(d) Lookahead horizon

Figure 18: *Understanding* SENSEI*'s improvements.*

throughput prediction [73, 83], or deep reinforcement learning [34, 35, 56]. Some ABR algorithms also rely on server-side processing [17, 47, 84]. Key parameters of the ABR logic can be customized to the network conditions or devices [16]. Though SENSEI reuses existing ABR algorithms, its contribution lies in identifying minimum changes (*e.g.,* adaptation actions they never would have taken) needed for these algorithms to fully leverage users' dynamic quality sensitivity.

Modeling and optimizing user-perceived quality: Visual quality assessment (VQA) traditionally models user's perception of encoded video using pixel-level patterns (*e.g.,* [38, 64, 68, 79]) as well as advanced data-driven models, such as SVM [11] and deep learning models (*e.g.,* [48]). Adaptive quality assessment (AQA), on the other hand, models streaming-related incidents, including join time, bitrate switches, rebuffering (*e.g.,* [18, 28, 49]). Recent QoE models combine VQA and AQA (*e.g.,* [19, 20, 22, 25, 29, 31, 33]) and sometimes uses spatial/temporal visual attention (*e.g.,* [30, 34, 34, 37, 59, 60, 82]). These perception-centric QoE models have inspired a large body of work that maximizes user-perceived quality with bitrate adaptation [58, 61], adaptive video encoding [17, 67, 89], adaptive bitrate levels [14, 15], dynamic chunk lengths [51], and super resolution [47, 84, 88].

Since the user-perceived quality metrics can vary across chunks, they may also treat video chunks differently, like SENSEI does. However, as elaborated in §2.3, SENSEI is complementary to these efforts: while they propose heuristics to how pixel-/motion-based visual features affect QoE, SENSEI customizes itself for each video (in a cost-efficient way) to capture the impact of the *substance of video content* on true user sensitivity to video quality. That said, actions like dynamic bitrate levels, chunk lengths, and super resolution could be used in SENSEI too, though SENSEI only considers actions directly supported by current DASH players.

QoE research using crowdsourcing: Prior work (*e.g.,* [23, 42, 43, 57, 62, 81]) provides methodologies for using commercial crowdsourcing platforms, *e.g.,* Amazon MTurk [1] and Microworkers [8], to systematically model user perception using objective quality metrics [23, 42, 43, 62, 81], investigate QoE impact of different types of low-quality events (*e.g.,* [32]), and build crowdsourcing platforms themselves for similar purposes (*e.g.,* [77, 83]). While SENSEI follows conventional crowdsourcing methodology (§5), SENSEI faces a unique challenge of scaling crowdsourcing to *per-video* QoE modeling. The cost of modeling QoE of each video separately is prohibitive, and SENSEI drastically prunes the cost by reusing an existing QoE model while profiling only a single weight per representative chunk to encode the content-induced quality sensitivity of each chunk.

9 Discussion

Participant selection bias: A concern of any crowdsourced user study is that the results could be biased because the workers who are willing to participate in the user study might have different characteristics than the real video viewers. A common approach to address this bias is to reweight the participant responses based on the demographics of real users (*e.g.,* [26, 55, 71, 76]). SENSEI could apply reweighting to the user study if we have knowledge of the target viewers' demographics, or it could directly recruit the user study participants from the target viewers themselves (*e.g.,* subscribers of the content provider).

Inapplicable scenarios: SENSEI does not apply to live video streaming and copyrighted videos. Live videos have strict delay requirements which our crowdsourcing-based video profiling cannot meet. Showing copyrighted videos to crowdsource workers poses the risk of copyright violation, though SENSEI could be used on already-released videos. Moreover, the profiling cost of $\sim$ \$31.4/minute video may still be impractical for videos with only a few views. Instead, we envision that SENSEI will be used for popular on-demand video by content providers who seek to improve their QoE-bandwidth tradeoffs. For example, providers such as Amazon, Netflix and YouTube recently lowered the default bitrate in Europe due to increased network traffic during the COVID lockdown [9].

10 Conclusion

We have described SENSEI, a video streaming system that optimizes video quality by exploiting dynamic quality sensitivity. Observing that quality sensitivity is inherent to video content and hence unique to each video, SENSEI scales out the profiling of quality sensitivity using a reliable crowdsourcing methodology. We show that with minor modifications to state-of-the-art ABR algorithms, SENSEI can improve their QoE by 15.1% or save bandwidth by 26.8% on average.

A Dataset

Figure 19 provides screenshots and descriptions of the 16 source videos used in our dataset. Table 1 summarizes the test videos.

B Reliable QoE Crowdsourcing

We provide a few additional details on our crowdsourcing methodology.

Population bias of MTurk: As mentioned in §9, the per-chunk quality sensitivity could be biased by the population distribution of MTurkers. We confirm that about 43.8% (and 67.3%) of the received ratings come from MTurkers who participate in our survey only once (at most twice). This suggests that the pool of MTurkers is large enough to avoid small population bias, which corroborates our sanity-check results (§5) that on average MTurker quality ratings are strongly correlated with in-lab survey results.

Name	Genre	Length	Source dataset

(p) BigBuckBunny	Animation	9:56	WaterlooSQOE-III

Table 1: *Summary of the test video set.*

Fast MTurker recruitment: While the MTurk platform cuts the overhead to publish our survey, if MTurkers sign up slowly, this can slow down the entire process. We take following steps to speedup the recruitment of MTurkers.

- *Competitive compensation:* We offer an hourly rate of $10, a competitive compensation on the MTurk platform — only 4% MTurkers are paid more than $7.25/hour [40], though we have not explored the impact of raising/lowering this rate. To prevent people from gaming the system by sitting on a job for too long, we pay each MTurker by the estimated amount of time needed to finish a survey (which is proportional to the total length of the videos per MTurker), rather than by how much time the MTurker actually spends. In practice, this only weeds out MTurkers who spend too much time on a survey.
- *Maintaining good reputation:* The MTurkers' signing-up speed also depends largely on the reputation of the publisher (*i.e.,* us), because MTurkers tend to sign up if the publisher historically has a low rejection rate. Thus, it is critical to be clear upfront about our study's rejection criteria. In the meantime, to keep our rejection rate low, we try to target reliable MTurkers by restricting ourselves to Master MTurkers (a common practice for publishers on MTurk [53]).

C Implementation

Automation of MTurk tests: We implement the pipeline shown in Figure 8 in Python (for the logic) and Javascript (for the video server). Given a source video, it first creates the

(a) Basket1 : A buzzer beater in a basketball game

(b) Soccer1 : A goal after a failed shoot

(c) Basket2 : A free throw followed by a one-on-one defense.

(o) Girl: A girl falling off the cliff

(n) Lava: A lava is waking up

(p) BigBuckBunny: A rabbit dealing with three tiny bullies

Figure 19: Summary of source videos in our dataset. They span four genres: sports (a - g), gaming (h - j), natural (k - m), and animation (n - p). They are compiled randomly from public QoE datasets: LIVE-MOBILE [36](a,k), LIVE-NFLX-II [21] (b, n), YouTube-UGC [78] (c - j and l - o); and WaterlooSQOE-III [31] (p).

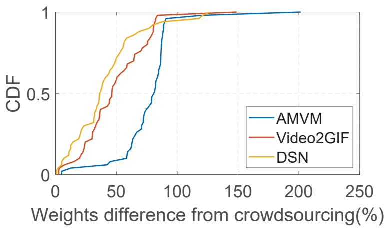

Figure 20: Chunk weight difference

rendered videos by adding specific low-quality incidents in the source video (via ffmpeg). It then uploads these videos to a video server, from which MTurkers later download the video. After that, it generates a unique link for this campaign and posts it on the MTurk website (the only step that requires manual intervention). MTurkers can join the test by clicking the link, which redirects them to our video server. Once an MTurker has rated all assigned videos, the server logs the ratings and notifies us. Once enough ratings are received, the server trains the per-chunk weights as described in §4.2.

Single survey procedure: As shown in Figure 21:

- (a) Each survey starts with the instructions and rejection criteria under which ratings of an MTurker will be rejected. Each MTurker is expected to read the instructions carefully.
- (b) The MTurker then watches an example video that includes a quality incident so that they know what their ratings should be based on.
- (c, d) After that, the MTurker is asked to watch a sequence of rendered videos (determined by the scheduler) and, after each video, rate the quality on a scale of 1-5.
- (d) Finally, the MTurker does an exit survey.

D More discussion on saliency models

Saliency models used in §2.3: We test four models in total, a traditional motion-based heuristic (AMVM [52]), a highlight detection model (video2GIF [39]), and a video summarization model (DSN [90], dppLSTM [87]). We used the pretrained models of Video2GIF (`https://github.com/gyglim/video2gif_code`), DSN (`https://github.com/KaiyangZhou/pytorch-vsumm-reinforce`), and dppLSTM (`https://github.com/kezhang-cs/Video-Summarization-with-LSTM`).

Saliency score vs. quality sensitivity: Although a variety of saliency models have been proposed, we argue that these visual heuristics can be misaligned with video quality sensitivity. For example, in the soccer video (Figure 1), the scene

right before the goal is most quality sensitive, but the highlight detection models and motion-based heuristics we evaluated believe the scenes showing the audience are the most important (probably because they show more human movements). Video summarization models pick all diverse moments of a video, but many of them may not be quality-sensitive. For example, in the same soccer video, the video summarization models identify every shot, rewind, and celebration clip as important, but the users pay more attention to shots that might score a goal.

We also acknowledge the potential use of viewership information to detect video highlights. While the popularity of a chunk is closely related to highlights (or high interestingness scenes) in a video, as we found in §2.3 and §7.3, these incidents may not perfectly align with users' sensitivity to video quality. Below are two examples specifically regarding the potential misalignment between content popularity and quality sensitivity.

- Example 1: A less popular part of a video can still be quality-sensitive. The "animal" video in our dataset is a part of a video about wildlife in Africa. Although a more "popular" or "interesting" scenes is one where the lions chase antelopes, we find that users are still highly quality-sensitive in the scene where warthogs jump into a small pond for bathing.
- Example 2: A quality-sensitive part of a video may be a small fraction of a popular segment. One of the soccer videos in our dataset is a compilation of highlight moments from a long game, so all of its content is supposed to be "popular". However, we still see that there is heterogeneity in the sensitivity of its chunks.

GAIA: A System for Interactive Analysis on Distributed Graphs Using a High-Level Language

Abstract

GAIA (GrAph Interactive Analysis) is a distributed system designed specifically to make it easy for a variety of users to *interactively* analyze big graph data on large clusters at low latency. It adopts a high-level language called Gremlin for graph traversal, and provides automatic parallel execution. In particular, we advocate a powerful new abstraction called Scope that caters to the specific needs in this new computation model to scale graph queries with complex dependencies and runtime dynamics, while at the same time maintaining the simple and concise programming model. GAIA has been deployed in production clusters at Alibaba to support a variety of business-critical scenarios. Extensive evaluations using both benchmarks and real-world applications have validated the effectiveness of the proposed techniques, which enables GAIA to execute complex Gremlin traversal with orders-of-magnitude better performance than existing high-performance engines, and at much larger scales than recent state-of-the-art Gremlin-enabled systems such as JanusGraph.

1 Introduction

Nowadays an increasing number of Internet applications generate large volume of data that are inherently connected in various forms. Examples include data in social networks, e-commerce transactions, and online payments. Such data are naturally modeled as graphs to encode complex relationships among entities with rich set of attributes. Unlike traditional graph processing that requires programming for each individual task, it is now very common for domain experts, typically non-technical users, to directly explore, examine, and present graph data in an interactive environment in order to locate specific or in-depth information in time.

As an example, consider the graph depicted in Figure 1, which is a simplified version of a real query employed at Alibaba for credit card fraud detection. By using a fake identifier, the "criminal" may obtain a short-term credit from a bank (vertex 1). He/she tries to illegally cash out money by forging a purchase (edge $2 \rightarrow 3$) at time t_1 with the help of a merchant (vertex 3). Once receiving payment (edge $1 \rightarrow 3$) from the bank (vertex 1) at time t_2, the merchant tries to send the money back (edges $3 \rightarrow 4$ and $4 \rightarrow 2$) to the "criminal" via multiple accounts of a middle man (vertex 4) at time t_3 and t_4, respectively. This pattern eventually forms a cycle ($2 \rightarrow 3 \rightarrow 4 \cdots \rightarrow 2$). Such fraudulent activities have become one of the major issues for online payments, where the graph could contain billions of vertices (e.g., users) and hundreds of billions to trillions of edges (e.g., payments). In reality, the entire fraudulent process can involve a complex chain of transactions, through many entities, with various constraints, which thus requires complex interactive analysis to identify.

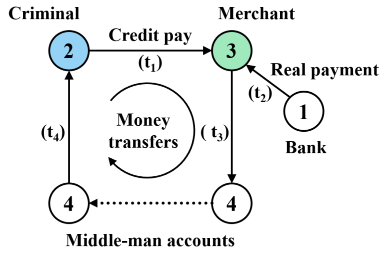

Figure 1: An example graph model for fraud detection.

Our goal is to make it easy for a variety of users to *interactively* analyze big graph data on large clusters at low latency. Achieving this goal requires a different distributed infrastructure than the popular batch-oriented big graph processing systems [4, 15, 16, 26, 39, 49] in two aspects:

Programming Model. Existing systems, including the most recent high-performance data engines such as Naiad [27], demonstrate that it is possible to scale well-known graph algorithms such as PageRank [5] and connected components [23] to large clusters. Even so, their programming interfaces all leave room for improvement for our target users, who typically lack the background on distributed computing or programming in general [13].

Memory Management. Existing systems[1] typically base their execution on the bulk synchronous parallel (BSP) model [44], where the computation proceeds iteratively, and

[1] Here, we focus on the distributed graph analytical systems. Other systems such as Neo4j, ZipG, and JanusGraph, etc. will be surveyed in Section 7.

```
Q1: g.V('account').has('id','2').as('s')
      .repeat(out('transfer').simplePath())
      .times(k-1)
      .where(out('transfer').as('s'))
      .path().limit(1)
```

Figure 2: An example Gremlin query for cycle detection.

in each iteration, all vertices in a graph will conduct the same computation , and send any updates along their edges to drive the computation of the next iteration. The BSP-based engines, however, are not suitable for interactive graph queries because of two reasons. Firstly, the interactive queries typically require maintaining application state along with the traversal paths to enable complex analysis [14, 37], which can grow exponentially with the number of iterations, and cause memory crisis in the underlying execution platforms. Secondly, in interactive environments, there are typically multiple queries sharing the limited amount of memory on the same set of machines, on which (a large part of) the input graph is cached in memory to provide required performance, making the above memory crisis a more critical issue.

In this work, we exploit Gremlin [37] to provide a high-level language for interactive graph queries. Gremlin is widely adopted by leading graph system vendors [1, 6, 21, 29, 30], which offers a flexible and expressive programming model to enable non-technical users to succinctly express complex traversal patterns in real-world applications. For example, one can write the above fraud-detection query in just a couple of lines using Gremlin, as shown in Figure 2 (which we explain in Section 3). In contrast, even common operations like cycle detection, which is a core part of the fraud-detection use case, is tricky to implement in existing graph systems [16, 36].

The flexibility of Gremlin mainly stems from nested traversal with dynamic control flow such as conditionals and loops. While attempting to scale Gremlin queries, we are immediately confronted with the challenges of resolving fine-grained data dependencies [10] with dynamic control flow [45]. Therefore, existing Gremlin-enabled, large-scale systems either adopt a *sequential* implementation in centralized query processing with data being pulled from a remote storage (such as JanusGraph [21] and Neptune [1]), or offer a limited subset of the language constructs (such as the lack of nested loops in [20]). In addition, GAIA must handle dynamics related to variations in memory consumption in an interactive context.

In this paper, we present a system, GAIA, that takes on the challenges of making Gremlin traversal work efficiently at scale with low latency. In particular, GAIA makes the following technical contributions.

- *Scope Abstraction.* We propose the Scope abstraction to allow GAIA to dynamically track fine-grained data dependencies in a Gremlin query. This enables Gremlin traversal to be modeled as a dataflow graph for efficient parallel execution with correctness guarantee.
- *Bounded-Memory Execution.* Leveraging the Scope abstraction, we are able to devise advanced optimizations in parallel graph traversal, such as bounded-memory execution and early-stop optimization, which lead to further runtime improvement and memory saving.
- *GAIA System.* We have developed a full-fledged distributed system, GAIA, and made it available at: https://github.com/alibaba/GraphScope/tree/main/research/gaia. An extended version of GAIA with enterprise features has been deployed in real production clusters at Alibaba to support a variety of business-critical scenarios. Extensive evaluations using both benchmarks and real-world applications have validated the effectiveness of the proposed techniques, which enables GAIA to execute complex Gremlin traversal with orders-of-magnitude better performance than existing engines, and at much larger scales than the state-of-the-art Gremlin-enabled systems such as JanusGraph.

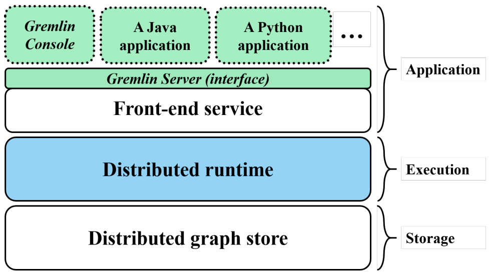

Figure 3: GAIA system architecture.

2 System Architecture

GAIA is a full-fledged, in-production system for interactive analysis on big graph data. Achieving this goal requires a wide variety of components to interact, including software for cluster management and distributed execution, language constructs, and development tools. Due to space limit, we highlight the three major layers that are sufficient to understand this paper, namely application, execution, and storage, in Figure 3, and give an overview to each of them below.

Apache TinkerPop [3] is an open framework for developing interactive graph applications using the Gremlin query language [37]. GAIA leverages the project to supply the application layer. GAIA implements the Gremlin Server [18] interface so that the system can seamlessly interact with the TinkerPop ecosystem, including development tools such as Gremlin Console [17] and language wrappers such as Java and Python.

The GAIA execution runtime provides automatic support for efficient execution of Gremlin queries at scale, which constitutes the main contribution of this paper. Each query is compiled by the front-end service into a distributed execution plan that is partitioned across multiple compute nodes for parallel execution. Each partition runs on a separate compute node, managed by a local executor, that schedules and executes computation on a multi-core server.

The storage layer maintains an input graph that is hash-partitioned across a cluster, with each vertex being placed

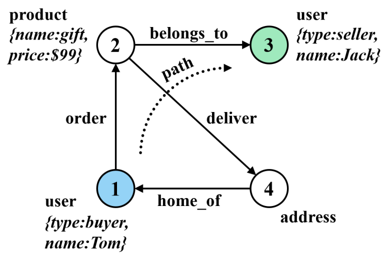

Figure 4: An example “e-commerce” property graph.

together with its adjacent (both incoming and outgoing) edges and their attributes. In this paper, we assume that the storage is coupled with the execution runtime for simplicity, that is each local executor holds a separate graph partition. In production, we implement a distributed graph storage with index and cache features, decoupled from the execution, that supports real-time updates with snapshot isolation (similar to Kineograph [11]), which allows users to query fast-changing graphs with consistency guarantee. Furthermore, GAIA provides multiple options for fault tolerance using checkpoints, replication, and/or relying on a Cloud storage. Production details are outside the scope of this paper.

3 Programming with GAIA

GAIA is designed to faithfully preserve the programming model of TinkerPop [3], and as a result it can be used to scale any existing TinkerPop applications to large compute clusters without any modification. In this section, we provide a high-level view of the programming model, highlighting the key concepts including the data model and query language.

Gremlin [37] enables users to define ad-hoc traversals on property graphs [2]. A property graph is a directed graph in which vertices and edges can have a set of properties. Every entity (vertex or edge) is identified by a unique identifier (`ID`), and has a (`label`) indicating its type or role. Each property is a key-value pair with combination of entity `ID` and property name as the key. Figure 4 shows an example property graph. It contains `user`, `product`, and `address` vertices connected by `order`, `deliver`, `belongs_to`, and `home_of` edges. A path following vertices $1 \to 2 \to 3$, shown as the dotted line, indicates that a buyer “Tom” ordered a product “gift” offered by a seller “Jack”, with a price of “$99”.

In a Gremlin traversal, a set of *traversers* walk a graph according to particular user-provided instructions, and the result of the traversal is the collection of all halted traversers. A traverser $T = (l, P)$[2] is the basic unit of data processed by a Gremlin engine. Each traverser maintains a location l that is a reference to the current vertex, edge or property being visited, and (optionally) the path history P. For example, consider a traversal which starts from vertex 1 (with only one traverser at the location of vertex 1), follows outgoing edges, and reaches its 2-hop neighbors in Figure 4. A possible intermediate result can be a collection of a single traverser located at vertex 2 with the corresponding path history. The final result is a collection of two traversers, located at vertex 3 and 4, respectively, with different paths, $1 \to 2 \to 3$ and $1 \to 2 \to 4$.

Nested traversal is another key concept in Gremlin. It allows a traversal to be embedded within another operator, and used as a function to be invoked by the enclosing operator for processing input. The role and signature of the function are determined by the type of the enclosing operator. For example, a nested traversal within the `where` operator acts as a predicate function for conditional filters, while that within the `select` or `order` operator maps each traverser to the output or ordering key for sorting the output, respectively.

Nested traversal is also critical to the support for loops, which are expressed using a pair of the `repeat` and `until`/`times` operators. A nested traversal within the `repeat` operator will be looped over until the given break predicate is satisfied. The predicate (or termination condition) is defined within the `until` operator, applied to each output traverser separately from each iteration. The `times` operator can also terminate a loop after a fixed number of k iterations.

Example 3.1. *Figure 2 shows a Gremlin query Q1 for the motivating example in Section 1 that tries to find cyclic paths of length k, starting from a given account. First, the source operator* `V` *(with the* `has` *filter) returns all the* `account` *vertices with an identifier of “2”. The* `as` *operator is a* modulator *that does not change the input collection of traversers but introduces a name (s in this case) for later references. Second, it traverses the outgoing* `transfer` *edges for exact $k-1$ times, skipping any repeated vertices (by the* `simplePath` *operator). Third, the* `where` *operator checks if the starting vertex s can be reached by one more step, that is, whether a cycle of length k is formed. Finally, for qualifying traversers, the* `path` *operator returns the full path information. The* `limit` *operator at the end indicates only one such result is needed.*

4 Compilation of Gremlin

GAIA compiles a Gremlin query into a dataflow graph, where each vertex (operator) performs a local computation on input streams from its incoming edges and produces output streams to its outgoing edges, and can optionally maintain a state. The input graph is modeled as a read-only state shared by all the dataflow operators. We map each Gremlin operator onto a dataflow operator, and the collections of traversers as data streams. In the following, we will use the term traverser interchangeably with data. Figure 5(b) shows an example dataflow graph corresponding to the following Gremlin query (Q2) that conducts a 2-hop traversal followed by an aggregation that counts the total number of traversed paths.

```
Q2: g.V(2).out().out().count()
```

We introduce source operators as special drivers that generate output only from the input graph to drive the rest of the

[2]In [37], a traverser is modelled as a 6-tuple set, while we include necessary elements to understand this paper.

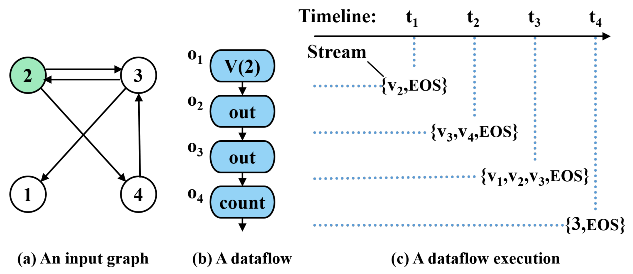

Figure 5: Dataflow graph and execution for query Q2.

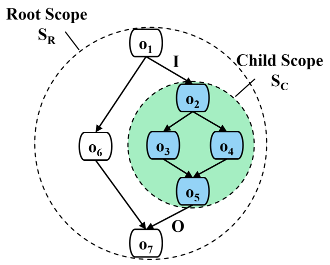

Figure 6: Dataflow and scope example: the filled circle highlights a scope with input stream I and output stream O.

dataflow computation (e.g., `V(2)`). We use sink operators to denote those that generate output streams for the computation to be consumed elsewhere (e.g., `count`). Since Gremlin imposes no restrictions on the execution order of traversers, we can pack a segment of traversers to a same operator into a batched input and schedule the computation at a coarse granularity for efficient execution.

To preserve the operator semantics for barriers, we insert an End-of-Stream (or EOS) marker at the end of the output streams of each source operators, as a special punctuation event that asserts the completeness of output. The EOS markers will be propagated through the dataflow, layer by layer, so that any downstream operators can be notified on the completeness of their inputs by waiting to collect those markers.

Example 4.1. *Figure 5(c) illustrates the progression of the dataflow execution of Q2 against the input graph in Figure 5(a). o_1 generates a data stream of {(v_2,∅), EOS} as output, where v_2 denotes the vertex with* `ID` *2. Note that the path history has been pruned (and omitted later) as the downstream operators do not need it. o_2 consumes v_2, generates output {v_3, v_4}, and finally propagates EOS to its output. Subsequently, o_3 outputs {v_1, v_2} after consuming v_3, and {v_3, EOS} for the rest of its input. Finally, o_4 outputs the counting of {3} - it can do so as the EOS marker has been received. The dataflow thus terminates.*

4.1 Challenges in Compiling Nested Traversal

Many of the salient features of Gremlin such as dynamic control flow rely on nested traversal, which introduces additional complexity to the above design. Let's look into another query Q3 slightly amended from Q2, in which a segment of operators (`out().count()`) is nested within a `select`-projection.

```
Q3: g.V(2).out()
      .select('neighbor_count')
      .by(out().count())
```

Given a set of vertices $N(v_2)$ as the outgoing neighbors of a vertex v_2, the query asks to count the number of k-hop paths starting from each vertex $u \in N(v_2)$ (let $k = 1$ for simplicity), and output pairs of (u, # paths starting from u). In this example, each input traverser that represents a vertex of $N(v_2)$ does its own computation (of the counting of paths), namely at a fine granularity. In other words, the `count` operation has to be executed separately for each vertex $u \in N(v_2)$.

We define a *context* as an execution environment for a dataflow that includes a unique (possibly empty) state for its computation. Without nested traversal (and/or dynamic control flow), all computation of each Gremlin operator, and the whole dataflow, can run in a single context. For example, in query Q2, only `count` maintains a state (for partial counting) - there is only one such state needed to count all traversed paths. With nested traversal, this property no longer holds as a stateful operator in a nested traversal can dynamically demand the separation of contexts. For example, in query Q3, due to the semantics of `select`, there must be an individual state (context) maintained for each vertex $u \in N(v_2)$ in order to produce correct results.

One may argue that the above example is not so hard to tackle. However, this is just a simplest example involving sub-traversals in Gremlin. Such context separation is also important in dynamic control flow such as loop, in which each iteration must run separately from another. One can even encounter sub-traversals involved with arbitrary combination of complex structuring constructs, making the system design uncontrollably complex. In addition, the number of separate contexts required for the correct execution of a *single* Gremlin traversal can be proportional to that of the intermediate traversers (e.g., `select` in query Q3), which can be of millions to billions in our case. While it is possible to dynamically create physical contexts as in [45], doing so at such a fine granularity for Gremlin is clearly infeasible in practice.

4.2 The Scope Abstraction

To address the issues posted by Gremlin traversal, we propose the Scope abstraction to help emancipate the system from the need of maintaining context information.We first define the concept of a Scope.

Definition 4.1. A Scope is a subgraph in a dataflow (sub-dataflow) that satisfies the following condition: for any operators o_1 and o_2 in the sub-dataflow and any operator o in the dataflow, o must also be in the sub-dataflow if o is on a directed path from o_1 to o_2.

A Scope has the same logical structure (and function) as a dataflow operator, which can thus be reduced to one virtual "operator" in the dataflow graph. Naturally, we refer to a Scope context, as the context of its enclosed operator. It is allowed that a Scope S_p contains another sub-dataflow as a nested Scope S_c as long as it satisfies the definition of Definition 4.1. S_p is called the parent Scope of S_c, and S_c is accordingly the child Scope of S_p. The whole dataflow is a special Scope that we call as *root* Scope. The dataflow regarding the nested relationships of Scopes naturally form a hierarchical structure.

Example 4.2. *In the dataflow graph as shown in Figure 6, the sub-dataflow comprised of o_2, o_3, o_4 and o_5 (as well as all their edges) is a* Scope *S_c (as highlighted) and can be reduced to one operator with I as its input stream, and O as its output stream. The whole dataflow is the root* Scope, *which is the parent* Scope *of S_c.*

As we mentioned earlier, it is costly to create physical dataflow operators as in [45] for a Gremlin query that potentially requires a separate context for each data item. We therefore propose the Scope abstraction to handle the separation of execution contexts in a Scope in a more light-weighted manner. A Scope abstraction consists of three primitives, namely `Enter`, `Exit`, and `GoTo`, and the interface of Scope policy. Specifically, `Enter` forwards a data item from a parent Scope[3] to a child Scope, while `Exit` sends data item back to a parent Scope. As `GoTo` is primarily used for loop control flow, we will introduce it in Section 4.3.

The Scope policy is installed by the compiler on each `Enter` and `GoTo` primitives to fulfil different context-switch mechanisms. Logically, we use a sequence number as context identifier to identify an execution context in a Scope, the Scope policy contains the following interfaces (their implementations are in Section 4.4):

- `CreateOrOpen(Data:`e`,CtxID:`s`)`: To create a new isolated context for the input data e, or open an existing context uniquely identified by s.
- `GetContext(Data:`e`)`: To obtain the context identifier of the data e.
- `Complete(Data:`e`,CtxID:`s`)`: To mark that there will be no more data for the context of s, after receiving e.

As an example, we present a built-in scope policy called `CONTEXT_PER_ENTRY` (more policies will be introduced as follows). `CONTEXT_PER_ENTRY` creates a new context for each input data. Let *seq* be a sequence number, initialized to 0. For each input e, the `CONTEXT_PER_ENTRY` policy first applies `CreateOrOpen(`e, *seq*`)` to create a new context for e. It then immediately calls `Complete(`e, *seq*`)` to indicate that there will be no more data for the context of *seq*. Finally, the policy increments *seq* by 1 such that any future data will enter a different context. In the following, we will detail how the Scope abstraction facilitates the compilation of a Gremlin query with nested traversals.

[3]It is more precisely a context of the Scope, while we refer to it as Scope for short.

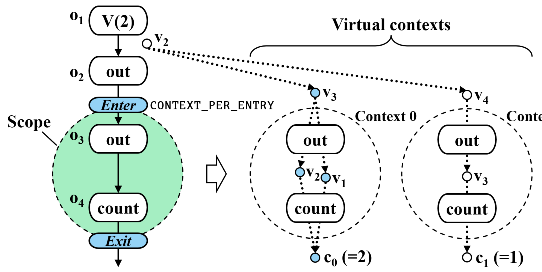

Figure 7: An example Scope execution with separate contexts.

4.3 Compilation of Gremlin using Scope

Compilation of a Gremlin query without dynamic control flow or nested traversal is as similar to that in existing systems [41, 46, 47], we do not elaborate on it further. Both dynamic control flow and nested traversal introduce sub-traversals in a Gremlin query. GAIA compiles each such sub-traversal into a Scope enclosed by a pair of `Enter` and `Exit` primitives (can be multiple of them nested within each other). The Scope abstraction handles the context separation in a unified way. Due to space limit, this section presents the compilation process of three representative Gremlin operators (`select`, `where`, and `repeat`) to highlight the common pattern of using the Scope abstraction.

Example 4.3. *Figure 7 illustrates an example that* GAIA *compiles the query Q3 (Section 4.1) into a dataflow using* Scope, *in which the* `select`*-projection introduces a* Scope *that encloses the sub-traversal of* `out().count()`*. As there requires a separate execution context for each data entering the* Scope, GAIA *installs a* `CONTEXT_PER_ENTRY` *policy on the* `Enter`*. This way, each data can drive their own computation of* `out().count()` *in isolation, without concerning about the context separation as posted in Section 4.1.*

Dynamic control flow such as `where`-conditionals and `repeat`-loops introduce addition complexity, as presented in the following query:

```
Q4: g.V(2).as('s')
      .repeat(out().simplePath())
      .times(k-1)
      .where(out().eq('s'))
      .path().limit(1)
```

We next focus on the compilation of these constructs, inspired by TensorFlow [45]. However, unlike [45], they can be applied to a much finer granularity of each individual traversal path in Gremlin. This is enabled by the Scope abstraction. We further introduce the following primitive operators:

- `Copy` takes in a data e and outputs two identical data.
- `Switch` takes a data from its input and a boolean value p, and forwards the data to either the `True` branch of d_t or `False` branch of d_f, based on the predicate p.
- `Merge` accepts two input streams and merges them into one single output stream.

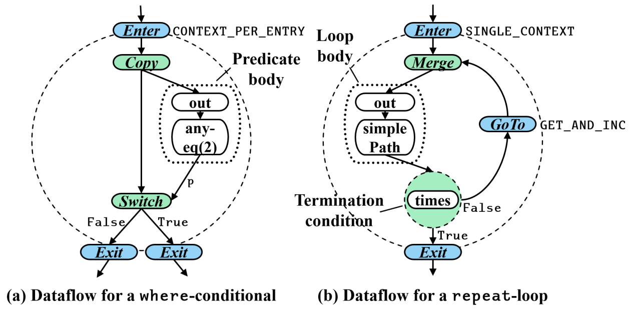

Figure 8: Compilation of control-flow constructs.

Conditional. Figure 8(a) shows an example of compiling a `where`-conditional. Conceptually, the `where` statement determines whether a data, while arriving at `where`, will continue to traverse, if the sub-traversal is evaluated to be true, or be abandoned otherwise. As the conditional check happens for each individual data, a `CONTEXT_PER_ENTRY` policy will be installed by the compiler in the `Enter` while entering the `where` Scope. Each data enters the `Copy`, where one data goes into the predicate body to drive the sub-traversal, and the other data goes to the `Switch`. Based on returned boolean value of the predicate body, the data with a `True` predicate will get out of the Scope via the `True` branch, and the data with a `False` predicate will go via the `False` branch (and get discarded if not further used).

Loop. We first introduce other two built-in Scope policies.

- `SINGLE_CONTEXT` policy calls `CreateOrOpen`$(e,0)$ for each data e indicating that they all enter one context of 0. It calls `Complete`$(e,0)$, if and only if $e = EOS$.
- `GET_AND_INC` policy first calls `GetContext`(e) to obtain the context of e as seq. Then it increases seq by 1 as seq', and calls `CreateOrOpen`(e, seq') to enter the new context. It finally calls `Complete`(e, seq'), if and only if $e = EOS$.

Figure 8(b) illustrates the compilation of `repeat`-loop. The compiler installs the `SINGLE_CONTEXT` policy on the `Enter` that forwards a data into the loop Scope, with a new context of 0, or, in the 0-th iteration. Additionally, it installs the `GET_AND_INC` policy on the `GoTo`. The `GoTo` primitive, as mentioned earlier in Section 4.2, is used to explicitly switch the context of data. Specifically in a loop, it leverages the `GET_AND_INC` policy to allow any data produced from current loop context to get switched to the next iteration. Naturally, the context identifier can now serve as the loop count. The loop body compiles any sub-traversal that will be run iteratively. Eventually, the data in the loop context will go though a conditional Scope as we have discussed above. This conditional Scope checks whether a termination condition is satisfied (such as arriving at the maximum iteration by `times`, or traversing to a certain vertex by `until`). The data with a `False` predicate is able to exit the loop, while the data with a `True` predicate will proceed to the next iteration as a feedback data stream via the `GoTo`, updating its context via the `GET_AND_INC` policy to indicate entering the next iteration. Note that a context must have been created or opened for each data e in a Scope, and thus `GetContext`(e) can be safely called. The feedback data will be eventually merged back to the input (of the sub-traversal) to drive the computation of next iteration.

4.4 Implementing Scope

It is challenging to implement Scope both correctly and efficiently. While it is always possible to create physical dataflow operators for each separate context, due to potentially unbounded number of such contexts in graph traversals (as described in Section 4.1), this is clearly infeasible in practice. GAIA instead dynamically tracks dependencies among input, output, and internal states for each operator in a dataflow.

GAIA labels each traverser with a tag, which is a k-ary vector of context identifiers, denoted as $T = [s_1, s_2, \dots, s_k]$[4], where the dimension indicates the level of potentially nested Scope. The root Scope is by default identified by a tag of $[\,]$. We define the following operations on a tag T:

$T[\wedge]$	To get the last context identifier of T.
$T[\wedge \to s]$	To replace the last context identifier of T with s.
$T[+1]$	To increase the dimension of T by 1, with the new slot filled with a $\emptyset$.
$T[-1]$	To reduce the dimension of T by 1.

From now, each data e will be tagged as $(T;e)$, which allows the system to be aware of the Scope and its different contexts. The primitives of `Enter` and `Exit`, and the interface functions in the Scope abstraction will explicitly modify the tag, as follows.

- `Enter` increases the dimension of the tag by 1 to indicate entering a Scope, as $(T[+1];e)$.
- `Exit` reduces the dimension of the tag by 1 to indicate leaving a Scope, as $(T[-1];e)$.
- `CreateOrOpen`$((T;e),s)$ return a newly tagged data with the last context identifier of T replaced as s, as $(T[\wedge \to s];e)$.
- `GetContext`$((T;e))$ returns the last context identifier of T, as $T[\wedge]$.
- `Complete`$((T;e),s)$ produces a tagged EOS marker to indicate the end of current context s, as $(T[\wedge \to s];EOS)$.

Such data tagging is automatically handled by GAIA system, and is transparent to any user interface. For the primitive operators introduced in Section 4.3, they do not need to worry about tags, and hence can still treat the tagged data as a "normal" data. For a computing operator o (with the logic f_o) in Gremlin, such as `out` and `count`, GAIA handles the computation as follows. It first extracts the actual data e, and apply the computation logic $f_o(e)$. The computation will generate a set

[4] Such tagging appears to be similar to the timestamps in Naiad [27], but it is used for dependency tracking in GAIA, without any physical meaning of event time as in Naiad [27].

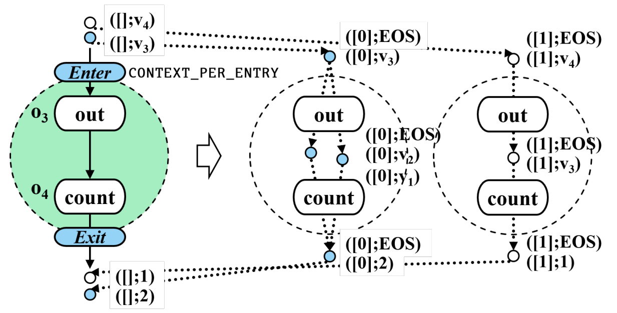

Figure 9: An execution with dynamic dependency tracking.

of traversers Ω, and potentially modify a state τ of the operator. Then for all $e' \in \Omega$, GAIA re-tags e' with T and sends it to the output stream. To handle any stateful computation, GAIA maintains an associated map with tag T as the key and state τ as the value, so that it can operate on the right state from different execution contexts transparently, as if the operator runs in isolation.

Example 4.4. *Figure 9 shows the above process for the dataflow in Figure 7. Initially, it accepts and computes inputs* $\{([\,];v_3),([\,];v_4)\}$ *(path history is omitted) from the parent* Scope *context. The* `Enter` *of the* `select` Scope *turns the inputs to* o_3 *as* $\{([0];v_3),([0];EOS),([1];v_4),([1];EOS)\}$ *according to the* `CONTEXT_PER_ENTRY` *policy. Next,* o_3 *outputs* $\{([0];v_1),([0];v_2),([1];v_3)\}$. *Note that EOS is omitted for now.* o_4 *can then maintain a hash table with the tag as key and the partial count as value. Finally, while* o_4 *receives the EOS for the corresponding context, it can output the results as* $\{([0];2),[[1];1]\}$. *The* `Exit` *restores the tags from* o_4*'s output and generates* $\{([\,];2),([\,];1)\}$.

Handling EOS Markers. An EOS marker can be introduced by both the source operator and the `Complete` function inside a Scope (`Enter`). An EOS marker can go through any computing operator without doing any de-facto computation, while it must be carefully handled in the primitive operators, especially `Enter` and `Exit` with the presence of Scopes.

Given a Scope, we call an EOS marker produced from outside the Scope as external EOS, and an EOS produced inside the Scope as internal EOS. An external EOS marks the termination of a context in the parent Scope, and must exit back to the parent Scope. Conversely, an internal EOS fulfills the same purpose only in the current Scope, and should only be propagated within. It is thus critical to differentiate the semantics of the EOS markers in a Scope. To do so, we implement the policy installed on the `Enter` to not call `CreateOrOpen` on the external EOS marker, which can then be recognized as a ∅ context. In the `Exit`, GAIA only allows the external EOS to leave the Scope.

Recall that `Switch` is another primitive operator used in conditional and loop Scope that delivers a data to either branch based on the predicate. The EOS marker, however, will always be propagated to both branches. In the loop Scope, the external EOS, once propagating through the nested conditional, will be held in the `Exit` of loop, and only released after the system verifies that all loop contexts terminate (using known techniques [45]). For the internal EOS, it will be tagged as the other data in the `GoTo`. As long as any data with a tag T is propagated to the next iteration, the EOS with T must also be propagated over to `GoTo` (meaning that the associated loop context has not terminated); otherwise, it will leave the loop Scope and get discarded.

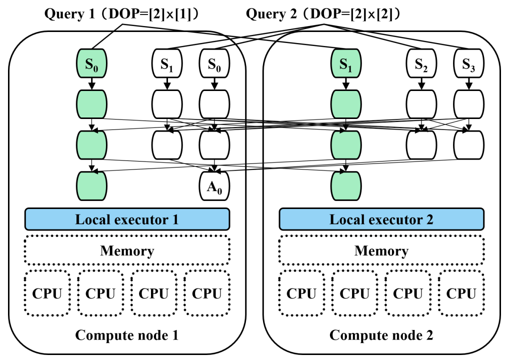

Figure 10: Distributed execution on two compute nodes.

5 Distributed Execution

GAIA runs queries via a set of worker processors in a shared-nothing cluster, where each worker executes a fragment of the computation. For each query, GAIA first compiles it into a dataflow graph using the techniques in Section 4, then it partitions the source operator in the dataflow according to the input graph partition, with the segment of operators that follow the source replicated across the set of workers. A local executor manages the computation on each worker by scheduling the operators to run. It starts from the source operator and repeatedly executes the following *ready* operators. Here, an operator is ready if all its inputs are available to consume. For now, GAIA requires the users to manually specify a degree of parallelism (DOP) for a query upon submission. We leave it as an interesting future work to automatically derive the DOP. According to the DOP, the local executor parallelizes the operators to execute on the multiple CPU cores, as illustrated in Figure 10. While GAIA can support multiple concurrent queries, we focus on single query processing in this paper.

5.1 Bounded-Memory Execution

Graph traversal can produce paths of arbitrary length, leading to memory usage growing exponentially with the number of hops. Although it is very common for Gremlin queries to terminate with a top-k constraint and/or aggregate operation, such an explosion of *intermediate* results can often lead to memory crisis, especially in an interactive environment with limited memory configuration. While several techniques exist for alleviating memory scarcity in dataflow execution, such as backpressure and memory swapping, they cannot be directly applied in GAIA due to potential deadlocks [25, 31] and/or high (disk I/O) latency. To ensure *bounded-memory execution* without sacrificing performance (parallelism), the local executor in GAIA employs a new mechanism for dataflow execution, called *dynamic scheduling*.

Dynamic Scheduling. For each operator, GAIA packs a segment of consecutive traversers in a stream into a single batch, and such a batch constitutes the finest data granularity for communication and computation. A *task* can be logically viewed as the combination of an operator and a batch of data to be computed. GAIA dynamically creates tasks corresponding to each operator when there is one or more batches available from all its inputs[5]. The local executor maintains all the tasks in a same scheduling queue to share resources.

We implement our own memory allocator that will report the total amount of memory used (for each query) so that the executor can watch the memory consumption. When it reaches a predefined threshold (high-watermark), the executor stops scheduling more tasks from the queue, except for those corresponding to the sink operators that will be sent to the clients. The executor resumes scheduling tasks when the memory consumption drops below another predefined threshold (low-watermark). It is possible that a single task (with a high-degree vertex) execution may produce too much output to exhaust the memory. To avoid this issue, we suspend a task when its output data exceeds a *capacity* bound, and resume it after the data has been consumed.

Data shuffling between two machines may introduce dependencies between their task scheduling. For example, a task can cause another executor to run into low memory, if it sends too much data to that executor. In this case, the sender task will be suspended until the receiver executor recovers from low memory. We implement a mechanism to send backpressure signals across network to allow cooperation of schedulers.

An execution of a dataflow graph with cyclic edges can potentially deadlock using bounded memory. In the specific context of graph traversal, this can be caused either by *infinite loops* such as traversing along a cyclic path without termination, or *inappropriate scheduling* such as buffer exhausted by a BFS-prioritized traversing (will be discussed later) that prevents downstream or sink operators from being scheduled to drain the buffered intermediate data. To address infinite loops, we apply a configurable limit N of the maximum number of iterations allowed in a loop (with a small buffer reserved for each iteration), and let the `GoTo` declare a deadlock when the limit N is reached. Once a deadlock is detected, the corresponding query is terminated with a clear error message. To handle inappropriate scheduling, we adopt a hybrid traversal strategy as described below.

Hybrid Traversal Strategy. As mentioned above, the memory crisis mainly stems from the intermediate paths, and therefore the traversal strategies can greatly impact the memory usage. There are two typical traversal strategies, namely (breadth-first-search) BFS-like traversal and (depth-like-search) DFS-like traversal. BFS-like traversal can better utilize parallelism, while it may produce data all at once that drives high the memory usage. On the contrary, DFS-like traversal tends to consume much less memory, while it may suffer from low parallelism. With this observation, we propose to allow the local executor to schedule tasks with priorities according to its topological order (i.e. the traversal depth) in the dataflow. Specifically, the executor can schedule the tasks located at the same order with higher priority for a BFS-like traversal, and prioritize those at downstream to follow a DFS-like traversal. Note that such strategy works naively for all the tasks but those in a loop context, where the traversers from different iterations may be executed in the same task. To resolve this, we let the operator's buffer reorder (and group) traversers by their iteration markers (obtained from the context identifier) before packing them into batches. This makes sure that we can prioritize tasks unambiguously even within loops. To balance the memory usage with the performance (parallelism), GAIA by default adopts a hybrid traversal strategy, that is, it uses BFS-prioritized scheduling as it has better opportunities for parallelization, and automatically switches to DFS-prioritized in case that the current operator arrives at the memory bound.

[5]The only exception is `Merge`, which is ready to run when data become available at any of its inputs.

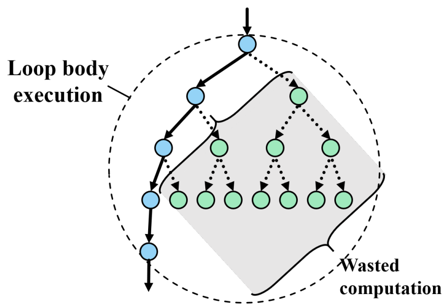

Figure 11: A loop execution with wasted computation.

5.2 Early-Stop Optimization

Traversing all candidate paths fully is often unnecessary, especially for interactive queries with dynamic conditions running on diverse input graphs. For example, in the following query Q5, only the first k results are needed.

```
Q5: g.V(2).repeat(out().simplePath())
     .times(4).path()
     .limit(k)
```

This leads to an interesting tradeoff between parallel traversal and wasted computation, as further illustrated in Figure 11. It shows an example run of query Q5 with $k = 1$. The circle denotes the traversal specified by the `repeat`-loop. Assume we have enough computation resource (CPU cores), the paths can be explored in a fully parallel fashion. However, once a 4-hop path is found, all the remaining parallel traversal will be no longer required.

For real-world queries on large graph data, such wasted computation can be hidden deeply in nested traversals (e.g., a predicate that can be evaluated early from partial inputs) and significantly impact query performance. While avoiding such wastage is straightforward in a sequential implementation, it is challenging to do so for a fully-parallel execution.

Normally, the execution of a particular context terminates when the EOS markers arrive at all the exits (from this context), including any `Exit` or `GoTo`. In the above example, an operator (e.g., `limit`) can actually terminates early after producing k outputs, before receiving any input EOS markers. GAIA further allows `Complete`$((T;e),s)$ to be called by any operators in a Scope to explicitly produce a tagged EOS marker (for current context s) to indicate the completeness of its output (after sending e downstream). However, this alone does not prevent upstream computation from continuing producing output that is no longer required and thus the corresponding computation is wasted.

To minimize such wastage, when a `Complete` is issued by an operator, it creates a *cancellation token* associated with the same context tag that is sent backward along input edges to its upstream operators within the Scope. The token serves as a signal for receiving operators to clear any unsent output data and immediately insert an EOS marker for the particular output stream. If such a token has been received from all output streams, the operator further propagates it to its own upstream operators, recursively, until it encounters the `Enter` for the same Scope. Such cancellation notification is implemented at a system level by GAIA. Due to space limit, We omit further details on propagation of cancellation tokens in any child Scope and/or through the `GoTo` to its dependent, previous contexts. We validate that such early-stop optimization can significantly improve query performance in Section 6.

6 Evaluation

6.1 Experimental Setup

Datasets. We generate 5 graph datasets as shown in Table 1 for experiments using Linked Data Benchmark Council (or LDBC) data generator [12], where G_x denotes that the graph is generated with $scale = x$. We use G_{300} as the default dataset if not otherwise specified. Note that G_{1000} is the largest data graph that LDBC can generate.

Table 1: The LDBC datasets.

Name	# vertices	# edges	Agg. Mem.
G_1	3M	17M	4GB
G_{30}	89M	541M	40GB
G_{100}	283M	1,754M	156GB
G_{300}	817M	5,269M	597GB
G_{1000}	2,687M	17,789M	1,960GB

Queries. For comparison, we consider graph queries from the Social Network Benchmark defined by LDBC [12] to model industrial use cases on a social network akin to Facebook. We choose 10 out of 14 *complex read* queries (denoted as CR-1...14) from LDBC's Interactive Workload[6].

In addition, the cycle-detection query Q6 is considered: given m (by default 10) starting nodes in V, it traverses from V via at most k (by default 4) hops, and returns those vertices among V that can form at least n (by default 10) cycles along the traversal. We modify the query based on the production query as shown in Figure 1 to align with the LDBC data. This query also shows the functionality of *prepared statement* ("Discussion", Section 4.3) enabled by the Scope abstraction, which wraps multiple starting vertices into one query.

The driver client provided by LDBC is modified to run each of the queries 20 times from a set of randomly selected parameters. Average query latency is reported.

Configurations. In the following experiments, we by default warm up all the systems to keep the computation-relevant data in memory. We do this to focus on benchmarking the computing engine instead of storage access.

All the queries have been implemented using Gremlin for all systems except Neo4j (using Cypher officially), with correctness cross-verified. The compiling time of these queries in our system is typically within 1ms, which is negligibly small compared to the query runtime, and will be ignored thereafter. We allow each query to run for at most 1 hour, and mark an OT if a query can not terminate in time. We manually configure the degree of parallelism (DOP) while running each query in GAIA. In the following, we denote DOP = $[x] \times [y]$ for running y threads in x machines.

We compare GAIA with the systems in Table 2. While Neptune [1] is another popular Gremlin-enabled graph database, we do not benchmark it as it is only available in AWS, and its performance is similar to JanusGraph as shown in [42]. Timely [43] is the publicly available implementation of Naiad [27]. Plato [32] is an open-sourced implementation of Gemini [49] (Gemini does not support (de)serializing vector-like data for sending paths across network). We implement GAIA using Rust [38], and are working on open-sourcing the engine and storage.

Table 2: The evaluated systems.

System	Version
TinkerGraph [3]	3.4.1
Neo4j-Community [29]	3.5.8
OrientDB [30]	tp3-3.0.15
JanusGraph [21]	0.4.0-hadoop2
Timely [43]	latest release in Github
Plato [32]	latest release in Github

We deploy a cluster of up to 16 machines, and each machine configures one 24-core Itel(R) Xeon(R) Platinum 8163 CPUs

[6]The remaining queries are either too simple (such as simple point-lookup queries) or rely on user-defined logic (such as CR-4, 10, 13, 14), which is not supported by other popular TinkerPop-based systems.

(f) Data size: small queries.

Figure 12: The scalability experiment.

at 2.5GHz and 512GB memory. The servers are connected through 25Gbps network.

6.2 Scalability

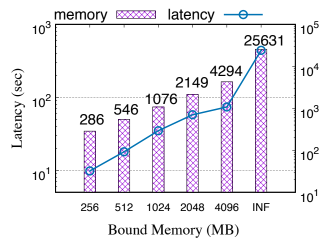
To the best of our knowledge, GAIA is the only system that can handle Gremlin queries at scale. In this experiment, we study the scalability of GAIA while running all LDBC queries. We divide these queries into two groups based on their runtime to better present the result: (1) large queries CR-3, 5, 6 and 9; (2) small queries CR-1, 2, 7, 8, 11, 12.

Scale-out. To study the scale-out performance, we fix y to 4 while varying x as 2, 4, 8, 16[7], and report the latency of each case in Figure 12a and Figure 12b. We analyze the result regarding the two query groups:

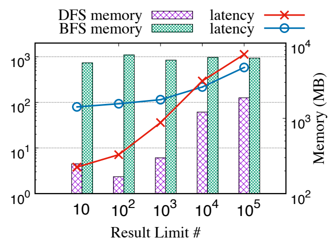
Large queries. These queries traverse large amount of data and run relatively longer, while they scale well with up to 6× performance gain from 2 machine to 16 machines. While CR-3 performs the worst to obtain only 3× performance gain, we recognize that it contains very complex nested sub-traversals that may introduce extra cost in synchronization (e.g. waiting for the EOS marker).

Small queries. Due to either effective filtering or small range of traversal, the small queries only touch a small amount of data and thus are not computation-intensive. We expect that their performance may not be improved with more parallelism, while CR-2 and CR-12 still run consistently faster as shown in Figure 12b. CR-1, as a relatively slow query in

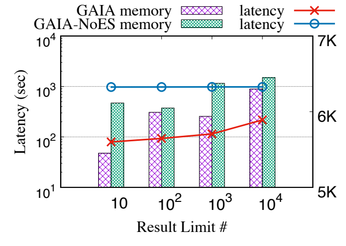
[7]G_{300} is too large to be held on one machine.



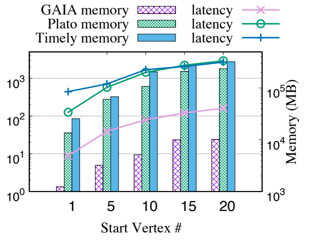
(a) Bound memory execution.



(b) Traversal strategy.



(c) Early stop.



(d) Compare with big engines.

Figure 13: The experiment of our design choices.

this group, demonstrates seemingly counter-intuitive result. The query actually asks to print out a lot of information after locating the target vertices, which constitutes a majority of the computation that cannot benefit from more parallelism.

Scale-up. We then fix x to 4, and vary y as 2, 4, 8, 16, and report the result in Figure 12c and Figure 12d. Similar to the scale-out cases, the large queries scale consistently, while small queries do not gain speedup, as more parallelism is used. It is interesting to compare the scale-out and scale-up cases with the same DOP, $[4] \times [16]$ vs. $[16] \times [4]$ as an example, we can observe $[16] \times [4]$ cases in-general perform better, even it requires more communication. The result shows that (1) communication cost is not a critical impact factor for GAIA, for which the dynamic scheduling techniques can seamlessly hide the communication cost by allowing ready tasks to get scheduled; (2) data contentions may be a more serious issue for interactive graph queries, as they are more often confronted in fewer machines.

Data Size. Finally, we fix the DOP as $[16] \times [4]$, and run the queries over the datasets of G_{30}, G_{100}, G_{300} and G_{1000}. Note that the sizes of these graphs are roughly linear to their *scale* factors. The result is in Figure 12e and Figure 12f. For the large queries, GAIA scales quite well with the growing of the data. For the small queries (except CR-1, as explained earlier), the performance stays roughly stable, as these queries only touch a small amount of data.

Discussions. The experiment demonstrates reasonable trends of scalability of GAIA: in general, the larger the query, the better the scalability. Due to the irregularity of graph data (and queries), it is challenging to derive the optimal DOP for each query, while we leave it as an interesting future work.

6.3 Our Design Choices

We study our design choices in this experiment by drilling down to the performance factors including bounded-memory execution (Section 5.1), hybrid traversal strategies (Section 5.1) and early-stop optimization (Section 5.2). We run Q6 on G_{300} using the DOP of $[16] \times [4]$, and report the query latency and peak memory usage among all machines. We use Q6 here as it includes complex nested Scopes with fine-grained dependency, and it is a real query in production. We conduct this experiment while adjusting the query parameters m (number of starting vertices), k (the hop limit) and n (the result limit) in Q6, and the system parameter of memory upper-bound of each query (default 10GB) and traversal strategies (default hybrid), and whether early stop is enabled (default enabled). We configure the following variants of GAIA, namely GAIA (default settings), GAIA-DFS (manual DFS-prioritized strategy)[8], GAIA-NoMB (without/infinity memory bound) and GAIA-NoES (without early stop).

Dynamic Scheduling. In this experiment, we study the effectiveness of dynamic scheduling. We vary the memory upper-bound as 256, 512, 1024, 2048, 4096 (MB) and infinity with $m = 10$ starting vertices, and report the result in Figure 13a. The actual memory usage (as labelled) of all cases is very close to the bounded value, and is noticeably smaller than the unbounded case, which has surged to more than 25GB. An interesting observation is that the latency increases with the memory bound. Note that graph traversal exhibits massive parallelism and all the CPU cores available can be fully utilized with just "enough" memory. Additional memory incurs overheads (in allocation, buffering, etc.) rather than benefits.

Traversal Strategy. To verify the effectiveness of the hybrid traversal strategy in GAIA, we compare GAIA with GAIA-DFS/BFS. We vary n from 10 to 10^5, and report the time cost and memory usage in Figure 13b. GAIA-DFS outperforms GAIA when $n \leq 1000$. This is because that DFS strategy will prioritize scheduling operators in the deeper order (in the dataflow), which can potentially escape earlier (thanks to early stop) as soon as n cycles have been found. As n increases, the hybrid strategy gradually catches up with, and eventually outperforms DFS, as it can compute the required number of cycles in a lower order. This experiment shows that the best traversal strategy can be query- (and data-) dependent, and the hybrid strategy is a more generic option.

Early Stop. We compare the performance of GAIA and GAIA-NoES (without early stop). We vary n from 10 to 10^4, and report the query latency and memory usage in Figure 13c. When early stop is turned off, both the query latency and memory usage remain fairly stable, as GAIA always computes all result, regardless of the limit number. When early stop is turned on, it can be observed that both the query latency and memory consumption drop noticeably, compared to the cases without early stop. In particular, the early-stop optimization enables $12\times$ improved performance and $1GB$ memory saving when the limit number is 10.

[8]Note that the BFS-prioritized strategy often causes out-of-memory, and is thus excluded from our test.

Table 3: Comparison GAIA variants with big-data engines.

	GAIA	-DFS	-NoMB	-NoES	Plato	Timely
Lat./Sec.	79	4	440	972	1431	1690
Mem./GB	5.2	0.3	25.6	6.1	108	205

Comparing with Big-Data Engines. Finally, we compare our GAIA with existing high-performance engines, Timely and Plato, in this experiment. We implement Q6 in Timely and Plato[9], which contains 105 and 95 logical lines of codes, respectively. In comparison, the Gremlin query is written in 5 lines as presented in Figure 2. The query latency and memory consumption of these engines, while varying m as 1, 5, 10, 15, 20, is shown in Figure 13d. GAIA achieves $16\times$ and $14\times$ better performance, and consumes $21\times$ and $10\times$ less memory, than Timely and Plato, respectively. To demonstrate how GAIA benefits from the proposed techniques to outperform existing engines, we further bring different variants of GAIA into the comparison, and the results of $m = 10$ are in Table 3. The performance of GAIA drops by $5.5\times$ without memory bound, and by over $12\times$ without early stop, while the latter is already in the same order as those of Plato and Timely. Note that GAIA-DFS even outperforms the default GAIA (hybrid) due to the small result limit ($n = 10$). This experiment shows that the novel design choices of GAIA, notably the Scope abstraction, and the techniques proposed on top of it, enable more convenient programming and efficient execution of the Gremlin queries over big-data engines.

6.4 Comparison with Graph Databases

Small-Scale DB. Although GAIA is designed to scale, we show that GAIA demonstrates efficiency while compared to graph databases on one single machine. Specifically, we use the small graph G_1 so that all the systems can load and process queries in reasonable time; and for each LDBC query, we choose the best query performance among the 4 systems (TinkerGraph, Neo4j, OrientDB and JanusGraph) as the *BSTI* for the query; then we vary the DOP of GAIA, and report the relative performance of GAIA to BSTI in Figure 14.

GAIA performs comparably to the BSTI in most cases except for queries CR-3 (up to $7\times$ worse) and CR-12. Neo4j performs better than any other systems on these queries. Further investigation shows that, instead of faithfully traversing the graph, Neo4j applies a *join* on some partial result to generate the output, which turns out to be more efficient in these cases. We leave better query optimization of Gremlin on GAIA as future work. As a whole, GAIA has an average relative performance of just around 1.8 using single thread, and of 0.73 using 16 threads, among all LDBC queries.

Large-scale DB. We use G_{100} in this experiment to run all LDBC queries. Note that we only compare JanusGraph, as

[9]For fair comparison, we implement cycle detection in Timely and Plato using the same algorithm as in GAIA. In addition, we exploit all possible optimizing options from both systems for the test.

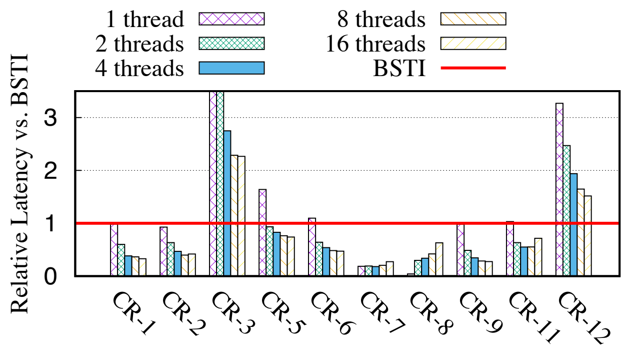


Figure 14: GAIA performance relative to the best single-threaded implementation (BSTI).

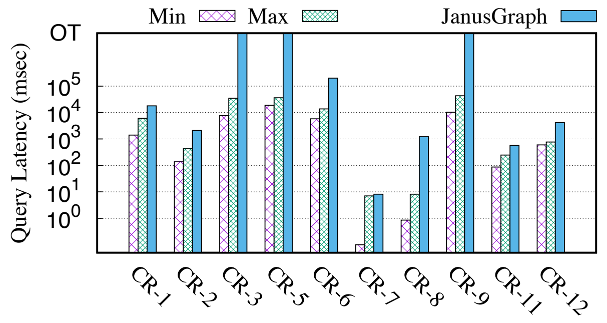

Figure 15: Compare GAIA with JanusGraph.

it is the only system that can store graph at this scale. JanusGraph cannot process query in parallel, and we run GAIA in one machine for fair comparison. The graphs are stored in 8 machines for JanusGraph, and one single machine[10] for GAIA. We run each query on GAIA with DOP varying from 1 to 16, and report its max and min latency for each query while compared to JanusGraph. The result is reported in Figure 15. JanusGraph fails to answer many queries (CR-3,5,9) due to OT. As shown, even the maximum latency (single-thread) of GAIA is much shorter than that of JanusGraph in all cases. Although GAIA is designed to scale in a cluster, it can further benefit from multi-core parallelism in a single machine to improve query performance, especially for large queries, as can be seen in Figure 15.

7 Related Work

Graph Databases. Gremlin is widely supported by many graph databases, such as Neo4j [29], OrientDB [30], JanusGraph [21], and cloud-based services including Cosmos DB [6] and Neptune [1]. However, their query processing is limited to one single process. Driven by rapidly growing needs to query large graph data, several distributed in-memory graph systems emerge, such as Trinity [40], ZipG [24], Wukong+S [48], Grasper [20], and A1 [9]. Trinity and ZipG offer their own programming models that are less flexible than Gremlin. Grasper adopts Gremlin but provides a limited subset of the language constructs (e.g., the lack of nested-loop support). Wukong+S and A1 leverage RDMA for serving *micro-second* queries with much higher concurrency, which is not the main target scenario of GAIA.

[10]Note that JanusGraph is properly warmed up to reduce the cost of pulling data from remote storage.

Graph Processing Systems. In contrast to many other systems that deal with batch-oriented iterative graph processing, such as Pregel [26], PowerGraph [15], GraphX [16], and Gemini [49], GAIA focuses on low-latency graph traversal at scale. It is hard to support graph traversal in existing graph processing systems. Firstly, their programming abstractions [22] are usually low-level, makes these systems a privilege for experienced users only [13]. Moreover, they typically adopt the bulk synchronous parallel (BSP) execution model, which is more suitable for an iterative *routine* processing over the *whole* graph, but can be inefficient for running graph traversal that visits an *arbitrary portion* of the graph.

Dataflow Engines and Dependency Tracking. A number of existing systems such as CIEL [28], Naiad [27], and TensorFlow [45] offer generic data-parallel computing infrastructures with support for dynamic control flow. While it is possible to program the logic of a Gremlin query on top of these frameworks, it is extremely challenging to do so in the pursuit of both correctness and efficiency, largely due to the fine-grained dependency in Gremlin traversal. Tracking dependency has been exploited to compute what is absolutely necessary when there are limited changes to the input (e.g., incremental computing as in Incoop [7], DryadInc [33], Nectar [19]), or frugal re-computation to repair lost state as in MadLINQ [34] and TimeStream [35].

Declarative Programming Languages. Graph queries are typically expressed using graph traversal and pattern matching. Correspondingly, Gremlin [37] and Cypher [14] are the most popular query languages. Cypher allows users to specify a graph pattern with variables. However, based on our production experience, it is often challenging to compose ad-hoc query pattern for a particular task. Therefore, we support Gremlin instead of Cypher in this work. Other notable research projects in parallel declarative languages, such as Cilk [8], can be leveraged by GAIA in theory, but they are not particularly tailored for distributed graph traversal.

8 Conclusion

GAIA has been in use by a small community of domain experts for over a year in production at Alibaba. Our overall experience is that GAIA, by combining the benefits of Gremlin with the power of distributed dataflow execution, proves to be a simple, useful and efficient programming environment for interactive analysis on big graph data.

Abstract

Several emerging *evolving graph* application workloads demand support for efficient ad-hoc analytics—the ability to perform ad-hoc queries on arbitrary time windows of the graph. We present TEGRA, a system that enables efficient ad-hoc window operations on evolving graphs. TEGRA allows efficient access to the state of the graph at arbitrary windows, and significantly accelerates ad-hoc window queries by using a compact in-memory representation for both graph and intermediate computation state. For this, it leverages persistent data structures to build a versioned, distributed graph state store, and couples it with an incremental computation model which can leverage these compact states. For users, it exposes these compact states using Timelapse, a natural abstraction. We evaluate TEGRA against existing evolving graph analysis techniques, and show that it significantly outperforms state-of-the-art systems (by up to 30×) for ad-hoc window operation workloads.

1 Introduction

Graph-structured data is on the rise, in size, complexity and dynamism [1, 61]. This growth has spurred the development of a large number of graph processing systems [16, 17, 19, 26, 27, 30, 33, 39, 42, 51, 54, 57, 59, 60, 68] in both academia and the open-source community. By leveraging specialized abstractions and careful optimizations, these systems have the ability to analyze large, *static* graphs, some even in the order of a trillion edges [20].

However, real-world graphs are seldom static. Consider, the familiar example of social network graphs such as in Facebook and Twitter. In these networks, "friends" relations and tweets with "mentions" are created continuously resulting in the graph's constant evolution. Similarly, each new call in a cellular network connects devices with receivers and can be used in real-time for network monitoring and diagnostics [31]. Additionally, emerging applications such as connected cars [13], real-time fraud detection [9], and disease analysis [23] all produce such graph data. Analyzing these *time-evolving* graphs can be useful, from scientific and commercial perspectives, and is often desired [61].

In this paper, we focus on the problem of *efficient ad-hoc window operations* on evolving graphs—the ability to perform ad-hoc queries on arbitrary time windows (i.e., segments in time) either in the past or in real-time. To illustrate the need for such operations, consider two examples. In the first, a financial expert wishes to improve her fraud-detection algorithm. For this, she retrieves the *complete states of the graph at different segments in time* to train and test variants of her algorithm. In the second example, a network administrator wishes to diagnose a transient failure. To do so, she retrieves a *series of snapshots*[1] *of the graph* before and after the failure, and runs a handful of queries on them. She iteratively refines the queries until she comes up with a hypothesis. In such scenarios, neither the queries nor the windows on which the queries would be run are predetermined.

To efficiently perform ad-hoc window operations, a graph processing system should provide two key capabilities. First, it must be able to quickly retrieve arbitrary size windows starting at arbitrary points in time. There are two approaches to provide this functionality. The first is to store a *snapshot* every time the graph is updated, i.e., a vertex or edge is added or deleted. While this allows one to efficiently retrieve the state of the graph at *any* point in the past, it can result in prohibitive overhead. An alternative is to store only the changes to the graph and reconstruct a snapshot on demand. This approach is space efficient, but can incur high latency, as it needs to re-apply all updates to reconstruct the requested snapshot(s). Thus, there is a fundamental trade-off between in-memory storage and retrieval time.

Second, we must be able to efficiently execute queries (e.g., connected components) not only on a single window, but also across multiple related windows of the graph. Existing systems, such as Chronos [30] allows executing queries on a single window, while Differential Dataflow [54] and GraphBolt [45] support continuously updating queries over sliding windows. However, none of the systems support efficient execution of queries across multiple windows, as they do not have the ability to share the computation state across windows and computations. This fundamental limitation of existing systems arises from their inability to efficiently store intermediate state from within a query for later reuse.

We present TEGRA[2], a system that enables efficient ad-hoc window operations on time-evolving graphs. TEGRA is based on two key insights about such real-world evolving graph workloads: *(1) during ad-hoc analysis graphs change slowly over time relative to their size , and (2) queries are frequently applied to multiple windows relatively close by in time.*

[1] A snapshot is a full copy of the graph, and can be viewed as a window of size zero. Non-zero windows have several snapshots.

[2] for **T**ime **E**volving **GR**aph **A**nalytics.

Leveraging these insights TEGRA is able to significantly accelerate window queries by reusing both storage and computation across queries on related windows. TEGRA solves the storage problem through a highly efficient, distributed, versioned *graph state store* which compactly represents graph snapshots in-memory as logically separate versions that are efficient for arbitrary retrieval. We design this store using persistent (functional) data-structures that lets us heavily share common parts of the graph thereby reducing the storage requirements by several orders of magnitude (§5). Second, to improve the performance of ad-hoc queries, we introduce an efficient in-memory representation of intermediate state that can be stored in our graph state store and enables non-monotonic[3] incremental computations. This technique leverages the computation pattern of the familiar graph-parallel models to create compact intermediate state that can be used to eliminate redundant computations across queries. (§4).

TEGRA exposes these compact persistent snapshots of the graph and computation state using a logical abstraction named *Timelapse*, which hides the intricacies of state management and sharing from the developer. At a high level, a timelapse is formed by a sequence of graph snapshots, starting from the original graph. Viewing the time-evolving graph as consisting of a sequence of independent static *snapshots* of the entire graph makes it easy for the developer to express a variety of computation patterns naturally, while letting the system optimize computations on those snapshots with much more efficient incremental computations (§3). Finally, since Timelapse is backed by our persistent graph store, users and computations always work on independent *versions* of the graph, without having to worry about consistency issues. Using these, TEGRA outperforms state-of-the-art systems significantly on ad-hoc window operation workloads (§7).

In summary, we make the following contributions:

- We present TEGRA, a time-evolving graph processing system that enables efficient ad-hoc window operations on both historic and live data. To achieve this, TEGRA shares storage, computation and communication across queries by compactly representing the evolving graph and intermediate computation state in-memory.
- We propose *Timelapse*, a new abstraction for time-evolving graph processing. TEGRA exposes timelapse to the developer using a simple API that can encompass many time-evolving graph operations. (§3)
- We design *DGSI*, an efficient distributed, versioned property graph store that enables timelapse APIs to perform efficient operations. (§5)
- Leveraging timelapse and DGSI, we present an incremental graph computation model which supports non-monotonic computations across (non-contiguous) windows. (§4)

[3] Allows vertex/edge deletions, additions and modifications on any graph algorithm implemented in a graph-parallel fashion.

2 Background & Challenges

We begin with a brief background on graph-parallel systems (§2.1) and then describe various types of time-evolving graph workloads (§2.2). The limitations of existing systems are discussed (§2.3) before we layout the challenges in enabling efficient ad-hoc analytics on evolving graphs (§2.4).

2.1 Graph-Parallel Systems

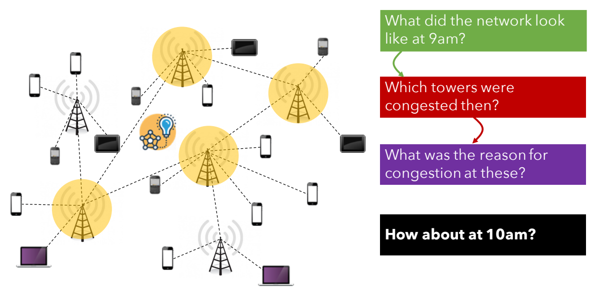
Most general purpose graph systems provide a *graph-parallel* abstraction for performing computations. In the graph-parallel abstraction, a user-defined program is run (in parallel) on every entity in the graph, who then change their state depending on the neighborhood. This process is iteratively done until convergence. Thus, the graph-parallel abstraction lets the end-developer view distributed graph computations as simpler entity centric computations, leaving the burden of orchestration to the system. The simplest of the graph-parallel abstraction is a vertex-centric model [46], where every vertex independently runs the user program. Several other forms have been proposed, such as the graph centric models [66], edge centric models [59] and the more recent subgraph centric models [57]. In all these models, the basic form of computation is implemented as message exchanges between the entities and their corresponding state changes. Communication is enabled either via shared memory model [63] or message passing interface [43]. PowerGraph [27] introduced the **Gather-Apply-Scatter (GAS)** model, a popular vertex-centric model adopted by many open-source graph processing systems, where a vertex program is represented as three conceptual phases: **gather** phase that collects information about adjacent vertices and edges and applies a function on them, **apply** phase that uses the function's output to update the vertex, and **scatter** phase that uses the new vertex value to update adjacent edges. To perform a graph algorithm computation, the system iteratively applies these phases until convergence. TEGRA focuses on the GAS model. (§6).

2.2 Time-evolving Graph Workloads

Time-evolving graph workloads, an important graph workload [61], can be classified into three categories:

Temporal Queries: Here, an analyst is querying the graph at different points in the past and evaluates how the result changes over time. Examples are *"How many friends did Alice have in 2017?"* or *"How did Alice's friend circle change in the last three years?"*. Such queries may have time windows of the form $[T-\delta, T]$ and are performed on offline data, executed in a batch fashion.

Streaming/Online Queries: These workloads are aimed at keeping the result of a graph computation up-to-date as new data arrives (i.e., $[Now-\delta, Now]$). For example, the analyst may ask *"What are the trending topics now?"*, or use a moving window (e.g., *"What are the trending topics in the last 10 minutes?"*). These focus on the most recent data, thus streaming systems operate on the live graph.



What did the network look like at 9am?
Which towers were congested then?
What was the reason for congestion at these?
How about at 10am?

Figure 1: Carol, a network administrator, diagnoses issues by performing ad-hoc queries on *snapshots* of the network at disjoint but *close-by* points in time.

Ad-hoc Queries: In these workloads, an analyst is likely to explore the graph by performing ad-hoc queries on arbitrary windows. Below, we illustrate a real-world use case. We omit some details and use fictitious names for anonymity.

Carol is a network administrator at a large cellular network operator in the United States [58]. Her job is to manage several thousands of wireless base stations, deployed across a large geographic region. When problems occur, Carol is tasked with finding the reason for the issue and fix them. For instance, she may be trying to answer *"What is the reason for poor download throughput for (several) users at 9:00am?"*.

Cellular network operators collect extensive data (several terabytes per day) from their network, and previous studies have shown the benefits of viewing cellular network analytics as a time-evolving graph problem [31]. Carol might start by asking *"What did the network look like at 9am?"*, when the problem was reported. The query returns a *graph view* of the network, depicted in fig. 1, where there are several base stations (towers) serving many users. Carol doubts congestion as the cause for low throughput, so the next query is *"Which towers were congested at this point?"* that returns a subset of towers from the original answer. Based on her extensive domain knowledge, she knows that temporary congestion in some towers do not cause persistent poor throughput, so she is interested in learning if *clusters* of towers were congested. To do so, she runs a *connected component* algorithm on the network graph. Then, to confirm her hypothesis, she asks *"How about at 10am?"* meaning to repeat the entire analysis again, but now on a different subset of the data. By the time Carol finishes her investigation, she has retrieved *100s of different subsets of data*, each depicting a *snapshot of the network* at some *disjoint, random* point in time around the failure, conducted exploratory analysis to test several of her hypothesis including one where she runs connected components.

Thus, in ad-hoc workloads, not only does the analyst need to access arbitrary windows, but also the queries and the windows on which they are executed are determined just-in-time (i.e., not predetermined). Further, the analyst applies the same query to multiple (close-by, discontinuous) windows.

2.3 State of the Art & Limitations

Recent work in graph systems has made considerable progress in the area of evolving graph processing. (§8)

Temporal analysis engines (e.g., **Chronos** [30], **ImmortalGraph** [50]) operate on *offline data* and focus on executing queries on one or a sequence of snapshots in the graph's history. Upon execution of a query, these systems load the relevant history of the graph and utilize a pre-processing step to create an in-memory layout that is efficient for analysis. Such preprocessing can often dominate the algorithm execution time [44]. As a result, these systems are tuned for operating on a large number of snapshots in each query (e.g., temporal changes over months or year), and are efficient in such cases. Fundamentally, the in-memory representation in these systems cannot support updates. Additionally, these systems do not allow updating the results of a query.

Proposals such as GraphOne [35, 36] and Aspen [21] focus on providing *efficient storage for streaming computations*. These (typically single-machine) systems allow only storing a few recent versions of the graph and do not support storing intermediate state, or updating the results of a previous query. **GraphOne** [35, 36] combines circular edge logs and adjacency store to allow storing a few recent versions of the graph and dual versioning to decouple computation from storage. However, the use of *chaining* (with compaction) in the adjacency store to enable versioning introduces an ordering constraint among the versions, and traversing (and applying operations e.g., deletions) is necessary to retrieve a specific snapshot. For ad-hoc analysis where arbitrary changes maybe applied on a version, this may be expensive and fundamentally difficult. **Aspen** [21] leverages functional/persistent datastructures to preserve previous version of the graph upon mutation and presents C-trees, a highly compressed functional tree that can store graphs efficiently (they do not allow property graphs). This is similar in spirit to our use of persistent datastructures in designing DGSI (§5). However, C-trees are tuned for streaming workloads where there is one (or a few) previous version(s) and thus employ aggressive garbage collection for efficiency. When large number of versions are required, main memory becomes a bottleneck and thus it is necessary to have a persistent storage based hybrid store (e.g., DGSI).

Streaming systems (e.g., Kineograph [19], Differential-Dataflow [49], Kickstarter [67], GraphBolt [45]) operate on *live data* and allow query results to be updated *incrementally* (rather than doing a full computation) when *new* data arrives. These systems only allow queries on the live graph, and do not support ad-hoc retrieval of previous state. Additionally, the incremental computation is tied to the live state of the graph, and cannot be utilized over multiple windows.

Differential Dataflow (DD) [49] is a distributed system that allows general, non-monotonic incremental computations using special versions of operators. Each operator stores "differences" to its input and produces the corresponding differences in output (hence the full output is not materialized), automatically incrementalizing algorithms written using them. While this technique is very efficient for real-time streaming queries, incorporating ad-hoc window operations in it is fundamentally hard. Since the computation model is based on the operators maintaining state (*differences* to their input and output) indexed by data (rather than time), accessing a particular snapshot can require a full scan of the maintained state. Further, since every operator needs to maintain state, the system accumulates large state over time which must be compacted (at the expense of forgoing the ability to retrieve the past). Finally, intermediate state of a query is cleared once completed and storing these efficiently for reuse is an open question.

GraphBolt [45], a *single-machine* streaming system, presents a dependency driven "refinement" based computation model for (non-monotonic) incremental computations that tracks dependency information as aggregation values at vertices thus reducing the state requirements to O|V| (in contrast to DD's O|E|). Users can implement incremental algorithms by defining user-defined refinement functions (e.g., `repropagate`, `retract` and `propagate`) whose implementations are algorithm specific (e.g., Algorithm 3 in [45] for PageRank), and iteratively refines aggregation values. GraphBolt only stores the value aggregations for the current snapshot of the graph and does not present a solution for storing multiple versions of aggregations or efficiently using/operating on them. Thus, GraphBolt does not support ad-hoc analysis. Building ad-hoc support requires building a state store, similar to the solution we present (DGSI), tuned for GraphBolt's computation model and exposing the right APIs.

2.4 Challenges

Several challenges stand in the way of enabling efficient ad-hoc analytics on evolving graphs. First is the ability to efficiently *store* and *retrieve* snapshots of the graph at arbitrary time windows. Second, we must be able to *compactly represent large amounts of computation state and use it to accelerate future queries, across multiple windows* using a computation model that can leverage the state efficiently. Finally, the system should be able to provide users a natural and intuitive way to operate on evolving graphs. Based on this, our solution, TEGRA, consists of three components:

Timelapse Abstraction (§3): In TEGRA, users interact with time-evolving graphs using the *timelapse* abstraction, which logically represents the evolving graph as a sequence of *static*, *immutable* graph snapshots (fig. 2). TEGRA exposes this abstraction via a simple API that allows users to save/retrieve/query the materialized *state* of the graph at any point.

Computational Model (§4): TEGRA proposes a computation model that allows *ad-hoc queries across windows to share computation and communication*. The model stores compact intermediate state as a timelapse, and uses it to perform general, *non-monotonic* incremental computations.

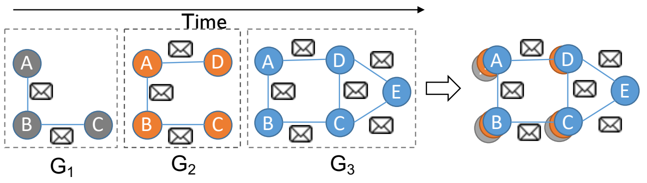


Figure 2: A timelapse of graph G consisting of three snapshots. For temporal analytics, instead of applying graph-parallel operations independently on each snapshot (left), timelapse enables them to be applied to all snapshots in parallel (right).

Distributed Graph Snapshot Index (§5): TEGRA stores evolving graphs, intermediate computation state and results in DGSI, an efficient indexed, distributed, versioned property graph store which *shares storage* between versions of the graph. Such decoupling of state from queries and operators allow TEGRA to share it across queries and users.

3 Timelapse Abstraction & API

TEGRA introduces *Timelapse* as a new abstraction for time-evolving graph processing that enables efficient ad-hoc analytics. The goal of timelapse is to provide the end-user with a simple, natural interface to run queries on time-evolving graphs, while giving the system opportunities for efficiently executing those queries. In timelapse, TEGRA *logically* represents a time-evolving graph as a sequence of immutable, static graphs (fig. 2), each of which we refer to as *snapshot* in the rest of this paper. A snapshot depicts a consistent state of the graph at a particular instance in time. TEGRA uses the popular property graph model [26], where vertices and edges in the graph are associated with arbitrary properties, to represent each snapshot in the timelapse. For the end-user, timelapse provides the abstraction of having access to a *materialized* snapshot at any point in the history of the graph. This enables the usage of the familiar static graph processing model in evolving graphs (e.g., queries on arbitrary snapshot).

Timelapses are created in TEGRA in two ways—by the system and by the users. When a new graph is introduced to the system, a timelapse is created for it that contains a single snapshot of the graph. Then, as the graph evolves, more snapshots are added to the timelapse. Similarly, users may create timelapses while performing analytics. Because snapshots in a timelapse are immutable, any operation on them creates new snapshots as a result (e.g., a query on a snapshot results in another snapshot as a result). Such newly created snapshots during an analytics session may be added to an existing timelapse, or create a new one depending on the kind of operations performed. For instance, for an analyst performing what-if analysis by introducing artificial changes to the graph, it is logical to create a new timelapse. Meanwhile, snapshots created as a result of updating a query result should ideally be added to the same timelapse. The system does not impose restrictions on how users want to book-keep timelapses. Instead, it simply tracks their lineage and allows

`save(id): id`	Save the state of the graph as a snapshot in its timelapse. ID can be autogenerated. Returns the id of the saved snapshot.
`retrieve(id): snapshot`	Return one or more snapshots from the timelapse. Allows simple matching on the id.
`diff(snapshot, snapshot): delta`	Difference between two snapshots in the timelapse. (§4)
`expand(candidates): subgraph`	Given a list of candidate vertices, expand the computation scope by marking their 1-hop neighbors. Used for implementing incremental computations (§4)
`merge(snapshot, snapshot,func): snapshot`	Create a new snapshot using the union of vertices and edges of two snapshots. For common vertices, run func to compute their value. Used for implementing incremental computations (§4)

Table 1: TEGRA exposes Timelapse via simple APIs.

users to efficiently operate on them. We describe how TEGRA implements timelapses in §5.3.

Since timelapse logically represents a sequence of related graph snapshots, it is intuitive to expose the abstraction using the same semantics as that of static graph. In TEGRA, users interact with timelapses using a language integrated API. It extends the familiar `Graph` interface, common in static graph processing systems, with a simple set of additional operations, listed in table 1. This enables users to continue using existing static graph operations on any snapshot in the timelapse obtained using the `retrieve` API. **(§6.2)**

3.1 Evolving Graph Analytics Using Timelapse

In addition to providing ad-hoc access to any snapshot, timelapse is also useful in enabling efficient time-evolving graph analysis. The natural way to do graph computations over the time dimension is to iterate over a sequence of snapshots. For instance, an analyst interested in executing the `degrees` query on three snapshots, G_1, G_2 and G_3 depicted in fig. 2 can do:

```
for(id <- Array(G1,G2,G3))
  result = G.retrieve(id).degrees
```

However, applying the same operation on multiple snapshots of a time-evolving graph independently is inefficient. In graph-parallel systems (§2), `degrees()` computation is typically implemented using a user-defined program where every vertex sends a message with value 1 to their neighbors, and all vertices adding up their incoming message values. Such message exchange accounts for a non-trivial portion of the analysis time [62]. In the earlier example, sequentially applying the query to each snapshot results in 11 messages of which 5 are duplicates (fig. 2).

To avoid such inefficiencies, timelapse allows access to the *lineage* of graph entities. That is, it provides efficient

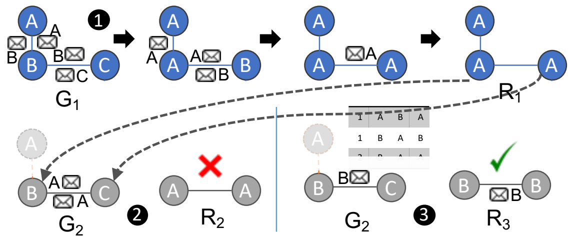

Figure 3: ❶ Connected components by label propagation on snapshot G_1 produces R_1. ❷ Vertex A and edge $A-B$ is deleted in G_2. Using the last result to bootstrap computation results in incorrect answer R_2. ❸ A strawman approach of storing all messages during the initial execution and replaying it produces correct results, but needs to store large amounts of state.

retrieval of the state of graph entities in any snapshot. Using this, graph-parallel phases can operate on the evolution of an entity (vertex or edge) as opposed to a single (at a given snapshot) value. In simple terms, each processing phase is able to see the history of the node's property changes. This allows *temporal* queries (§2.2) involving multiple snapshots, such as the degree computation, to be expressed as:

```
  results = G.degrees(Array(G1,G2,G3))
```

where `degrees` implementation takes advantage of timelapse by combining the phases in graph-parallel computation for these snapshots. That is, the user-defined vertex program is provided with state in all the snapshots. Thus, we are able to eliminate redundant messages and computation.

4 Computation Model

To improve interactivity, TEGRA must be able to efficiently execute queries by effectively reusing previous query results to reduce or eliminate redundant computations, commonly referred to as performing *incremental computation*. Here, we describe TEGRA's incremental computation model.

4.1 Incremental Graph Computations

Supporting incremental computation requires the system to manage *state*. The simplest form of state is the previous computation result. However, many graph algorithms are iterative in nature, where the graph-parallel stages are repeatedly applied in sequence until a fixed point. Here, simply restarting the computations from previous results do not lead to correct answers. To illustrate this, consider a connected components algorithm using label propagation on a graph snapshot, G_1 as shown in ❶ in fig. 3 which entails result R_1 after three iterations. When the query is to be repeated on G_2, restarting the computation from R_1 as shown in ❷ computes incorrect result. In general, correctness in such techniques depend on the properties of the algorithm (e.g., abelian group) and the monotonicity of updates (e.g., the graph only grows). Hence, supporting general non-monotonic iterative computations requires maintaining *intermediate* state.

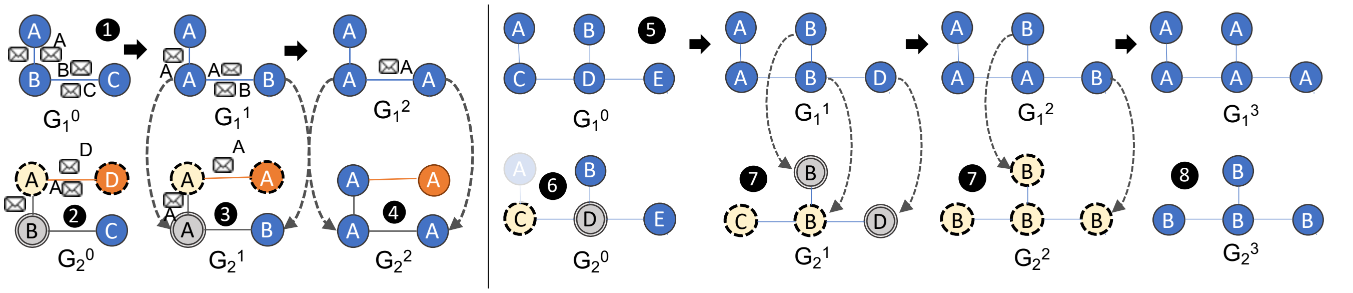

Figure 4: Two examples that depict how ICE works. Dotted circles indicate vertices that recompute, and double circles indicate vertices that need to be present in the subgraph to compute the correct answer, but do not recompute state themselves. ❶❺ Iterations of initial execution is stored in the timelapse. ❷❻ ICE bootstraps computation on a new snapshot, by finding the subgraph consisting of affected vertices and their dependencies (neighbors). In ❻, C is affected by the deletion of $A-C$. To recompute state it needs D (yields subgraph $C-D$). ❸❼ At every iteration, after execution of the computation on the subgraph, ICE copies state for entities that did not recompute. Then finds the new subgraph to compute by comparing the previous subgraph to the timelapse snapshot. In ❼, though C recomputes the same value as in previous iteration, its state is different from the snapshot in timelapse and hence needs to be propagated. ❹❽ ICE terminates when the subgraph converges and no entity in the graph needs the state copied from stored snapshots in the timelapse.

TEGRA proposes a general, incremental iterative graph-parallel computation model that is *algorithm independent*. It leverages the fact that graph-parallel computations proceed by making iterative changes to the original graph. Thus, *iterations of a graph-parallel computation can be seen as a time-evolving graph*, where the snapshots are the materialized state of the graph at the end of each iteration. In each of the snapshots, the intermediate state can be stored as vertex and edge properties. Since timelapse can efficiently store and retrieve these snapshots, we can perform incremental computations in a generic fashion by invoking graph-parallel computations on *affected neighborhood*. We call this model *Incremental Computation by entity Expansion* (ICE).

4.2 ICE Computation Model

ICE executes computations only on the subgraph that is affected by the updates *at each iteration*. To do so, it needs to find the relevant entities that should participate in computation at any given iteration. For this, it uses the state stored as timelapse, and the computation proceeds in four phases:

Initial execution: When an algorithm is executed for the first time, ICE stores the state (using the `save` API) of the vertices (and edges if the algorithm demands it) as properties in the graph. At the end of every iteration, a snapshot of the graph is added to the timelapse. The ID is generated using a combination of the graph's unique ID, an algorithm identifier and the iteration number. As depicted in ❶ and ❺ in fig. 4, the timelapse contains three and four snapshots, respectively.

Bootstrap: When the computation is to be executed on a new snapshot, ICE needs to bootstrap the incremental computation. Intuitively, the subgraph that must participate in the computation at bootstrap consists of the updates to the graph, and the *entities affected by the updates*. For instance, any newly added or changed vertices should be included. Similarly, edge modifications would result in the source and/or destination vertices to be included in the computation. However, the affected entities alone are not sufficient to ensure correctness of the results. This is because in graph-parallel execution, the state of a graph entity is dependent on the collective input from its neighbors. Thus, ICE must also include the one-hop neighbors of *affected entities*, and so the bootstrapped subgraph consists of the affected entities and their one-hop neighbors. ICE uses the `expand` API for this purpose. The graph computation is run on this subgraph. ❷ in fig. 4 shows how ICE bootstraps when a new vertex D and a new edge $A-D$ is added. D and A should recompute state, but for A to compute the correct state, it must involve its one-hop neighbor B, yielding subgraph $D-A-B$.

Iterations: At each iteration, ICE needs to find the right subgraph to perform computations. ICE exploits the fact that the nature of the graph-parallel abstraction restricts the propagation distance of updates in an iteration. Intuitively, the graph entities that might possibly have a different state at any iteration will be contained in the subgraph that ICE has already executed computation on from the last iteration. Thus, after the initial bootstrap, ICE can find the new subgraph at a given iteration by examining the changes to the subgraph from the previous iteration (using `diff`) and expanding to the one-hop neighborhood of affected entities (using `expand`). For the vertices/edges that did not recompute the state, ICE simply copies the state from the timelapse (using `merge`). For instance, in ❸ in fig. 4, though A and D recomputed, only D changed state and needs to be propagated to its neighbor A which needs B.

Termination: It is possible that modifications to the graph may result in more (or less) number of iterations compared to the initial execution. Unlike normal graph-parallel computations, ICE does not necessarily stop when the subgraph converges. If there are more iterations stored in the timelapse for the initial execution, ICE needs to check if the unchanged parts of the graph must be copied over. Conversely, if the subgraph has not converged and there are no more corresponding iterations, ICE needs to continue. To do so, it simply switches to normal (non-incremental) computation from that point. Thus, ICE converges only when the subgraph converges and no entity needs their state to be copied from the stored snapshot in the timelapse. (❹ and ❽ in fig. 4)

By construction, ICE generates the exact same intermediate states for all edges and vertices at all iterations, as compared to running a full execution on the entire graph. Thus, not only does ICE guarantee correctness of the incremental execution, but also enables *any* algorithm implemented in a graph-parallel fashion to be made incremental.

4.3 Improving ICE Model

Sharing State Across Different Queries Many graph algorithms consist of several stages of computations, some of which are common across different algorithms. For example, variants of connected components and pagerank algorithms both require the computation of vertex degree as one of the steps. Since ICE decouples state, such common computations can be stored as separate state that is shared across different queries. Thus, ICE enables developers to generate and *compose* modular states. This reduces the need to duplicate common state across queries which results in reduced memory consumption and better performance.

Incremental Computations Can Be Inefficient Incremental computation is not useful in all cases. For instance, in graphs with high degree vertices, a small change may result in a domino effect in terms of computation—that is, during later iterations, a large number of graph entities might need to participate in computation (e.g., Example 2 in fig. 4). To perform incremental computation, ICE needs to spend computations cycles to identify the set of vertices that should recompute (using `diff`) and copy the state of vertices that did not do computations (using `merge`). As a result, the total work done by the system may exceed that of completely executing the computation from scratch [24, 67]. Fortunately, the design of ICE lets us overcome this inefficiency. Since ICE generates the same intermediate states at every iteration as full re-execution, it can switch to full re-execution at any point.

A Simple Learning Based Model for Switching A key requirement for avoiding the inefficiencies with incremental execution detailed previously is to determine *when* to switch to full re-execution. This can be done at two places: at the start of the incremental execution, or at iteration boundaries (i.e., at the beginning of an iteration during the execution). In TEGRA, we picked the latter. A strawman approach is to use a simple threshold—for instance, *active* vertices in an iteration—to determine when to switch. Unfortunately, such approaches did not perform well in our evaluation, as we found that the optimal point for the switch depends on a number of factors, including the query, the properties of the graph and the nature of the modifications. Thus, we use a simple learning based approach to determining when TEGRA makes the switch.

In our approach, we train a simple random forest classifier [14] to predict, at the beginning of an iteration, if switching to full re-execution from that point would be faster compared to continuing with incremental execution. We do the training in an offline phase, where we use several runs of queries both in a full incremental and full re-execution mode as the input, ensuring enough runs in both cases to avoid class sensitivity. For each run, in every iteration, we record the following fields that we use as *features* for the learning: number of vertices that participate in the computation, the average degree of the active vertices, the number of partitions active, the number of messages generated per vertex, the number of messages received per vertex, the amount of data transferred over the network and the time taken for the iteration to complete. To make the learning general, we also use a few graph-specific characteristics such as the average degree of vertices, the average diameter and clustering coefficient. The label indicates whether switching to full recomputation in the next iteration resulted in faster execution.

While simple, we found that this approach works well as we show in fig. 11. Examination of the model revealed that it tries to learn the significance of vertices that participate in the computation (in terms of average degrees), the layout (how they are partitioned) and graph characteristics (in terms of diameter and clustering coefficient) in relation to the execution time. We plan to explore ways to improve our technique (e.g., better/robust models) as part of our future work.

5 Distributed Graph Snapshot Index (DGSI)

To make timelapse abstraction and ICE computation model practical, TEGRA needs to back them with a storage that satisfies the following three requirements: (1) enable ingestion of updates in real-time, and make it available for analysis in the minimum time possible, (2) support space-efficient storage of snapshots and intermediate computation state in a timelapse, and (3) enable fast retrieval and efficient operations on stored timelapses. These requirements, crucial for efficiently supporting ad-hoc analytics on time-evolving graphs, pose several challenges. For instance, they prohibit the use of preprocessing, typically employed by many graph processing systems, to compactly represent graphs and to make computations efficient. In this section, we describe how TEGRA achieves this by building DGSI. It addresses (1) and (2) by leveraging persistent data structures to build a graph store (§5.1, §5.2) that enables efficient operations (§5.3) while managing memory over time (§5.4).

5.1 Leveraging Persistent Data Structures

In TEGRA, we leverage persistent data structures [22] to build a distributed, versioned graph state store. The key idea in persistent data structures is to maintain the previous versions of data when modified, thus allowing access to earlier ver-

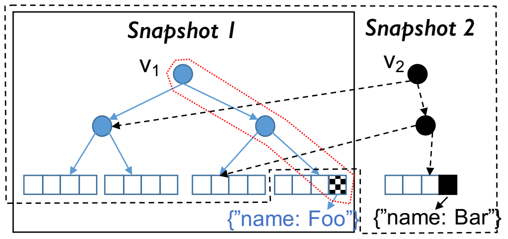

Figure 5: DGSI has one pART for vertices and one for edges in each partition. Version 1 (v_1) of a vertex pART stores properties of vertices in its leaves. Vertex id traverses the tree to its properties (e.g., *name*). Changes to vertices (e.g., property *name* changed from *Foo* to *Bar*) generates a new version v_2. The snapshot of the vertex pART before (Snapshot 1, shown in solid box) and after (Snapshot 2, shown in dotted box) the change share common leaves. (§5.2)

sions. DGSI uses a persistent version of the Adaptive Radix Tree [38] as its data structure. ART provides several properties useful for graph storage such as efficient updates and range scans. Persistent Adaptive Radix Tree (PART) [5] adds persistence to ART by simple path-copying. For the purpose of building DGSI, we reimplemented PART (hereafter pART) in Scala and made several modifications to optimize it for graph state storage. We also heavily engineered our implementation to avoid performance issues, such as providing fast iterators, avoiding unnecessary small object creation and optimizing path copying under heavy writes.

5.2 Graph Storage & Partitioning

TEGRA stores graphs using two pART data structures: a *vertex* tree and an *edge* tree. The vertices are identified by a 64-bit integer key. For edges, we allow arbitrary keys stored as byte arrays. By default, the edge keys are generated from their source and destination vertices and an additional short field for supporting multiple edges between vertex pairs. pART supports prefix matching, so using matching on this key enables retreiving all the destination edges of a given vertex. The leaves in the tree store pointers to arbitrary properties.We create specialized versions of pART to avoid (un)boxing costs when properties are primitive types.

TEGRA supports several graph partitioning schemes, similar to GraphX [26], to balance load and reduce communication. To distribute the graph across machines in the cluster, vertices are hash partitioned and edges are partitioned using one of many schemes (e.g., 2D partitioning). We do not partition the pART structures, instead TEGRA partitions the graph and creates *separate* pART structures locally in each partition. Hence logically, in each partition, the vertex and edge trees store a subgraph (fig. 5). By using local trees, we further amortize the (already low) cost[4] associated with modifying the tree upon graph updates.

To consume updates, TEGRA needs to send the updates to the right partition. Here, we impose the *same* partitioning as the original graph on the vertices/edges in the update.

[4]Modifications to nodes in ART trees only affect the $O(\log_{256} n)$ ancestors

5.3 Version Management

DGSI is a versioned graph state store. Every "version" corresponds to a root in the vertex and edge tree in the partitions—traversing the trees from the root pair materializes the graph snapshot. For version management, DGSI stores a mapping between a root and the corresponding "version id" in every partition. The version id is simply a byte array.

For operating on versions, DGSI exposes two low level primitives inspired by existing version management systems: `branch` and `commit`. A `branch` operation creates a new working version of the graph by creating a new (transient) root that points to the original root's children. Users operate on this newly created graph without worrying about conflicts because the root is exclusive to them and not visible in the system. Upon completing operations, a `commit` finalizes the version by adding the new root to version management and makes the new version available for other users in the system. Once a `commit` is done on a version, modifications to it can only be done by "branching" that version. Any timelapse based modifications cause `branch` to be called, and the timelapse `save` API invokes `commit`.

TEGRA can interface with external graph stores, such as Neo4J [4] or Titan [6] for importing and exporting graphs. While importing new graphs, DGSI automatically assigns an integer id (if not provided) and commits the version when the loading is complete. We create a version by batching updates. The batch size is user-defined. In order to be able to retrieve the state of the graph in between snapshots, TEGRA stores the updates between snapshots in a simple log file, and adds a pointer to this file to the root.

The simplest retrieval is by using its id. In every partition, DGSI then gets a handle to the root element mapped to this id, thus enabling operations on the version (e.g., branching, materialization). By design, versions in DGSI have no global ordering because branches can be created from any version at any time. However, in some operations, it may be desirable to have ordered access to versions, such as in incremental computations where the system needs access to the consecutive iterations. For this purpose, we enable suffix, prefix and simple ranges matching primitives on version id.

5.3.1 Implementing Timelapses

TEGRA implements timelapses using DGSI with its version ids and the matching primitives it provides. Recall that each timelapse logically represents a sequence of graph snapshots. Hence, every snapshot stored in DGSI is part of one or more timelapses. As a simple example, a user intending to track the Twitter graph by time could create snapshots by appending UNIX epoch to a unique ID for the graph (e.g., `TWTR`). In this scheme, a snapshot created at 9:00AM on 01/01/2020 may be given ID `TWTR_1577869200`. Prefix matching `TWTR` provides the entire timelapse for this graph. When this snapshot is chosen for a query, say PageRank, TEGRA can automatically append an algorithm ID (e.g., `PR`) and an iteration number to gener-

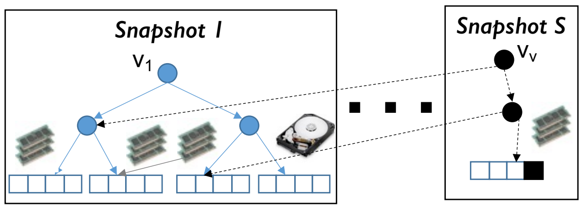

Figure 6: DGSI has fine-grained control over leaves (where data is stored). Here DGSI has 1000s of snapshots. All snapshots except *S* are on disk, their parents just hold pointers to files on disk. Parents are also dynamically written to disk if all of their children are on disk. Data structure uses adaptive leaf sizes for efficiency.

ate version IDs such as `TWTR_1577869200_PR_1`. Here, prefix matching on `TWTR_1577869200_PR` provides the timelapse of the execution of the page rank algorithm.

Currently, TEGRA only manages automatic ID generation for time-based snapshots and iterations of query execution. For instance, creating snapshots every hour is automated by doing a `branch` on the last snapshot in the `TWTR` timelapse and `commit`ing the new changes with new timestamp appended (e.g., `TWTR_1577872800`). Similarly, saving iterations of a query is as simple as keeping track and `branch` ing the last snapshot in the corresponding timelapse, and saving the new iteration with incremented iteration number (e.g., `TWTR_1577869200_PR_2`). However, since TEGRA stores IDs as byte arrays, users are free to choose any ID generation schemes; for instance it is possible to come up with complex hierarchical IDs that enable sophisticated retrievals using the matching capabilities on IDs provided by DGSI.

5.4 Memory Management

Over time, DGSI stores several versions of a graph, and hence TEGRA needs to manage these versions efficiently. We employ several ways to do this. Between `branch` and `commit` operations, it is likely that many transient child nodes are formed. We aggressively remove them during the `commit` operation. In addition, we enable in-place updates when the operations are local, such as after a branch and before a commit. Further, during ad-hoc analysis, analysts are likely to create versions that are never committed. We periodically mark such orphans and adjust the reference counting in our trees to make sure that they are garbage collected.

For managing stored versions, we leverage a simple Least Recently Used (LRU) eviction policy. Each time a version is accessed, we annotate the version and all its children with a timestamp. The system then employs a thread for periodically removing versions that were not accessed in a long time. The eviction is done by saving the version to local disk (or distributed file system). We do this in the following way. Since every version in DGSI is a branch, we write each subtree in that branch to a separate file and then point its root to the file identifier (e.g., in fig. 5, we can store v_2's leaf that is different from v_1 in disk as a file and point the parent node to this file). By writing subtrees to separate files, we ensure that different versions sharing tree nodes in memory can share tree nodes written to files. Due to this technique, we can ensure that leaf nodes (which are most memory consuming) that are specific to a version (not shared with any other version) are always written to disk if the version is evicted. As depicted in fig. 6, a large number of versions can be flushed to disk over time while still being retrievable when necessary. Thus, only active snapshots are fully materialized in memory, thereby allowing TEGRA to store several snapshots.

6 Implementation

TEGRA is a drop-in replacement for GraphX [26]. It uses the popular Gather-Apply-Scatter (GAS) [27] graph parallel model. We utilize the barrier execution mode to implement direct communication between tasks to avoid most Spark overheads. Spark provides fault tolerance by checkpointing inputs and operations for reconstructing the state. TEGRA provides coarse-grained fault tolerance by leveraging Spark's `rdd.checkpoint` semantics. Users can explicitly run checkpoint operation, upon which TEGRA flushes the contents in DGSI to persistent storage. We currently do not support fine-grained lineage-based fault tolerance provided by Spark.

6.1 ICE on GAS Model

As described in §4.2, the `diff()` API marks the candidates that must perform graph-parallel computation in a given iteration. In GAS decomposition [27], the `scatter()` function, invoked on `scatter_nbrs`, determines the set of active vertices which must perform computation. Starting with an initial candidate set (e.g., at bootstrap the changes to the graph, and at any iteration the candidates from the previous iteration) the `diff()` API uses `scatter_nbrs` (`EdgeDirection` in GraphX) in the user-defined vertex program to mark all necessary vertices for computation. We mark all `scatter_nbrs` of a vertex if its state differs from the previous iteration, or from the previous execution stored in the timelapse. For instance, a vertex addition must inspect all its neighbors (as defined by `scatter_nbrs`) and include them for computation.

The vertices in GAS parallel model perform computation using the user defined `gather()`, `sum()` and `apply()` functions, where `gather_nbrs` determine the set of neighbors to gather state from. The `expand` API enables correct `gather()` operations on the candidates marked for recomputation by also marking the `gather_nbrs` of the candidates. After the `diff` and `expand`, TEGRA has the complete subgraph on which the graph-parallel computation can be performed.

6.2 Using TEGRA as a Developer

TEGRA provides feature compatibility with GraphX, and expands the existing APIs in GraphX to provide ad-hoc analysis support on evolving graphs. It extends all the operators to operate on user-specified snapshot(s) (e.g., `Graph.vertices(id)` retrieves vertices at a given snapshot id, and `Graph.mapV([ids])` can apply a map function on vertices of

```
def IncPregel(g: Graph[V, E],
     prevResult: Graph[V, E],
     vprog: (Id, V, M) => V,
     sendMsg: (Triplet) => M,
     gather: (M, M) => M): Graph[V, E] = {
 iter = 0
 // Loop until no active vertices and nothing to copy
 // from previous results in timelapse.
 while (!converged) {
   // Restrict to vertices that should recompute
   val msgs: Collection[(Id, M)] =
     g.expand(g.diff(prevResult.retrieve(iter))).
      .aggregateMessages(sendMsg, gather)
   iter += 1
   // Receive messages and copy previous results
   g = g.leftJoinV(msgs).mapV(vprog)
        .merge(prevResult.retrieve(iter)).save(iter) }
 return g }
```

Listing 1: Implementation of incremental Pregel using TEGRA APIs.

the graph on a set of snapshots). Graph-parallel computation is enabled in GraphX using the `Graph.aggregateMessages()` (previously `mrTriplets()`) API. To use TEGRA, users incorporate the TEGRA API in table 1 in their normal, static (non-incremental) versions of the algorithm at places where graph's state is mutated. These are places where GraphX's `Graph.aggregateMessages()` is used.

GraphX further offers iterative graph-parallel computation support through a Pregel API which captures the GAS decomposition using repeated invocation of the `aggregateMessages` and `joinVertices` until a fixed point. Listing 1 shows how a user might use TEGRA APIs to implement an incremental version of Pregel. The code is reproduced from GraphX [26], with minimal changes to incorporate TEGRA APIs to store and retrieve state. In general, a developer can write incremental versions of any iterative graph parallel algorithm by using the TEGRA APIs along with `aggregateMessages`.

7 Evaluation

We have evaluated TEGRA through a series of experiments.

Comparisons: We compare TEGRA against many state-of-the-art systems (§2.3). For streaming system, we use GraphBolt [45] and the Rust implementation of Differential Dataflow (DD) [3]. Since we were unable to obtain an open source implementation of a temporal engine, we developed our version of Chronos [30] in GraphX [26], which we call Chlonos (Clone of Chronos) in this section. This implementation emulates the array based in-memory layout of snapshots and the incremental computation model in Chronos. We note that while Chronos supports updates to graphs by storing the temporal changes on disk, it uses a pre-processing step to create an in-memory layout which is used for every query. This in-memory layout does not support updates (§2.3) and needs to be recreated every time. We compare DGSI against GraphOne [35] and Aspen [21].

Dataset	Vertices / Edges
twitter [11]	41.6 M / 1.47 B
uk-2007 [12]	105.9 M / 3.74 B
Facebook Synthetic Data [2]	Varies / 5, 10, 50 B

Table 2: Datasets in our evaluation. M = Millions, B = Billions.

Evaluation Setup: All of our experiments were conducted on 16 commodity machines available as Amazon EC2 instances, each with 8 virtual CPU cores, 61GB memory, and 160GB SSDs. The cluster runs a recent 64-bit version of Linux. We use Differential Dataflow v0.10.0 and Apache Spark v2.4.4. We warm up the JVM before measurements. For single machine systems, we use a x1.32xlarge instance with 128 virtual CPUs and 2 TB memory to be comparable with our cluster.

Dataset & Workloads: We evaluate TEGRA on a number of real-world graphs depicted in table 2, with up to 50 billion edges. TEGRA creates default properties at vertices and edges to allow queries that compute on them (our comparisons do not support *arbitrary* properties). We use three standard, well understood, iterative graph algorithms with varying computation and state requirements, commonly used to evaluate graph processing systems as queries: Connected Components (CC), Page Rank (PR) [55] and Belief Propagation (BP) [74]. We run PR until a specific convergence or 20 iterations, whichever is lower. Note that while the queries in this section do not access the vertex and edge properties explicitly (i.e., queries do not ask for them), TEGRA depends on them extensively to store intermediate state (§4).

Caveats. While perusing the evaluation results, we wish to remind the reader a few caveats. Though many of the graphs we use fit in the memory of a modern machine, TEGRA is focused on ad-hoc analytics which requires storage of multiple snapshots (and computation state) of the graph. Further, ad-hoc analytics requires the use of property graphs. TEGRA supports edge and vertex properties and creates a default value, which increases the graph size by several magnitudes and also affects performance. Finally, DD's connected component uses the union-find based implementation (hard to fit in a vertex centric model) which is superior to TEGRA's label propagation based implementation.

7.1 Microbenchmarks

We first present experiments that highlight the effectiveness of DGSI. GraphBolt is excluded as it doesn't allow storing multiple versions or intermediate state. (§2.3).

Snapshot Retrieval Latency: We generate 1000 snapshots of the Twitter and UK graphs by randomly modifying (adding and removing equal number) 1% of the edges (no computations are performed) to emulate the evolution of the graph. Table 3 shows the average latency for 10 random retrievals with varying number of snapshots in the system.

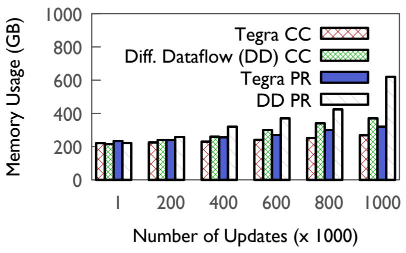

Figure 7: Differential dataflow generates state at every operator, while TEGRA's state is proportional to the number of vertices.

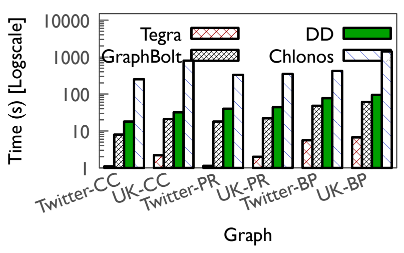

Figure 8: On ad-hoc queries on snapshots, TEGRA is able to significantly outperform due to state reuse.

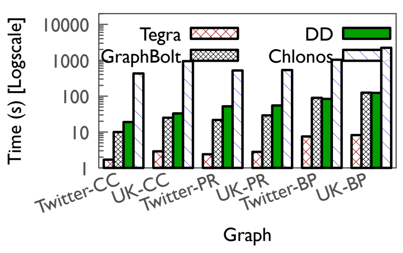

Figure 9: TEGRA's performance is superior on ad-hoc window operations even with materialization of results.

Graph	System	# Snapshots in memory				
		200	400	600	800	1000
Twitter	DD	30.2	44.8	92.4	131.6	180.2
	GraphOne	32.3	50.1	105.5	141.2	201.2
	Aspen	0.43	0.54	0.53	0.57	0.65
	TEGRA	1.34	1.5	1.25	1.78	2.1
UK	DD	63.1	86.4	220	271.5	283.2
	GraphOne	74.3	102.2	263.5	321.4	332.5
	Aspen	0.86	1.04	1.12	1.25	1.31
	TEGRA	2.2	2.5	2.6	2.25	2.3

Table 3: Snapshot retrieval latency (in seconds). DD and GraphOne require reconstruction, while TEGRA and Aspen can simply traverse the data structure from a version's root.

We see that TEGRA is able to return the queried snapshot within seconds due to DGSI which stores and retrieves materialized snapshots efficiently. In contrast, DD needs to reconstruct the graph from indexed differences and takes several minutes. It also exhibits high variance in retrieval time based on the amount of reconstruction required. GraphOne faces similar challenge with its `get-prior-edges()` API which needs to reconstruct the historic view from the durable edge log. While not shown, Chlonos too exhibits similar characteristics as DD but is significantly slower, in some cases up to an order of magnitude. This is because it stores updates on disk and needs an intensive preprocessing step to create the in-memory layout. DD exhausts the memory available in our cluster ($\approx$1TB) in this experiment which limited the number of snapshots we could store to $\approx$1000. One solution is to store the updates in a persistent storage, but this incurs significant performance degradation while retrieving (like Chlonos). Aspen performs similar to TEGRA (slightly faster since it is able to compress the graph significantly better) due to its use of persistent data structures, hence it only needs to traverse the tree from a specific root to retrieve a version (like DGSI). However, it neither supports intermediate state storage nor includes an incremental computation model.(§2.3)

Computation State Storage Overhead: To measure the memory overhead due to computation state, we perform PR and CC computation on the Twitter graph in an incremental fashion, where we add and delete 1000 edges to create a snapshot. We note the memory usage by each system after every 200 such computations until 1000 computations (for a total of 1 million edge updates). Figure 7 shows this experiment's results. When the number of updates is small, both TEGRA and DD use comparable amount of memory to store the state, even with DD's highly compact layout (native arrays compared to TEGRA's property graph). However, DD's state size increases rapidly as it does more computation and takes up to 2$\times$ that of TEGRA. TEGRA's memory requirement also increases over time, but much more gracefully. This is due to the combined effect of TEGRA's compact state representation (proportional to the number of vertices) and the ability of DGSI to manage memory efficiently (§5.4), while DD needs to keep state (proportional to the number of edges) at every operator. The amount of increase also depends on the algorithm. For instance, page rank generates the same amount of state in every iteration while connected component's state requirement reduces over iterations. Note that DD uses compaction in this experiment which is automatically done by the system. While GraphBolt also reduces the state requirement to be proportional to the number of vertices, it does not allow storing computational state for later reuse.

7.2 Ad-hoc Window Operations

Here, we present evaluations that focus on TEGRA's main goal. In these experiments, we emulate an analyst performing ad-hoc analytics. We load the graph, and apply a large number of sequential updates to it, where each update modifies 0.1% of the edges (adds and removes equal number) to adhere to our assumption that during ad-hoc analysis the graph doesn't change much and it is possible to leverage incremental computation (we show results with large changes in fig. 11). We then retrieve 100 random windows of the graph that are close-by, and apply queries in each. We assume that *some* earlier results are available so that the system could do incremental computations. We do not consider the window retrieval time in this experiment for any system. We present the average time taken to compute the query result.

Single Snapshot Operations: In the first experiment, we set the window size to zero so that every window retrieval returns a single snapshot. The results are depicted in fig. 8. DD,

Graph	5B			10B			50B		
	PR	CC	BP	PR	CC	BP	PR	CC	BP
DD	1m	8s	1.5m	2m	34s	-	-	-	-
GraphBolt	29s	21s	1.1m	1.2m	28s	2.2m	5.3m	54s	12m
TEGRA	10s	5s	6.5s	19s	7s	9.3s	1.5m	18s	2.4m

Table 4: Ad-hoc analytics on big graphs, with 5 billion, 10 billion and 50 billion edges. A '-' indicates the system failed to run the workload. TEGRA can handle big graphs and large amounts of state due to its efficient memory management (§5.4)

GraphBolt and Chlonos do not allow reusing computation across queries, so they compute from scratch for every retrieval. In contrast, TEGRA is able to leverage the compact computation state stored in its DGSI from earlier queries to do incremental computation. In this case, most of the snapshots incur no computation overhead because of the small amount of changes between them, and TEGRA is able to produce an answer within a few seconds. DD and GraphBolt take a few 10s of seconds, while Chlonos requires 100s of seconds. TEGRA's benefits range from 18-30× compared to DD and 8-18× compared to GraphBolt.

Window Operations: Here we set the window size to be 10 snapshots. GraphBolt, Chlonos and DD are able to apply incremental computations once the query has been computed on the first snapshot. Figure 9 shows the results. We see that DD is fast once the first result has been computed. This is due to the combination of its extremely efficient streaming computation model (no materialization) and recent optimizations such as shared arrangements [48]. Chlonos incurs a penalty initially because it uses the first result to bootstrap the rest using its LABS model. TEGRA's performance remains consistent. This is due to two reasons. First, since TEGRA separates state from computation, it can reuse the state across multiple snapshots. Second, due to the use of persistent data structures, snapshot can be independently and concurrently operated on (§3.1). Since GraphBolt does not support concurrent processing, it does sequential computation (in an incremental fashion) on the snapshots. For simple queries (e.g., CC), the penalty is unnoticeable. It becomes pronounced in BP which is more computationally heavy. TEGRA is still 9-17× (5-23×) faster compared to DD (GraphBolt).

Large Graphs & Large Amounts of State: Here we answer two questions: (1) can TEGRA support ad-hoc analysis on large graphs, and (2) can TEGRA efficiently manage memory when large amounts of state need to be stored? We use synthetic graphs provided by Facebook [2] modeled using the social network's properties. We execute the queries once on the original graph, then modify the graph by a tiny percentage (0.01%) randomly 1000 times to create 1000 snapshots. We then pick a snapshot, run the queries on it and provide the average of 100 such runs in table 4. DD works well when both the graph and the updates (and the generated state) are small. However, as the graph becomes larger, DD needs to push a large number of updates through the computation, and state becomes a bottleneck in its performance. On the largest graph, we were unable to get DD to work as it failed due to excessive memory usage during initial execution. GraphBolt doesn't store any previous state, and hence is unable to do incremental computations. It also required several optimizations to support the largest graph. In contrast, TEGRA is not only able to efficiently use memory and disk (§5.4) and scale to large graphs and snapshots, but also provide significant benefits by using previous computation state.

Table 5: Running time (in seconds) for TEGRA and GraphBolt when doing ad-hoc analysis with different batch sizes and algorithms.

Effect of Batch Size & Additional Algorithms: In this experiment, we evaluate the effect of batch size on the ad-hoc analysis capability of TEGRA. For this, we fix the batch size to a specific number in each run, and use several other algorithms. Specifically, we use Label Propagation (LP), Collaborative Filtering (CF) and Triangle Count (TC) and Co-Training Expectation Maximization (CoEM) as used in GraphBolt [45]. For CoEM, we use the Latent Dirichlet Allocation (LDA) implementation in GraphX which uses EM. We also provide results on k-hop, which computes the set of vertices that are k hops away, and Breadth First Search (BFS). For the k-hop algorithm, we set k to 4 for all batch sizes.

In each run, we execute the algorithm first. We then generate several snapshots using varying batches of equal edge additions and deletions. We choose three fixed numbers: 1K, 10K and 100K. We pick a random snapshot and repeat the same algorithm on it. The results are shown in table 5.TEGRA is able to perform incremental computation using previous results, while GraphBolt does not support ad-hoc analysis and hence need to execute the algorithm fully. We also notice that varying batch size doesn't affect TEGRA much, and that it is able to provide results efficiently.

We note a few caveats here. In TC, the incremental computations are simple (edge additions and deletions do not result in multiple iterations) and involves just updating a count based on the edges added or deleted. Similarly, BFS and 4-hop algorithms are light weight and result in only a very small part of the graph to be active, especially during incremental computation. Due to this reason, for these algorithms, we only measure the actual computation time and ignore the scheduling overhead in TEGRA. Hence, the times we report for these

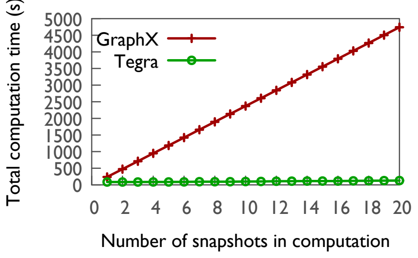

Figure 10: Timelapse lets queries to be executed simultaneously on a sequence of snapshots, enabling efficient temporal analysis.

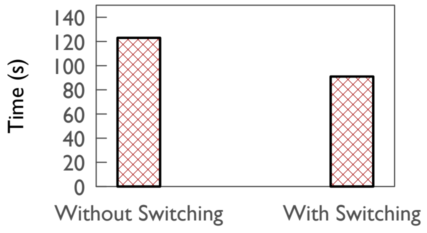

Figure 11: TEGRA can switch to full re-execution when incremental computations are not useful.

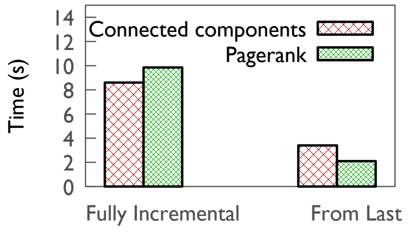

Figure 12: Monotonicity of updates (additions only) can be leveraged to speed up computations by starting from the last answer.

three algorithms are not end-to-end, but just the time it takes for the computation task to complete.

7.3 Timelapse & ICE

Parallel computations. Here we evaluate the ability of Timelapse to do temporal queries, where a query is applied to a sequence of snapshots in parallel (§3.1). We create 20 snapshots of the Twitter graph by starting with 80% of the edges and adding 1% to it repeatedly. We run the connected components algorithm, each time varying the number of snapshots on which the computation is run. In each run, we measure the time taken to obtain the results on all the snapshots considered. For comparison, we use GraphX and apply the algorithm to each snapshot in a serial fashion. The results are depicted in fig. 10. We see that TEGRA significantly outperforms GraphX. The improvement for a single snapshot is due to TEGRA's optimizations and use of barrier execution mode in Spark. Further, we see a linear trend with increasing number of snapshots. By sharing computation and communication, TEGRA is able to achieve up to 36× speedup.

ICE's switching capability: To test ICE's switching capability when incremental computations are not useful (§4.3), we run the CC algorithm on the Twitter graph. Next, we introduce a batch of deletions in the largest components so that incremental computation executes on a large portion of the graph. We then make TEGRA recompute with and without the switching enabled and average the results over 10 such runs. The results are shown in fig. 11. We see that without the switching, TEGRA incurs a penalty—the incremental execution takes more time than complete re-execution of the algorithm. With switching, TEGRA is easily able to identify that it needs to switch and hence does not incur this penalty.

ICE's versatility: Since ICE differs from streaming engines, it can also provide flexibility in how it uses state. For instance, if updates are monotonic (only additions), then ICE can simply restart from the last answer instead of using full incremental computations. Figure 12 shows this on two algorithms on the UK graph. PR and CC can benefit, but PR is faster since it only needs to converge within a given tolerance.

Sharing state across queries: To evaluate how much benefits sharing state between different queries provides, we run an experiment with CC and PR. For these queries, the degree computation can be shared. We run the algorithms with and without sharing enabled on the Twitter graph, and average the results of 10 runs of incremental computations on random snapshots. The results in fig. 13 show 20% and 30% reduction in memory usage and runtime.

7.4 TEGRA Shortcomings

Finally, we ask "What does TEGRA **not** do well?".

Purely Streaming Analysis: We consider an online query (§2) of CC. To emulate a streaming graph, we first perform CC computation on the graph. Then we continuously change 0.01% of the graph by adding and deleting equal number of edges. After fixed number of changes (every 200), we show the average runtime of 10 runs in fig. 14. We see that DD and GraphBolt are significantly better than TEGRA for such workloads. This is due to a combination of DD and GraphBolt optimized for online queries (pushing small updates really fast through computation) and their Rust/C++ implementation. We remind the reader of two caveats here. First, DD uses a much superior union-find approach to CC while TEGRA and GraphBolt use an iterative approach. Second, TEGRA only executes queries when it is asked to, whereas DD and GraphBolt executes queries for every batch of updates (thus TEGRA accumulates more updates when executing queries). While TEGRA can theoretically process each small update separately, the computation engine it builds on (Spark) is tuned for batched updates.

Purely Temporal Analysis: We assume that the queries and the window are known, and the system has optimized the data layout. We run a query on a window size of 10 and compare TEGRA and Chlonos on the incremental processing time (we discard the time for full execution). Excluding processing time, fig. 15 shows that TEGRA incurs a 15% performance hit due to its use of tree structure.

COST Analysis: The COST metric [47] is not designed for incremental systems, but we note that TEGRA is able to match the performance of an optimized single threaded implementation using 4 machines, each with 8 cores and has a COST of 32 cores. However, TEGRA uses property graphs while the optimized implementation does not.

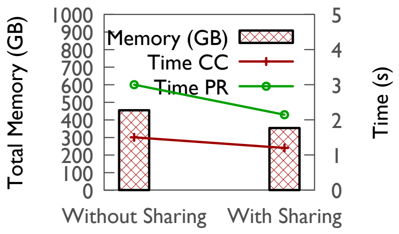

Figure 13: Sharing state across queries leads to reduction in memory usage and improvement in performance.

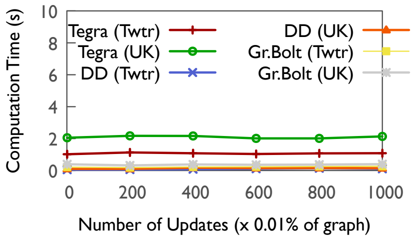

Figure 14: Both DD and GraphBolt significantly outperform TEGRA for purely streaming analysis.

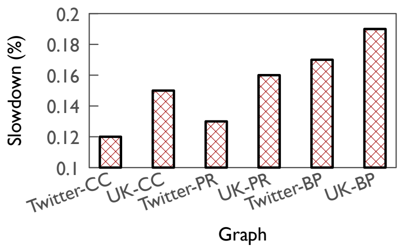

Figure 15: Tree based data structures in TEGRA result in a 15% slowdown compared to Chlonos for purely temporal analysis.

8 Related Work

Analytics on Static Graphs: A large number of graph processing systems [7, 8, 16, 18, 25–28, 37, 39–41, 56, 57, 59, 60, 65, 68–73, 76–81] focus on static graph processing, some of which are single machine systems and some are distributed. These systems do not consider evolving graph workloads.

(Transactional) Graph Stores: The problem of managing time-evolving graph has been studied in the context of graph stores [15,52,53,56]. These focus on optimizing point queries which retrieves graph entities and do not support storing multiple snapshots. This yields a different set of challenges compared to iterative graph analytics.

Managing Graph Snapshots: DeltaGraph [33] proposes a hierarchical index that can manage multiple snapshots of a graph using deltas and event lists for efficient retrievals, but lacks the ability to do windowed iterative analytics. TAF [34] fixes this, but it is a specialized framework that does not provide a generalized incremental model or ad-hoc operations. LLAMA [42] uses a multi-version array to support incremental ingestion. It is a single machine system, and it is unclear how the multi-version array can be extended to support data parallel operations required for iterative analytics. Version Traveler [32] achieves switching between snapshots of a graph by loading the common subgraph in the compressed-sparse-row format and extending it with deltas. It does not support incremental computation. GraphOne [35, 36] uses dual-versioning to provide access to recent snapshots. It doesn't support ad-hoc analysis or efficient retrieval of arbitrary snapshots. Aspen [21] leverages functional data structures to build a compressed streaming graph engine, but doesn't support incremental computations. Chronos [30] and ImmortalGraph [50] optimizes for efficient computation across a series of snapshots. They propose an efficient model for processing temporal queries, and support snapshot storage of the graph on-disk using a hybrid model. While their technique reduces redundant computations in a given query, they cannot store and reuse intermediate computation results. Their in-memory layout of snapshots requires preprocessing and cannot support updates. None of these systems support storing computation state for later reuse.

Incremental Maintenance on Evolving Graphs: Kineograph [19] supports constructing consistent snapshots of an evolving graph for streaming computations but does not allow ad-hoc analysis. WSP [75] focuses on streaming RDF queries. GraphInc [17] supports incremental graph processing using memoization of the messages in graph parallel computation, but does not support snapshot generation or maintenance. Kickstarter [67] and GraphBolt [45] support non-monotonic computations, but do not support ad-hoc analysis or compactly storing graph and state. Differential Dataflow [48, 49, 51, 54] leverages indexed differences of data in its computation model to do non-monotonic incremental computations. However, it is challenging to do ad-hoc window operations using indexed differences (§2.3). As we demonstrate in our evaluation, compactly representing graph and computation state is the key to efficient ad-hoc window operations on evolving graphs.

Incremental View Maintenance (IVM): In databases, IVM algorithms [10, 29] maintain a consistent view of the database by reuse of computed results. However, they are tuned for different kinds of queries and not iterative graph computations. Further, they generate large intermediate state and hence require significant storage and computation cost [49].

Versioned File Systems (e.g., [64]) allow several versions of a file to exist at a time. However, they are focused on disk based files in contrast to in-memory efficiency.

9 Conclusion

In this paper, we present TEGRA, a system that enables efficient ad-hoc window operations on evolving graphs. The key to TEGRA's superior performance in such workloads is a compact, in-memory representation of both graph and intermediate computation state, and a computation model that can utilize it efficiently. For this, TEGRA leverages persistent data structures and builds DGSI, a versioned, distributed graph state store. It further proposes ICE, a general, non-monotonic iterative incremental computation model for graph algorithms. Finally, it enables users to access these states via a natural abstraction called Timelapse. Our evaluation shows that TEGRA is able to outperform existing temporal and streaming graph systems significantly on ad-hoc window operations.

Abstract

This paper presents DST, a *decentralized scalar timestamp* scheme to scale distributed transactions using multi-version concurrency control (MVCC). DST is efficient in storage and network by being a scalar timestamp but requiring no centralized timestamp service for coordination, which may become a scalability bottleneck. The key observation is that concurrency control (CC) protocols like OCC and 2PL already imply a serializable order among concurrent read-write transactions through conflicting database tuples. To this end, DST piggybacks on CC protocols to maintain the timestamp ordering with low cost and no new scalability bottleneck for read-write transactions. DST further provides snapshot reads with bounded staleness by using a hybrid scalar timestamp (physical clock and logical counter).

To demonstrate the generality of DST, we provide a general guideline for the integration of DST and further show the effectiveness by using three representative transactional systems (i.e., DrTM+R, MySQL cluster, and ROCOCO) with different CC protocols. Experimental results show that DST can achieve more than 95% of optimal performance (using Read Committed) without compromising correctness. With DST, DrTM+R achieves up to 1.8X higher peak throughput for `TPC-E` and outperforms other timestamp schemes by 6.3X for `TPC-C`. DST also leads up to 1.9X and 2.1X speedup on `TPC-C` for MySQL cluster and ROCOCO, respectively.

1 Introduction

Many large-scale applications like Web services, stock exchange, and e-commerce require accessing scalable sharded data stores in a consistent way. Among such accesses, a large fraction requires consistently scanning data over many shards despite concurrent updates on the fly. For example, an examination of `TPC-E` [57], a sophisticated online transaction processing benchmark that models stock exchange, uncovers that 79% of transactions are read-only ones at run time. It was also reported that 99.8% of accesses to Facebook's distributed data store TAO are reads [16], which need strong consistency along with transactional writes [7].

However, it is costly to provide transactional isolation to read-only transactions [39] because a user read request may result in thousands of sub-queries [7]. Pessimistically executing a read-only transaction may cause unnecessary blocking to itself and concurrent read-write transactions, while optimistically executing it is likely to cause excessive aborts. For instance, as shown in Fig. 1(a), there is a notable performance gap between using optimistic concurrency control (OCC) [29] and read committed (RC) protocol for `TPC-E`.[1]

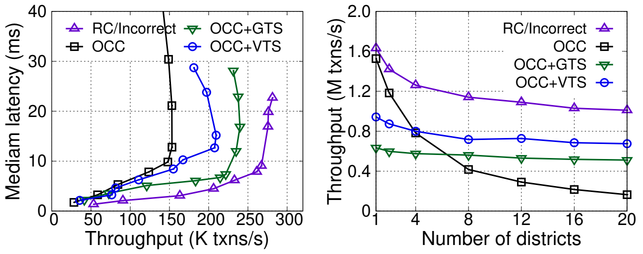

Fig. 1: *Performance of (a) `TPC-E` and (b) `TPC-C` on a local 16-node cluster using different CC protocols and TS schemes (see §5 for details). GTS and VTS stand for using OCC protocol, while the read-only transactions read the snapshots delimitated by GTS and VTS. RC/Incorrect stands for using RC protocol, which can provide optimal performance, but at the expense of correctness. One machine is dedicated for timestamp oracle, even OCC and RC have no need.*

A common approach is to leverage multi-version concurrency control (MVCC) [13, 65] for transactional systems, which has been widely adopted by nearly every commercial database like PostgreSQL [3], Oracle [4], MySQL/InnoDB [2], Hekaton [21], and SAP HANA [50]. MVCC simultaneously maintains multiple database snapshots by using timestamps to delimitate them. Thus, readers may read tuples from a stale snapshot while writers can write the tuples concurrently. It essentially unleashes the parallelism between concurrent readers and writers.

While MVCC extracts more concurrency for transactions (especially for read-only transactions), it does not necessarily approach optimal performance and/or scalability improvement (see Fig. 1), due to the overhead of maintaining timestamp ordering at scale (§2.3). More specifically, a centralized sequencer (timestamp oracle) is usually used to provide snapshot timestamp to transactions, which reflects a total order among transactions (i.e., global timestamp (GTS)). However, such a mechanism not only adds more communications but also causes overly-constrained concurrency control for read-write transactions, leading to performance degradation and scalability bottlenecks [14]. Vector timestamp (VTS), which leverages a clock per worker or machine, only mitigates the scalability bottleneck of centralized timestamp schemes but causes more network traffic, which grows lin-

[1] We evaluate different timestamp schemes on DrTM+R [18]. RC cannot provide correct results as it completely disregards the conflicts between read-write and read-only transactions. Detailed setup can be found in §5.

early with the increase of workers or machines in the system. Although recent work ameliorates the performance of centralized and/or vectorized timestamp schemes (e.g., batching requests [46, 27], timestamp compression [70], and dedicated fetch thread [70]), the fundamental performance and scalability bottlenecks remain.

In this paper, we propose a new timestamp scheme, namely, *decentralized scalar timestamp* (DST), which enables MVCC without a centralized sequencer or vector timestamps. DST is motivated by a key observation: *transaction ordering provided by existing CC protocols already implies serializable ordering among transactions, which can be reused to maintain timestamp ordering in a lightweight and scalable way.* This is because any pair of conflicting transactions must have conflicting accesses to a particular tuple. Thus, the *later* transaction should see the timestamp of the *former* transaction from the conflicting tuple and have a *larger* timestamp.

DST piggybacks on CC protocols to derive a scalable timestamp, in contrast to providing a separate timestamp scheme. Specifically, DST starts with a scalar timestamp for each transaction from a local clock and dynamically refines the tentative timestamp through transaction execution with the largest one from tuples in the read/write set. Upon commit, a transaction will also install the refined timestamp to the read/write set so that any transactions serialized after this transaction will have a larger timestamp.

One key challenge is how to derive a *consistent* yet *fresh* snapshot. DST leverages a decentralized design for read-only transactions, which introduces a *hybrid* scalar timestamp to provide snapshot reads with *bounded staleness*. Specifically, the read-only transaction can read fresh tuples whose timestamp is within two times the maximum physical clock drift under loosely synchronized clocks.[2] The fresh and consistent snapshot is obtained by attempting to read tuples using the latest hybrid timestamp while detecting and reordering any concurrent conflicting read-write transactions. In the hybrid timestamp, the physical part (a loosely synchronized clock) ensures the read-only transaction can read a fresh snapshot, and the logical part (a monotonically increasing counter) avoids possible overflow of the physical part.

To demonstrate the effectiveness and generality of DST, we have implemented DST on three representative transactional systems with different CC protocols, namely DrTM+R [18] (OCC), MySQL cluster [1] (2PL), and ROCOCO [43]. We also implemented two centralized timestamp schemes (GTS and VTS) on DrTM+R by following the state-of-the-art [46, 70]. The experimental results on three clusters show that DST can achieve more than 95% of optimal performance (using RC protocol) without compromising correctness. With DST, DrTM+R achieves up to 1.8X and 6.1X performance improvements for `TPC-E` and `TPC-C`.

[2]The clock drift (aka clock skew) can be obtained using a network time protocol like the precision time protocol (PTP), which only affects the freshness of reads in DST rather than correctness.

A comparison with other timestamp schemes shows DST is up to 1.7X and 6.3X faster than best of them for `TPC-E` and `TPC-C`, respectively. Further, DST also leads up to 1.9X and 2.1X speedup on `TPC-C` for MySQL cluster and ROCOCO.

DST shares some similarities with decentralized timestamps proposed in prior work [68, 37], which optimize a specific CC protocol for multi-core databases. For instance, TicToc [68] uses a data-driven timestamp scheme to reduce transaction aborts for OCC. Differently, DST is a general timestamp scheme for various CC protocols (§4.2) and can piggyback on each one efficiently in a distributed setting.

In summary, the contributions of this paper are:

- A *decentralized scalar* timestamp scheme called DST for MVCC that enables efficient read-only transactions with little impact on read-write transactions (§3.1 and §3.2), as well as an intuitive proof of correctness (§3.3).
- A *consistent* yet *fresh* snapshot-read approach based on a hybrid timestamp that provides bounded staleness (§3.4).
- To demonstrate the generality, DST is integrated into three representative transactional systems with different CC protocols, including OCC, 2PL, and ROCOCO (§4).
- A set of evaluations on three clusters with both microbenchmarks and applications (e.g., `TPC-E`, `TPC-C`, and `SmallBank`) confirms the performance gains of DST (§5).

The source code of three transactional systems with DST, including all benchmarks and experimental results, are available at `https://github.com/SJTU-IPADS/dst`.

2 Background and Motivation

2.1 Target Systems

DST is designed for general distributed transactions over database data partitioned to multiple storage nodes. The client's transaction request is handled by a coordinator, which interacts with storage nodes for executing the transaction. During the transaction's execution, the coordinator may send read/write requests to read/write data from the storage nodes; or send transactional requests (e.g., lock or unlock) according to the database's concurrency control protocol. It batches requests (e.g., write and unlock) to avoid extra network roundtrip.

Our goal is to support serializable read-only transaction that never aborts, and does not interfere with read-write transaction. Further, it is desirable to execute reads in the read-only transaction in one-roundtrip, i.e., the coordinator can retrieve a consistent view of the data from the storage nodes in one request.

2.2 MVCC and Timestamps

A common approach to support serializable read-only transaction without interfering with read-write transaction is through multi-version concurrency control (MVCC). There are two major design considerations for an efficient MVCC system compared with single-version mechanisms [65]. The first is *how to cheaply allocate a globally-ordered version*

2PL with global timestamp (GTS)

```
At Oracle:                          ▸ timestamp server
+ GlobalTS                  ▸ monotonic global timestamp
+ StableGTS                  ▸ snapshot global timestamp
+ Queue                       ▸ pending global timestamp

  INSTALL(gts):
+1  add gts to Queue

  STABILIZE( ):                    ▸ run asynchronously
+1  for each gts in Queue do
+2    if gts is ready then
+3      dequeue gts and gts → StableGTS

At Worker_i:                  ▸ i denotes the worker number
  WRITE(tx, id, data)
 1  acquire lock
 2  add ⟨id, data⟩ to tx.wset

  READ(tx, id)
 1  acquire lock and get latest ⟨data⟩
 2  add ⟨id, data⟩ to tx.rset
 3  return ⟨data⟩

  COMMIT(tx)
+1  tx.TS ← Oracle.GlobalTS        ▸ network round trip
 2  for each w in tx.wset do
:3    update ⟨w.data, tx.TS⟩ and release lock
 3  for each r in tx.rset do
 4    release lock
+5  Oracle.INSTALL(tx.TS)          ▸ network round trip

  ROTX(tx)                              ▸ snapshot read
+1  tx.TS ← Oracle.StableGTS
+2  for each r in tx.rset do
+3    get ⟨r.data⟩ up to tx.TS
```

Fig. 2: *Using GTS (i.e., blue code lines) to enable consistent snapshots for read-only transactions with 2PL.* +N *and* :N *denote new and modified lines of code respectively.*

for updating tuples transactionally. Deciding the version installed with tuples should have minimal impacts on read-write transactions. The second is *how to efficiently allocate a freshly-stable version for reading tuples consistently*. Read-only transactions should have access to consistent snapshots with low latency and high freshness. MVCC schemes typically adopt the concept of *timestamps* for tuple versions. However, it is non-trivial to design a general timestamp scheme that supports *efficient* snapshot reads while incurring *minimal overhead* for broad CC protocols.

To motivate the design of DST, we start by briefly reviewing how existing timestamp schemes are applied to two-phase locking (2PL) for MVCC and snapshot reads [45, 65].

Global timestamp (GTS). This approach leverages a timestamp service, namely *timestamp oracle*, to manage globally ordered timestamps [46, 15, 21]. It provides two functions for MVCC systems, as shown in Fig. 2. First, the read-write transaction contacts the oracle for a commit timestamp (GlobalTS) at the commit phase. Upon a successful commit, this transaction creates a new version denoted by the commit timestamp for each tuple in the write set (*line:3* of COMMIT) and sends back the committed timestamp to the oracle (*line:5*). Second, the read-only transaction contacts the ora-

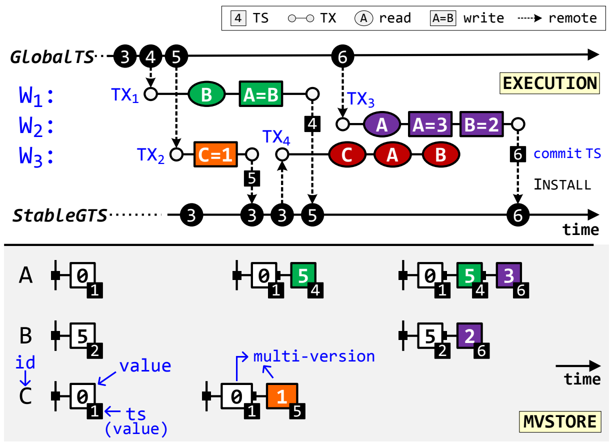

Fig. 3: *A sample case of using GTS, where four transactions (TX_1-TX_4) operate on three tuples (A, B, and C).*

cle for a read timestamp (StableGTS) and retrieves tuples in the read set with versions no larger than the read timestamp (*line:2-3* of ROTX).

Given the specification of extensions to 2PL with GTS in Fig. 2, we analyze the transaction behavior in the case shown in Fig. 3 to explain the design of GTS. There are four transactions (TX_1–TX_4), which operate on three tuples (A, B, and C). Note that non-conflicting transactions TX_1 (green) and TX_2 (orange) are both forced to acquire GlobalTS according to the specification. This operation is necessary to maintain the global timestamp ordering, yet results in overly-constrained concurrency control and an extra network round trip compared to the vanilla 2PL.

The necessity of the oracle to maintain StableGTS can be revealed with the conflict between the timestamp order and the commit order concerning TX_1 and TX_2. In this case, TX_2 acquires a larger GlobalTS but commits before TX_1. When read-only transaction TX_4 (red) starts, it cannot simply use the latest committed timestamp (GlobalTS=5) for snapshot reads. The snapshot would be inconsistent if the read-only transaction observes TX_2 before TX_1 commits. Thus, transactions must install commit timestamps so that the oracle can determine the read timestamp (StableGTS=3) for TX_4.

Vector timestamp (VTS). To reduce the overhead of acquiring GlobalTS in the critical path of read-write transactions, VTS replaces the global timestamp counter with a vector of local timestamps. The vector contains a slot for each worker, which records the per-worker timestamp. In each worker, a local counter (LocalTS) is used to assign the commit timestamp for transactions, hence reducing one network round trip compared to GTS. However, the oracle is retained in VTS to maintain the StableVTS with similar reasons as GTS. Fig. 4 shows the specification of extensions to 2PL with VTS.

Fig. 5 presents a concrete case of using VTS. Each worker maintains its local counter (W_1:3, W_2:2, and W_3:5). The version of a tuple is represented as $\langle i : ts \rangle$, where i is the worker ID, and ts is the commit timestamp of the transaction that writes the tuple. The initial StableVTS is $(3, 2, 5)$, which means that tuples with versions less than $\langle 1 : 3 \rangle$, $\langle 2 : 2 \rangle$, and

```
2PL with vector timestamp (VTS)

At Oracle:                              ▸ timestamp server
+ StableVTS                      ▸ snapshot global timestamp
+ Queues                          ▸ pending global timestamp

  INSTALL(⟨i:ts⟩, deps)
+1  add ⟨⟨i:ts⟩, deps⟩ to a Queues[i]

  STABILIZE( )                       ▸ run asynchronously
+1  for each queue in Queues do
+2    for each ⟨⟨i:ts⟩, deps⟩ in queue do
+3      if deps is ready then        ▸ stability protocol
+4        dequeue ⟨⟨i:ts⟩, deps⟩
+5        ⟨i:ts⟩ → StableVTS

At Worker_i:                   ▸ i denotes the worker number
+ LocalTS                         ▸ monotonic local timestamp

  WRITE(tx, id, data)
:1  acquire lock and get latest ⟨i:ts⟩
 2  add ⟨id, data⟩ to tx.wset
+3  add ⟨i:ts⟩ to tx.deps

  READ(tx, id)
:1  acquire lock and get latest ⟨data, ⟨i:ts⟩⟩
 2  add ⟨id, data⟩ to tx.rset
+3  add ⟨i:ts⟩ to tx.deps
 4  return ⟨data⟩

  COMMIT(tx)
+1  tx.TS ← LocalTS
 2  for each w in tx.wset do
:3    update ⟨w.data, ⟨i:tx.TS⟩⟩ and release lock
 4  for each r in tx.rset do
 5    release lock
+6  Oracle.INSTALL(⟨i:tx.TS⟩, tx.deps)  ▸ NT round trip

  ROTX(tx)                                ▸ snapshot read
+1  tx.TS ← Oracle.StableVTS
+2  for each r in tx.rset do
+3    get ⟨r.data⟩ up to tx.TS
```

Fig. 4: *Using VTS (i.e., blue code lines) to enable consistent snapshots for read-only transactions with 2PL. +N and :N denote new and modified lines of code respectively.*

$\langle 3:5 \rangle$ can be consistently read by read-only transactions.

Maintaining the stable timestamp (StableVTS) becomes more complex in VTS because the per-worker timestamps are not directly comparable [70, 8]. To convey the ordering of transactions to the oracle for deciding StableVTS, workers collect observed timestamps of accessed tuples from other workers (e.g., $\langle 1:2 \rangle$ of C for TX_2). Note that when read-write transactions (TX_1, TX_2, and TX_3) commit, they must send all observed timestamps (*deps*) to the oracle (INSTALL in Fig. 4). Moreover, read-only transactions (TX_4) must request the whole vector timestamp (StableVTS) from the oracle to start a snapshot read.

2.3 Analysis of Network Overhead

We present an in-depth analysis of centralized timestamp schemes[3] and attribute performance overhead and scalability bottleneck to three main aspects:

[3]For brevity, we avoid prior sophisticated optimizations (incl. batching requests [46, 27], timestamp compression and dedicated fetch thread [70]) for timestamps in here, but enable all of them in the evaluation (§5).

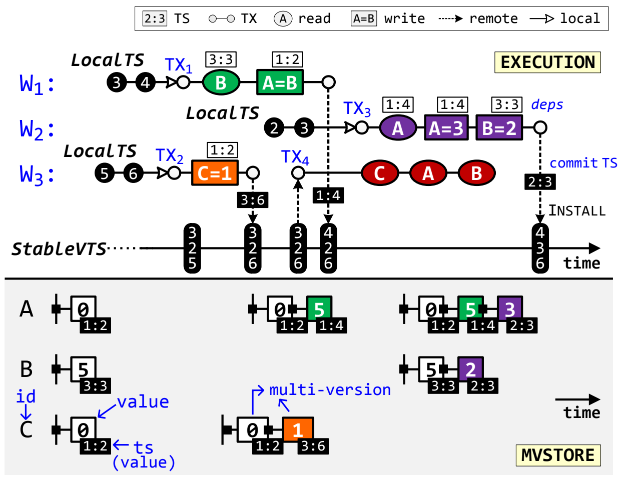

Fig. 5: *A sample case of using VTS, where four transactions (TX_1-TX_4) operate on three tuples (A, B, and C).*

Non-scalable timestamp oracle. Prior work [46, 61, 11, 59, 67, 37] has shown that a centralized timestamp oracle will become the scalability bottleneck of MVCC systems. The throughput of schemes using a shared counter with atomic operations (GTS) [31, 21, 25] is limited to less than 10 M ops/s (GlobalCNT in Fig. 6(a)). The throughput will further decrease due to maintaining the stable timestamp for read-only transactions (+StableTS). VTS mitigates the scalability issue by using a local counter for read-write transactions. Besides, prior work [70] avoids the mechanism for the stable timestamp (reaching close to 40 M ops/s) at the expense of increasing transaction aborts. However, the network will first become the bottleneck for both GTS and VTS (Network). Consequently, the throughput of timestamp oracle (TSOracle) can only reach 1.26 M and 2.39 M ops/s for GTS and VTS respectively, which may be enough for TPC-E (281 K txns/s) but far not enough for TPC-C (1.64 M txns/s) and SmallBank (80 M txns/s) even only scaling out to 16 machines.

Using fast networks can boost the throughput of timestamp oracle, while the performance of transactional systems will also increase much [23, 64, 26, 70], and CPU may first become the bottleneck [59]. Moreover, batching requests [46, 27] or dedicated fetch thread [70] can alleviate the timestamp-related load on the network[4], while these techniques also amplify the staleness of the data retrieved by read-only transactions, and increase the abort rate and the end-to-end latency of read-write transactions (see §5.1).

Costly timestamp allocation. A centralized timestamp scheme will inevitably cause extra network communication overhead for each read-write transaction. GTS demands two network round trips, one for obtaining the commit timestamp and one for installing it. VTS uses per-worker local counters to assign the commit timestamp, but still demands one network round trip to install the timestamp. Given that most transactions operate on tuples in local partitions [56, 54, 55], especially for read-write transactions, additional network round trips will notably lengthen the critical section of trans-

[4]We enabled these optimizations for GTS and VTS in our evaluation (§5).

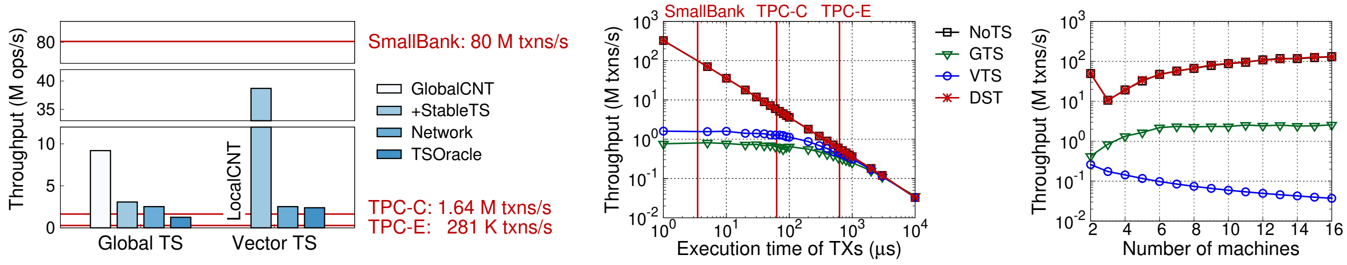

Fig. 6: *(a) Analysis of peak performance and bottleneck of timestamp oracle for GTS and VTS using a 24core machine with 10GbE. (b) The performance of `read-write` transactions with the increase of execution time for different timestamp schemes. The weighted average median latency of read-write transactions in `TPC-E`, `TPC-C` and `SmallBank` are labeled by red lines. (c) The performance of `read-only` transactions with the increase of machines for different timestamp schemes. All experiments are conducted on a local 16-node cluster with 10GbE network (§5). One machine is dedicated for timestamp oracle, even NoTS has no need. Each machine spawns 24 server workers.*

actions and further increase the chance of conflicts, causing extra transaction aborts or blocking time. Thus, it is non-trivial to hide the network round trips without sacrificing the latency of transactions (e.g., batching requests [46, 27]).

The overhead of timestamp allocation highly depends on the execution time of transactions. Hence, we implement a microbenchmark only consisting of read-write transactions, which do not access any tuples and just spin in a loop for a given time. As shown in Fig. 6(b), the overhead of VTS is moderate (from 10% to 30%) compared to not using timestamp schemes (NoTS), when the execution time is close to that of read-write transactions in `TPC-E` (from 1,400μs to 470μs). The throughput will significantly drop more than 80% when transactions execute in about 50μs, which is similar to that of read-write transactions in `TPC-C`. Further, GTS can only achieve half of VTS throughput, since it demands one more round trip to obtain the commit timestamp.

Large traffic size. VTS mitigates the timestamp overhead by using per-worker local counters as the commit timestamp for read-write transactions. However, a critical downside is that a whole vector of per-worker timestamps must be obtained as the read timestamp first, and then be transferred to every tuple for performing consistent snapshot reads. In contrast to the scalar timestamp (e.g., GTS), this overhead grows linearly with the increase of workers or machines in the system. For most transactional workloads [54, 55, 56, 57], the size of the vector timestamp can become orders of magnitude larger than the tuple size, even in a moderate-sized cluster. Using the per-machine counter in VTS (i.e., all workers on one machine share one timestamp slot) can reduce traffic size [8]. However, these workers have to share a local counter by using *atomic* operations (e.g., CAS), which will incur additional overhead on read-write transactions [70].

To demonstrate the impact of traffic size, we implement a microbenchmark only consisting of read-only transactions, which read ten 8-byte tuples with 90% of which being local accesses. In Fig. 6(c), the performance collapse of VTS is due to the increase of timestamp vector obtained from the oracle and transferred to remote tuples. Note that GTS is still one order of magnitude slower due to extra one round-trip to fetch the read timestamp (even scalar), compared to NoTS.

3 Decentralized Scalar Timestamp (DST)

Managing globally ordered timestamps in a centralized service inevitably results in the problem of maintaining the consistency between timestamp ordering and transaction ordering. More importantly, without a holistic decentralized design, the timestamp scheme cannot achieve good scalability. This observation can be backed by the aforementioned performance bottlenecks due to acquiring commit/read timestamps and installing committed timestamps. Such operations add significant overhead to the execution of CC protocols.

To fundamentally overcome the above drawbacks of traditional timestamp schemes, we propose DST, a *decentralized scalar timestamp* that facilitates the multi-version concurrency control (MVCC) implementation for broad CC protocols with efficient snapshot read support and minimal overhead. The intuition behind our design is that *the timestamp scheme can piggyback on concurrency control protocols to maintain the timestamp ordering with low cost and no new scalability bottleneck to read-write transactions*.

In this section, we first use two-phase locking (2PL) as an example to explain the basic protocol of DST for read-write and read-only transactions (§3.1 and §3.2). We then prove the serializability of read-only transactions with DST (§3.3) and introduce a hybrid scalar timestamp to provide snapshot reads with bounded staleness (§3.4). Finally, we discuss the impact of DST on the fault-tolerance scheme (§3.5).

3.1 Timestamps in Read-write Transaction

DST is a fully decentralized timestamp without a centralized sequencer (timestamp oracle) to provide total order timestamps for read-write transactions and stable timestamps for read-only transactions. Therefore, DST must ensure that the derived timestamps for read-write transactions always match the transaction ordering.

The CC protocol is used to ensure the serializable transaction ordering and provide the following three properties, where Transaction A (TX_A) commits before Transaction B (TX_B), and both of them access a conflicting tuple O.

PROPERTY 1: Write-Write. TX_B's write ($W_B(O)$) should overwrite TX_A's write ($W_A(O)$) or generate a newer version.

```
Read-write Transaction: 2PL with DST
At Worker_i:              ▸ i denotes the worker number
+  LocalTS                 ▸ monotonic local timestamp

   START(x)
+1    x.TS ← LocalTS

   WRITE(x, id, data)
:1    acquire lock and get ts
 2    add ⟨id, data⟩ to x.wset
+3    x.TS ← max(x.TS, ts+1)

   READ(x, id)
:1    acquire lock and get latest ⟨data, ts⟩
 2    add ⟨id, data⟩ to x.rset
+3    x.TS ← max(x.TS, ts+1)
 4    return data

   COMMIT(x)
 1    for each w in x.wset do
:2      update ⟨w.data, x.TS⟩ and release lock
 3    for each r in x.rset do
:4      update ⟨x.TS⟩ and release lock
+5    LocalTS ← max(LocalTS, x.TS)
```
Fig. 7: *Specification of* `read-write` *transaction for 2PL with DST. +N and* `:N` *denote new and modified lines of code respectively.*

PROPERTY 2: Write-Read. TX_B's read ($R_B(O)$) should retrieve TX_A's write ($W_A(O)$).

PROPERTY 3: Read-Write. TX_A's read ($R_A(O)$) should not retrieve TX_B's write ($W_B(O)$).

To match the transaction ordering, DST should ensure TX_B's commit timestamp (TS_B) is larger than TX_A's commit timestamp (TS_A) under the above case. The general idea is to piggyback over the CC protocol to derive a commit timestamp from conflicting tuples. Fig. 7 presents how DST is integrated with two-phase locking (2PL), and Fig. 8 also illustrates the execution of sample transactions with DST. DST leverages conflicting tuples and above three properties to transmit commit timestamps between dependent transactions. The additional codes for DST in WRITE, READ, and COMMIT (see Fig. 7) are commented on corresponding operations in the following explanations.

Write-Write property. Transaction TX_A installs value (V_A) with commit timestamp (TS_A) into the tuple O.

$$\begin{aligned} \langle V_A, TS_A\rangle &\rightarrow O \\ TS_A &\rightarrow O.ts && \triangleright\ \textit{line:2} \text{ of } \textsc{Commit} \end{aligned}$$

Transaction TX_B reads the timestamp of tuple O (O.ts) and installs new value (V_B) with a *larger* commit timestamp (TS_B) into the tuple O.

$$\begin{aligned} O.ts &\rightarrow ts && \triangleright\ \textit{line:1} \text{ of } \textsc{Write} \\ max(ts{+}1, TS_B) &\rightarrow TS_B && \triangleright\ \textit{line:3} \text{ of } \textsc{Write} \\ \langle V_B, TS_B\rangle &\rightarrow O \\ TS_B &\rightarrow O.ts && \triangleright\ \textit{line:2} \text{ of } \textsc{Commit} \end{aligned}$$

In Fig. 8, TX_1 (green) commits before TX_3 (purple), and both of them write tuple A. Therefore, the commit timestamp of TX_3 should be larger than that of TX_1. Using DST, TX_1 installs its value (5) with its commit timestamp (TS_1=4) into tuple A. After that, TX_3 should derive a larger timestamp (TS_3=5) from the timestamp of tuple A (A.ts=4) and use it to install new value (3) into tuple A. Note that the write operations will update both the tuple's timestamp and the value's timestamp (as a tuple may have multiple values with different versions).

Write-Read property. Transaction TX_A installs value V_A with its commit timestamp TS_A into tuple O.

$$\begin{aligned} \langle V_A, TS_A\rangle &\rightarrow O \\ TS_A &\rightarrow O.ts && \triangleright\ \textit{line:2} \text{ of } \textsc{Commit} \end{aligned}$$

Transaction TX_B reads value V_A of tuple O with timestamp O.ts and installs a larger commit timestamp TS_B.

$$\begin{aligned} O &\rightarrow \langle V_A, ts\rangle && \triangleright\ \textit{line:1} \text{ of } \textsc{Read} \\ max(ts{+}1, TS_B) &\rightarrow TS_B && \triangleright\ \textit{line:3} \text{ of } \textsc{Read} \\ TS_B &\rightarrow O.ts && \triangleright\ \textit{line:4} \text{ of } \textsc{Commit} \end{aligned}$$

In Fig. 8, TX_1 (green) commits before TX_3 (purple), and TX_1 writes tuple A before TX_3 reads it. Therefore, the commit timestamp of TX_3 should be larger than that of TX_1. Using DST, TX_1 installs its value 5 with its commit timestamp (TS_1=4) into tuple A. After that, TX_3 reads the timestamp of tuple A (A.ts=4) and derives a larger timestamp (TS_3=5).

Read-Write property. Transaction TX_A installs commit timestamp TS_A into tuple O since it has read the value of tuple O.

$$TS_A \rightarrow O.ts \qquad \triangleright\ \textit{line:4} \text{ of } \textsc{Commit}$$

TX_B reads timestamp of tuple O (O.ts) and installs new value V_B with a larger timestamp TS_B into tuple O (O.ts).

$$\begin{aligned} O.ts &\rightarrow ts && \triangleright\ \textit{line:1} \text{ of } \textsc{Write} \\ max(ts{+}1, TS_B) &\rightarrow TS_B && \triangleright\ \textit{line:3} \text{ of } \textsc{Write} \\ \langle V_B, TS_B\rangle &\rightarrow O \\ TS_B &\rightarrow O.ts && \triangleright\ \textit{line:2} \text{ of } \textsc{Commit} \end{aligned}$$

In Fig. 8, TX_1 (green) commits before TX_3 (purple), and TX_1 reads tuple B before TX_3 writes it. Therefore, the commit timestamp of TX_3 should be larger than that of TX_1. Using DST, TX_1 reads an old value (5) of tuple B and installs its commit timestamp (TS_1=4) into tuple B. After that, TX_3 will derive a larger timestamp (TS_3=5) and use it to install new value (2) into tuple B.

3.2 Timestamps in Read-only Transaction

DST ensures that the order of derived commit timestamps for read-write transactions always matches the transaction ordering. Therefore, read-only transactions can directly pick any timestamp (TS_{RO}) to read a consistent snapshot by comparing its read timestamp with the timestamps of tuples.

Since the (snapshot) read-only transaction does not follow the CC protocol (e.g., lock/unlock tuples before/after reading values), the read-only transaction may read a part of updates of a concurrent read-write transaction. For example, in Fig. 8, the read-only transaction TX_4 (red) and the read-write transaction TX_3 (purple) are concurrently executed. If TX_3 commits between the read operations to tuple A and tuple B in TX_4, and then TX_4 will read an old version of tuple A (5) and a new version of tuple B (2).

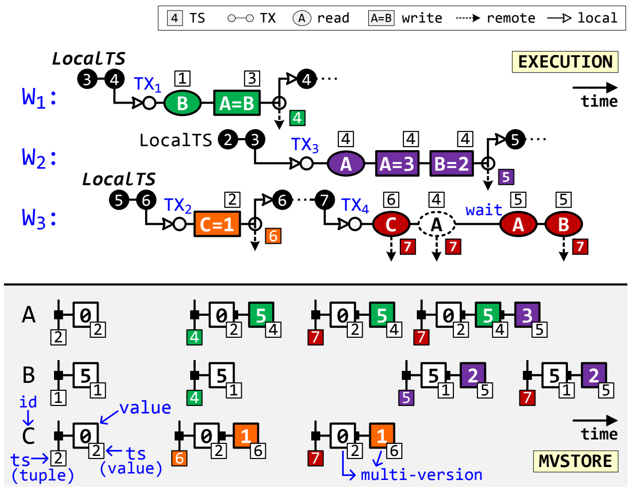

Fig. 8: *A sample case of using DST, where four transactions (TX_1-TX_4) operate on three tuples (A, B, and C).*

To ensure the serializability of read-only transactions, DST asks the read-only transaction to claim its operations actively before reading the tuple. It first installs its read timestamp (TS_{RO}) into the tuple and waits until the conflicting read-write transaction commits (e.g., the tuple is not locked), if the timestamp of the tuple is not larger than the read timestamp (DEP_READ in Fig. 9). Note that the read-only transaction will only wait for at most one conflicting read-write transaction because if the concurrent read-write transaction starts after the claim, it will definitely see the read timestamp through accessing the tuple and derive a larger commit timestamp. Consequently, the read-only transaction will skip all of the updates from this transaction. If the concurrent read-write transaction starts before the claim, it will hold the lock of the tuple. The read-only transaction will wait until the read-write transaction commits. No matter the commit timestamp is larger or smaller than the read timestamp, a read-only transaction can always read a consistent snapshot by ignoring or reading all of the updates from conflicting transactions. Note that CC protocols ensure the atomicity of read-write transaction's updates.

As shown in Fig. 8, the read-only transaction TX_4 will install its read timestamp (TS_4=7) into tuples with smaller tuple timestamps (*line:1* of DEP_READ in Fig. 9). For unlocked tuple C, TX_4 will directly read the value up to the timestamp (1). For locked tuple A and B, TX_4 will wait until the concurrent read-write transaction TX_3 commits. In this example, since TX_3 does not see the read timestamp of TX_4, the commit timestamp of TX_3 is still smaller than the read timestamp of TX_4 (5 vs. 7). Hence, TX_4 can read all updates from TX_3 (A=3 and B=2).

3.3 Proof of Correctness

Theorem (Serializability). *DST implements serializable read-only transactions, which always read a consistent snapshot generated by serializable read-write transactions.*

Proof sketch. The intuition of the proof is that if a read-only transaction can be serialized with read-write transactions, then it reads a consistent snapshot. We provide a proof sketch by contradiction based on this intuition: i.e., if a read-only transaction cannot be serialized with read-write transactions, then it leads to a contradiction. Before giving the proof, we need to prove following two lemmas first:

```
Read-only Transaction: 2PL with DST
At Worker_i:                    ▸ i denotes the worker number
+  LocalTS                      ▸ monotonic local timestamp

   ROTX(x)                      ▸ snapshot read
+1    x.TS ← LocalTS
+2    for each r in x.rset do
+3       DEP_READ(x, r)

   DEP_READ(x, r)
+1    if r.ts <= x.TS then
+2       r.ts ← x.TS             ▸ atomic (CAS)
+3       wait until r not Locked ▸ if conflict
+4    get ⟨r.data⟩ up to x.TS
```

Fig. 9: *Specification of* `read-only` *transaction for 2PL with DST.*

Lemma 1. *Given two dependent read-write transactions TX_1 and TX_2, if TX_2 depends on TX_1, then TX_2's timestamp (TS_2) is larger than TX_1's timestamp (TS_1).*

Proof. If TX_2 directly depends on TX_1[5], this lemma follows directly from the algorithm (see §3.1) that TX_2 always calculates TS_2 based TS_1. If TX_2 transitively depends on TX_1, in a proof by contradiction we assume TS_1 is not smaller than TS_2, then in the partial dependent graph denoted by $TX_1 \rightarrow \ldots \rightarrow TX_i \rightarrow TX_j \ldots \rightarrow TX_2$[6], there exists TX_i and TX_j that TX_j directly depends on TX_i, but its timestamp is not larger than TX_i's, which is a contradiction with the first case. □

Lemma 2. *Given a read-only transaction TX_{RO} and a read-write transaction TX_{RW}, TX_{RO} observes TX_{RW}'s update on tuple O[7], if and only if TX_{RO}'s timestamp (TS_{RO}) is not smaller than TX_{RW}'s timestamp (TS_{RW}).*

Proof. First, if TX_{RO} observes TX_{RW}'s update on O, then TS_{RO} is not smaller than TS_{RW}. Because TX_{RW} updates O with TS_{RW} and content atomically (e.g., 2PL), TX_{RO} waits for TX_{RW}'s commit. Second, if TS_{RO} is not smaller than TS_{RW}, then TX_{RO} eventually observes TX_{RW}'s update on O. Assume TX_{RO} does not observe TX_{RW}'s update, then TX_{RO} reads O before TX_{RW} commits its update. One situation is TX_{RO} reads O before TX_{RW}'s request arrives, it leads a contradiction that TX_{RO} update O's timestamp to be TS_{RO} before the read. Another situation is TX_{RO} reads O after TX_{RW} calculates TS_{RW}, but before committing its update. This leads to the contradiction that TX_{RO} always waits for the concurrent TX_{RW} to commit (e.g., 2PL). □

Proof of the Theorem. TX_1 updates A, TX_2 updates B, and TX_2 depends on TX_1. Assume read-only transaction TX_{RO} only observes TX_2's update on B, but does not observe TX_1's

[5] TX_2 is conflicting with TX_1, and TX_2 accesses the conflicting tuples immediately after TX_1.

[6] The symbol $\rightarrow$ indicates the happen-before relation.

[7] It means TX_{RO}'s read on O happens after TX_{RW}'s update.

update on A (i.e., inconsistent reads).[8] From LEMMA 2, we have $\mathsf{TS_{RO}}$ is not smaller than $\mathsf{TS_2}$, while $\mathsf{TS_1}$ is larger than $\mathsf{TS_{RO}}$. Therefore, we have $\mathsf{TS_1}$ is larger than $\mathsf{TS_2}$, which is contradictory to LEMMA 1. □

3.4 Hybrid Timestamp and Bounded Staleness

Hybrid timestamp. The commit timestamp of a read-write transaction is derived from the timestamps of tuples in its read/write set, and the read timestamp of a read-only transaction can be any timestamp in the past, at present, or even in the future. Therefore, the local timestamp (LocalTS) is not essential for the correctness of DST. However, the read-only transaction may suffer from either staleness or performance issues if using an improper read timestamp. If the read timestamp is too small (past), the read-only transaction may read an excessively stale snapshot. If the read timestamp is too large (future), the read-only transaction will frequently install its read timestamp into tuples and wait until conflicting read-write transactions commit (DEP_READ in Fig. 9).

DST adopts a combination of *physical* clock and *logic* counter as a hybrid timestamp. The 64-bit timestamp consists of the 48-bit physical part (high-order bits) and the 16-bit logic part (low-order bits). DST uses a loosely synchronized clock as the physical part and uses a monotonically increasing counter as the logical part. At the beginning of the transaction, it will acquire a local hybrid timestamp composed of the current physical clock and zero-initialized logic counter (START in Fig. 7 and *line:1* of ROTX in Fig. 9). The logical part of the hybrid timestamp is used to avoid possible overflow of the physical part since the timestamp will be incremented when calculating the maximum timestamp (e.g., *line:3* of WRITE in Fig. 7). On the other hand, the physical part of the hybrid timestamp is used to ensure the read-only transaction can read a fresh snapshot.

Bounded staleness. Based on the hybrid timestamp, DST can provide snapshot reads with bounded staleness.

THEOREM (BOUNDED STALENESS). *The updates of read-write transactions can be observed in at most Δ, where Δ is the maximal duration any machine needs to make its local clock increased by $2 \times \varepsilon$, and ε is the maximal clock drift between any two machines in the cluster.*

PROOF SKETCH. First, we prove the following two lemmas:

LEMMA 1. *Given a read-write transaction $\mathsf{TX_{RW}}$, its commit timestamp ($\mathsf{TS_{RW}}$) is not larger than $t_m + \varepsilon$, where t_m is the local machine time on $\mathsf{TX_{RW}}$ commits.*

PROOF. If $\mathsf{TS_{RW}}$ is larger than $t_m + \varepsilon$, then there is a $\mathsf{TX_i}$ which accesses a tuple before $\mathsf{TX_{RW}}$, and $\mathsf{TS_i}$ is larger than $t_m+\varepsilon$. As the timestamp is calculated from its local machine time or the tuples it accessed, we can inductively find a transaction $\mathsf{TX_j}$ whose timestamp is larger than $t_m + \varepsilon$, and it is calculated from its local machine time. It is a contradiction to the maximal clock drift between any two nodes is ε. □

[8]The proof is also correct for $\mathsf{TX_1}$ and $\mathsf{TX_2}$ are the same transaction.

LEMMA 2. *For any read-only transaction $\mathsf{TX_{RO}}$ starts after $\mathsf{TX_{RW}}$ commits, its read timestamp $\mathsf{TS_{RO}}$ is larger than $t_m - \varepsilon$.*

PROOF. This follows that $\mathsf{TX_{RO}}$ calculates its timestamp based on local machine time and the clock drift between any two nodes cannot be larger than ε. □

PROOF OF THE THEOREM. With LEMMA 1 and 2, we can have a fact that, if $\mathsf{TX_{RO}}$ starts after $\mathsf{TX_{RW}}$, then $\mathsf{TS_{RO}}$ cannot be smaller than $\mathsf{TS_{RW}}-2 \times \varepsilon$. Since any machine is able to increase its local machine time by $2 \times \varepsilon$ in Δ, we can conclude that the updates of $\mathsf{TX_{RW}}$ will be visible in the duration of Δ. □

3.5 Failure and Recovery

The CC protocol should provide a proper fault-tolerance scheme to recover the transactional system from various failures. For example, the primary-backup replication [30] is widely used to provide high availability in prior work [23, 18, 26]. The fault-tolerance schemes can usually work with various timestamp schemes by replicating tuples together with the commit timestamps of read-write transactions. However, the fully decentralized design of DST has two sides. The advantage of this approach is to avoid handling the failure of centralized timestamp oracle, which may cause a stop-the-world recovery [70]. The disadvantage is the potential cost to maintain the consistency of decentralized timestamps before and after some failure occurs.

An obvious, but costly solution is to replicate the read timestamps of read-only transactions together with tuples, as the commit timestamps of read-write transactions. Because the missing read timestamp may cause a new conflicting read-write transaction to use a smaller commit timestamp to write tuples; the read-only transaction may read some tuples with an old version and other tuples with a new version before and after the failure occurs, respectively.

To avoid replicating or persisting read timestamps, DST provides two alternative solutions that can be selected according to the behavior of workloads or the CC protocol associated. More specifically, after recovery, DST can selectively abort and re-execute either the remaining read-only transactions that read tuples on crashed machines or the remaining read-write transactions that write tuples on crashed machines. Consequently, there is no additional overhead and modification associated with the normal execution of transactions, regardless of which approach is selected.

4 Generality of DST

DST is a general timestamp scheme to enable efficient read-only transactions with little impact on read-write transactions. Hence, it is easy to integrate DST with various CC protocols, and DST can also cooperate with many optimizations [37, 43] on CC protocols. In this section, we first lay out a general guideline for piggybacking DST on various CC protocols, and then demonstrate the efficacy of this guideline by applying it to three representative transactional systems

(DrTM+R, MySQL cluster, and ROCOCO) with different CC protocols (OCC, 2PL, and ROCOCO).

4.1 A Guideline for Integrating DST

Read-write transaction. DST should allocate a commit timestamp for the read-write transaction that is larger than any dependent transactions' timestamp. Thus, two following tasks (`RW1` and `RW2`) should piggyback on CC protocols.

1. *select a commit timestamp larger than both the current local timestamp and the timestamps of tuples in the read/write set.* (`RW1`)
2. *install the commit timestamp to tuples in the read/write set before the transaction commits.* (`RW2`)

Read-only transaction. DST should guarantee the read-only transaction can read the value of tuples up to the read timestamp. Thus, two following tasks (`RO1` and `RO2`) should piggyback on CC protocols.

1. *select an appropriate read timestamp according to the current local timestamp.* (`RO1`)
2. *ensure the tuple has an equal or larger timestamp before reading its value up to the read timestamp.* (`RO2`)

4.2 Case Study

The description below focuses on the general comments about integrating DST; we omit a few details and corner cases due to space limitations.

DrTM+R. Optimistic concurrency control (OCC) is widely adopted by modern transactional systems [21, 10, 59, 62, 22, 23, 18, 26, 63]. The read-only transaction in OCC will take two or more rounds of reads for consistent results without MVCC and timestamp schemes, due to conflicting read-write transactions. We use DrTM+R [18] to demonstrate how DST piggybacks on OCC.[9]

For the read-write transaction, we can obtain the timestamp of tuples in the read and write set when validating and locking them respectively and then derive a larger commit timestamp (`RW1`). Before committing, we should install the commit timestamp to the tuples in the read and write set (`RW2`). Note that there is no need to lock tuples in the read set since dummy timestamps from aborted transactions are benign. For the read-only transaction, all CC protocols share (almost) the same implementation (see Fig. 9). The only difference is how to wait for conflicting transactions (*line:3* of DEP_READ). For OCC, the conflicting read-write transaction will lock the tuple when installing its timestamp for updates. Therefore, similar to 2PL, the read-only transaction will confirm that the tuple is not locked before reading the value up to its read timestamp.

MySQL cluster. Two-phase locking (2PL) is another classic CC protocol used by many transactional systems [1, 19, 36]. The read-only transaction in 2PL will be blocked without MVCC and timestamp schemes, due to conflicting read-write transactions. We use MySQL cluster [1] (v7.6.8) to show the integration of 2PL and DST, mainly following the specification in Fig. 7 and 9.[10] To support the read-write lock in MySQL cluster, the transaction only needs to install timestamp into tuples in the read set atomically (i.e., compare-and-swap) and avoids overwriting a larger timestamp. Further, we leverage the lock queue mechanism in MySQL cluster to wait for conflicting transactions (*line:3* of DEP_READ in Fig. 9), which avoids spinning on the tuple.

[9]We use the version of DrTM+R [63] without HTM, which also enables coroutine and supports various networks (e.g., TCP/IP and RDMA).

Table 1: *Measurement clusters.*

Name	#	Hardware
AWS	32	r4.2xlarge (8x vCPU, 61GB DRAM, up to 10GbE)
VAL	16	2x Intel Xeon E5-2650 v4 (12 cores), 128GB DRAM, 1x Intel I350 10GbE
VLR	16	2x Intel Xeon E5-2650 v4 (12 cores), 128GB DRAM, 2x Mellanox ConnectX-4 100Gbps InfiniBand RNICs

ROCOCO. ROCOCO [43] is a research CC protocol that outperforms traditional protocols under high contention workloads by reordering conflicting read-write transactions instead of aborting them. The read-write transaction is chopped into pieces by an offline checker and uses a two-phase mechanism. The *start* phase explores a dependency graph, and then the *commit* phase executes conflicting transactions with a serializable order according to the dependency graph. The read-only transaction in ROCOCO is blocked until the completion of conflicting transactions and uses multiple rounds for reading consistent results.

To extend ROCOCO[11] with DST, the general idea is to use the dependency graph to collect timestamps of dependent tuples and derive a larger commit timestamp for the read-write transaction in the start phase (`RW1`). Then the commit timestamp can be installed to tuples in the commit phase (`RW2`). For the read-only transaction, the blocking mechanism in ROCOCO is reused to wait for conflicting transactions (*line:3* of DEP_READ in Fig. 9).

5 Evaluation

We have integrated DST with three representative transactional systems, namely DrTM+R, MySQL cluster, and ROCOCO, with different CC protocols, and also implemented two centralized timestamp schemes (GTS and VTS) by following the state-of-the-art [46, 70][12] with many carefully tuned optimizations (e.g., batching requests [46, 27], cooperative multitasking [26], timestamp compression and dedicated fetch thread [70]). These optimizations have significant performance improvements on GTS and VTS. For example, cooperative multitasking improves the peak per-machine throughput of GTS on DrTM+R by 3.04X, and timestamp compression improves VTS by 2.7X on a 16-node cluster.

Testbed and setup. To study the impact of hardware plat-

[10]Although MySQL cluster uses read committed (RC) protocol by default, it also provides serializability by using per-row 2PL.

[11]Source code: `https://github.com/shuaimu/rococo`.

[12]Different than Percolator [46], we use the stabilization process to avoid holding locks when acquiring write timestamp, since it will significantly increase transaction abort rate.

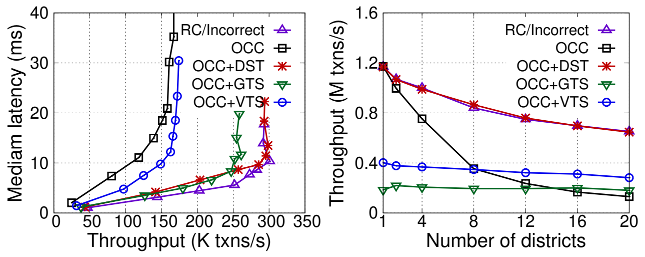

Fig. 10: *Performance of (a)* `TPC-E` *and (b)* `TPC-C` *on AWS.*

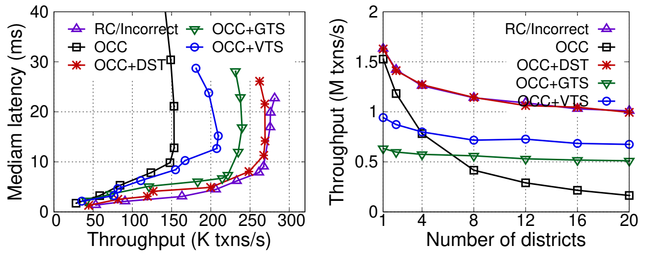

Fig. 11: *Performance of (a)* `TPC-E` *and (b)* `TPC-C` *on VAL.*

forms on DST, we use three clusters with different networks and CPU processing power (Table 1). Without explicit mention, one machine in each cluster is dedicated to the timestamp oracle, even only GTS and VTS need. Other machines serve as both database nodes and clients. We use these machines in a *symmetric* setting [23], namely each machine both executes transactions and store database data.

Benchmarks and performance overview. As the performance benefit of using MVCC and snapshot reads is sensitive to characteristics of read-only transactions in OLTP workloads, we chose three different benchmarks, namely `TPC-E`, `TPC-C`, and `SmallBank`, to show the benefits of DST comprehensively. `TPC-E` [57] presents the workload of a brokerage firm with a high proportion of read-only transactions (79% of the standard mix) and complicated operations (massive range queries and distributed accesses). DST is expected to improve the performance much compared to the vanilla CC protocols for this target workload, with *a relaxed consistency level from strict serializability to serializability*. `TPC-C` [56] simulates a warehouse-centric order processing application with a few read-only transactions (8% of the standard mix). DST is expected to show gradual improvement with the increase of execution time in read-only transactions (not affect proportion). We increase the number of districts (one district by default) accessed by the read-only `stock-level` transactions (4%). `SmallBank` [54] models a simple banking application where transactions perform very simple read and write operations (less than four) on user accounts. DST is expected not to incur perceptible overhead and show order-of-magnitude speedup compared to centralized timestamp schemes (GTS and VTS). In all benchmarks, DST should achieve close to optimal performance using RC (5%) but without compromising correctness, which can be backed by the experimental results of DST on motivating microbenchmarks (see Fig. 6).

5.1 DrTM+R

We deploy one server at each machine and co-locate clients to saturate the performance of servers as prior work [58, 60, 23, 64, 26]. Due to space limitations, we do not report the experimental results on `SmallBank`, which are as expected.

TPC-E. Fig. 10(a) shows the results of `TPC-E` on AWS. `TPC-E` has a high proportion of read-only transactions, and most of them are distributed. Compared to using snapshot reads (GTS, VTS, and DST), the vanilla OCC protocol provides *strict serializability* and requires an additional round to validate tuples in the read set. Thus, many read-only transactions will abort under heavy workloads. As a reference, RC can outperform OCC by 1.79X (yet with incorrect results), since it simply skips the validation phase. DST achieves almost the same performance as RC, as it also avoids the validation phase and never aborts read-only transactions. Differently, DST ensures the read-only transaction can read a consistent yet fresh snapshot. Moreover, compared to GTS and VTS with the same consistency level (*serializability*), DST can outperform the throughput of them by 1.16X and 1.72X, respectively. Because DST omits the communication to the timestamp oracle and avoids large traffic size due to using a fully decentralized design and scalar timestamps (see §2.3).

We further evaluate `TPC-E` on VAL. As shown in Fig. 11(a), DST can still achieve similar performance as RC and provides 1.13X and 1.29X speedup compared to GTS and VTS, respectively. VTS performs slightly better on VAL due to using a relatively smaller vector timestamp.

TPC-C. Fig. 10(b) and Fig. 11(b) show the peak throughput of `TPC-C` on AWS and VAL with the increase of districts accessed by the read-only `stock-level` transactions. Note that the default setting in `TPC-C` accesses one district (the first data point of every line). Besides, we retain all default settings, like the proportion of `stock-level` transactions (4%).

As shown in Fig. 10(b), when accessing one district, DST has a very close performance compared to RC. These results indicate that DST has little overhead to read-write transactions. In comparison to DST, GTS and VTS are 6.29X and 2.93X slower than RC, due to the significant cost for maintaining centralized and/or vectorized timestamps (see §2.3).

OCC performs well on the original TPC-C due to the limited read-only transactions in the standard-mix (8%). On the other hand, when increasing the execution time of read-only `stock-level` transactions (by accessing more districts), the performance difference between RC and OCC is more evident because OCC has more overheads for validating the read-set of the `stock-level`. DST still performs close to RC and is 4.94X faster than vanilla OCC (accessing 20 districts) with a relaxed consistency level. Finally, DST still outperforms VTS and GTS by 2.29X and 3.56X when accessing 20 districts, respectively.

In Fig. 11(b), the performance of DST is also very close to RC for `TPC-C` on VAL. On the other hand, the overhead of GTS and VTS still incurs up to 2.57X (from 1.95X) and 1.73X (from 1.47X) slowdown, compared with DST. Differ-

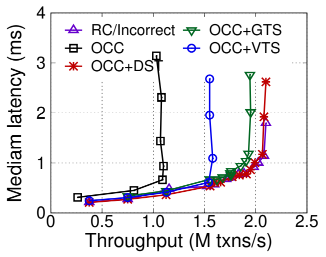

Fig. 12: *Performance of (a)* `TPC-E` *and (b)* `TPC-C` *on VLR.*

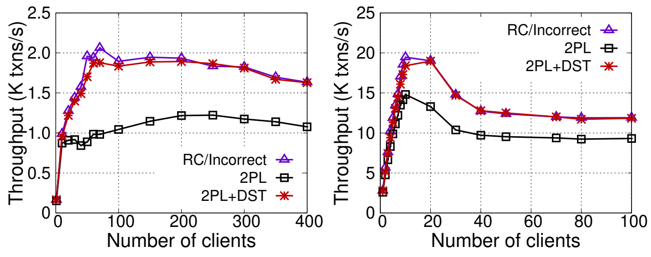

Fig. 13: *Performance of (a)* `TPC-C` *and (b)* `SmallBank` *for MySQL cluster with different CC protocols on VAL.*

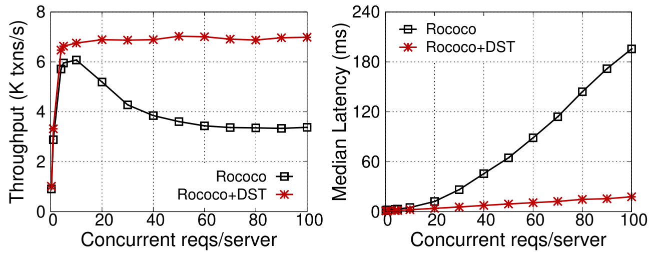

Fig. 14: *(a) Throughput of* `new-order` *transactions and (b) median latency of* `stock-level` *transactions in* `TPC-C` *mixed workload.*

ent than AWS, the lower latency of network round-trip on VAL (90μs) is beneficial for centralized timestamp schemes, but the effect is quite limited.

Using fast network (i.e., RDMA). Readers might be interested in how the performance of networks impacts the performance of timestamp schemes, especially using RDMA. DrTM+R naturally supports RDMA, and we adopt FaSST-RPC [26] to implement the timestamp oracle for GTS and VTS. By using 100Gbps RDMA, the CPU may become the bottleneck in the timestamp oracle for GTS, about 3.0 M ops/s (see §2.3). For VTS, the timestamp oracle will not limit the performance of `TPC-E` and `TPC-C` with only 16 machines, while the increase of transaction abort rate (due to optimizations [70]) and large traffic size still incur non-trivial costs, compared to the decentralized scalar timestamp (like DST).

As shown in Fig. 12, the fast network (RDMA) in VLR has a significant positive impact on all of the settings, as expected. For `TPC-E`, DST still outperforms GTS and VTS by 1.07X, and 1.32X, respectively. RDMA reduces the overhead of centralized timestamp allocation for GTS, while the impact of traffic size in VTS remains. For `TPC-C`, DST is still 4.49X (from 1.19X) and 1.76X (from 1.15X) faster than GTS and VTS.

5.2 MySQL cluster

We evaluate MySQL cluster with DST by using `TPC-C` and `SmallBank` on VAL. We increase the number of clients until the throughput is saturated. As shown in Fig. 13, with DST, MySQL cluster achieves up to 1.91X (from 1.09X) and 1.28X (from 1.07X) higher throughput for `TPC-C` and `SmallBank`, respectively. The main reason is due to enabling snapshot reads to avoid blocking for the read-only transactions. It also mitigates the contention in the read-write transactions. DST is more effective in `TPC-C` since it is more sensitive to blocking time from conflicting transactions due to relatively longer execution time compared to `SmallBank`. On the other hand, DST can provide comparable performance to RC but still guarantee serializability for correctness.

5.3 ROCOCO

We follow the methodology (benchmarks and settings) in prior work [43, 39] to evaluate ROCOCO on VAL.[13] Fig. 14 shows the performance of ROCOCO by increasing the number of concurrent requests per server. In Fig. 14(a), using DST on ROCOCO can improve the throughput of `new-order` transactions by 2.09X with 100 concurrent requests per server, due to reducing transaction aborts and skipping the validation process in read-only transactions. For example, less than 4% of `stock-level` transactions can be committed when there are more than 50 concurrent requests per server. Thus, the server CPU is wasted on retrying and validating read-only transactions. Further, as shown in Fig. 14(b), ROCOCO+DST has a much lower median latency of (read-only) `stock-level` transactions, thanks to reading a consistent snapshot by one round of execution without validation.

[13]We try our best to compare with ROCOCO-SNOW [39], which also optimizes the read-only transaction of ROCOCO. Unfortunately, it failed to run on our testbed.

5.4 A Study of DST Cost

To study the overhead from blocking and additional timestamp updates in DST, we use two workloads that share most characteristics with `TPC-C`. We tuned the workload behavior to better reflect these overheads.

Blocking overhead. One read-only transaction accesses 10 tuples, while another write-only transaction continuously updates these tuples with locking. This is considered as the worst-case scenario for DST, since the read tuples are locked most of the time. Fig. 15(a) shows the impact on the median latency of read-only transactions when varying the staleness of read timestamps. When using the current time (staleness=0ms) as the read timestamp, 10% of the reads are blocked by concurrent writes, which incur 83% overhead of the median latency (1.72ms vs. 0.96ms). With the increase of staleness (smaller timestamp), fewer reads are blocked since the tuples have been updated with larger commit timestamps. The blocking overhead becomes trivial when staleness exceeds 100ms. Note that this is an extreme case for blocking: reads always touch the locked tuples. In reality, we only observe about 160 and 200 blocks per second at each machine

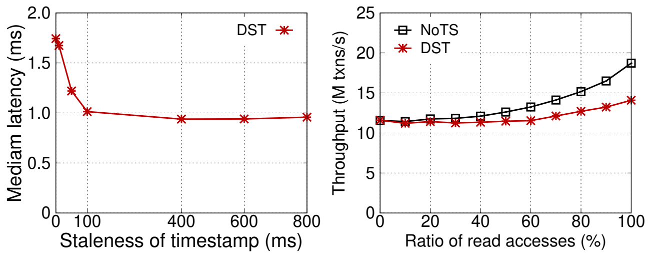

Fig. 15: *(a) The impact of latency for read-only transactions by using stale timestamp. (b) The overhead of DST with the ratio increase of read-only accesses in read-write transactions.*

under peak throughput for `TPC-E` and `TPC-C`, respectively.

Timestamp update overhead. Fig. 15(b) presents the overhead of DST to read-write transactions. Each transaction accesses 10 tuples, while some tuples are made read-only. We can see that when all tuples are updated, there is no overhead for DST, since the timestamp update will piggyback on the unlock operation. With the increase of read(-only) ratio, DST adds up to 25% overhead to the overall performance. Because DST will update the timestamp of tuples even just reading them, which requires additional synchronizations using atomic operations. Fortunately, most of the read and write sets are overlapping in OLTP workloads.

6 Discussion

Performance overhead. Compared to traditional centralized timestamp schemes, DST needs to update the timestamps of tuples in the read set for read-write transactions, which may incur additional costs. However, these operations can easily piggyback on original operations in CC protocols (see Fig. 7), like the locking and the validating in 2PL and OCC, respectively. Moreover, the read-only transaction may also update the timestamps of tuples, while it only happens as the read timestamp is larger (DEP_READ in Fig. 9). Thus, using a hybrid timestamp can effectively mitigate it. To study the potential performance overhead for DST, we designed two microbenchmarks to model the worst-case scenarios (see §5.4), and the experimental results show limited cost.

Range scans and phantom reads. DST relies on the CC protocol to detect conflicts, including range scans and phantom reads, and also needs to assign timestamps to certain "guard" (e.g., index structures) [32, 48]. For example, the next-key locking mechanism [42] is widely used by 2PL to support range scans. The CC protocol acquires such locks, and DST assigns timestamps to them. For OCC, DST assigns timestamps to the internal nodes in the index structure as the versions during the validation phase.

The SNOW theorem. The SNOW Theorem [39] describes the fact that strict serializability (`S`), non-blocking read-only transactions (`N`), one-response from each tuple (`O`), and compatible with conflicting write transactions (`W`) cannot be satisfied at the same time. Yet, SNOW-optimal and latency-optimal read-only transactions can achieve three of the above properties (i.e., `N+O+W`) without strict serializability (`S`). DST also relaxes `S` to serializability for read-only transactions, and satisfies `O` and `W` apparently. DST can simply satisfy `N` by letting reads return a relatively stale data. However, it may be not reasonable; thus, DST chooses to provide bounded staleness with much fewer blocking operations (see §5.4).

Session strict serializability. DST only ensures *serializability* to read-only transactions rather than *strict serializability*, while it is equal to or better than most snapshot-based systems [39, 19, 6, 1]. Further, DST can provide session guarantees [53, 8] (i.e., read-my-write [52] and read-after-write [40] consistency), such that read-only transactions can always observe the latest updates of read-write transactions within the same session (e.g., issued from the same client or handled by the same server). DST returns the commit timestamp to the session manager (e.g., client or server) after the transaction commits. The session manager will always use the largest observed commit timestamp as the read timestamp for successive read-only transactions.

7 Related Work

Using timestamp for snapshot reads. A centralized timestamp is the most straightforward way to support MVCC for snapshot reads, which is widely adopted by centralized systems [21, 25, 31, 28, 44, 66, 33]. Many distributed systems also use timestamps to provide MVCC [46, 17, 51, 19, 6, 14, 70], while most of them only support weaker isolation guarantees (e.g., Snapshot Isolation) [46, 6, 14, 70]. For example, Percolator [46] uses a global timestamp oracle, and NAM-DB [70] uses vectorized centralized timestamps. Spanner [19] is based on a combination of 2PL and MVCC developed in previous decades [45]. Spanner relies on TrueTime API to provide scalable timestamps for strict serializable read-only transactions and snapshot reads, which requires specific hardware (GPS and atomic clocks) to ensure clocks with bounded uncertainty. Further, the read-write transactions still require blocking to ensure the match of timestamp and transaction ordering. DST chooses to support serializable read-only transactions with bounded staleness. It requires no external timestamp service and does not block read-write transactions. RAMP [9] introduces Read Atomic isolation and uses timestamps to identify and retry inconsistent reads. TxCache [47] provides a distributed transactional cache that always returns a consistent snapshot by lazily selecting the timestamps for transactions. Causalspartan [49] also uses Hybrid Logical Clocks to optimize timestamps in causal consistency systems.

DST naturally piggybacks timestamp allocation to existing CC protocols, which avoids additional communications for maintaining timestamps. Further, DST can work with a border range of CC protocols and is orthogonal to prior optimizations on CC protocols [37, 43].

Using timestamp for concurrency control. Many systems directly leverage a timestamp-based mechanism to commit transactions orderly [12, 5, 20, 34, 35, 71, 8]. CLOCC [5] combines optimistic timestamp ordering with loosely synchronized clocks, which avoids a centralized counter for checking serializability in the original OCC protocol [29]. Granola [20] uses the timestamp based on a distributed voting mechanism to order independent transactions deterministically and treats distributed transactions in locking mode. TAPIR [71] uses loosely synchronized clocks at the clients in OCC's validation for read-write transactions. The clock drift in these systems will increase false aborts and impact the execution of read-write transactions. On the contrary, the clock drift in DST only affects the freshness of snapshot reads.

Several variant timestamp schemes have been proposed to *mitigate the cost from frequent aborts due to the violation between timestamp and transaction ordering*. Lomet et al. [38] introduce timestamp ranges to reduce transaction conflicts, while the timestamp management is centralized. MaaT [41] uses dynamic timestamp ranges to avoid distributed locking for the atomic commitment in OCC. Further, some prior systems also use decentralized timestamp schemes, but most of them focus on *optimizing one particular CC protocol*. TicToc [68] introduces a data-driven timestamp scheme for multicore platforms, which allows each read-write transaction to compute a valid commit timestamp from tuples before it commits. However, the read-only transaction still needs additional validations and incurs more aborts due to conflicts. Clock-SI [24] also uses loosely synchronized clocks to create consistent snapshots with fewer network round trips, while snapshot reads must be delayed due to concurrent transactions and clock drift. Sundial [69] uses logical timestamps as leases to reduce aborts in distributed read-write transactions. Pelieus [52] derives a commit timestamp for the read-write transaction from all involved servers (not tuples), which is used in the validation phase with different rules to support different concurrency levels (e.g., SI and Serializability).

Differently, DST is a decentralized timestamp scheme for various CC protocols and can piggyback on them efficiently. Thus, DST will not interfere with the execution of read-write transactions and has no need of extra validations and aborts.

8 Conclusion

This paper presents DST, a decentralized scalar timestamp that can unify timestamp management with existing CC protocols. We have integrated DST with two classic protocols, namely 2PL and OCC, and a recent research proposal, ROCOCO. Our evaluation with three transactional systems and three benchmarks confirmed the benefit of DST.

9 Acknowledgment

We sincerely thank our shepherd Irene Zhang and the anonymous reviewers for their insightful comments and feedback. We also thank Hong Yang for porting DST to ROCOCO. When to Hedge in Interactive Services

Abstract

In online data-intensive (OLDI) services, each client request typically executes on multiple servers in parallel; as a result, "system hiccups", although rare within a single server, can interfere with many client requests and cause violations of service-level objectives. Service providers have long been fighting this "tail at scale" problem through "hedging", *i.e.,* issuing redundant queries to mask system hiccups. This, however, can potentially cause congestion that is more detrimental to tail latency than the hiccups themselves.

This paper asks: when does it make sense to hedge in OLDI services, and how can we hedge enough to mask system hiccups but not as much as to cause congestion? First, we show that there are many realistic scenarios where hedging can have no benefit—where *any* hedging-based scheduling policy, including the state-of-the-art, yields no latency reduction compared to optimal load balancing without hedging. Second, we propose LÆDGE, a scheduling policy that combines optimal load balancing with work-conserving hedging, and evaluate it in an AWS cloud deployment. We show that LÆDGE strikes the right balance: first, unlike the state of the art, it never causes unnecessary congestion; second, it performs close to an ideal scheduling policy, improving the 99th percentile latency by as much as 49%, measured on 60% system utilization—without any difficult parameter training as found in the state of the art.

1 Introduction

This work concerns Online Data-Intensive (OLDI) services like web search (searching through inverted document indices), content-based image similarity search, recommendation services, graph processing and social applications. Such services involve hundreds or thousands of "leaf" nodes, each holding a part ("shard") of the data needed to answer client requests; a tier of "root" nodes receives client requests, breaks each client request into distinct queries, forwards the queries to different leaves, and waits for the slowest query to finish in order to create the final client response.

OLDI services typically operate under hard-to-meet service-level objectives (SLOs) expressed in terms of tail latency [7, 8, 16, 18, 32, 36, 37, 40]. Each SLO captures a customer expectation and failing to meet it has concrete consequences, *e.g.,* a hit to the service provider's reputation, a loss of customers, and a drop in revenue [11, 15, 23, 73]. The nature of OLDI services makes meeting such SLOs challenging at large scale: because answering a client request involves many queries, a small fraction of slow queries can impact a significant fraction of client requests [16].

We focus on two main causes of latency variability: One is variable queuing delay, *e.g.,* due to load fluctuations [16, 20, 31, 62]. Another one is variable service time, which, in turn, comes from two distinct sources: (1) Different queries may take different amounts of time to execute on a given hardware and software stack, because of different complexities [33, 44, 53, 81]. (2) Different instances of the same query may take significantly different amounts of time to execute on a given system because of system events that are unrelated to the service itself: decisions made by an OS scheduler or power-management algorithm, interrupts, garbage collection, virtualization effects, interfering with other applications, *etc.,* [12, 16, 19, 26, 41–43, 46–48, 54, 57, 59, 69, 75, 80].

Even though a lot can and has been done to reduce latency variability, completely eliminating its causes has proved elusive. In a modern cloud environment, where different services share resources, there always exist unexpected performance "hiccups". Debugging these hiccups is notoriously hard. For instance, there is the case of an application suffering random 12*ms* scheduling delays, because a kernel feature caused the jitter of interrupt requests to be significantly higher than the timer interval [12]; or the case of non-work-conserving scheduling, in which the kernel was throttling programs that exceeded a misconfigured purchase quota [69]. But even when performance hiccups are easy to debug, fixing them is often beyond the control of the interested parties: most service providers do not own a datacenter and do not develop their

[*]The project was completed while the author was at EPFL.

own operating systems and entire software stacks—yet they still offer interactive services that need to meet strict SLOs.

This reality has given birth to *hedging*. In a modern large-scale service, each data shard is typically replicated in at least two nodes for fault tolerance [16, 55]. Hence, any query for a distinct shard can be replicated and sent to multiple nodes that serve that shard. This way, the system "hedges its bets", as it needs to wait only for the fastest response to each query. Hedging was initially proposed and adopted in combination with performance monitoring, to improve completion time of map-reduce-style [17] jobs that may take tens to hundreds of seconds [3–5]. More recently, hedging is proposed as a general solution for reducing tail latency in large-scale services, including OLDI services [16, 25, 32, 37, 39, 40, 64, 67, 72, 74, 78], where expected query completion time is orders of magnitude shorter. This change in time scale makes it significantly harder to determine whether hedging will improve tail latency or make it worse.

Hedging masks service-time variability at the cost of extra system load (caused by the replicated queries), hence extra queuing delay. So, if we take any standard hedging policy and any standard load-balancing policy (that tries to minimize latency without hedging), and we measure latency as a function of system load, we expect to see a tipping point: at first, hedging will outperform plain load balancing; however, for some offered system load, the cost of replicating queries will start to outweigh the benefit and the situation will be reversed. The challenge, then, is knowing *when* to hedge in order to operate before the tipping point.

In this paper, we look critically at hedging for OLDI services. We make two contributions:

- We study *when* hedging makes sense: when does it have the potential to improve tail latency relative to plain load balancing, and by how much? To answer this question, we define Idealized Hedge, a theoretical hedging policy that, by design, maximizes the hedging potential of any implementable hedging policy for a given setup. We experimentally compare Idealized Hedge to Per-Shard Queuing, which is, in our context, the best load-balancing policy that does not hedge [45, 76]. This allows us to identify regimes where hedging has the potential to improve tail latency, and to bound the potential improvement.
- We propose LÆDGE (short for "Load-Aware Hedge", pronounced like "*ledge*"), a combination of Per-Shard Queuing and hedging that hedges only if the current system load allows for latency improvement through hedging. The gist of LÆDGE is to only hedge when a replica is idle, through a work-conserving centralized scheduler.

Through a combination of simulations and experiments, we show that LÆDGE approximates Idealized Hedge and outperforms the state-of-the-art hedging policies. We implemented LÆDGE within an open-source OLDI framework [28] and evaluated it on a popular enterprise search engine deployed in the AWS cloud. Our experimental results closely match

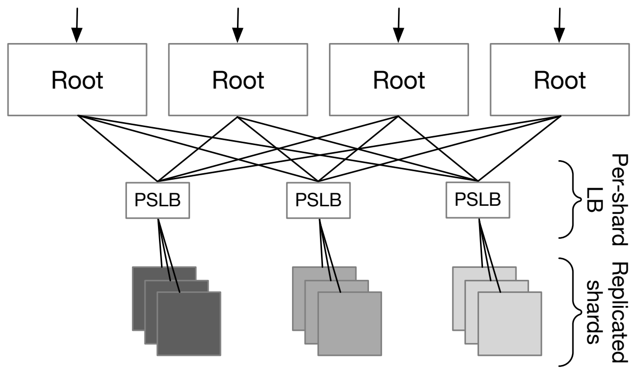

Figure 1: Architecture of an OLDI service with per-shard load balancers (PSLBs).

theoretical expectations and show significant gains: for jobs with mean service times as low as 800µs, and system utilization up to 60%, LÆDGE reduces the 99^{th} percentile latency of Per-Shard Queuing by, on average, 5.3*ms*—an improvement that corresponds to 6.4× the mean service time.

The rest of the paper is organized as follows: §2 presents our simulation setup and defines IQ-jitter—the metric we use to model and measure performance hiccups. §3 presents Idealized Hedge and uses it to identify when hedging has the potential to improve tail latency. §4 presents LÆDGE and evaluates it through simulation, while §5 evaluates it based on a system implementation using a real OLDI application deployed in the AWS cloud. §6 discusses open issues, §7 presents related work, and §8 concludes.

2 Background and Setup

In this section, we describe a standard OLDI setup (§2.1); define IQ-jitter, which helps us model performance hiccups (§2.2); summarize state-of-the-art hedging (§2.3) and load-balancing (§2.4) policies; and describe the simulation (§2.5) that drives the rest of the paper (up until §5).

2.1 OLDI Setup

We consider a cluster that serves OLDI applications, as illustrated in Fig. 1: a tier of root nodes serves client requests, while a tier of leaf nodes stores shards of application data sets; the root and leaf tiers are connected via a tier of per-shard load balancers (PSLBs). The load balancers are "per shard," in the sense that they maintain *a distinct queue per shard*. In practice, the same process implements multiple PSLBs; PSLB processes run either in servers that are dedicated to load balancing, or within the root nodes when that is permitted by the scheduling policy.

A client request requires accessing multiple data shards. When a root receives a client request, it issues one query per distinct shard, and sends each query to the corresponding

Table 1: Existing and proposed tail-mitigation strategies using hedging and load balancing.

PSLB, which schedules the query on one or more leaves. Each leaf is equipped with a queue and processes queries first-come, first-serve (FCFS) [40, 57], which is the best non-preemptive scheduling policy when tail latency is the most important metric [10,40,48,57,76]. To compute the final client response, the root needs one response per distinct shard.

We define the *end-to-end latency* of a client request as the time from the moment a root fans-out the original request into multiple queries until it has received at least one response per distinct shard. It is equal to the service time plus queuing delay experienced by the slowest query that needs to be answered in order to compute the final response.

2.2 IQ-jitter: Modelling Hiccups

Consider a set of leaves with identical hardware and software configuration, serving queries of a given application.

We define *IQ-jitter* (short for *intra-query jitter*), denoted by J, as the service-time variability that results from the fact that two leaves hosting the same data shard may take different amounts of time to serve the same query.

Similarly to Mirhosseini *et al.* [57], we express the query service time S as the sum of two random variables:

$$S = P + J,$$

where P is determined by query complexity and shard content/size, while J (IQ-jitter) is determined by system events that are independent of the application: OS-scheduler decisions, power-management algorithm decisions, interference by other applications—in general, the current software and hardware state of the leaf executing the query.

2.3 Hedging State of the Art

Hedging was invented to mitigate the effect of IQ-jitter on tail latency: As long as the system events causing performance hiccups are independent across leaves, two or more leaves hosting the same data shard are unlikely to all suffer a hiccup while serving the same query. Hence, by replicating a query across multiple leaves and collecting the response that arrives first, we reduce the probability of the query suffering a hiccup.

In this paper, we consider three representative hedging policies (top three rows in Table 1):

Naïve Hedge [72]: The PSLB *always and immediately* sends each query to any two leaves that host the corresponding shard. This is conceptually the simplest hedging policy as it does not require storing any state at the PSLB. It has been applied to many different contexts, including map-reduce jobs [3–5, 14, 82], DNS queries, database servers, and packet forwarding [72].

Delayed Hedge (d-Hedge) [16, 40]: For each query, the PSLB randomly picks a leaf that hosts the relevant shard and sends the query to it; if the reply does not arrive within a pre-configured, fixed delay d, the PSLB replicates the query on another leaf. When a query finishes, the PSLB cancels its replica if it exists. The value of d is tuned by the system operator to control the number of replicated queries in the system. This is the policy that was proposed by Dean *et al.* when they introduced the "tail at scale" problem [16].

Probabilistic Hedge (p-Hedge) [40]: This is similar to d-Hedge, but introduces an extra tuning knob: the probability q of replicating each delayed query; both the probability q and the delay d are trained based on the workload. This was proposed by Kaler *et al.* in their recent study of hedging policies for data centers [40] and is the most sophisticated hedging policy that we found in the literature.

We should clarify that all these policies—as any hedging policy we are aware of—limit the number of simultaneously run hedged requests to two. We follow the same strategy in all the policies that we define in this paper.

Ideally, a hedging policy walks the fine line between (a) replicating too many queries and adding too much system load (hence queuing delay), and (b) not replicating enough queries and failing to mitigate the effect of IQ-jitter on tail latency. Naïve Hedge errs toward the former (it always replicating as much as possible); Vulimiri *et al.* [72] have showed that this reduces tail latency only when system load is below 30% [72]. d-Hedge and p-Hedge provide knobs for controlling the added load; however, as we will see, they still do not enable a good balance between (a) and (b), *i.e.,* they can still unnecessarily overload the system or fail to mitigate the effect of IQ-jitter, even if their knobs are carefully tuned (§3.3).

2.4 Load Balancing: State of the Art

The standard approach to managing latency is load balancing (LB). In this paper, we compare hedging with four standard LB policies ((d) to (g) in Table 1):

Random: For each query, the PSLB randomly picks a leaf that hosts the relevant shard and sends the query to it.

Join-shortest-queue (JSQ) [29]: For each query, the PSLB picks a leaf that hosts the relevant shard and sends the query to it; of all the candidate leaves, the PSLB picks the one with the smallest number of pending queries for that shard. JSQ outperforms Random but is far from optimal for FCFS servers with highly-variable job sizes [29,34,35]. We consider it because it is simple to implement and very popular in the industry, *e.g.,* it is widely deployed in reverse-proxies [29,58].

Per-Shard Queuing (PSQ): The PSLB stores each query until a leaf that can serve it becomes available. In other words, the PSLB dispatches a query to a leaf *only* if the leaf is idle. From a queuing-theory perspective, PSQ corresponds to a single-queue $M/G/k$ model, where k is the number of leaves to choose from. In theory, this outperforms any LB policy that uses multiple distinct queues (*e.g.,* JSQ) in the presence of non-deterministic service times [68]. In practice, PSQ exposes the round-trip latency between the PSLB and the leaf tiers, which may significantly impact throughput. It is, however, an excellent candidate for low-latency environments like modern datacenters [57,60] (*e.g.,* it takes $< 20\mu$s to perform an RPC between two VMs in Microsoft Azure [22]).

Join-bounded-shortest-queue (JBSQ) [45]: This policy combines PSQ and JSQ by splitting the pending queries between the PSLB and leaf tiers. It takes a parameter n, which specifies the number of pending requests that each leaf can hold, *e.g.,* JBSQ(1) is equivalent to PSQ, while JBSQ(∞) is equivalent to JSQ. The value of n can be configured so as to hide the round-trip latency between the PSLB and leaf tiers and enable full throughput.

2.5 Simulation Setup

In the next two sections, we rely on discrete event simulation to compare hedging against standard LB policies. The goal is not to evaluate precisely how these policies perform in real systems (we use different experiments for that, later in the paper), but to understand some of their fundamental properties, *e.g.,* how does hedging compare to PSQ in an idealized setting (where PSQ is the optimal LB policy)?

Our simulation setup mimics an OLDI application deployed in a small- to medium-sized cluster: (a) The number of shards ranges from $N = 5$, which represents small-scale public-cloud deployments, and it is the default number of shards in Elasticsearch [21]; to $N = 500$ distinct shards, which represents larger public-cloud deployments [21,70]. Each shard is replicated in $r = 2$, 3 or 6 leaves (depending on the experiment). The number of replicas in OLDI applications tends to be limited given DRAM costs [55]; 6 was the highest number of replicas per shard that we found in the literature [14,40,63,70]. There are $N \times r$ leaves processing queries, all with the same hardware and software configuration. Leaves process queries FCFS [40]. All queues have infinite capacity. (b) Each PSLB fans out queries to leaves according to the simulated (hedging or LB) policy. Network latency between any two nodes is zero (revisited in § 5). (c) Client requests arrive at the root tier following an open-loop Poisson arrival process. (d) As stated earlier, guided by previous studies [57] and our own observations, we model query service time as the sum of two components, $S = P + J$. Unless otherwise noted, P follows an exponential distribution (the randomness comes from different queries of a workload), while J (IQ-jitter) follows a bimodal distribution. This means that, in any single experiment, an instance of a query executing at a leaf node experiences a hiccup with some probability (*e.g.,* 10^{-3}), while all hiccups have the same duration (*e.g.,* $15 \times \bar{P}$)—which approximates the results in [12] and reflects our observations from § 5.1. Across experiments, we vary hiccup probability and duration to model a range of real problematic system events.

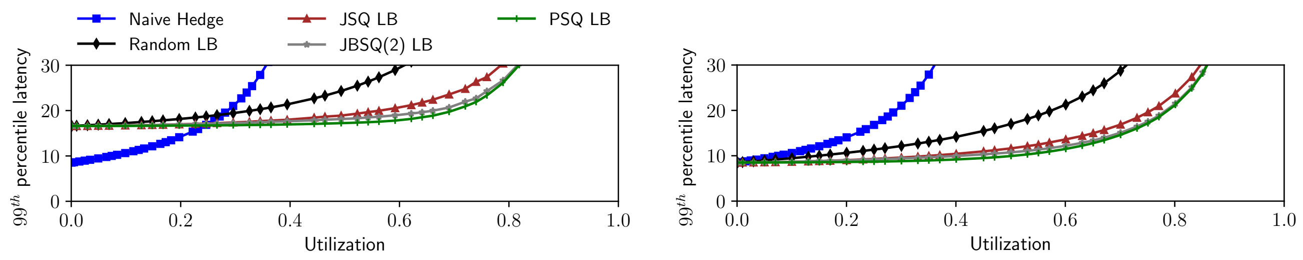
We report tail latency as a multiple of $\bar{P}$ (average application-dependent latency). For example, when we report that 99th percentile latency is equal to 30, this means that the slowest 1% of client requests experience end-to-end latency that is higher than $30 \times \bar{P}$. We think that this provides more insight than an absolute number, especially since (in these particular experiments) we are measuring a simulated, idealized setup. In several plots, we show tail latency as a function of system utilization; a maximum utilization of 1.0 corresponds to $r/\bar{S}$ queries per time unit, where r is the replication factor.

3 Idealized Hedging

In this section, we present Idealized Hedge—an idealized hedging policy—and use it to gain insight into the applicability of hedging, as a general policy, to OLDI services.

3.1 Two Simple Observations

We start by comparing all the LB policies and Naïve Hedge: Fig. 2 shows 99th percentile latency as a function of system utilization in a cluster with $N = 50$ shards, each replicated



(a) IQ-jitter with hiccup probability $\frac{1}{1000}$, hiccup duration $15 \times \bar{P}$.

(b) No IQ-jitter.

Figure 2: 99^{th} percentile latency as a function of utilization, in a cluster with 50×2 leaves, with and without IQ-jitter.

in $r = 2$ leaves, first with IQ-jitter of probability 10^{-3} and duration $15 \times \bar{P}$ (left), then without IQ-jitter (right).

We make two observations:

First, PSQ outperforms the other LB policies in all situations. This is expected from queuing theory. The performance difference is greater in the presence of IQ-jitter (Fig. 2a), which makes sense given that performance hiccups increase the dispersion of service-time distribution—and more service-time dispersion creates a bigger challenge for policies like JSQ and Random.

Second, in the presence of IQ-jitter (Fig. 2a), there is a clear "turning point": At low utilization, Naïve Hedge (despite its naïveté) delivers significantly lower tail latency than any LB policy. For instance, in an unloaded system, tail latency is $8 \times \bar{P}$ with Naïve Hedge and $17 \times \bar{P}$ with PSQ—close to a $2\times$ improvement. However, when utilization exceeds 25%, the LB policies deliver lower tail latency and higher throughput.

As a side note, in the absence of IQ-jitter (Fig. 2b), hedging unsurprisingly does not improve tail latency relative to LB, for any system utilization.

These observations suggest that a combined hedging/PSQ policy, which adapts the fraction of hedged queries to system utilization, might achieve lower tail latency than either hedging or LB alone.

3.2 The Design of Idealized Hedge

Idealized Hedge maximizes the potential of hedging to reduce latency in the following way:

1. A leaf is never idle when it can serve a pending query currently being served by at most one other leaf.

2. A leaf serves a hedged (replicated) query only when it cannot serve a non-hedged (yet-unserved) one.

The second property ensures that hedged queries never increase the queuing delay experienced by non-hedged queries. The two properties together ensure what we might call *work conservation in the presence of hedging*: no resources are idle when they could be doing useful work, and no resources are dedicated to hedging when they could be used for other work.

Idealized Hedge is not implementable because it requires perfect prediction of the completion times of currently executing queries: To ensure that the two properties stated above always hold, the system may need to cancel one copy of a hedged query currently executing on a leaf (so that the leaf can serve a new, non-hedged query that just arrived). To maximize the potential of hedging in our setup, Idealized Hedge must always cancel the copy that will take longer to complete, hence the need for perfect prediction.

We simulated Idealized Hedge as follows: Each PSLB maintains a queue with all the pending queries in order of arrival, and it knows the status of each leaf and which query it is processing (if busy). Moreover, if two copies of a hedged query are executing on different leaves and a new query arrives (that can be served by the same leaves), the PSLB's scheduler perfectly predicts which copy will finish executing first. With this knowledge, the PSLB performs the following operations: (a) Dispatches queries to the leaves in an FCFS manner using a pull-based discipline like PSQ. (b) Hedges a query as soon as a leaf that can serve it becomes idle. (c) Cancels any copy of a hedged query if another copy finishes first (we call this a *cleanup cancellation* or CC for brevity). (d) Cancels one copy of a hedged query upon arrival of a new query that can be served by the same leaf (we call this a *pre-emptive cancellation* or PC).

Fig. 3 shows the finite-state machine of Idealized Hedge for a given shard that is replicated in two leaves:

S_0 Both leaves are idle. There are no pending queries.

S_1 (Initial hedging) Both leaves are serving the same query Q_A, which they started to serve simultaneously; there are no other pending queries. This state occurs on a transition from S_0, following the arrival of query Q_A.

S_2 (No hedging) The two leaves are serving different queries, Q_A and Q_B, and there are no additional pending queries. This state occurs on a transition from S_1, following the arrival of query Q_B, at which point one copy of Q_A (the one that would have finished later) was pre-emptively cancelled.

S_3 (PSQ) The two leaves are serving different queries, Q_A and Q_B, and there are additional pending queries. In this

Figure 3: The finite-state machine of both Idealized Hedge and LÆDGE with CC+PC on one shard with two replicas. The states show: whether the shard queue is empty, whether replicas are running the same or different queries (Q), and whether the queries started at the same time (t).

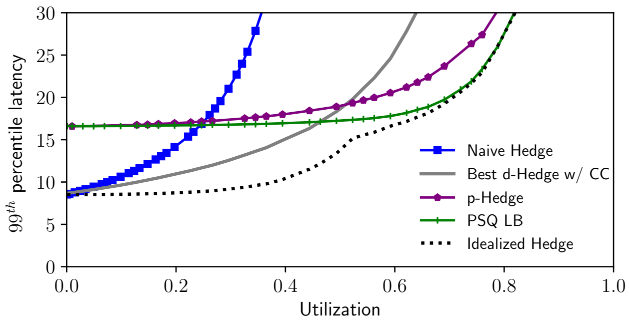

Figure 4: 99th percentile latency as a function of utilization. Ideal Hedge vs. existing hedging policies and PSQ. Same setup as in Fig. 2a.

state, when a leaf finishes serving its query, it pulls the next one from the head of the queue (without hedging), as in the PSQ policy.

S_4 (Delayed hedging) Both leaves are serving the same query Q_A, which they started to serve at different times; there are no other pending queries. This state occurs on a transition from S_2, following the completion of one query, at which point the other query (Q_A) is reissued to the otherwise idle leaf.

3.3 Idealized Hedge versus State of the Art

Fig. 4 compares Idealized Hedge against the three hedging policies (Naïve Hedge, d-Hedge, p-Hedge), as well as PSQ (the best LB policy). The experimental setup matches that of Fig. 2a (50×2 leaves and IQ-jitter with probability 10^{-3} and duration $15 \times \bar{P}$).

Idealized Hedge outperforms (as expected) the real policies and exhibits the following behavior: at low utilization (until around 5%), when the leaves are mostly in states S_0 and S_1, it behaves like Naïve Hedge; at high utilization (from around 60%), when the leaves are mostly in state S_3, it converges to PSQ; in between, it clearly outperforms (by up to $8 \times \bar{P}$) all the real policies.

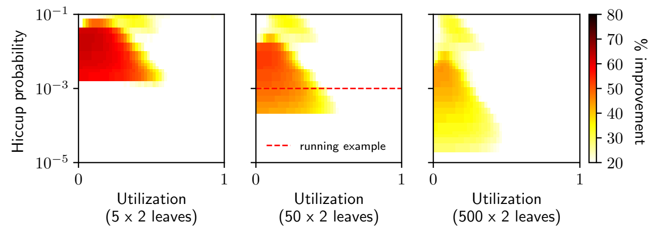
The most interesting comparison is between Idealized Hedge (black dotted line) and PSQ (green solid line with vertical lines), because it provides an upper bound on the tail-latency benefit that can be expected from *any* form of hedging. This comparison indicates two points: (1) There exists a significant utilization range (from ∼60% and up, in our setup) where no real hedging policy may bring any significant benefit relative to PSQ. (2) Outside this range, hedging *may* bring significant benefit, but the two state-of-the-art hedging policies cannot fulfill this potential. Only Naïve Hedge (blue solid line with squares) achieves all the benefit that hedging could achieve, but only at low utilization (until around 5%, in our setup). d-Hedge (gray solid line) outperforms the other real policies for a utilization range between ∼10 and ∼45%, but it remains far from Idealized Hedge. p-Hedge (purple solid line with pentagons) is outperformed by PSQ in all situations.

Of course, the behavior of d-Hedge and p-Hedge depends dramatically on how their configuration parameters are tuned; we followed all the instructions in the relevant literature, and we did our best to maximize their performance. For instance, in d-Hedge, we set the delay after which hedging occurs to $d = 5 \times \bar{P}$, because we experimentally found that higher values do not noticeably mitigate tail latency on low and medium loads; differently said, we allowed the least amount of hedging that has an impact on tail latency on low and medium loads comparable to that of Naïve Hedge (and yet the algorithm still led to congestion collapse at ∼60% utilization). In p-Hedge, we trained the parameters d and q, using the most successful of the methods explored in [40]: for each level of system utilization, we computed a "reissue budget" (the percentage of hedged queries in the system) using their iterative algorithm; then, for each level of system utilization, we trained d and q on sampled latency measurements using the proposed training algorithm that accounts for queuing delays for a fixed reissue budget. We tried sampling rates up to 80%; the results we show are for a sampling rate of 60%, because increasing it further did not significantly change the results: p-Hedge did not capture the rare hiccups through sampling, as they only occur once every 1000 queries. None of this proves that d-Hedge and p-Hedge could not perform any better, but it illustrates the difficulty of tuning them so as to achieve a desired balance between too little and too much hedging.

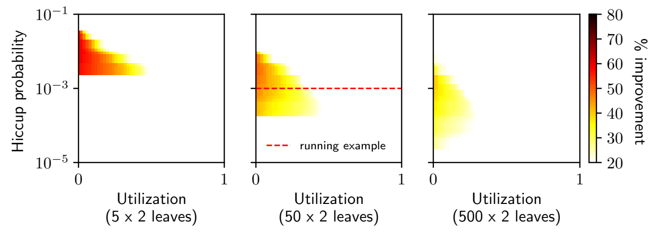
3.4 Beyond One Example

We now extend our observations beyond the specific setup of Fig. 4: how much potential does hedging have to improve tail latency as the cluster size and nature of IQ-jitter vary?

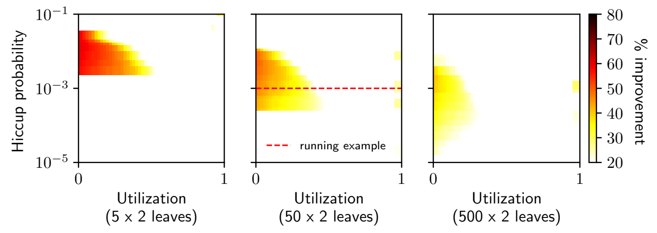
We consider the following scenarios: clusters of 5×2, 50×2, and 500×2 leaves, *i.e.,* small, medium, and large; hiccup probability ranging from 10^{-1} to 10^{-5}; hiccup duration $15 \times$



(a) Idealized Hedge

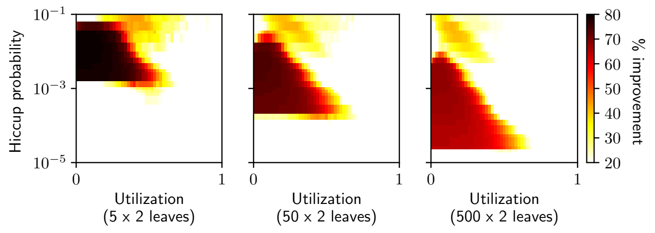


(b) LÆDGE

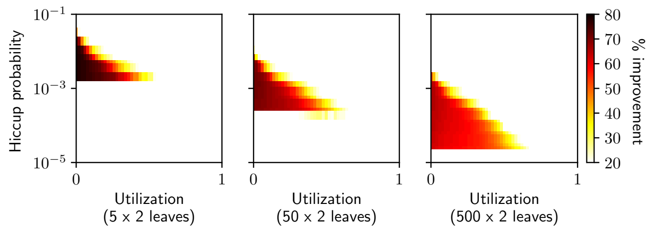


(c) LÆDGE with CC

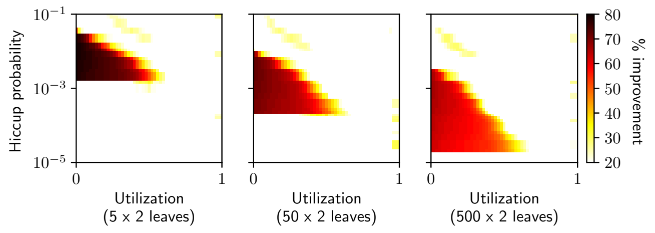
Figure 5: Heat maps showing how much various hedging policies improve the 99th percentile latency relative to PSQ. Hiccup duration is $15 \times \bar{P}$.



(a) Idealized Hedge



(b) LÆDGE



(c) LÆDGE with CC

Figure 6: Heat maps showing how much various hedging policies improve the 99th percentile latency relative to PSQ. Hiccup duration is $30 \times \bar{P}$.

$\bar{P}$ and $30 \times \bar{P}$. Regarding the latter, our choice of parameters is motivated by the literature: $15 \times \bar{P}$ has occurred as the result of badly configured timer intervals [12], while $30 \times \bar{P}$ as a result of non-conserving job-to-core allocation [69].

We summarize our results in two sets of heat maps, one for hiccup duration $15 \times \bar{P}$ (Fig. 5a), the other for $30 \times \bar{P}$ (Fig. 6a). Each heat map illustrates the relative improvement in 99th percentile latency that Idealized Hedge brings relative to PSQ: the x-axis is system utilization, the y-axis is hiccup probability (on a logarithmic scale), and the intensity of each data point is the relative improvement in the 99th percentile latency (so, a darker data point indicates higher potential for hedging to improve tail latency). We only show improvement greater than 20%, to focus on scenarios with significant improvement potential. Each column corresponds to a different cluster size: 5×2, 50×2, and 500×2 leaves, from left to right. The dashed horizontal line in Fig. 5a, middle heat map (so, 50×2 leaves) corresponds to the setup of Fig. 2a and 4.

First, we observe that **hedging cannot significantly improve tail latency when system utilization exceeds** $\sim$**60%** (all heat maps are empty beyond $\sim$60% utilization). Beyond this turning point, hedging improves latency at most by 20%, independently from cluster size and hiccup probability or duration. The intuition is simple: as system utilization increases and leaves become busier, opportunities for hedging disappear; as a result, Idealized Hedge eventually converges to PSQ. The turning point corresponds to medium-heavy utilization, where queues are starting to form, and below the point where the well-known heavy-traffic approximation determines behavior irrespective of service-time distribution [30]. Between $\sim$60% and $\sim$80% utilization, hedging provides at most 10% improvement (not visible in the heat maps); and beyond $\sim$80% utilization, no improvement at all.

Second, **hiccup duration does not affect the existence of potential improvement (the heat-map shape), only the amount of potential improvement (the heat-map intensity)**. Compare any two heat maps for the same cluster size in Figures 5a and 6a: they shade mostly the same (x, y) surface, but the heat map on the right (longer hiccup duration) is darker than the one on the left. The intuition is that, for any given cluster size, hedging can be useful only within a given hiccup probability range; outside this range, performance hiccups are either too rare or too frequent for hedging to make any difference, and this is independent of hiccup duration.

Third, **the larger the cluster size, the smaller the hiccup probability for which hedging may be useful**. For example, when the hiccup probability is between 10^{-4} and 10^{-5}, hedging may be useful only in the 1000-leaf cluster (and would be useful in larger clusters as well); in the two smaller clusters, each request needs access to fewer distinct shards, and the probability of IQ-jitter slowing down the serving of one or more of these shards becomes insignificant. Conversely, the higher the hiccup probability, the smaller the cluster size for which hedging may be useful. For example, when hiccup probability exceeds 10^{-2}, hedging may be helpful in all three clusters (but less so in the 1000-leaf cluster, where it may improve tail latency by at most 35%).

4 LÆDGE: Approaching Idealized Hedge

In this section, we present Load-Aware Hedge (LÆDGE), an implementable policy that approximates Idealized Hedge by adapting hedging to system utilization.

Algorithm 1 shows LÆDGE in pseudo code: $SQ[i]$ is a shard queue that corresponds to shard i; q is a query that belongs to request r and concerns shard s, while q' is a replica of q. Each query that concerns a given shard may be: (a) hedged, i.e., sent to two nodes that serve the shard (line 7), (b) sent to a single node that serves the shard if that is the only available one (line 9), or (c) queued up at a shard queue if zero nodes that serve the shard are available (line 11). When a node becomes available, the oldest query in the shard's queue is sent to the node (line 18). If there are no queries in the shard's queue, the oldest running query that concerns the shard is hedged, i.e., a replica of the query is sent to the node (line 21).

LÆDGE has the following properties:

1. A leaf is never idle when it can serve a pending query currently being served by at most one other leaf.

2. A leaf *starts* to serve a hedged (replicated) query when it cannot serve a non-hedged (yet-unserved) one.

Unlike Idealized Hedge, LÆDGE does not guarantee that, at any point in time, any leaf serving a hedged query could not be serving a non-hedged one; it only guarantees that when a leaf *starts* to serve a hedged query it could not be serving a non-hedged one. Like PSQ, an efficient LÆDGE implementation requires a PSLB with µs-scale round-trip latency to the leaves, which is commonly found in datacenter environments [22,45].

We implemented three variants of LÆDGE, which differ only in the type of query cancellation that they support:

Plain LÆDGE: Similarly to PSQ, a PSLB dispatches queries to leaves from a centralized queue; similarly to Idealized Hedge, a leaf serves both non-hedged and hedged queries, prioritizing the former. There are no query cancellations.

LÆDGE with CC: This policy augments plain LÆDGE with cleanup cancellation (CC), *i.e.,* all copies of a hedged query are cancelled when another copy finishes executing first. An efficient implementation of this policy requires a low-overhead mechanism for interrupting a query and cleaning up its side effects. Whether such a mechanism exists or not depends on the application itself (for instance, Boucher *et al.* [13] enabled efficient µs-scale cancellations for microservices [1,27,56] written in Rust).

Algorithm 1: Generalized LÆDGE

```
1  // Initialize a shard queue (SQ) per shard
2  $SQ[i] \leftarrow [\,],\ i \in [1,\dots,n_{shards}]$ ;
3  on request $r$ arrival
4      for each shard $s$ do
5          if available replicas of shard $s \geq 2$ then
6              // Replication on arrival
7              send $q$ and $q'$ to 2 random replicas of shard $s$;
8          else if available replicas of shard $s == 1$ then
9              send $q$ to the available replica ;  // No replication
10         else
11             enqueue $q$ to $SQ[s]$ ;
12         end
13     end
14 end;
15 on response $p$ arrival from node $n$ serving shard $s$
16     if size($SQ[s]$) $> 0$ then
17         pop a pending query $q$ from $SQ[s]$ ;
18         send $q$ to $n$ ;                          // No replication
19     else
20         if $\exists$ a non-replicated unfinished query on shard $s$ then
21             replicate the oldest query to node $n$ ;
                 //Delayed replication
22         end
23     end
24 end;
```

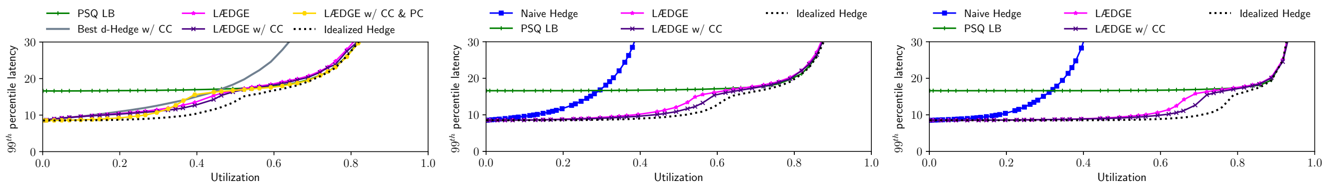
LÆDGE with CC+PC: This policy adds pre-emptive cancellation (PC), *i.e.,* one copy of a hedged query is cancelled when a new query arrives that can be served by the same leaves. The state machine corresponds to that of Idealized Hedge, shown in Fig. 3; the only difference is the lack of perfect completion-time prediction (while transitioning from S_1 to S_2, and from S_4 to S_2); instead, this policy cancels the copy that started executing most recently.

All cancellations are zero cost, in the sense that they introduce no extra processing delay and no extra communication between the PSLB and leaf tiers.

4.1 LÆDGE versus Idealized Hedge

Fig. 7a compares the three LÆDGE variants against Idealized Hedge, as well as d-Hedge and PSQ (the two best existing policies among the ones we simulated). The setup matches that of Figures 2a and 4.

We observe that plain LÆDGE reduces the gap to Idealized Hedge to at most $3.8 \times \bar{P}$ (while hiccup duration is $15 \times \bar{P}$, in this setup). At low utilization (up to ~20%), it behaves like d-Hedge, which is the best existing policy at that utilization range. From some point on (~50%), it converges to PSQ, which is the best existing policy at that utilization range. In between 20% and 50% utilization, it outperforms the existing policies, without using cancellations or parameter training, closing the average gap to Idealized Hedge to only $2.16 \times \bar{P}$.



(a) 50×2 shards (2 replicas) (b) 50×3 shards (3 replicas) (c) 50×6 shards (6 replicas)

Figure 7: 99th percentile latency as a function of utilization. Comparing LÆDGE with different number of replicas per shard.

Second, we observe that cancellations not only do not significantly help LÆDGE but may actually hinder it. Adding CCs to LÆDGE marginally improves tail latency (given our assumption of zero-cost cancellations, it could not increase it). More interestingly, adding PCs to LÆDGE-with-CC *increases* tail latency at some utilization levels, starting from $\sim$30%. It turns out that cancelling the wrong copy of a hedged query (the one that would have finished first) is an expensive mistake; without any sophisticated completion-time predictors, one is better off not cancelling at all.

To better understand these results, we completed a careful analysis of PCs and their effect on tail latency. We define the "prediction accuracy" of a LÆDGE policy with cancellations as the proportion of PCs that correctly cancel the copy that would finish later. Overall, LÆDGE achieves $> 99\%$ prediction accuracy, which is unsurprising given the rarity of IQ-jitter events. However, once we consider only the PCs where at least one copy of the cancelled query experiences IQ-jitter, LÆDGE's prediction accuracy drops significantly. For example, at 40% system utilization, when transitioning from S_1 to S_2 in the presence of IQ-jitter, LÆDGE achieves prediction accuracy $\sim$50%; when transitioning from S_4 to S_2, prediction accuracy drops to $\sim$19%. The reason is that LÆDGE does not attempt to predict whether an IQ-jitter event is likely to have occurred—it simply picks the most-recently started copy. Cancellations appear to pay off only if we can assume a good predictor of performance hiccups due to system events; while this may be feasible according to Hao *et al.* [32], LÆDGE was designed in the absence of such an assumption.

So far, we considered only $r = 2$ replicas per shard. While this is typical in practice (the replication factor is often limited by high DRAM costs [55]), research proposals consider replication factors between $r = 2$ and 6 replicas per shard [40, 63]. The simulation behind the Figures 7b and 7c is set up the same way as Figure 7a, but with 3 and 6 replicas per shard, respectively. We see that, for the larger number of replicas, (1) the tail latency of Idealized Hedge and LÆDGE follows the minimal latency of Naïve Hedge up to 60% utilization (for 6 replicas), and (2) LÆDGE continues to achieve a significant part of the tail latency reduction of Idealized Hedge.

Finally, we should note that, out of curiosity, we experimented with two more types of application-independent noise (other than bimodal): exponential and bimodal+exponential. For the former, not even Idealized Hedge can improve tail latency, PSQ is the best policy, and LÆDGE performs almost the same as PSQ; this is not surprising, given that hedging was invented to deal with noise due to unpredictable system events, which is better modelled with a bimodal distribution. For the latter, the results were almost identical to the ones we got for bimodal noise.

4.2 Beyond One Example

We now extend our observations beyond the specific setup of Fig. 7: how well does LÆDGE fulfill the hedging potential as the cluster size and nature of IQ-jitter vary?

We consider the same scenarios as in §3.4 and once more summarize our results in heat maps in Figures 5 and 6. To assess how well LÆDGE approximates Idealized Hedge, we have to compare the heat maps. To simplify the comparison, we introduce Table 2, which summarizes Figures 5 and 6 as a percentage of the "surface" of each heat map that indicates improvement above a certain threshold (20%, 30% and 40%). For instance, consider the row that corresponds to hiccup duration $30 \times \bar{P}$ and cluster size 50×2 leaves, and the two columns that correspond to Idealized Hedge and LÆDGE, with $> 30\%$ latency improvement; the two cells where this row and columns intersect indicate that Idealized Hedge achieves such improvement for 29.7 % of the data points, while LÆDGE does for 12.6 % of data points.

To summarize, LÆDGE fulfills as much as half of the hedging potential, depending on the setup. Consider again the columns that correspond to Idealized Hedge and LÆDGE with $> 30\%$ latency improvement, and compare the values of these two columns that are in the same row; LÆDGE improves from 23% to 56% of the data points that are improved by Idealized Hedge (*i.e.,* that could possibly be improved through hedging). In general, LÆDGE is closer to Idealized Hedge for the medium and large clusters, and the longer hiccup duration.

On a side note, LÆDGE does not deteriorate lower latency percentiles compared to PSQ (*e.g.,* the median), but improves the tail. The rare hiccups that we analyzed, however, only influence the tail—not, for example, the 50th percentile latency.

	% reduction	Idealized Hedge			LÆDGE			LÆDGE with CC			LÆDGE with PC		
	wrt PSQ$\rightarrow$	>20	>30	>40	>20	>30	>40	>20	>30	>40	>20	>30	>40
$15\times\bar{P}$	5×2 leaves	26.3	19.6	15.6	9.8	8.3	6.4	13.6	11.8	9.6	14.4	11.6	10.1
	50×2 leaves	29.9	21.5	15.4	13.4	9.8	3.8	16.8	12.2	5.2	15.9	12.3	9.2
	500×2 leaves	31.9	17.9	4.4	12.6	4.2	0.2	14.8	5.2	0.2	15.5	8.0	0.9
$30\times\bar{P}$	5×2 leaves	36.9	28.1	22.3	9.6	7.6	6.2	18.9	13.4	11.8	21.8	15.6	12.6
	50×2 leaves	40.5	29.7	22.5	15.2	12.6	11.1	22.6	17.4	15.5	23.3	18.2	14.5
	500×2 leaves	43.1	33.4	26.7	20.9	19.0	16.7	27.2	22.2	20.5	25.1	21.2	17.9

Table 2: Percentage of the total surface (in Figures 5 and 6) that has more than 20%, 30% and 40% reduction in 99th percentile tail latency over Per-Shard Queuing for the workloads with the hiccup duration of $15\times\bar{P}$ and $30\times\bar{P}$.

4.3 Are Cancellations Worth the Effort?

First, in agreement with [4], our sensitivity analysis confirms that cleanup cancellation (CC) improves LÆDGE only marginally. Consider the columns of Table 2 that correspond to LÆDGE and LÆDGE with CC; on average, LÆDGE with CC offers the same improvement to 2.3% more data points than LÆDGE when hiccup duration is $15\times\bar{P}$, and to 5.6% more data points than LÆDGE when hiccup duration is $30\times\bar{P}$.

Second, while our sensitivity analysis in Table 2 shows that PCs have a marginally positive impact on LÆDGE, actually there exist a few areas of highly-negative impact. We have already discussed the intuition in §4.1; further analysis shows that the effect persists across the parameter space.

In a way, the non-effectiveness of cancellations is good news for application developers: Cancellations can be complicated and expensive to implement, they often require non-trivial application changes and language-specific mechanisms to avoid memory leaks and inconsistent application state [13], as well as additional interaction between the scheduler and the leaves. The fact that our simulated zero-cost cancellations bring no significant improvement to tail latency suggests that real-life cancellations are not worth the effort in our context.

5 System Evaluation with Lucene

We now evaluate LÆDGE on Lucene, a popular open-source enterprise search engine. It is representative of OLDI services because (1) it involves sharding, and (2) client requests are interactive, with expected latency in the millisecond scale.

Our workload is Lucene's standard nightly regression test, which consists of $\sim$10,000 search queries of four different types: phrase, term, multiterm and boolean [51]. The data consists of an inverted index of 18 million Wikipedia English web pages [77], split into 16 sub-indices (for parallel execution in 16 threads). Lucene comes in C++ and Java flavors; we used the former [52].

We implemented two LB policies (Random and PSQ) and two hedging policies (Naïve Hedge and LÆDGE) in OLDIsim, Google's open-source OLDI cloud benchmarking framework [28]. We changed its architecture to support shard replication, and we added PSLBs (as in Fig. 1). The I/O part of the framework stayed unchanged: it uses the event-based `libevent` API [49], on top of vanilla Linux and TCP. We extended the framework with request generation following an open-loop Poisson arrival process.

We ran our Lucene workload on AWS EC2 virtual machines (VMs) organized in a "cluster" placement group [2] in the same availability zone. We used two VM types: (1) compute-optimized instances with 16 vCPUs @3.0 *GHz* and 32 *GB* of memory (*c*5.4*xlarge*), and (2) general-purpose instances with 16 vCPUs @2.2 *GHz* and 64 *GB* of memory (*m*5*a*.4*xlarge*). All VMs were running the default Ubuntu 16.04.6 image, kernel version 4.4.0-1092-aws.

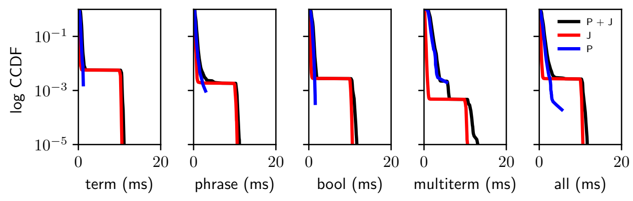
We deployed 5×2 leaf servers, *i.e.,* 5 distinct shards, each replicated in 2 leaves. When a leaf executes a query, it uses 16 parallel threads (one per vCPU). To avoid the introduction of data-driven bias in our results, we replicated the same index on all 5 shards (though, from the point of view of the application, they are still distinct shards served by different leaves). This decision simplifies the comparison with the simulation results in §4 without fundamentally changing the conclusions.

5.1 Empirical IQ-jitter Measurement

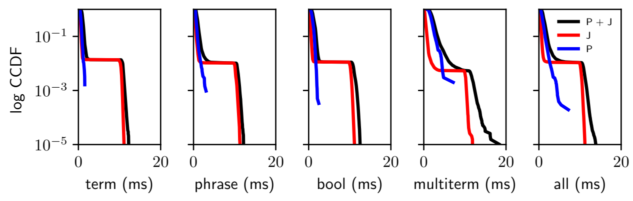
We started our experimental evaluation by measuring the real IQ-jitter experienced by our Lucene workload.

We executed the 10,000 queries of our workload 1000 times each, in a random order, always on the same server type. Consider a specific query Q. For each execution of this query, $Q_i, i = 1\ldots1000$, we measured the service time S_i (which does not include any queuing or network delay). We approximated the application-dependent component of the service time experienced by Q as the minimum service time across executions: $P(Q) = \min_{i=1\ldots1000} S_i$. Then we approximated the IQ-jitter experienced by each query execution Q_i as $J_i = S_i - P(Q)$. By putting together all the IQ-jitter values for a given query type, we obtained the IQ-jitter distribution for this query type.

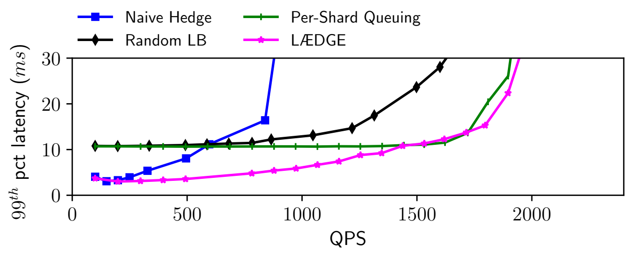
Fig. 8a and 8b show (in the form of CCDFs) the empirical distributions of P, J, and $P+J$, for the four query types of our workload, and for the two different server types. The curves differ in length as P's distribution size depends on the number of queries ($\sim$10,000), whereas the two other distribution sizes depend on the duration of the measurement experiment. The means of P and J in the two server types are 0.637 *ms* and



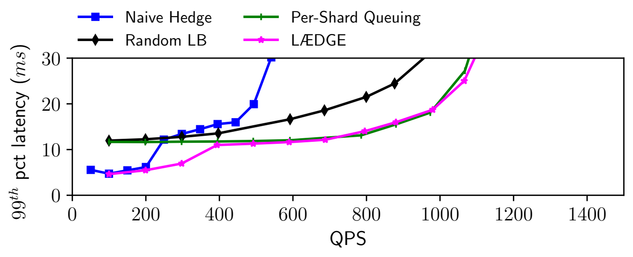
(a) Lucene service time in compute-optimized VM



(b) Lucene service time in general-purpose VM



(c) Latency vs throughput with compute-optimized VMs



(d) Latency vs throughput with general-purpose VMs

Figure 8: Mitigating the Lucene hiccups in a system implementation deployed on 2×5 leaves in EC2 VMs.

0.198 *ms* in Fig. 8a, and 0.926 *ms* and 0.444 *ms* in Fig. 8b, while the hiccup duration and probability are 10.162 *ms* and 0.0027 in Fig. 8a, and 10.249 *ms* and 0.0109 in Fig. 8b.

As a side note, we measured the latency between our VMs and found that the round-trip time is on average 91.2µs, with minimum and maximum latency 61.5µs and 150.6µs, respectively. The average network latency amounts to 10.94% and 6.7% of Lucene's mean service time ($P+J$) in the compute-optimized and general-purpose scenario, respectively.

We observe that IQ-jitter is substantial in both server types, and that the empirical distributions are consistent with our simulation setup: the application-dependent component (P) can be well approximated with an exponential distribution (a straight line on a log-based CCDF), while the IQ-jitter component (J) has a clear bimodal nature. This holds across the four query types that vary significantly in complexity (with "multiterm" queries being the most complex ones).

We investigated the reasons behind IQ-jitter and found that a significant part is due to involuntary rescheduling of Lucene threads, which occurs less frequently in the compute-optimized VMs. Of course, different Lucene deployments may experience less IQ-jitter: if the same workload runs on fully-controlled physical machines, IQ-jitter can be reduced by tweaking the OS or the application itself to mitigate the impact of involuntary thread rescheduling on tail latency.

5.2 Mitigating Tail Latency Through Hedging

Next, we measured the end-to-end latency experienced by our Lucene workload under varying system load. Figures 8c and 8d show the 99th percentile latency as a function of queries per second, for the two server types, respectively.

LÆDGE behaves as expected: it matches Naïve Hedge at low utilization, converges to PSQ at some point, and outperforms the best alternative in between. The exact behavior depends on server type: On the compute-optimized VMs, LÆDGE converges to PSQ at about 60% utilization; before that, it improves tail latency by 49%, or 5.3 *ms*, on average, relative to PSQ. On the general-purpose VMs, convergence to PSQ happens quite earlier—at about 27% utilization—and the improvement of tail latency before that point is somewhat smaller (40%, or 4.7 *ms*, on average).

Our LÆDGE implementation (deployed in the cloud with real system noise and non-zero network latencies) behaved as our simulation predicted: With compute-optimized VMs, our experimental setup consists of 5×2 leaves with IQ-jitter of hiccup probability 0.0027 and hiccup duration $15.95 \times \bar{P}$. The closest simulated setup is a cluster of the same size with IQ-jitter of the same hiccup probability and hiccup duration $15 \times \bar{P}$. This corresponds to the leftmost heat map in Fig. 5b, y-axis value 0.0027 (which is close to the base of the triangular shape of the heat map). If we observe this heat map at the given y-axis value, we can see that our simulated LÆDGE policy significantly outperforms PSQ until utilization ∼40% and then converges to PSQ at utilization ∼60%—matching the behavior of our LÆDGE implementation.

6 Discussion

Scalability: PSQ-based scheduling scales naturally with the number of leaves, because the queues are centralized *only within* a shard. The degree of shard replication is typically small due to DRAM costs [55], and easily manageable by a single PSLB. As more shards are needed, this design scales horizontally by adding more machines for (co-located)

PSLBs, as well as adding more root nodes.

Higher network latency: LÆDGE exposes the round-trip latency between the PSLB and leaf tiers. In the Amazon environment that we used for our system evaluation (§5), this latency is an order of magnitude smaller than the service time. In an environment with higher PSLB-leaf latency, however, exposing this latency could significantly impact throughput. Adapting LÆDGE to such an environment would be straightforward: we would replace LÆDGE's Per-Shard Queuing component with JBSQ [45] (described in §2.4). More specifically, in Alg. 1, instead of always enqueuing the query at line 11, the PSLB would keep track of the queue sizes on the leaf nodes and send the query to the leaf with the shortest queue.

Hedging to more replicas: Kaler *et al.* [40] have shown that hedging the same query to more than two replicas does not provide additional latency benefits. This is consistent with our evaluation results, where hedging to two replicas was enough to mitigate *rare* hiccups.

Fault-tolerance: The architecture in Fig. 1 is resilient to the failure of all of its components: (1) the state in PSLBs is soft, (2) the shards are replicated across different leaf nodes, and (3) if a root fails, another one can take over.

Scheduling in the leaf nodes: We considered only FCFS scheduling in the leaf nodes (see § 2.1). It is possible that a change in scheduling discipline affects service time. However, as long as service time has a component J that depends on application-independent events and has a bimodal distribution, our insights still apply.

7 Related Work

Taming map-reduce latency: Early attempts of hedging studied long-running map-reduce jobs with execution times measured in seconds or minutes [17]. This timescale allows for "observe-then-predict" type of algorithms, with sophisticated execution profiling based on which a decision can be made about when it pays off to hedge [4, 5, 61, 82]. Systems such as LATE [82], Mantri [5] and Dolly [4] used hedging to mitigate the stragglers that would delay the entire phase. We focused on OLDI services operating at different timescales and do not lend themselves to heavy-weight profiling.

Hedging at low latencies: § 2.3 describes Naïve Hedge [72], d-Hedge [16] and p-Hedge [40] that we compared against. State-of-the-art reissue policies such as p-Hedge [40] address the throughput limitations of Naïve Hedge and d-Hedge. Recent work by Mirhosseini *et al.* [57], advocates PSQ as a plausible means to reduce tail latency. We show in §3.3 that PSQ-based hedging policies can outperform carefully-designed push-based ones. Hedging techniques that target network latency [24, 72, 79] are out of the scope of this work.

Early stop: In some cases, the user can receive a meaningful response without her request querying all the shards. In the literature, there are two main such scenarios: First, when accuracy of the results is sacrificed for lower latency [36, 66]. Second, when the final result can be decoded if only *a part* of queries finish [46, 65]. Such approaches are orthogonal ours and can be integrated to further reduce latency.

Advanced load balancing: Lu *et al.* [50] decouple discovery of lightly-loaded servers from job assignment. Since it offers no redundancy, this technique is prone to increased tail latency in the presence of IQ-jitter. "Snitching" is another interesting LB technique in which the root node monitors request latency and picks the fastest replica [6, 71]. This technique also offers no redundancy and is ineffective in case of bursty noise [32].

Adaptive parallelism: Many researchers have tried to predict the service time of interactive services and accordingly adjust the level of parallelism in the processing nodes, or prioritize short-running queries over long-running ones [33, 38, 44, 53, 70]. This approach trades-off service-time for throughput adaptively as a function of the load but does not attempt to reduce jitter due to underlying system events.

Cancellations: Prior work extensively studied cancellations [4, 9, 13, 16, 32]. Ananthanarayanan *et al.* [4] observed that cancellations do not improve tail latency of map-reduce workloads. Recent advances have shown that canceling microsecond-scale RPCs can be feasible, but memory leaks remain a problem. Bashir *et al.* [9] recently studied duplications and cancellations at multiple layers of a cloud system, while Hao *et al.* studied application-specific or OS-level instrumentation to increase the accuracy of cancellation decisions [32]. LÆDGE is simple and can be deployed everywhere, including in the cloud. It applies duplication only at the application level, and our results show comparable latency reductions with and without cancellations. We leave the study of combining cancellations with profiling to future work.

Infrastructure jitter: §1 includes numerous examples of system events that cause jitter. Hao *et al.* [32] observe and quantify noise in EC2 with a focus on disk read and write jitter. Our work focuses on in-memory, CPU-bound applications, which also observe a varying amount of jitter determined in part by the underlying cloud VM.

8 Conclusion

This paper demonstrates that hedging can be applied without significant throughput reduction by combining the best of hedging and load balancing, *i.e.,* by hedging only when the current system load allows it. We show the drawbacks of existing policies and, in turn, propose LÆDGE, an integration of hedging within a per-shard load-balancer, and quantify its benefits against an idealized hedging policy designed to outperform any realistic hedging policy. We show that LÆDGE can yield significant latency reductions over the state-of-the-art approaches. We also validate its benefits with a cloud-based deployment of an interactive web search application.

Move Fast and Meet Deadlines: Fine-grained Real-time Stream Processing with Cameo

Le Xu[1*], Shivaram Venkataraman[2], Indranil Gupta[1], Luo Mai[3], and Rahul Potharaju[4]

[1]University of Illinois at Urbana-Champaign, [2]UW-Madison, [3]University of Edinburgh, [4]Microsoft

Abstract

Resource provisioning in multi-tenant stream processing systems faces the dual challenges of keeping resource utilization high (without over-provisioning), and ensuring performance isolation. In our common production use cases, where streaming workloads have to meet latency targets and avoid breaching service-level agreements, existing solutions are incapable of handling the wide variability of user needs. Our framework called Cameo uses fine-grained stream processing (inspired by actor computation models), and is able to provide high resource utilization while meeting latency targets. Cameo dynamically calculates and propagates priorities of events based on user latency targets and query semantics. Experiments on Microsoft Azure show that compared to state-of-the-art, the Cameo framework: i) reduces query latency by 2.7×in single tenant settings, ii) reduces query latency by 4.6×in multi-tenant scenarios, and iii) weathers transient spikes of workload.

1 Introduction

Stream processing applications in large companies handle tens of millions of events per second [16, 68, 89]. In an attempt to scale and keep total cost of ownership (TCO) low, today's systems: a) parallelize operators across machines, and b) use multi-tenancy, wherein operators are collocated on shared resources. Yet, resource provisioning in production environments remains challenging due to two major reasons:
(i) High workload variability. In a production cluster at a large online services company, we observed orders of magnitude variation in event ingestion and processing rates, *across time*, *across data sources*, *across operators*, and *across applications*. This indicates that resource allocation needs to be dynamically tailored towards each operator in each query, in a nimble and adept manner at run time.
(ii) Latency targets vary across applications. User expectations come in myriad shapes. Some applications require quick responses to events of interest, i.e., short end-to-end

*Contact author: Le Xu <lexu1@illinois.edu>

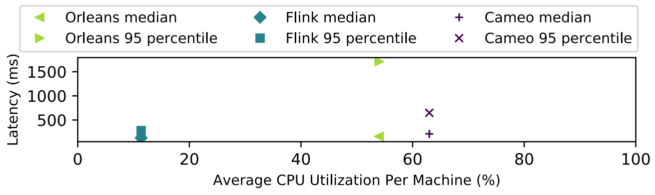

Figure 1: *Slot-based system (Flink), Simple Actor system (Orleans), and our framework Cameo.*

latency. Others wish to maximize throughput under limited resources, and yet others desire high resource utilization. Violating such user expectations is expensive, resulting in breaches of service-level agreements (SLAs), monetary losses, and customer dissatisfaction.

To address these challenges, we explore a new *fine-grained* philosophy for designing a multi-tenant stream processing system. Our key idea is to provision resources to each operator based solely on its *immediate* need. Concretely we focus on deadline-driven needs. Our fine-grained approach is inspired by the recent emergence of event-driven data processing architectures including actor frameworks like Orleans [10, 25] and Akka [1], and serverless cloud platforms [5, 7, 11, 51].

Our motivation for exploring a fine-grained approach is to enable resource sharing directly among operators. This is more efficient than the traditional *slot-based* approach, wherein operators are assigned dedicated resources. In the slot-based approach, operators are mapped onto processes or threads—examples include task slots in Flink [27], instances in Heron [57], and executors in Spark Streaming [90]. Developers then need to either assign applications to a dedicated subset of machines [13], or place execution slots in resource containers and acquire physical resources (CPUs and memory) through resource managers [8, 47, 84].

While slot-based systems provide isolation, they are hard to dynamically reconfigure in the face of workload variability. As a result it has become common for developers to "game" their resource requests, asking for over-provisioned resources, far above what the job needs [34]. Aggressive users starve other jobs which might need immediate resources, and the upshot is unfair allocations and low utilization.

At the same time, today's fine-grained scheduling systems like Orleans, as shown in Figure 1, cause high tail latencies. The figure also shows that a slot-based system (Flink on YARN), which maps each executor to a CPU, leads to low resource utilization. The plot shows that our approach, Cameo, can provide both high utilization and low tail latency.

To realize our approach, we develop a new priority-based framework for fine-grained distributed stream processing. This requires us to tackle several *architectural* design challenges including: 1) translating a job's performance target (deadlines) to priorities of individual messages, 2) developing interfaces to use real-time scheduling policies such as earliest deadline first (EDF) [65], least laxity first (LLF) [69] etc., and 3) low-overhead scheduling of operators for prioritized messages. We present *Cameo*, a new scheduling framework designed for data streaming applications. Cameo:

- *Dynamically* derives priorities of operators, using both: a) *static input*, e.g., job deadline; and b) *dynamic stimulus*, e.g., tracking stream progress, profiled message execution times.
- Contributes new mechanisms: i) *scheduling contexts*, which propagate scheduling states along dataflow paths, ii) a *context handling* interface, which enables pluggable scheduling strategies (e.g., laxity, deadline, etc.), and iii) tackles required scheduling issues including per-event synchronization, and semantic-awareness to events.
- Provides low-overhead scheduling by: i) using a stateless scheduler, and ii) allowing scheduling operations to be driven purely by message arrivals and flow.

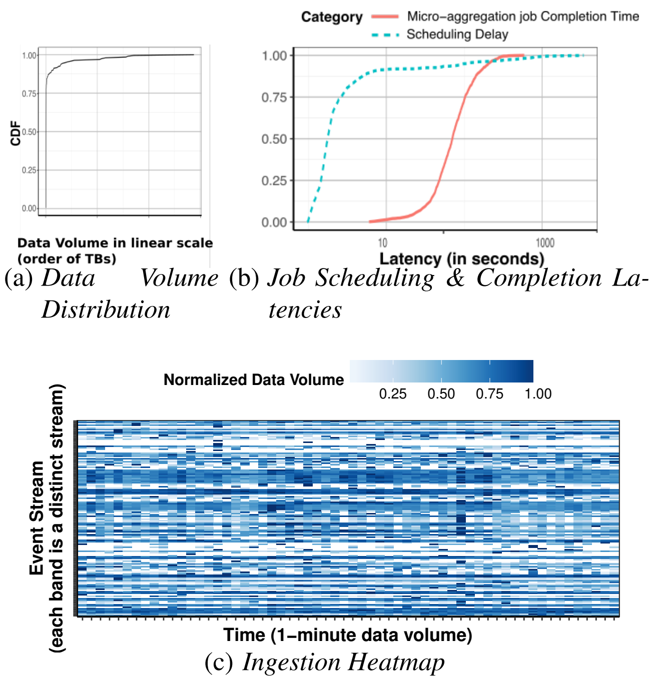
We build Cameo on Flare [68], which is a distributed data flow runtime built atop Orleans [10, 25]. Our experiments are run on Microsoft Azure, using production workloads. Cameo, using a laxity-based scheduler, reduces latency by up to 2.7× in single-query scenarios and up to 4.6× in multi-query scenarios. Cameo schedules are resilient to transient workload spikes and ingestion rate skews across sources. Cameo's scheduling decisions incur less than 6.4% overhead.

2 Background and Motivation

2.1 Workload Characteristics

We study a production cluster that ingests more than 10 PB per day over several 100K machines. The shared cluster has several internal teams running streaming applications which perform debugging, monitoring, impact analysis, etc. We first make key observations about this workload.

Long-tail streams drive resource over-provisioning. Each data stream is handled by a standing *streaming* query, deployed as a dataflow job. As shown in Figure 2(a), we first observe that 10% of the streams process a majority of the data. Additionally, we observe that a long tail of streams, each processing small amount data, are responsible for over-



(a) *Data Volume Distribution* (b) *Job Scheduling & Completion Latencies*

(c) *Ingestion Heatmap*

Figure 2: *Workload characteristics collected from a production stream analytics system.*

provisioning—their users rarely have any means of accurately gauging how many nodes are required, and end up over-provisioning for their job.

Temporal variation makes resource prediction difficult. Figure 2(c) is a heat map showing incoming data volume for 20 different stream sources. The graph shows a high degree of variability across both sources and time. A single stream can have spikes lasting one to a few seconds, as well as periods of idleness. Further, this pattern is continuously changing. This points to the need for an agile and fine-grained way to respond to temporal variations, as they are occurring.

Users already try to do fine-grained scheduling. We have observed that instead of continuously running streaming applications, our users prefer to provision a cluster using external resource managers (e.g., YARN [2], Mesos [47]), and then run periodic micro-batch jobs. Their implicit aim is to improve resource utilization and throughput (albeit with unpredictable latencies). However, Figure 2(b) shows that this ad-hoc approach causes overheads as high as 80%. This points to the need for a common way to allow all users to perform fine-grained scheduling, without a hit on performance.

Latency requirements vary across jobs. Finally, we also see a wide range of latency requirements across jobs. Figure 2(b) shows that the job completion time for the micro-aggregation jobs ranges from less than 10 seconds up to 1000 seconds. This suggests that the range of SLAs required by queries will vary across a wide range. This also presents an opportunity for priority-based scheduling: applications have longer latency constraints tend to have greater flexibility in

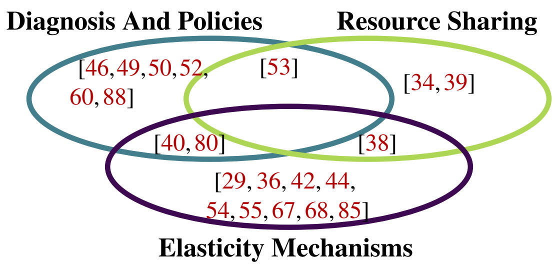


Figure 3: *Existing Dataflow Reconfiguration Solutions.*

terms of *when* its input can be processed (and vice versa).

2.2 Prior Approaches

Dynamic resource provisioning for stream processing. Dynamic resource provisioning for streaming data has been addressed primarily from the perspective of dataflow reconfiguration. These works fall into three categories as shown in Figure 3:
i) *Diagnosis And Policies*: Mechanisms for when and how resource re-allocation is performed;
ii) *Elasticity Mechanisms*: Mechanisms for efficient query reconfiguration; and
iii) *Resource Sharing*: Mechanisms for dynamic performance isolation among streaming queries.
These techniques make changes to the dataflows in reaction to a performance metric (e.g., latency) deteriorating.

Cameo's approach does not involve changes to the dataflow. It is based on the insight that the streaming engine can delay processing of those query operators which will not violate performance targets right away. This allows us to quickly prioritize and provision resources proactively for those other operators which could immediately need resources. At the same time, existing reactive techniques from Figure 3 are orthogonal to our approach and can be used alongside our proactive techniques.

The promise of event-driven systems. To achieve fine-grained scheduling, a promising direction is to leverage emerging event-driven systems such as actor frameworks [43,74] and serverless platforms [24]. Unlike slot-based stream processing systems like Flink [27] and Storm [83], operators here are not mapped to specific CPUs. Instead event-driven systems maintain centralized queues to host incoming messages and dynamically dispatch messages to available CPUs. This provides an opportunity to develop systems that can manage a unified queue of messages across query boundaries, and combat the over-provisioning of slot-based approaches. Recent proposals for this execution model also include [11,24,26,58].

Cameo builds on the rich legacy of work from two communities: classical real-time systems [63,75] and first-generation stream management systems (DSMS) in the database community [14, 15, 31, 71]. The former category has produced rich scheduling algorithms, but unlike Cameo, none build a full working system that is flexible in policies, or support streaming operator semantics. In the latter category the closest to our work are event-driven approaches [14,22,28]. But these do not interpret stream progress to derive priorities or support trigger analysis for distributed, user-defined operators. Further, they adopt a centralized, stateful scheduler design, where the scheduler *always* maintains state for all queries, making them challenging to scale.

Achieving Cameo's goal of dynamic resource provisioning is challenging. Firstly, messages sent by user-defined operators are a black-box to event schedulers. Inferring their impact on query performance requires new techniques to analyze and re-prioritize said messages. Secondly, event-driven schedulers must scale with message volume and not bottleneck.

3 Design Overview

Assumptions, System Model: We design Cameo to support streaming queries on clusters shared by cooperative users, e.g., within an organization. We also assume that the user specifies a latency target at query submission time, e.g., derived from product and service requirements.

The architecture of Cameo consists of two major components: (i) a scheduling strategy which determines message priority by interpreting the semantics of query and data streams given a latency target. (Section 4), and (ii) a scheduling framework that 1. enables message priority to be generated using a pluggable strategy, and 2. schedules operators dynamically based on their current pending messsages' priorities (Section 5).

Cameo prioritizes operator processing by computing the *start deadlines* of arriving messages, i.e., latest time for a message to start execution at an operator without violating the downstream dataflow's latency target for that message. Cameo continuously reorders operator-message pairs to prioritize messages with earlier deadlines.

Calculating priorities requires the scheduler to continuously book-keep both: (i) per-job static information, e.g., latency constraint/requirement[1] and dataflow topology, and (ii) dynamic information such as the timestamps of tuples being processed (e.g., stream progress [19,61]), and estimated execution cost per operator. To scale such a fine-grained scheduling approach to a large number of jobs, Cameo utilizes *scheduling contexts*— data structures attached to messages that capture and transport information required to generate priorities.

The scheduling framework of Cameo has two levels. The upper level consists of *context converters*, embedded into each operator. A context converter modifies and propagates scheduling contexts attached to a message. The lower level is a *stateless scheduler* that determines target operator's priority by interpreting scheduling context attached to the message. We also design a programmable API for a pluggable scheduling strategy that can be used to handle scheduling contexts. In summary, these design decisions make our scheduler scale to a large number of jobs with low overhead.

[1]We use latency constraint and latency requirement interchangeably.

Figure 4: *Scheduling Example: J1 is batch analytics, J2 is latency-sensitive. Fair-share scheduler creates schedules "a" and "b". Topology-aware scheduler reduces violations ("c"). Semantics-aware scheduler further reduces violations ("d"). We further explain these examples in Section 4.2*

Example. We present an example highlighting our approach. Consider a workload, shown in Figure 4, consisting of two streaming dataflows $J1$ and $J2$ where $J1$ performs a batch analytics query and $J2$ performs a latency sensitive anomaly detection pipeline. Each has an output operator processing messages from upstream operators. The default approach used by actor systems like Orleans is to: i) order messages based on arrival, and ii) give each operator a fixed time duration (called "quantum") to process its messages. Using this approach we derive the schedule "a" with a small quantum, and a schedule "b" with a large quantum — both result in two latency violations for $J2$. In comparison, Cameo discovers the opportunity to postpone less latency-sensitive messages (and thus their target operators). This helps $J2$ meet its deadline by leveraging topology and query semantics. This is depicted in schedules "c" and "d". This example shows that *when* and *how long* an operator is scheduled to run should be dynamically determined by the priority of the next pending message. We expand on these aspects in the forthcoming sections.

4 Scheduling Policies in Cameo

One of our primary goals in Cameo is to enable fine-grained scheduling policies for dataflows. These policies can prioritize messages based on information, like the deadline remaining or processing time for each message, etc. To enable such policies, we require techniques that can calculate the priority of a message for a given policy.

We model our setting as a non-preemptive, non-uniform task time, multi-processor, real-time scheduling problem. Such problems are known to be NP-Complete offline and cannot be solved optially online without complete knowledge of future tasks [33, 81]. Thus, we consider how a number of commonly used policies in this domain, including Least-Laxity-First (LLF) [69], Earliest-Deadline-First (EDF) [65] and Shortest-Job-First (SJF) [82], and describe how such policies can be used for event-driven stream processing.We use the LLF policy as the default policy in our description below.

The above policies try to prioritize messages to avoid violating latency constraints. Deriving the priority of a message requires analyzing the impact of each operator in the dataflow on query performance. We next discuss how being deadline-aware can help Cameo derive appropriate priorities. We also discuss how being aware of query semantics can further improve prioritization.

Symbol	Definition
ID_M	ID of Message M.
ddl_M	Message start deadline.
o_M	target operator of M.
C_{o_M}	Estimated execution cost of M on its target operator.
t_M, and p_M	Physical (and logical) time associated with the last event required to produce M.
L	Dataflow latency constraint of the dataflow that M belongs to.
p_{M_F}, and t_{M_F}	Frontier progress, and frontier time.

Table 1: *Notations used in paper for message M.*

4.1 Definitions and Underpinnings

Event. Input data arrives as *events*, associated with a *logical time* [30] that indicates the *stream progress* of these events in the input stream.

Dataflow job and operators. A dataflow job consists of a DAG of *stages*. Each stage operates a user-defined function. A stage can be parallelized and executed by a set of dataflow *operators*.

We say an operator o_k is *invoked* when it processes its input message, and o_k is *triggered* when it is invoked and leads to an output message, which is either passed downstream to further operators or the final job output.

Cameo considers two types of operators: i) regular operators that are triggered immediately on invocation; and ii) windowed operators [61] that partitions data stream into sections by logical times and triggers only when all data from the section are observed.

Message timestamps. We denote a message M as a tuple $(o_M, (p_M, t_M))$, where: a) o_M is the operator executing the message; b) p_M and t_M record the *logical* and *physical* time of the input stream that is associated with M, respectively. Intuitively, M is influenced by input stream with logical time $\leq p_M$. Physical time t_M marks the system time when p_M is observed at a source operator.

We denote C_{o_M} as the estimated time to process message M on target operator O, and L as the latency constraint for the dataflow that M belongs to.

Latency. Consider a message M generated as the output of a dataflow (at its sink operator). Consider the set of all events E that influenced the generation of M. We define latency as the difference between the last arrival time of any event in E and the time when M is generated.

4.2 Calculating Message Deadline

We next consider the LLF scheduling policy where we wish to prioritize messages which have the least laxity (i.e., flexibility). Intuitively, this allows us to prioritize messages that are closer to violating their latency constraint. To do this, we discuss how to determine the *latest time* that a message M can start executing at operator O without violating the job's latency constraint. We call this as the *start deadline* or in short the *deadline* of the message M, denoted as ddl_M. For the LLF scheduler, ddl_M is the message priority (lower value implies higher priority).

We describe how to derive the priority (deadline) using topology-awareness and then query (semantic)-awareness.

4.2.1 Topology Awareness

Single-operator dataflow, Regular operator. Consider a dataflow with only one regular operator o_M. The latency constraint is L. If an event occurs at time t_M, then M should complete processing before $t_M + L$. The start deadline, given execution estimate C_{o_M}, is:

$$ddl_M = t_M + L - C_{o_M} \tag{1}$$

Multiple-operator dataflow, Regular operator. For an operator o inside a dataflow DAG that is invoked by message M, the start deadline of M needs to account for execution time of downstream operators. We estimate the maximum of execution times of critical path [49] from o to any output operator as C_{path}. The start deadline of M is then:

$$ddl_M = t_M + L - C_{O_M} - C_{path} \tag{2}$$

Schedule "c" of Figure 4 showed an example of topology-aware scheduling and how topology awareness helps reduce violations. For example, $ddl_{M2} = 30 + 50 - 20 = 60$ means that $M2$ is promoted due to its urgency. We later show that even when query semantics are not available (e.g., UDFs), Cameo improves scheduling with topology information alone. Note that upstream operators are not involved in this calculation. C_{O_M} and C_{path} can be calculated by profiling.

4.2.2 Query Awareness

Cameo can also leverage dataflow semantics, i.e., knowledge of user-specified commands inside the operators. This enables the scheduler to identify messages which can tolerate further delay without violating latency constraints. This is common for windowed operations, e.g., a `WindowAggregation` operator can tolerate delayed execution if a message's logical time is at the start of the window as the operator will only produce output at the end of a window. Window operators are very common in our production use cases.

Multiple-operator dataflow, Windowed operator. Consider M that targets a windowed operator o_M, Cameo is able to determine (based on dataflow semantics) to what extent M can be delayed without affecting latency. This requires Cameo to identify the minimum logical time (p_{M_F}) required to trigger the target window operator. We call p_{M_F} *frontier progress*. Frontier progress denotes the stream progress that needs to be observed at the window operator before a window is complete. Thus a windowed operator will not produce output until frontier progresses are observed at all source operators. We record the system time when all frontier progresses become available at all sources as *frontier time*, denoted as t_{M_F}.

Processing of a message M can be safely delayed until all the messages that belong in the window have arrived. In other words when computing the start deadline of M, we can extend the deadline by $(t_{M_F} - t_M)$. We thus rewrite Equation 2 as:

$$ddl_M = \mathbf{t_{M_F}} + L - C_{O_M} - C_{path} \tag{3}$$

An example of this schedule was shown in schedule "d" of Figure 4. With query-awareness, scheduler derives t_{M_F} and postpones $M1$ and $M3$ in favor of $M2$ and $M4$. Therefore operator $o2$ is prioritized over $o1$ to process $M2$ then $M4$.

The above examples show the derivation of priority for a LLF scheduler. Cameo also supports scheduling policies including commonly used policies like EDF, SJF etc. In fact, the priority for EDF can be derived by a simple modification of the LLF equations. Our EDF policy considers the deadline of a message prior to an operator executing and thus we can compute priority for EDF by omitting C_{O_M} term in Equation 3. For SJF we can derive the priority by setting $ddl_M = C_{O_M}$—while SJF is not deadline-aware we compare its performance to other policies in our evaluation.

4.3 Mapping Stream Progress

For Equation 3 frontier time t_{M_F} may not be available until the target operator is triggered. However, for many fixed-sized window operations (e.g., `SlidingWindow`, `TumblingWindow`, etc.), we can *estimate* t_{M_F} based on the message's logical time

p_M. Cameo performs two steps: first we apply a TRANSFORM function to calculate p_{M_F}, the logical time of the message that triggers o_M. Then, Cameo infers the frontier time t_{M_F} using a PROGRESSMAP function. Thus t_{M_F} = PROGRESSMAP(TRANSFORM(p_M)). We elaborate below.

Step 1 (Transform): For a windowed operator, the completion of a window at operator o triggers a message to be produced at this operator. Window completion is marked by the increment of window ID [61,62], calculated using the stream's logical time. For message M that is sent from upstream operator o_u to downstream operator o_d, p_{M_F} can be derived using p_M using on a TRANSFORM function. With the definition provided by [62], Cameo defines TRANSFORM as:

$$p_{M_F} = \text{TRANSFORM}(p_M) = \begin{cases} (p_M/S_{o_d}+1)\cdot S_{o_d} & S_{o_u} < S_{o_d} \\ p_M & \text{otherwise} \end{cases}$$

For a sliding window operator o_d, S_{o_d} refers to the *slide size*, i.e., value step (in terms of logical time) for each window completion to trigger target operator. For the tumbling window operation (i.e., windows cover consecutive, non-overlapping value step), S_{o_u} equals the window size. For a message sent by an operator o_u that has a shorter slide size than its targeting operator o_d, p_{M_F} will be increased to the logical time to trigger o_d, that is, $= (p_M/S_{o_d}+1)\cdot S_{o_d}$.

For example if we have a tumbling window with window size 10 s, then the expected frontier progress, i.e., p_{M_F}, will occur every 10th second (1, 11, 21 ...). Once the window operator is triggered, the logical time of the resultant message is set to p_{M_F}, marking the latest time to influence a result.

Step 2 (ProgressMap): After deriving the frontier progress p_{M_F} that triggers the next dataflow output, Cameo then estimates the corresponding frontier time t_{M_F}. A temporal data stream typically has its logical time defined in one of three different time domains:

(1) *event time* [3,6]: a totally-ordered value, typically a timestamp, associated with original data being processed;

(2) *processing time*: system time for processing each operator [19]; and

(3) *ingestion time*: the system time of the data first being observed at the entry point of the system [3,6].

Cameo supports both event time and ingestion time. For processing time domain, M's timestamp could be generated when M is observed by the system.

To generate t_{M_F} based on progress p_{M_F}, Cameo utilizes a PROGRESSMAP function to map logical time p_{M_F} to physical time t_{M_F}. For a dataflow that defines its logical time by data's ingestion time, logical time of each event is defined by the time when it was observed. Therefore, for *all* messages that occur in the resultant dataflow, logical time is assigned by the system at the origin as $t_{M_F} = \text{PROGRESSMAP}(p_{M_F}) = p_{M_F}$.

For a dataflow that defines its logical time by the data's event time, $t_{M_F} \neq p_{M_F}$. Our stream processing run-time provides channel-wise guarantee of in-order processing for all target operators. Thus Cameo uses linear regression to map p_{M_F} to t_{M_F}, as: $t_{M_F} = \text{PROGRESSMAP}(p_{M_F}) = \alpha \cdot p_{M_F} + \gamma$, where α and γ are parameters derived via a linear fit with running window of historical p_{M_F}'s towards their respective t_{M_F}'s. E.g., For same tumbling window with window size 10s, if p_{M_F} occurs at times $(1, 11, 21\ldots)$, with a 2s delay for the event to reach the operator, t_{M_F} will occur at times $(3, 13, 23\ldots)$.

We use a linear model due to our production deployment characteristics: the data sources are largely real time streams, with data ingested soon after generation. Users typically expect events to affect results within a constant delay. Thus the logical time (event produced) and the physical time (event observed) are separated by only a small (known) time gap. When an event's physical arrival time cannot be inferred from stream progress, we treat windowed operators as regular operators. Yet, this conservative estimate of laxity does not hurt performance in practice.

5 Scheduling Mechanisms in Cameo

We next present Cameo's architecture that addresses three main challenges:

1 How to make static and dynamic information from both upstream and downstream processing available during priority assignment?

2 How can we efficiently perform fine-grained priority assignment and scheduling that scales with message volume?

3 How can we admit pluggable scheduling policies without modifying the scheduler mechanism?

Our approach to address the above challenges is to separate out the priority assignment from scheduling, thus designing a two-level architecture.This allows priority assignment for user-defined operators to become programmable.To pass information between the two levels (and across different operators) we piggyback information atop messages passed between operators.

More specifically, Cameo addresses challenge 1 by propagating *scheduling contexts* with messages. To meet challenge 2, Cameo uses a two-layer scheduler architecture. The top layer, called the *context converter*, is embedded into each operator and handles scheduling contexts whenever the operator sends or receives a message. The bottom layer, called the *Cameo scheduler*, interprets message priority based on the scheduling context embedded within a message and updates a priority-based data structure for both operators and operators' messages. Our design has advantages of: (i) avoiding the bottleneck of having a centralized scheduler thread calculate priority for each operator upon arrival of messages, and (ii) only limiting priority to be per-message. This allow the operators, dataflows, and the scheduler, to all remain stateless.

To address 3 Cameo allows the priority generation process to be implemented through the context handling API. A context converter invokes the API with each operator.

5.1 Scheduling Contexts

Scheduling contexts are data structures attached to messages, capturing message priority, and information required to perform priority-based scheduling. Scheduling contexts are *created*, *modified*, and *relayed* alongside their respective messages. Concretely, scheduling contexts allow capture of scheduling states of both upstream and downstream execution. A scheduling context can be seen and modified by both context converters and the Cameo scheduler. There are two kinds of contexts:

1. **Priority Context** (PC): PC is necessary for the scheduler to infer the priority of a message. In Cameo PCs are defined to include local and global priority as $(ID, PRI_{local}, PRI_{global}, Dataflow\_DefinedField)$. PRI_{local} and PRI_{global} are used for applications to enclose message priorities for scheduler to determine execution order, and $Dataflow\_DefinedField$ includes upstream information required by the pluggable policy to generate message priority.

A PC is attached to a message before the message is sent. It is either created at a source operator upon receipt of an event, or inherited and modified from the upstream message that triggers the current operator. Therefore, a PC is seen and modified by all executions of upstream operators that lead to the current message. This enables PC to address challenge 1 by capturing information of dependant upstream execution (e.g., stream progress, latency target, etc.).

2. **Reply Context** (RC): RC meets challenge 1 by capturing periodic feedback from the downstream operators. RC is attached to an acknowledgement message [2], sent by the target operator to its upstream operator after a message is received. RCs provide processing feedback of the target operator and all its downstream operators. RCs can be aggregated and relayed recursively upstream through the dataflow.

Cameo provides a programmable API to implement these scheduling contexts and their corresponding policy handlers in context converters. API functions include:

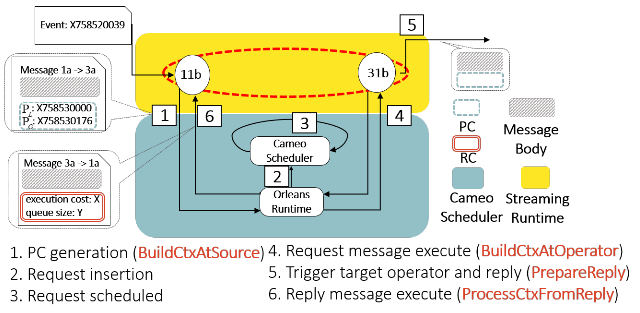
1. **function** BUILDCXTATSOURCE(EVENT e) that creates a PC upon receipt of an event e;
2. **function** BUILDCXTATOPERATOR(MESSAGE M) that modifies and propagates a PC when an operator is invoked (by M) and ready to send a message downstream;
3. **function** PROCESSCTXFROMREPLY(MESSAGE r) that processes RC attached to an acknowledgement message r received at upstream operator; and
4. **function** PREPAREREPLY(MESSAGE r) that generates RC containing user-defined feedbacks, attached to r sent by a downstream operator.

5.2 System Architecture

Figure 5(a) shows context converters at work. After an event is generated at a source operator $1a$ (step 1), the converter creates a PC through BUILDCXTATSOURCE and sends the message to Cameo scheduler. The target operator is scheduled (step 2) with the priority extracted from the PC, before it is executed. Once the target operator $3a$ is triggered (step 4), it calls BUILDCTXATOPERATOR, modifying and relaying PC with its message to downstream operators. After that $3a$ sends an acknowledgement message with an RC (through PREPAREREPLY) back to $1a$ (step 5). RC is then populated by the scheduler with runtime statistics (e.g, CPU time, queuing delays, message queue sizes, network transfer time, etc.) before it is scheduled and delivered at the source operator (step 6).

Cameo enables scheduling states to be managed and transported alongside the data. This allows Cameo to meet challenge 2 by keeping the scheduler away from centralized state maintenance and priority generation. The Cameo scheduler manages a two level priority-based data structure, shown in Figure 5(b). We use PRI_{local} to determine M's execution priority within its target operator, and PRI_{global} of the next message in an operator to order all operators that have pending messages. Cameo can schedule at either message granularity or a coarser time quanta. While processing a message, Cameo *peeks* at the priority of the next operator in the queue. If the next operator has higher priority, we swap with the current operator after a fixed time quantum (tunable).

[2]A common approach used by many stream processing systems [27, 57, 83] to ensure processing correctness



(a) *Scheduling contexts circulating between two operators.*

24:     else $r.\texttt{RC}.C_{path} \leftarrow \texttt{RC}.C_m + \texttt{RC}.C_{path}$
```

5.3 Implementing the Cameo Policy

To implement the scheduling policy of Section 4, a PC is attached to message M (denoted as $PC(M)$) with these fields:

ID	PRI_{local}	PRI_{global}	$Dataflow-DefinedField$
ID_M	p_{M_F}	ddl_{M_F}	(p_{M_F}, t_{M_F}, L)

The core of Algorithm 1 is CXTCONVERT, which generates PC for downstream message M_d (denoted as $\texttt{PC}(M_d)$), triggered by $\texttt{PC}(M_u)$ from the upstream triggering message. To schedule a downstream message M_d triggered by M_u, Cameo first retrieves stream progress p_{M_u} contained in $\texttt{PC}(M_u)$. It then applies the two-step process (Section 4.3) to calculate frontier time t_{M_F} using p_{M_u}. This may extend a message's deadline if the operator is not expected to trigger immediately (e.g., windowed operator). We capture p_{M_F} and estimated t_{M_F} in PC as message priority and propagate this downstream. Meanwhile, p_{M_u} and t_{M_u} are fed into a linear model to improve future prediction towards t_{M_F}. Finally, the context converter computes message priority ddl_{M_u} using t_{M_F} as described in Section 4.

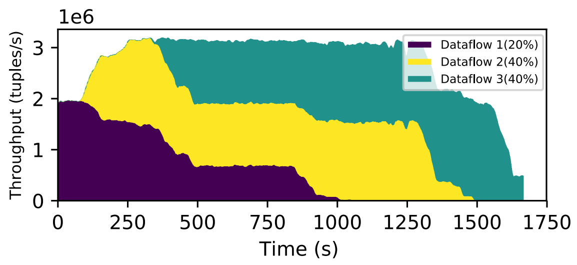

Figure 6: *Proportional fair sharing using Cameo.*

Cameo utilizes RC to track critical path execution cost C_{path} and execution cost C_{O_M}. RC contains the processing cost (e.g., CPU time) of the downstream critical path up to the current operator, obtained via profiling.

5.4 Customizing Cameo: Proportional Fair Scheduling

We next show how the pluggable scheduling policy in Cameo can be used to support other performance objectives, thus satisfying 3 . For instance, we show how a token-based rate control mechanism works, where token rate equals desired output rate. In this setting, each application is granted tokens per unit of time, based on their target sending rate. If a source operator exceeds its target sending rate, the remaining messages (and all downstream traffic) are processed with operator priority reduced to minimum. When capacity is insufficient to meet the aggregate token rate, all dataflows are downgraded equally. Cameo spreads tokens proportionally across the next time interval (e.g., 1 sec) by tagging each token with the timestamp at each source operator. For token-ed messages, we use token tag PRI_{global}, and interval ID as PRI_{local}. Messages without tokens have PRI_{global} set to `MIN_VALUE`. Through PC propagation, all downstream messages are processed when no tokened traffic is present.

Figure 6 shows Cameo's token mechanism. Three dataflows start with 20% (12), 40% (24), and 40% (24) tokens as target ingestion rate per source respectively. Each ingests 2M events/s, starting 300 s apart, and lasting 1500 s. Dataflow 1 receives full capacity initially when there is no competition. The cluster is at capacity after Dataflow 3 arrives, but Cameo ensures token allocation translates into throughput shares.

6 Experimental Evaluation

We next present experimental evaluation of Cameo. We first study the effect of different queries on Cameo in a single-tenant setting. Then for multi-tenant settings, we study Cameo's effects when:

- **Varying environmental parameters** (Section 6.2): This includes: a) workload (tenant sizes and ingestion rate), and b) available resources, i.e., worker thread pool size, c) workload bursts.
- **Tuning internal parameters and optimization** (Section 6.3): We study: a) effect of scheduling granularity, b)

frontier prediction for event time windows, and c) starvation prevention.

We implement streaming queries in Flare [68] (built atop Orleans [10, 25]) by using Trill [30] to run streaming operators.We compare Cameo vs. both i) default **Orleans** (version 1.5.2) scheduler, and ii) a custom-built **FIFO** scheduler. By default, we use the 1 ms minimum re-scheduling grain (Section 5.2). This grain is generally shorter than a message's execution time. Default Orleans implements a global run queue of messages using a ConcurrentBag [9] data structure. ConcurrentBag optimizes processing throughput by prioritizing processing thread-local tasks over the global ones. For the FIFO scheduler, we insert operators into the global run queue and extract them in FIFO order. In both approaches, an operator processes its messages in FIFO order.

Machine configuration. We use DS12-v2 Azure virtual machines (4 vCPUs/56GB memory/112G SSD) as server machines, and DS11-v2 Azure virtual machines (2 vCPUs/14GB memory/28G SSD) as client machines [12]. Single-tenant scenarios are evaluated on a single server machine. Unless otherwise specified, all multi-tenant experiments are evaluated using a 32-node Azure cluster with 16 client machines.

Evaluation workload. For the multi-job setting we study performance isolation under concurrent dataflow jobs. Concretely, our workload is divided into two control groups:

- **Latency Sensitive Jobs (Group 1):** This is representative of jobs connected to user dashboards, or associated with SLAs, ongoing advertisement campaigns, etc. Our workload jobs in Group 1 have sparse input volume across time (1 msg/s per source, with 1000 events/msg), and report periodic results with shorter aggregation windows (1 second). These have strict latency constraints.
- **Bulk Analytic Jobs (Group 2):** This is representative of social media streams being processed into longer-term analytics with longer aggregation windows (10 seconds). Our Group 2 jobs have input of both higher and variable volume and high speed, but with lax latency constraints.

Our queries feature multiple stages of windowed aggregation parallelized into a group of operators. Each job has 64 client sources. All queries assume input streams associated with event time unless specified otherwise.

Latency constraints. In order to determine the latency constraint of one job, we run multiple instances of the job until the resource (CPU) usage reaches 50%. Then we set the latency constraint of the job to be twice the tail (95th percentile) latency. This emulates the scenario where users with experience in isolated environments deploy the same query in a shared environment by moderately relaxing the latency constraint. Unless otherwise specified, a latency target is marked with grey dotted line in the plots.

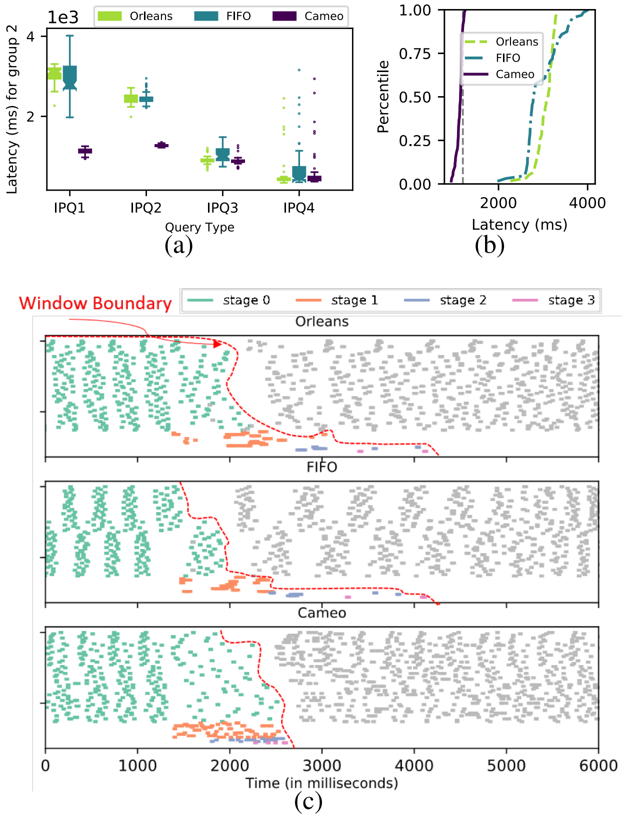

Figure 7: *Single-Tenant Experiments: (a) Query Latency. (b) Latency CDF. (c) Operator Schedule Timeline: X axis = time when operator was scheduled. Y axis = operator ID color coded by operator's stage. Operators are triggered at each stage in order (stage 0 to 3). Job latency is time from all events that belong to the previous window being received at stage 0, until last message is output at stage 3.*

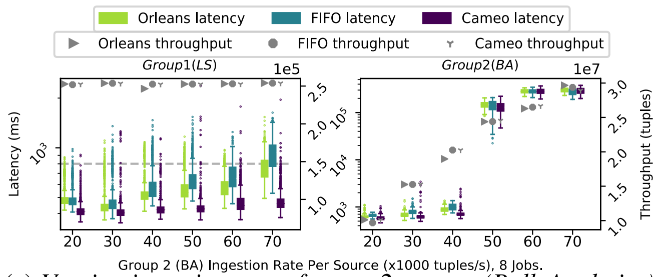
6.1 Single-tenant Scenario

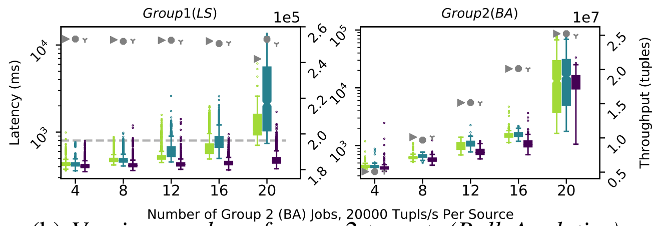
In Figure 7 we evaluate a single-tenant setting with 4 queries: IPQ1 through IPQ4. IPQ1 and IPQ3 are periodic and they respectively calculate sum of revenue generated by real time ads, and the number of events generated by jobs groups by different criteria. IPQ2 performs similar aggregation operations as IPQ1 but on a sliding window (i.e., consecutive window contains overlapped input). IPQ4 summarizes errors from log events via running a windowed join of two event stream, followed by aggregation on a tumbling window (i.e., where consecutive windows contain non-overlapping ranges of data that are evenly spaced across time).

From Figure 7(a) we observe that Cameo improves median latency by up to 2.7×and tail latency by up to 3.2×.We also observe that default Orleans performs almost as well as Cameo for IPQ4. This is because IPQ4 has a higher execution time with heavy memory access, and performs well when pinned to a single thread with better access locality.

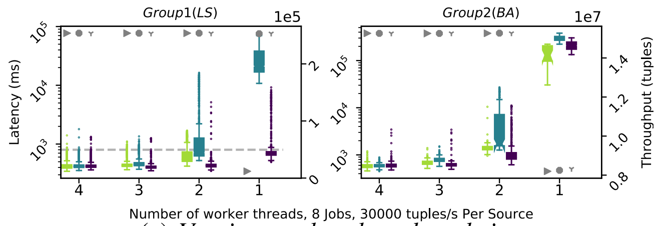
Effect on intra-query operator scheduling. The CDF in



(a) *Varying ingestion rate of group 2 tenants (Bulk Analytics).*



(b) *Varying number of group 2 tenants (Bulk Analytics).*



(c) *Varying worker thread pool size.*

Figure 8: *Latency-sensitive jobs under competing workloads.*

Figure 7(b) shows that Orleans' latency is about 3× higher than Cameo. While FIFO has a slightly lower median latency, its tail latency is as high as in Orleans.

Cameo's prioritization is especially evident in Figure 7(c), where dots are message starts, and red lines separate windows. We first observe that Cameo is faster, and it creates a clearer boundary between windows. Second, messages that contribute to the first result (colored dots) and messages that contribute to the second result (grey dots) do not overlap on the timeline. For the other two strategies, there is a *drift* between stream progress in early stages vs. later stages, producing a prolonged delay. In particular, in Orleans and FIFO, early-arriving messages from the next window are executed *before* messages from the first window, thus missing deadlines.

6.2 Multi-tenant Scenario

Figure 8 studies a control group of latency-constrained dataflows (group 1 LS jobs) by fixing both job count and data ingestion rate. We vary data volume from competing workloads (group 2 BA jobs) and available resources. For LS jobs we impose a latency target of 800 ms, while for BA jobs we use a 7200s latency constraint.

Cameo under increasing data volume. We run four group 1 jobs alongside group 2 jobs. We increase the competing group 2 jobs' traffic, by increasing the ingestion speed (Figure 8(a)) and number of tenants (Figure 8(b)). We observe that all three strategies (Cameo, Orleans, FIFO) are comparable up to per-source tuple rate of 30K/s in Figure 8(a), and up to twelve group 2 jobs in Figure 8(b). Beyond this, overloading causes massive latency degradation, for group 1 (LS) jobs at median and 99 percentile latency (respectively): i) Orleans is worse than Cameo by up to 1.6 and 1.5× in Figure 8(a), up to 2.2 and 2.8× in Figure 8(b), and ii) FIFO is worse than Cameo by up to 2 and 1.8× in Figure 8(a), up to 4.6 and 13.6× in Figure 8(b). Cameo stays stable. Cameo's degradation of group 2 jobs is small— with latency similar or lower than Orleans and FIFO, and Cameo's throughput only 2.5% lower.

Effect of limited resources. Orleans' [74] underlying SEDA architecture [86] resizes thread pools to achieve resource balance between execution steps, for dynamic re-provisioning. Figure 8(c) shows latency and throughput when we decrease the number of worker threads. Cameo maintains the performance of group 1 jobs except in the most restrictive 1 thread case (although it still meets 90% of deadlines). Cameo prefers messages with impending deadlines and this causes back-pressure for jobs with less-restrictive latency constraints, lowering throughput. Both Orleans and FIFO observe large performance penalties for group 1 and 2 jobs (higher in the former). Group 2 jobs with much higher ingestion rate will naturally receive more resources upon message arrivals, leading to back-pressure and lower throughput for group 1 jobs.

Effect of temporal variation of workload. We use a Pareto distribution for data volume in Figure 9, with four group 1 jobs and eight group 2 jobs. (This is based on Figures 2(a), 2(c), which showed a Power-Law-like distribution.) The cluster utilization is kept under 50%.

High ingestion rate can suddenly prolong queues at machines. Visualizing timelines in Figures 9(a), 9(b), and 9(c) shows that for latency-constrained jobs (group 1), Cameo's latency is more stable than Orleans' and FIFO's. Figure 9(d) shows that Cameo reduces (median, 99th percentile) latency by (3.9×, 29.7×) vs. Orleans, and (1.3×, 21.1×) vs. FIFO. Cameo's standard deviation is also lower by 23.2× and 12.7× compared to Orleans and FIFO respectively. For group 2, Cameo produces smaller average latency and is less affected by ingestion spikes. Transient workload bursts affect many jobs, e.g., all jobs around $t = 400$ with FIFO, as a spike at one operator affects all its collocated operators.

Ingestion pattern from production trace. Production workloads exhibit high degree of skew across data sources. In Figure 10 we show latency distribution of dataflows consuming two workload distributions derived from Figure 2(c): Type 1 and 2. Type 1 produces twice as many events as Type 2. However, Type 2 is heavily skewed and its ingestion rate varies by 200× across sources. This heavily impacts operators that are collocated. The success rate (i.e., the fraction of outputs that meet their deadline) is only 0.2% and 1.5% for Orleans and 7.9% and 9.5% for FIFO. Cameo prioritizes critical messages, maintaining success rates of 21.3% and 45.5% respectively.
